Subdivisions [n]	12	13	8	6
Buckling [-]	0.46	0.81	0.70	0.90
Cross section [-]	0.39	0.30	0.30	0.37
Deformation [mm]	7	5	8	7
Weight [kg]	147.5	145.4	137.6	125.5
Resource reduction [%]	-	-1.4	-6.7	-14.9

The authors pursued the optimisation focusing on different fitness values. The early optimisation processes were calculated with deformation as the fitness value. For these calculations the value was set to be as low as possible. The results were very stiff trusses, with deformations smaller than 5 mm, a value of less than one sixth of the limit of 32 mm according to Eurocode 5 (EN1995-1-1:2019-06-01). The resulting material savings of 1.4 % were not considered as relevant improvements.

The next attempt was optimising the structure using the maximum absolute normal force (both compression and tension forces). The compression forces were considerably reduced by the algorithm (-22 %), while the tension forces decreased only slightly (-6 %). The goal of achieving an optimal structure through the even distribution of the occurring normal forces in all struts and chord beams of the truss resulted in a mass reduction of 6.7 %.

The previously described optimisation approaches did not lead to a minimisation of the material quantity and thus the environmental impact. The optimisation was most successful when the fitness value was set as the total mass of the construction, with it being directly proportional to the wood consumption. This resulted in a significant reduction of 14.9 % compared to the reference model.

Only chosen variables were released within the optimisation for the truss configuration of the housing. The distance between the divisions was defined evenly in order to meet aesthetic requirements. Figure 2 (middle) shows a truss with an uneven distribution of the subdivisions. In addition, the cross section of the chords and struts was set to 80 x 80 mm in regard to the envisaged node configuration.

For the final implementation of the housing, shown in Figure 1 and Figure 2 (right), a truss with 7 segments, regular spacing between the subdivisions and free diagonal member arrangement was defined, requiring 129.4 kg of timber, 18.1 kg less than the reference model.

If the entire truss structure is calculated on a pure theoretical basis, without the consideration of node configurations or national standards, the mass can be reduced even further. By allowing the algorithm to change the cross-sectional dimensions of the chords and struts a reduction of the material consumption by about 60 % is possible. For this case the truss would need more subdivisions, use smaller cross sections and have a total weight of 59.3 kg for the 8.2 m span.

4. Joining of the truss members

The load-bearing behaviour of timber trusses is particularly influenced by the material properties, the geometry and the joint performance. Based on this fact, the authors also focus on investigating the load-bearing behaviour of the joints as part of their research. The main requirement of the research was to transfer the loads without using any steel elements in order to minimise the environmental impact. Following the research presented in [13], a easily produced node element was used that can connect truss members at different angles while also allowing the transfer compressions and tensile forces. In this particular case, the authors chose plywood panels which would be notched into the truss members before being fixed with wooden pegs. For a first characterisation of the chosen configuration and due to the fact that plywood plates in combination with wooden pegs are not covered by Eurocode 5 the authors performed compression as well as tensile tests on the all-wood connections to find the optimal design as well as wood species and to investigate the occurring load-bearing mechanisms.

4.1. Design of the wood-wood connections

For the above-mentioned curved optimised truss, spruce (C24) with a cross section of 80 x 80 mm was chosen for all truss members, making this the first boundary condition for the joint design. Due to manufacturing tolerances however, the cross sections of all provided specimens turned out to be 78 x 78 mm. The node elements (plates) were made from plywood panels and were inserted into the truss members and fixed with wooden pegs. According to [14] the spacing of the pegs in the direction of force was chosen with three times the peg diameter (3d). As the cutting depth for notching the truss member for the plywood panel was limited by the manufacturing process to 115 mm, the diameter of the pegs was set to 14 mm. The combination of all geometric boundary conditions resulted in a total of four pegs per connection.

4.2. Experimental investigations on pegged joints with different wood species of the pegs

In this test series the influence of the wood species of the pegs on the mechanical behaviour of the connection was investigated. The authors manufactured the connections with the robot and tested a total of nine configurations in regard to the transmission of tensile forces (with three specimen each). The test setup is shown in Figure 3.

According to [14], the thickness of the plywood panel should be approximately equal to the diameter of the pegs diameter to ensure an adequate load-bearing behaviour and a ductile failure of the connection. For the first tests birch plywood panel was chosen with a thickness of 15 mm (BI15). The following wood species were examined for the pegs: thermo ash (TA), ash (A), oak (O), larch (L), beech (B), spruce (S), beech LVL along the layers (B_LVL_0), beech LVL perpendicular to the layers (B_LVL_90).

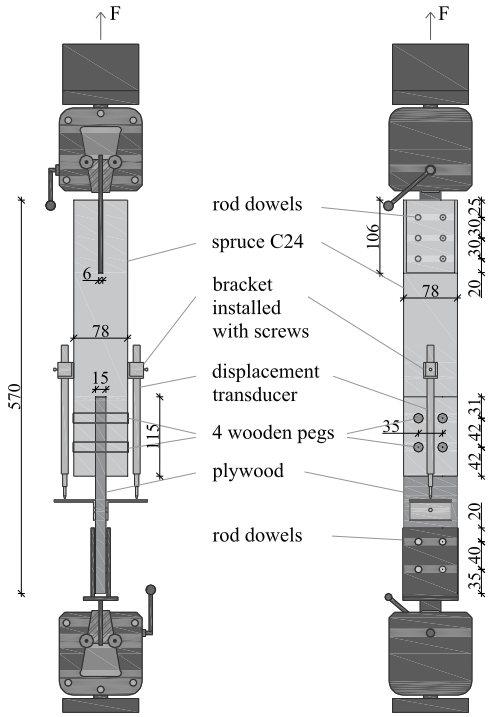

Figure 3. Test setup for the tensile connections [mm].

The tested configurations and results are summarised in Table 2 and Figure 4, respectively. The result curves represent regressive lines of summarising the three specimens of every configuration. To limit the deformation in the final structure, the stiffness in the joint should be as high as possible. The results of the experimental investigation show that the combination of beech pegs and 15 mm birch plywood (B-BI15) provided the highest stiffness. However, in this configuration, the failure for this configuration occurred in the plywood panel next to the pegs in a brittle manner after a short period of softening (see Figure 5). As brittle failure is unwanted, a further series of tests was carried out. The 15 mm birch plywood was replaced with 18 mm beech plywood to ensure that the failure would not occur in the plywood panel. With the combination of 14 mm beech pegs and 18 mm beech plywood (B-BI18), it was not only possible to achieve ductile failure, but also to increase the load-bearing capacity from 25.01 kN in the first series up to 29.56 kN (see Figure 4).

Table 2. Test configurations of the tensile tests.

Configuration	Wood species of pegs	Ø of the pegs [mm]	Wood species of plywood	Thickness of plywood [mm]
TA-BI15	Thermo ash	14	birch	15
A-BI15	ash	14	birch	15
L-BI15	larch	14	birch	15
O-BI15	oak	14	birch	15
B-BI15	beech	14	birch	15
S-BI15	spruce	14	birch	15

B-B 18	beech	14	beech	18

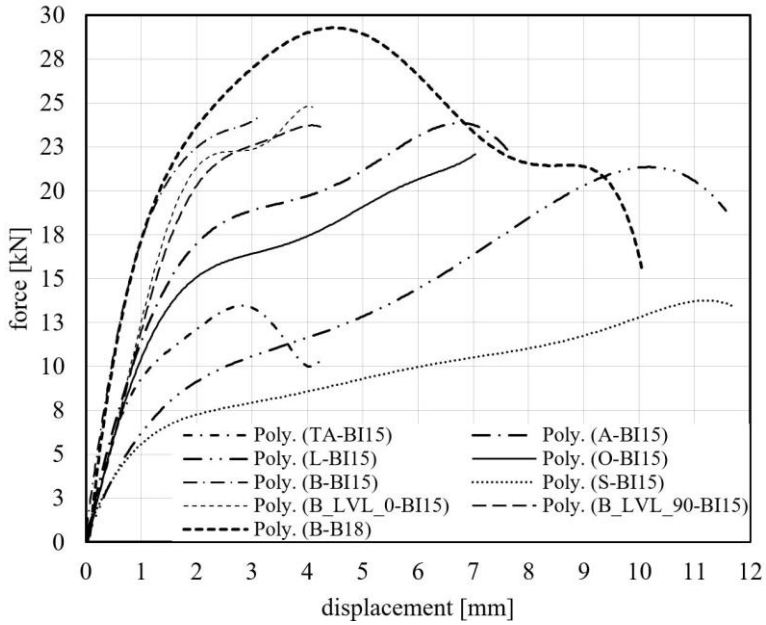

Figure 4. Comparison of the influence of the wood species of pegs on the load-bearing capacity and stiffness of the tensile joint of test series I (xx-BI15) and the ultimately chosen combination from series II (B-B18). Results are shown as regressive lines of the mean values of three specimens each. Coefficient of determination R2>0.992 (xx-BII5) and R2=0.949 (B-B18).

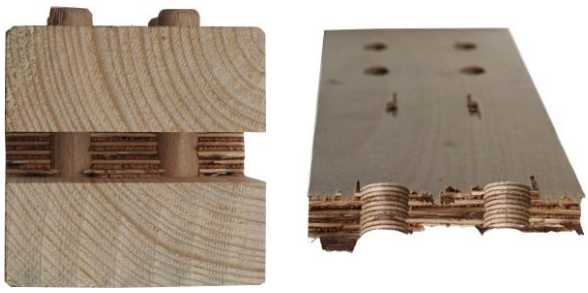

Figure 5. Test specimen from configuration B-BI15 after failure; truss member with beech dowels (left), birch plywood plate (right).

4.3. Experimental investigations on buckling of beech plywood

In some cases, the design of the curved truss resulted in acute angles between the truss members, as shown in Figure 9. Hence, a free length of the plywood panel of up to 650 mm had to be implemented. Since the joints of the truss structure do not only have to transmit tensile stresses but also compressive stresses, the risk of out-of-plane buckling of the slender plywood panel had to be ruled out. To investigate the influence of different free lengths of the plywood panels regarding buckling failure, a series of compression tests was performed. The test setup is shown in Figure 6.

As the truss nodes are stressed in different directions, three orientations of the main load-bearing direction of the plywood panel were tested. The joints consisted of 18 mm beech plywood panels inserted into the truss members and fixed with four wooden pegs (beech) with a 14 mm diameter. The joint configuration was chosen according to test Series 2 of the tensile tests, presented in Section 4.2. The aim was to transfer the compression loads not only through the peg/plywood joint but also through the contact surface between the beech plywood panel and the spruce truss member. The free length in this test series was set to 250 mm and increased in 100 mm steps up to 650 mm. Each step of free length

was tested in an angle of 0°, 45° and 90° of the plywood's main load-bearing direction to the direction of force. The investigated configurations are summarised in Table 3. In order to obtain feasible results three specimens per configuration were tested. The test results are shown in Figure 8.

Table 3. Test configurations of the compression tests.

Configuration	Free length of the plywood	Angle of the plywood's load-bearing direction [°]	Wood species of the pegs	Ø of the pegs [mm]
25-0	25	0	beech	14
25-45	25	45	beech	14
25-90	25	90	beech	14
35-0	35	0	beech	14
35-45	35	45	beech	14
35-90	35	90	beech	14
45-0	45	0	beech	14
45-45	45	45	beech	14
45-90	45	90	beech	14
55-0	55	0	beech	14
55-45	55	45	beech	14
55-90	55	90	beech	14
65-0	65	0	beech	14
65-45	65	45	beech	14
65-90	65	90	beech	14

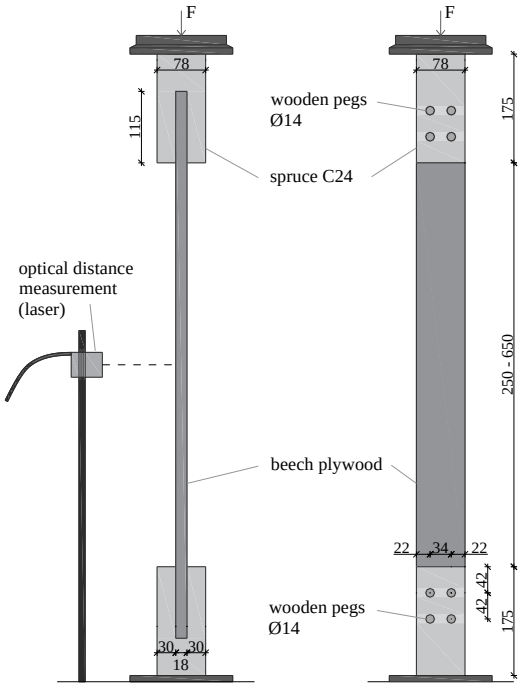

Figure 6. Illustration of the test setup for the compression tests to investigate local buckling failure [mm].

As expected, the results of the test series prove that the load-bearing capacity decreases with an increase of free length. A test specimen under load showing buckling is depicted in Figure 7. In each configuration of free length the specimens with an angle of 45° between the main load-bearing direction and the direction of force show the lowest load-bearing capacity. Each specimen with an angle of 0° between the orientation of the main layers of the plywood and the direction of force, labelled xx-0 in, provided the highest load-bearing capacity for each defined plate length.

Figure 7. Test specimen under compression.

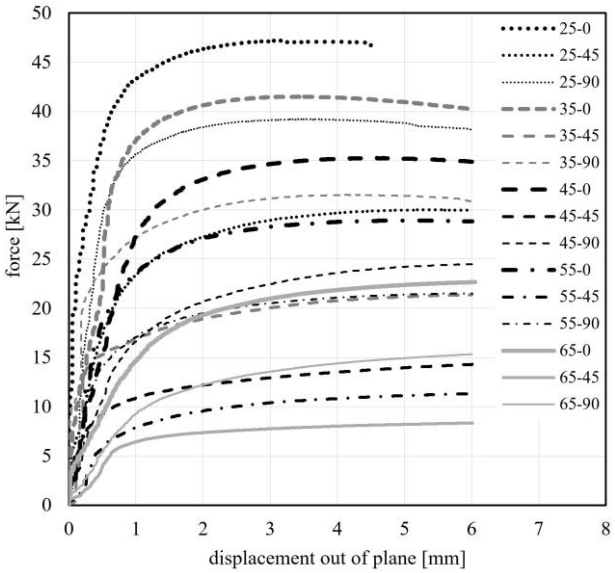

Figure 8. Comparison of the influence of the orientation of the load-bearing direction and the free length of the plywood panel on the load-bearing capacity. Mean values of three specimens each. Legend: free length in cm – angle between load-bearing direction and force direction, e.g. 25-45 means 250 mm of free length and an angle of 45° between load-bearing direction of the plywood and direction of force.

The findings show that the governing stress direction in the truss node has to coincide with the load-bearing direction of the plywood in order to fully utilise its potential. Furthermore, it was observed that the bending shape was similar to Euler case 4, leading to the assumption that the designed joints act like rigid ends.

4.4. Final design of the truss joints

For the final design of the curved truss, the members consist of spruce with a cross section of 80 x 80 mm (78 x 78 mm). One joint design was chosen for all joints to simplify the manufacturing process. Thus, four beech pegs with a 14 mm diameter and 18 mm beech plywood panels are used for the joints. A rendering of the upper part of the final design can be seen in Figure 9.

Figure 9. Rendering of the upper part of the curved timber truss.

5. Conclusions

Industrialising the complete process chain shows great potential for the wood construction sector allowing for an increase in resource efficiency and the ability to compete with other construction materials regarding economic efficiency. Within this context the present paper focuses on the optimisation of the geometry and the connections of trusses by solely using wood as the construction material for all building elements. The housing of the BOKU Vienna robot laboratory was chosen as the first pilot project.

The optimisation of the geometry by use of a parametric model and a genetic solving algorithm allowed for a reduction of the required construction material by 14.9 % in comparison to the first design based on engineering knowledge. For this case the cross section of the truss members was predefined to 80 x 80 mm. A theoretical optimisation of the cross section showed further reduction potential of 60 %.

A pure wood-wood connection was chosen using plywood as the connection panel and wooden pegs as shear connectors to minimise the environmental impact of the load-bearing structure.

A test series of tensile investigations was performed to determine the influence of the wood species of the pegs on the mechanical behaviour of the connection. The results show that using beech pegs provide the stiffest connection and the highest load-bearing capacity. Furthermore, the investigations showed that special attention needed to be paid to the interaction between peg diameter and the thickness of the plywood panel in order to ensure ductile failure of the pegs. To estimate local buckling failure in the plywood panel, compression tests were conducted giving information on the influence of the free length. The results show the importance of the main load-bearing direction of the plywood panel.

All the acquired knowledge was then applied within the pilot project where the team of the Institute of Green Civil Engineering built the structure, as seen in Figure 10, in the autumn of 2020.

Figure 10. Finished housing for the robot laboratory

Acknowledgements

The authors gratefully acknowledge the company Rubner Holzbau GmbH for the good cooperation and support. Furthermore, the authors thank the entire team of the Institute of Green Civil Engineering as the structure for the housing of the laboratory was produced in many hours of hard labour of every single one of them!

Abstract

The study and practice of linear building façade systems have been relatively mature, through which the realm has cultivated an integrated and comprehensive design and construction framework. As the need for the complexity of architectural form in the design market increases, there is an ever-growing challenge to the existing façade design and construction system with the emergence of forms with double curvature and other types of complexity. Although digital toolsets have been around in the field to cope with such problems, their uses have long been scattered across the entire design and construction workflow, not presenting a unified trend where a highly efficient coordination system is established, and building information is generated and managed in totality so that the barriers between different construction bodies are overcome to facilitate communication, reduce risks and optimize costs. This article, with the example of the construction process of the Chongqing Center for Planning and Exhibition, aims at tackling this challenge through discussions on establishing a unified design and construction workflow centered around an exclusive digital fabrication team and a digital framework, making Building Information Modelling a crucial vessel for data management, and how the construction process is empowered by such frameworks and information.

Keywords: complex façade, building façade, construction coordination, digital fabrication, BIM

1. Introduction

As one of the most technically demanding branches of the construction industry, complex curved surface architectural façades present a significant challenge, particularly in the design and construction of double-curved façades [1]. While the industry has introduced digital tools and workflows to address these challenges and establish certain working paradigms, the intelligent integration of project stakeholders remains elusive due to insufficient knowledge of digital technology and a shortage of professional talent. Given the construction industry has always been labor-intensive, the current close-loop working mode of mainstream construction projects is becoming increasingly inadequate in the face of more advanced and innovative architectural design schemes, especially during the project development stage where it is difficult to plot and unify drawing information [2], and where effective delegation of workload and integration of outcomes is almost impossible. Therefore, establishing a digital construction workflow to fully leverage the unparalleled advantages of Building Information Modelling (BIM) in integrating complex geometric design and construction processes is the future trend of the construction industry [3].

This paper demonstrates the data generation, evolution, and empowerment process of the entire façade construction workflow for the Chongqing Planning Exhibition Gallery's new building project (Figure 1), and argues that the use of an independent digital construction team to control and process data throughout the entire construction workflow has a positive impact on optimizing construction efficiency, improving overall project quality, shortening construction periods, and reducing construction costs. This paper aims to provide useful insights into the promotion and application of digital workflows and building information data in construction projects.

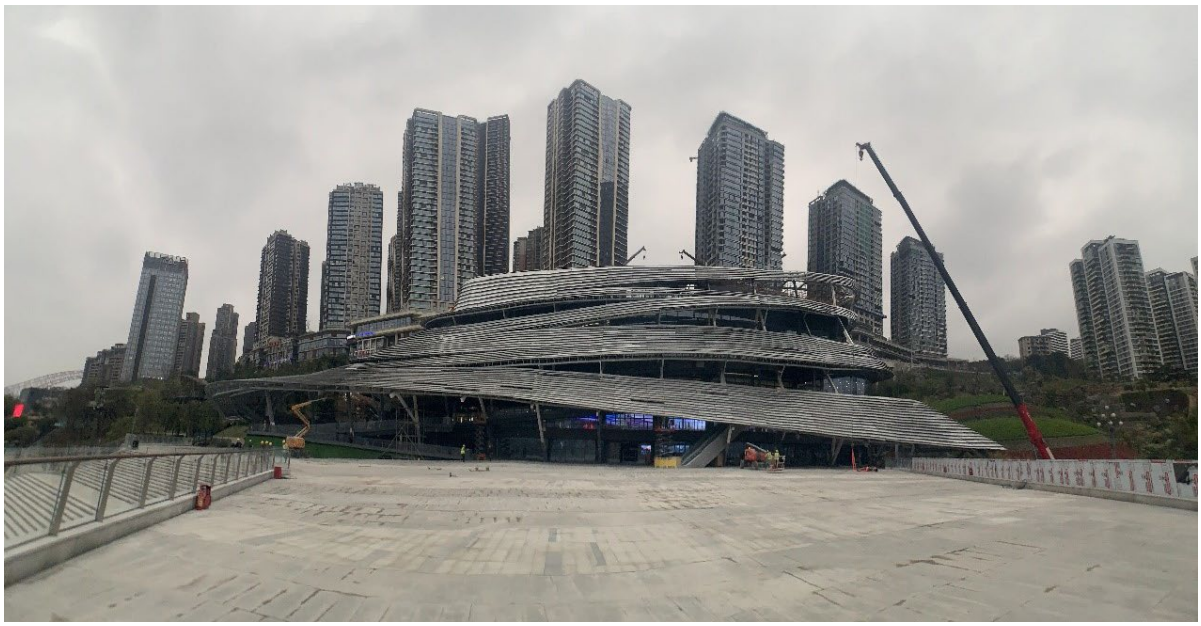

Figure 1. Chongqing Center for Planning and Exhibition (2022).

2. Generation of initial data

All the construction data of the façade can be traced back to the final version of the hyperboloid-shaped skin that was determined in the conceptual design phase. In a complex façade design, the skin and structure are interrelated. With the form of the skin determined, the structure emphasizes the surface layer of the form, which reveals and reinforces the logical core of the structure and is a genuine and logical response of the structure to the skin. Due to the semi-outdoor grey space designed between the skin and the main building, all the secondary structures of the façade can only be supported by the main steel structure, which is similar to an external skeleton. Therefore, the construction structure of the entire façade comes from the superimposition and interaction of two types of initial data, namely the skin and the structure, to varying degrees.

2.1. Initialization of façade data

The façade design primarily consists of non-linear hyperboloid shapes, with only a small portion of the back side of the building being flat, and the rest having non-zero curvature in the UV direction. After freezing the surface design, the deepened panel units are overlapped in a staggered manner and adjusted in length based on changes in curvature, resulting in a more coordinated and rational overall design for the façade pattern (Figure 2). Additionally, the open overlapping connection method with staggered joints can significantly improve the fault tolerance of the façade panel joints from a structural perspective, providing greater buffering space for design development and construction work.

During this stage, the complexity of the hyperboloid shapes is simplified by reducing the continuously changing curvature to gradually planar panel units. In the process of reducing the three-dimensional hyperboloid shapes to two-dimensional planar panel units, core initial data for the skin are generated,

such as the numbering system for the panel units, gradient sizes, relative positions, normal directions, joint distances, and planar angles.

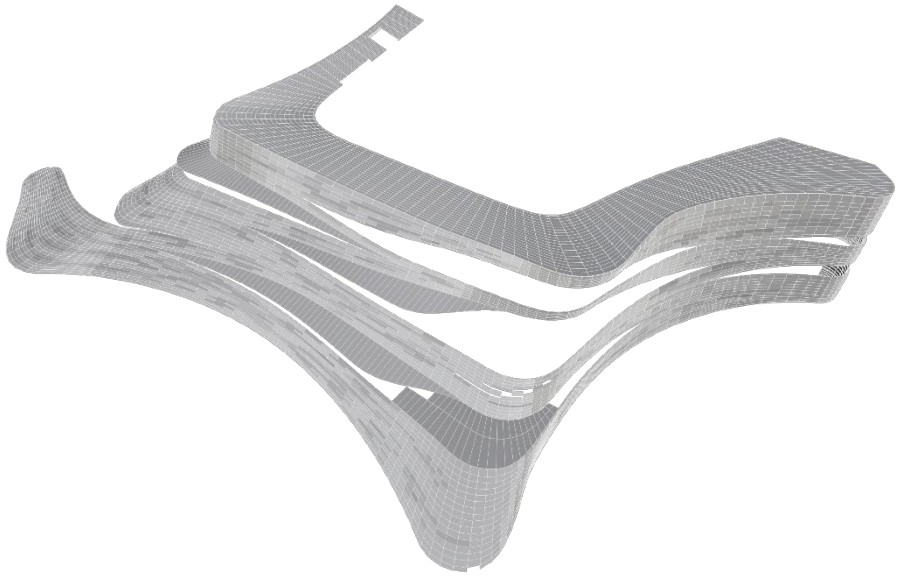

Figure 2. Façade panel units for further development.

2.2. Initialization of structural data

In the design of façades, the final form depends on the cladding scheme, while meeting the load-bearing requirements. Due to the adoption of transverse panel units with staggered joints for the hyperboloid cladding, the supporting framework is arranged using longitudinal and diagonal square-section steel beams, as well as transverse circular-section steel beams, with reference to the cladding curvature. Given the significant difference in curvature between the primary steel structure and the façade panel units, purlin systems are inserted to connect the panel units and steel structure as secondary structures. After freezing the position of the purlins, the design development of the exterior façade panel units can be independently carried out from the internal steel structure adjustment. Once the façade is completed, any design and installation errors are eliminated through the overall structure of the steel structure, purlins, and ear plates. Therefore, it is generally advisable to adopt an exterior-to-interior process from the cladding to the structure for the development of complex façade schemes.

As the corresponding framework among the façade panel units, purlins, and steel structure (Figure 3) gradually takes shape, the initial hyperboloid cladding is transformed into a façade unit system and a purlin system that can be orthogonally decomposed, with the potential adjustment space gradually fixed. This lays a good foundation for mid-term batch production and later precise and efficient construction.

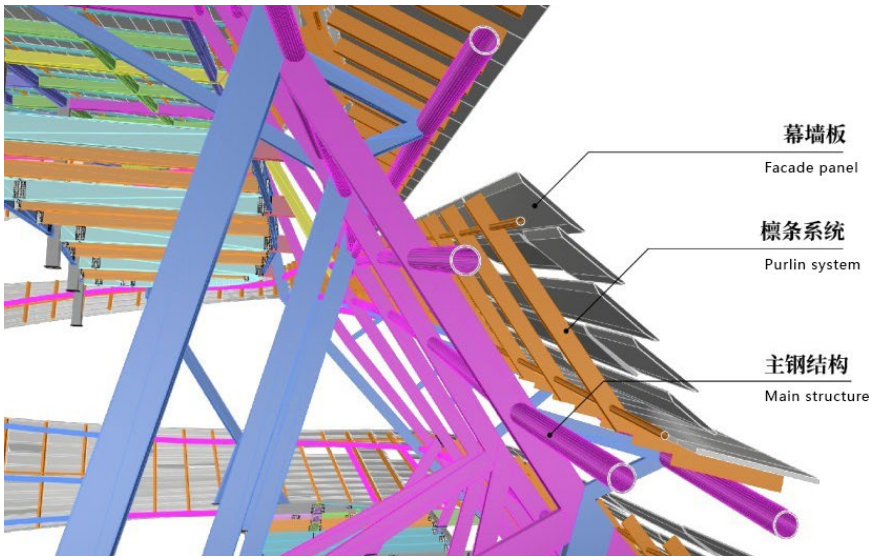

Figure 3. Façade composition: panel—purlin—main structure.

3. Development of construction data

The success of the project lies in creating a BIM model of the façade, which contains rich geometric and segmentation information that develops into a thorough construction data package at a later stage [4]. During the development process of façade design, after the scheme is finalized, the panel system and purlin system of the façade unit serve as mutually supporting constraints, leading to the derivation of more specific data for guiding precise development and large-scale production.

3.1. Batching & numbering

Taking into account factors such as structural design, manufacturing techniques, production cycles, and construction schedules, a total of 5,980 façade units were divided into 14 zones and underwent developing work in batches. Considering that the entire façade system adopts either a butt-joint or overlapping joint method with zone boundaries as the dividing line, the 14 zones were numbered using two methods: longitudinal and transverse gradients, with the zone break points as the boundary (refer to Figure 4).

The use of a numbering system as a unique identification symbol within the global scope of the project is adopted. The use of this numbering system is consistent throughout the entire project and is incorporated into the workflow loop composed of three sub-processes: façade design development, manufacturer production, and on-site installation. This system facilitates the smooth and orderly progress of the project rapidly and efficiently.

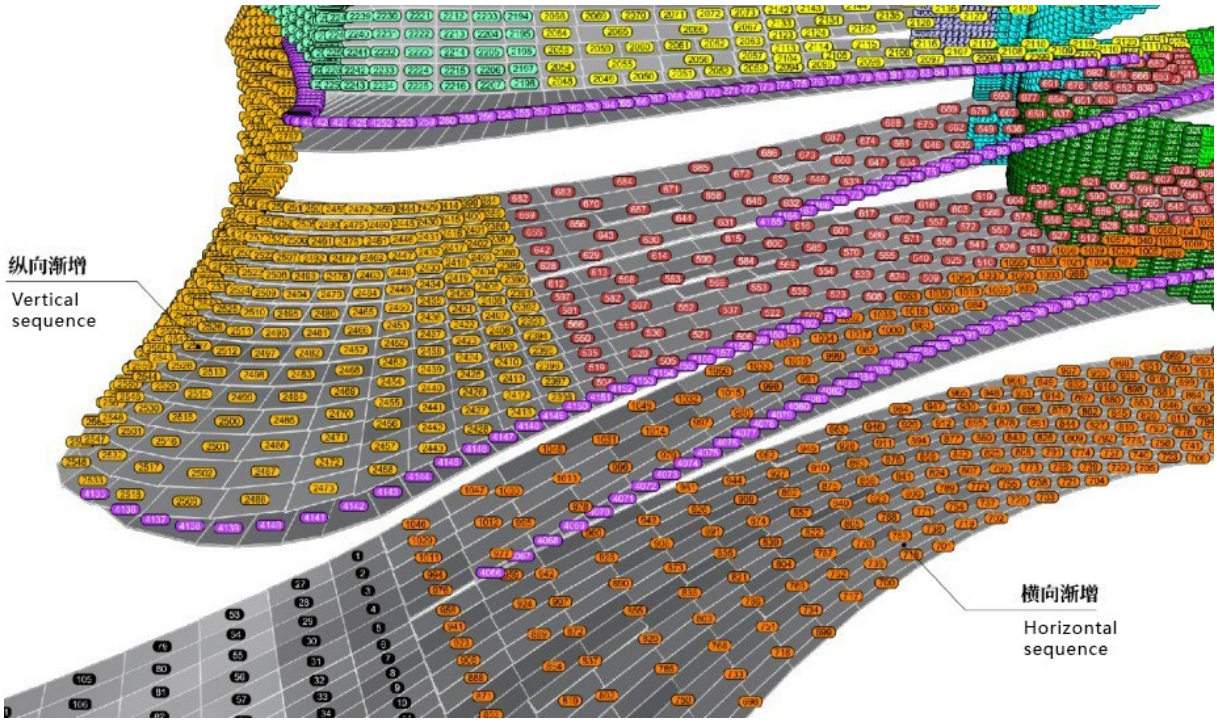

Figure 4. The two numbering systems for panel clusters.

3.2. Data generation for core components

Combining two different numbering methods from the previous step, a grouping algorithm program was applied to match the 14 partitioned façade panels with their corresponding mullions in Rhino3D and Grasshopper platforms. This process resulted in the derivation of geometric data, including vertex coordinates, normal directions, seam distances, and plane angles, which resolved issues such as displacement of points, excessively long review cycles, and high labor costs that could occur with manual development. The core content of this development phase was mainly reflected in the following three aspects.

3.2.1. Accurate grooving and hole-punching of façade panels

Once the grouping algorithm is completed, the panel units can be further perforated. Based on structural calculations and technical support from the aluminum plate manufacturer, technical drawings were obtained (Figure 5). Each panel needs to be perforated with 12 bolt holes, ranging from 120mm to 150mm in length, along the direction of the internal ribs of the panel to connect the angle steel and ear plate, and finally correspond to the purlins. Due to approximately half of the panel units being arranged in staggered rows, each purlin corresponds to both a certain number of end holes and a certain number of middle holes (Figure 6/7), with different reference lines for the two types of holes. As a result, the grouping algorithm for the panels occupies the majority of the workload in the hole-programming process. After the honeycomb panels in the 14 regions are perforated in the model, they are batch-converted into technical drawings (Figure 8) and sent to the manufacturer for large-scale production. After the production is completed, the panels are transported to the site for installation and testing. Following the completion of one cycle of perforation-production-installation for the first batch of panels, the subsequent 13 batches are constructed progressively using the same cycle. This is the most time-consuming and technically demanding core process in the façade development process.

From a purely technical perspective, in the construction process of highly customized complex curved façades, precise grooving, perforating, and joint interface design are relatively complex procedures. These procedures are also the most crucial steps for empowering similar engineering projects with

digital workflows. Their importance has been repeatedly demonstrated in research on designing and constructing highly customized architectural space frameworks and other practical projects [5]. For example, in this step, the selection and finalization of reference construction forms require a series of steps, such as case references, structural design, and program-assisted calculation. The calculation process is highly tense and requires a relatively high level of computer technology proficiency. Ideally, the construction form and the scheme design of the building envelope should be highly unified, and the implementation of the entire process relies on specialized digital teams' support.

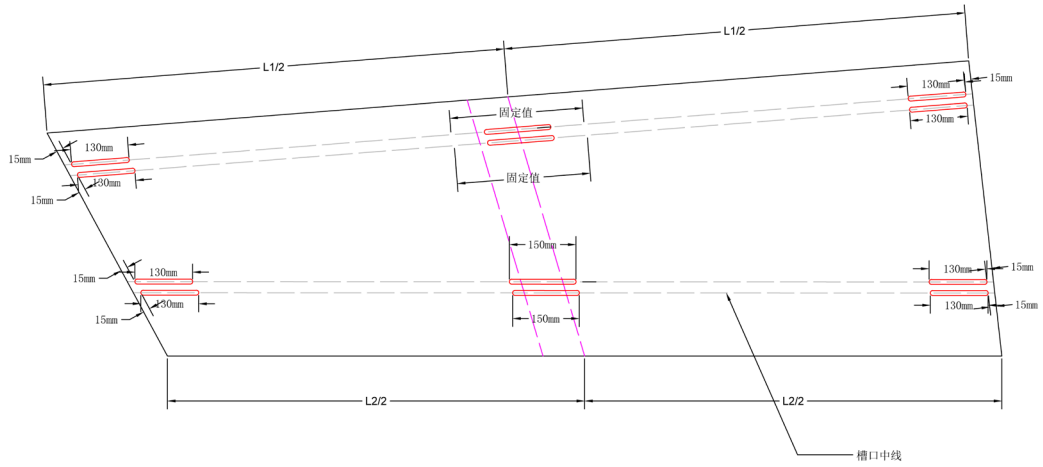

Figure 5. Drawing of façade panel with slots information

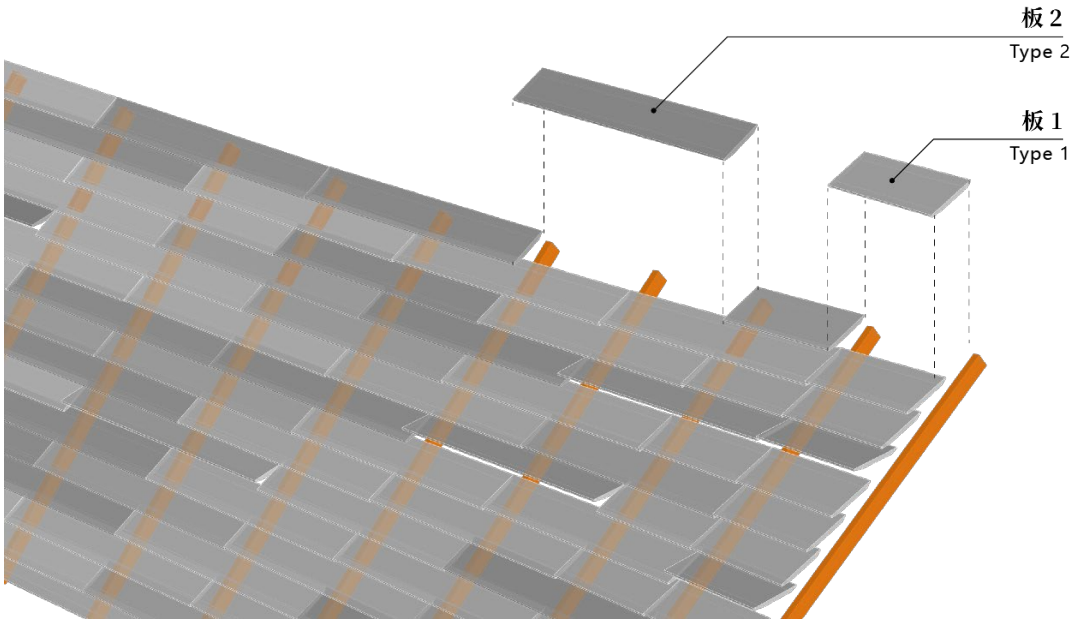

Figure 6. Purlin—panel matching.

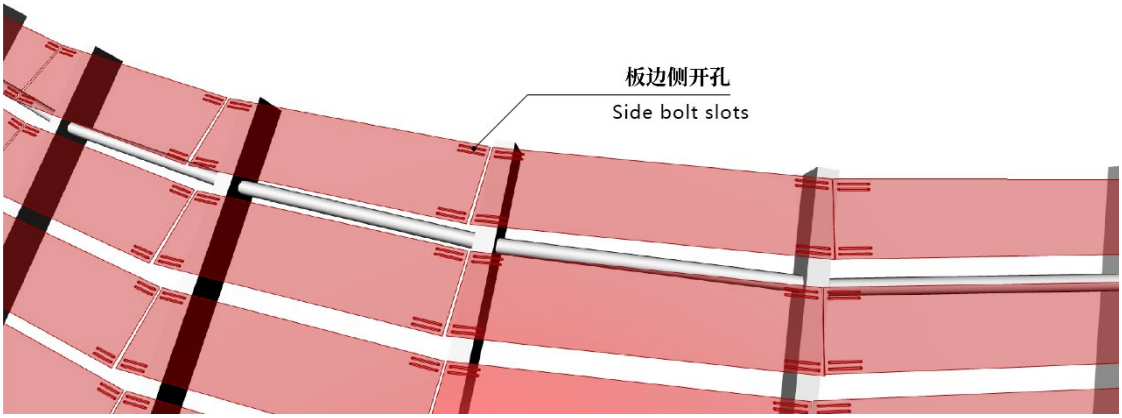

Figure 7. Purlin—slot matching.

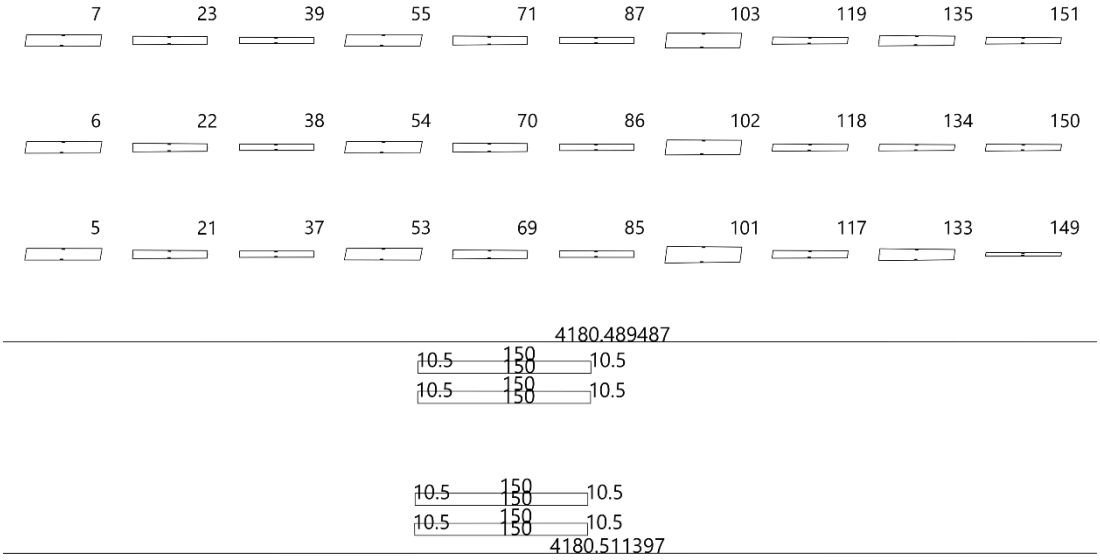

Figure 8. Drawings of flattened panels for digital fabrication.

3.2.2. Composition of angle steel, ear plates, and diagonal bracing

Based on the grouping algorithm from the previous step, precise positioning and dimensional data for components such as angle steel and ear plates can be further obtained. As a significant portion of the panel units in the primary area can reach a length of up to 4 meters, diagonal braces were used underneath the honeycomb panel to increase structural stability due to excessive weight caused by the length. Since the cross-sectional and projection dimensions of each panel are different, the hole positions for the side ear plates and diagonal braces gradually change as the curvature of the façade changes. Thus, the hole-punching task for the diagonal braces of the façade panels still needs to rely on the grouping algorithm.

According to structural calculations, panel units longer than 3 meters require additional diagonal braces (Figure 9). The intersection points between the diagonal braces and the panel units vary with the corresponding panel's angle, maintaining the diagonal braces' regular angle changes to meet the aesthetic requirements of the curved surface (Figure 10).

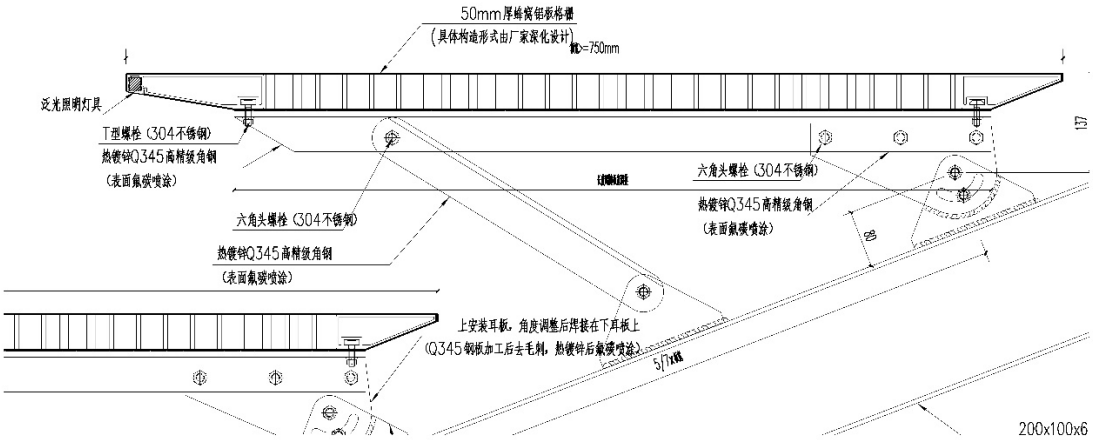

Figure 9. Detail drawing of panels with a length larger than 4m.

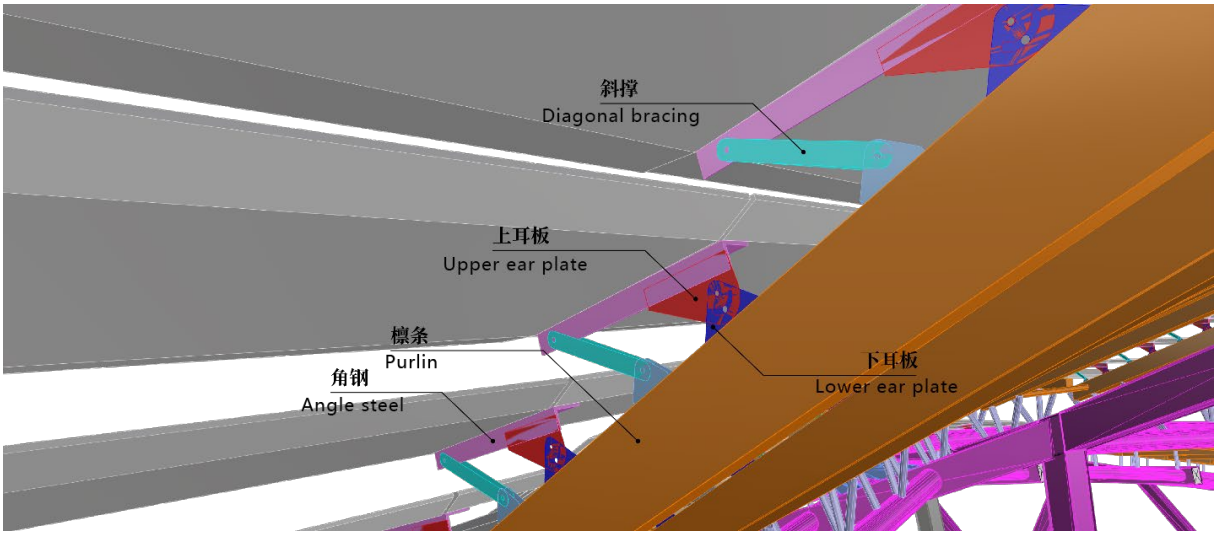

Figure 10. Purlin—panel connection.

3.2.3. Connection between purlins and the primary structure frame

Considering the precision of façade construction as a core requirement for ensuring project quality, during the positioning process, a large number of actual purlins still underwent corresponding displacement and angle adjustments based on the specific situation of the façade panel units, to ensure the highest smoothness of the gradual curvature jointly embodied by both. Adjustable-length connecting pieces were used as support between the purlins and the transverse round pipes of the steel structure through point-to-point distance measurement, ensuring that the connecting pieces were perpendicular to both the purlins and the round pipes to minimize material usage. Finally, length data tables were directly exported from the model as production references. In consideration of the support strength, an additional oblique strengthening connecting piece with an angle no less than 45 degrees was added next to each vertical connecting piece (Figure 11), and the total length of the connecting pieces was calculated based on the existing point data and angle calculation as a material preparation and post-settlement basis during the construction process.

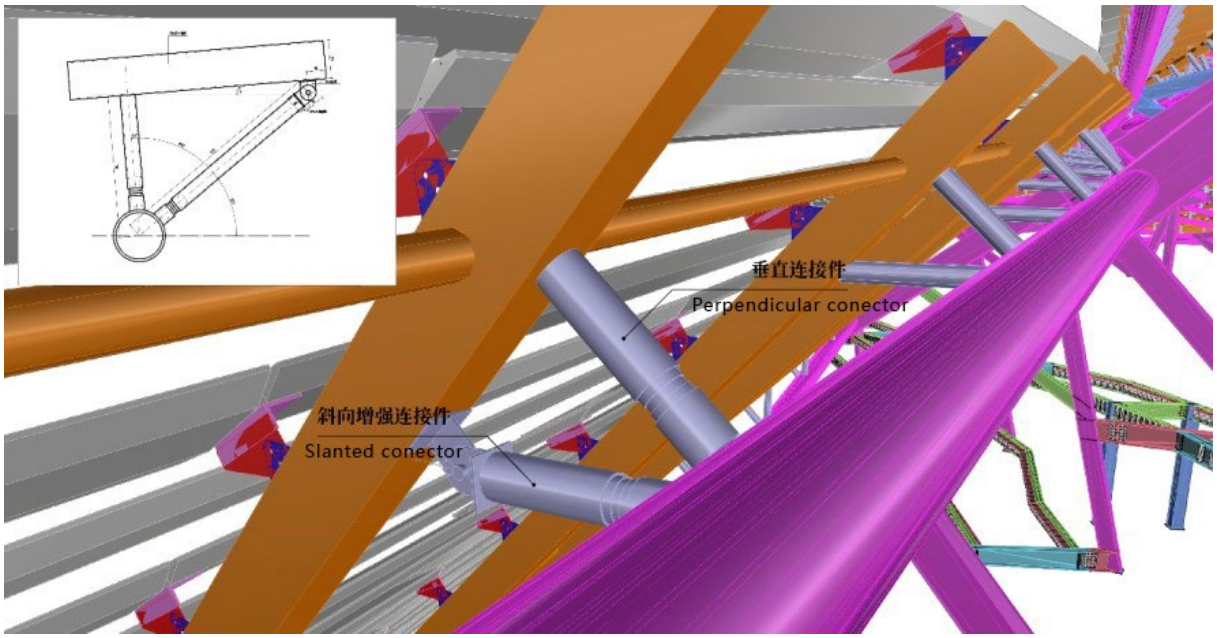

Figure 11. Purlin—main structure connection.

3.3. Development of construction data

With the completion of the algorithmic framework in the model, the development of unit-level data derived from collaboration has greatly facilitated the construction team during the actual construction process. This has truly achieved one-click generation and repeated extraction, simplifying the complex manual processes that require significant risk-taking and directly reducing them to basic operations such as coordinate positioning at a lower level. It has greatly improved construction efficiency and avoided construction risks. Additionally, using precise models and data as guidance for construction arrangements has transformed multiple single-threaded processes into multi-threaded parallel processes. This not only enhances project completion but also significantly optimizes project duration and cost, contributing the highest marginal benefit to the entire project. Construction data extracted in the later stages of the project include:

3.3.1. Batch processing dimensions for various construction components

These include angle irons with different lengths of unit plates, the identification numbers and lengths of purlins, and the length of diagonal braces. The application of automated processes in generating fabrication drawings can improve the productivity of construction processes by reducing unnecessary work and potential errors [6]. The key point of composing a detailed information model of the façade is to automate and batch-print all the fabrication drawings to be sent out to the manufacturer of the panels.

3.3.2. Extraction of coordinates for construction

These include all connector endpoint coordinates (Figure 12), the coordinates of the two endpoints of all purlins (Figure 13), the coordinates of the welding points for the upper and lower ear plates, the coordinates of the bolt-hole positions for the upper and lower ear plates, and so on.

Figure 14. Extracted coordinates data of ear plates.

The installation positioning of the ear plate has always been a core issue for construction teams as it directly determines the accuracy of the positioning and installation of the façade panel. Before the involvement of the digital design development team, the construction team's method was to calculate the distance between each ear plate on the beam and the endpoint of the beam, and then weld them

together. They completed the ear plate welding of panels No. 504 to 597 and the corresponding trial installation work, but the installation error was very obvious. The digital team corrected the ear plate errors in the trial installation area by directly extracting and exporting the coordinate values of the ear plate relative to the overall construction origin of the project. This was used as construction guidance data to complete the positioning and welding work of all ear plates. According to on-site measurements, the accuracy error range between the distance measurement method and the direct coordinate positioning method is between 0 to 80mm.

3.3.4. Other information

This includes the total length of LED strips in the longitudinal direction of each unit panel, as well as the placement and length of segmented data and control cables, the calculation of the façade panel area, the positioning of the electrical box, and the routing of cables. These factors are all relevant to the project's design and implementation. In future similar projects, this set of information packages can be used for process mining to provide insight into improving design and construction quality and efficiency [7].

4. Result

According to the data collected (Figure 15) during the construction of Zone 1 (through manual labor) and Zone 9 (through digital process), beside an obvious improvement on installation accuracy, a projected 715% increase in construction efficiency and 483% decrease in construction duration is achieved.

	Construction Duration	Number of Panels	Efficiency	Efficiency Improvement	Total Construction Duration (projected)	Duration Improvement
Manual Process (Zone 1)	360 h	503	1.39 panles/h	715%	4279.9 h	483%
Digital Process (Zone 9)	80 h	652	8.15 panels/h		733.7 h	

Figure 15. Data collected during construction

5. Conclusion

The façade subproject of the Chongqing Center for Planning and Exhibition is a typical Building Information Modeling (BIM) project that empowers the entire process of complex projects with increased efficiency. In ideal situations, BIM models for such projects can be integrated with blockchain technology to establish a decentralized information network for parallel processing of building information [8]. However, due to the need for digital construction empowerment for the façade part with uniform height, the scheme design team and the structural design team need to cooperate in depth. Compared with ordinary BIM projects based on Revit or ArchiCAD BIM platforms, the information modeling technology and data usage hierarchy and difficulty involved in this project have increased significantly, so the digital platform used for design development of the entire façade part is Rhino3D and Grasshopper plugin. To ensure that the surface modeling information on the design end is retained to the maximum extent and extended to the end of the construction process, the digital team has developed a series of Grasshopper algorithm programs (Figure 16) based on the design and partition schemes to extract and deepen various façade information from different angles and degrees of operation.

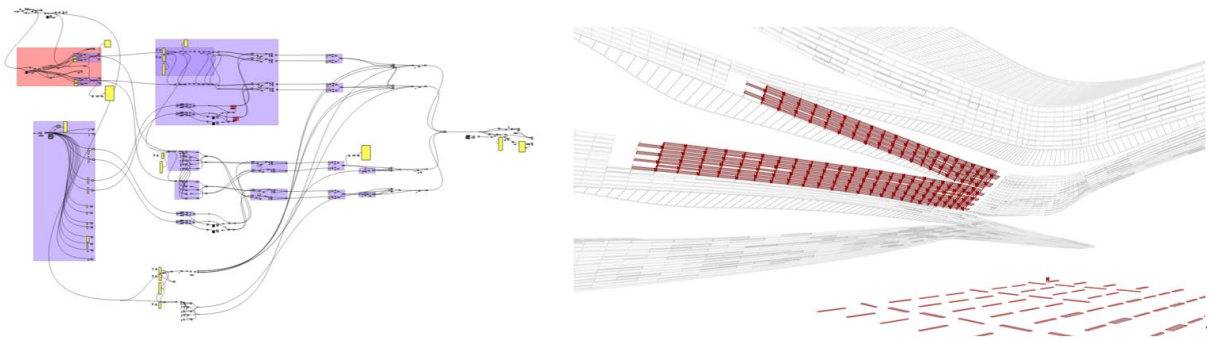

Figure 16. Grasshopper scripts for design and construction development.

Overall, the introduction of digital tools into the façade design and construction process has brought practical advantages, including breaking through the efficiency ceiling of manual construction, establishing a design and construction delivery system based on building information modeling, and greatly optimizing project duration and construction costs, enabling the entire construction process to be fully empowered and achieving a significant improvement in project completion.

Abstract

Principal stresses and moments are increasingly used to design efficient structural geometries in concrete slabs and shells. These are typically obtained through Finite Element Analysis (FEA) packages and represented as vector fields with singularities, such as high convergence or divergence areas. Designing architectural structures interpreting these fields currently relies on laborious parametric modelling. This paper introduces a generative method for isostatic ribbed slab design, where the stiffening topology layout is found with an anisotropic Reaction-Diffusion system. Based on FEA for a given slab design, the system emergently finds structural patterns along the principal stress and moment fields, which can be easily tuned into rib stiffeners, controlling their density and thickness. This bio-inspired approach, associated with field compositing, allows us to streamline the accurate modelling of structural elements with appropriate geometrical and dimensional control, which considers fabrication constraints. The workflow is successfully applied to proof-of-concept ribbed concrete slab prototypes, successfully designed, built and tested using this novel method.

Keywords: reaction-diffusion, field-based modelling, ribbed slabs, isostatics, computational design

1. Introduction

Structural optimisation is of utmost importance in the age of decarbonisation of architecture. Computational means of design and fabrication support a progressive redefinition of building technology, which can be increasingly reconceived with bespoke elements of high structural - and, therefore, ecological - performance. Recent research has focused on studying new concepts per mass-reduction of horizontal structures, such as slab and beam elements, using combinations of computation-driven optimisation techniques with advances in digital fabrication [1,2,3]. However, the design optimisation of slab structures was already a topic of interest during the XX century. Still, it is rarely adopted in contemporary construction because of its increased costs when using traditional means of design and construction. Remarkable is the example from Pierluigi Nervi, who designed the wool-factory building “Lanificio Gatti” in 1951, featuring a reinforced concrete slab system with stiffening rib elements following the direction of primary and secondary principle moments [4]. This milestone project introduced a new language for material-efficient ribbed concrete slabs, which inspires contemporary research.

SDU CREATE demonstrated with a series of experiments the structural efficiency of a series of beams whose design for concrete 3D printing is parametrically developed based on the isostatic fields of principal moments and stresses [5,6]. The diffusion of FEA software integration into parametric modelling environments has made exploring such structures more accessible to designers without an advanced engineering background. However, existing software and workflows do not support a straightforward translation of structural analysis into usable isostatic paths and structural shapes, requiring laborious modelling procedures.

In search of an alternative approach, we refer to observing natural structures, where geometrical stiffening of plates in bending can be found in species such as plant leaves and insect wings. One example is the Victoria leaf which adopts a two-way network of radiating ribs to enhance bending stiffness [7]. This and other natural pattern formations provide exciting role models for the optimisation of ribbed plates and suggest the possibility of linking the fields of biological morphogenesis with structural optimisation. Following this line of investigation, this paper describes a novel bio-inspired method for designing geometrically stiffened plate structures, adopting anisotropic Reaction-Diffusion (RD) to generate various structural patterns following the information obtained from vector fields of principal stresses and moments in a provided structure.

1.1 Background

The formation of structural patterns in Nature finds recurring similarities across species and scales, and it is still unexplained if those arise from similar self-organising behaviours [8]. The theory of Reaction-Diffusion, introduced in 1952 by Alan Turing [9], provides a universal model to explain pattern formation using simple reactions of two diffusible components. It generates various emerging patterns by manipulating a few diffusion and reaction parameters. Because of this property, RD has been recently used in mechanical engineering as a form-finding strategy to generate structural patterns [10,11]. In the work of [12], an anisotropic RD system that grows adaptively following provided tensor fields to generate 3D lattice structures is implemented.

Inspired by this approach, our work developed a custom RD system to interpret and react to vector fields of principal stress and moments obtained from shell-based FEA of structural plates subjected to bending forces. We combine this with structural, morphological and functional information layers, described with a set of 2D plots consisting of scalar and vector fields to automate the 3D modelling of geometrically stiffened structures.

2. Modelling approach

2.1 Reaction-Diffusion

RD is a computational model that generates emergent patterns closely resembling some of the ones found in animals´ skin and plants. According to Alan Turing's theory, these patterns can be generated by two reacting chemical substances spreading along a tissue at different speeds. The Gray-Scott mathematical model was developed from that assumption to simulate such a chemical reaction [13]. Since then, this was widely adopted to simulate the pattern formation using two differential equations that describe the variation in the concentrations of two substances, A and B, in a given time interval [14]. The chemical reaction between the two substances is controlled by the parameters F and k, representing respectively the *feed* and *kill* values. For the case of a bi-dimensional space, which is of interest to this article, the model is implemented by evaluating the values of the two chemicals, A and B, stored in the pixels of an image. The model´s diffusive behaviour is based on computing the Laplacian function that requires the evaluation of the neighbours' pixels to spread the concentration for the substances.

$$\frac{\partial A}{\partial t} = Diff_A \nabla^2 A - AB^2 + F(1 - A),$$
$$\frac{\partial B}{\partial t} = Diff_B \nabla^2 B + AB^2 - (F + k)B. \quad (1)$$

The variation of these few parameters produces a highly varied range of patterns, including continuous, closed cellular, maze-like networks and dotted configurations adapting to the conditions of the organism. Some of these patterns offer opportunities for generating geometrical stiffeners in complex structures.

2.2 Phase plot for isotropic Reaction-Diffusion

An RD phase plot is used to evaluate the pattern formations achieved by varying F and k parameters in an isotropic system (Figure 1). It is worth noticing how the gradual transition between phases is seamlessly processed locally, ensuring overall coherence and continuity. Since A and B substances generate nearly complementary values, the study of the pattern phase behaviour can be fairly observed in the sole substance A (Figure 1A). Here five phases can be identified according to the topological properties of the generated pattern: Z0 is mostly substance A without any relevant geometric features; Z1 is defined by dotted elements filling the space isotropically; Z2 has linear labyrinth-like elements with a directionality that is subject to the initial distribution of the substances; Z3 is similar to Z2 but exhibits a more robust network-like structure transitioning to negative spots on the lower part; Z4 does not exhibit any pattern. All phases show a slight change in scale parallel to their transition line, from a larger scale in the bottom-left corner to a finer scale towards the top-right corner. In addition, it is observed that the behaviour of the pattern is highly dynamic and unstable with low-value parameters and becomes slow and stable when adopting higher values. The perceivable colour gradient represents the dynamic behaviour obtained by overlaying three different states at 20 iterations of distance as *Red*, *Green* and *Blue* (RGB) channels. The pattern's scale changes by multiplying DiffA and DiffB with the same factor, preserving the same characteristics. This can be correlated to an input scalar field represented by a grayscale image (Figure 1B).

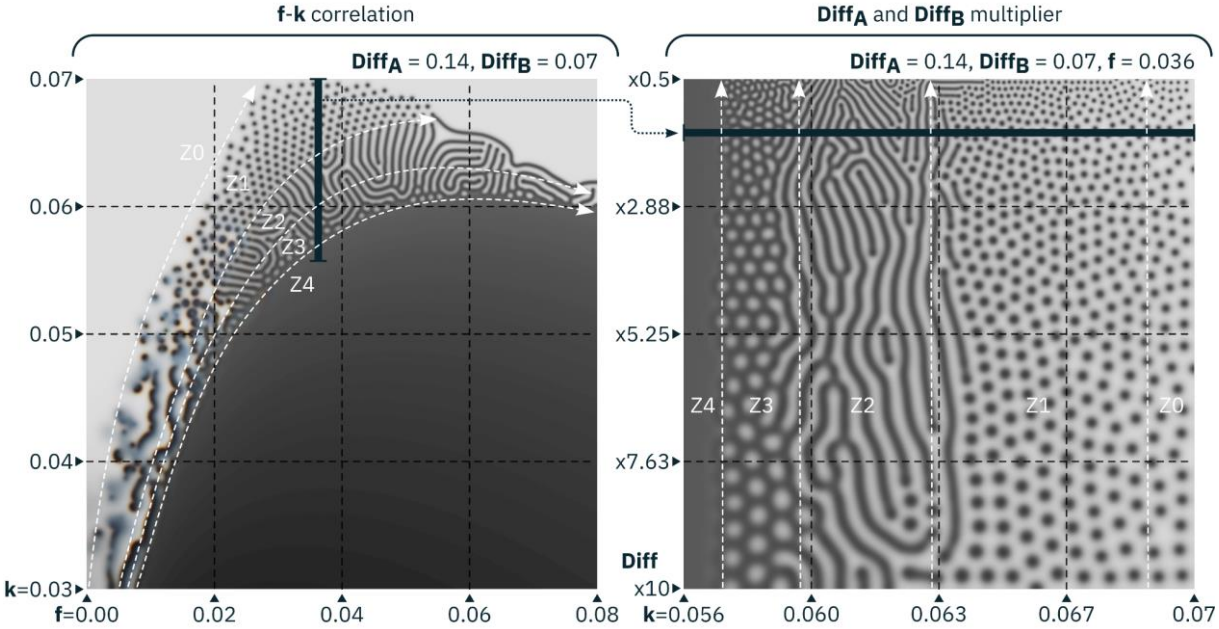

Figure 1A. Phase diagram for isotropic Gray-Scott model according to a variation of both f and k; 1B - Scale variation of the selected range of variation of the parameter k given a constant f value.

2.2 Anisotropic Reaction-Diffusion growth

In the model described above, the RD exhibits patterns with labyrinthine stripes features in Z2 and Z3, which cannot be controlled in their direction. The growth process primarily governs their orientation. To enable the control of these patterns´ direction and use them as structural patterns, it is necessary to introduce anisotropic conditions during the simulation to obtain tissue with varying diffusive behaviour

according to their direction. Provided a vector field, the diffusion model is controlled by the Laplacian function, which evaluates the neighbourhood in both *x* and *y*:

$$\nabla \cdot \nabla f = \nabla^2 f = \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} \tag{2}$$

An anisotropic behaviour is obtained along the main axis by reducing or increasing the derivative in one of the axes. To obtain this, a typical 4-neighbours cell was updated into an 8-neighbours model, towards which the Laplacian function is computed (Figure 2). The top row shows a Laplacian mask (or kernel) considering only 4-neighbours (Figure 2A). The numeric values represent the information weight for each pixel in determining the value of the Laplacian. While altering the proportions in x and y produces an anisotropic behaviour in the main axis (Figure 2B), it does not allow an anisotropic diffusion along any arbitrary direction (Figure 2C). The bottom row shows the 8-neighbours mask used for this work (Figure 2D). This approximates the diffusion along the main axis (Figure 2E) and towards any arbitrary direction (Figure 2F).

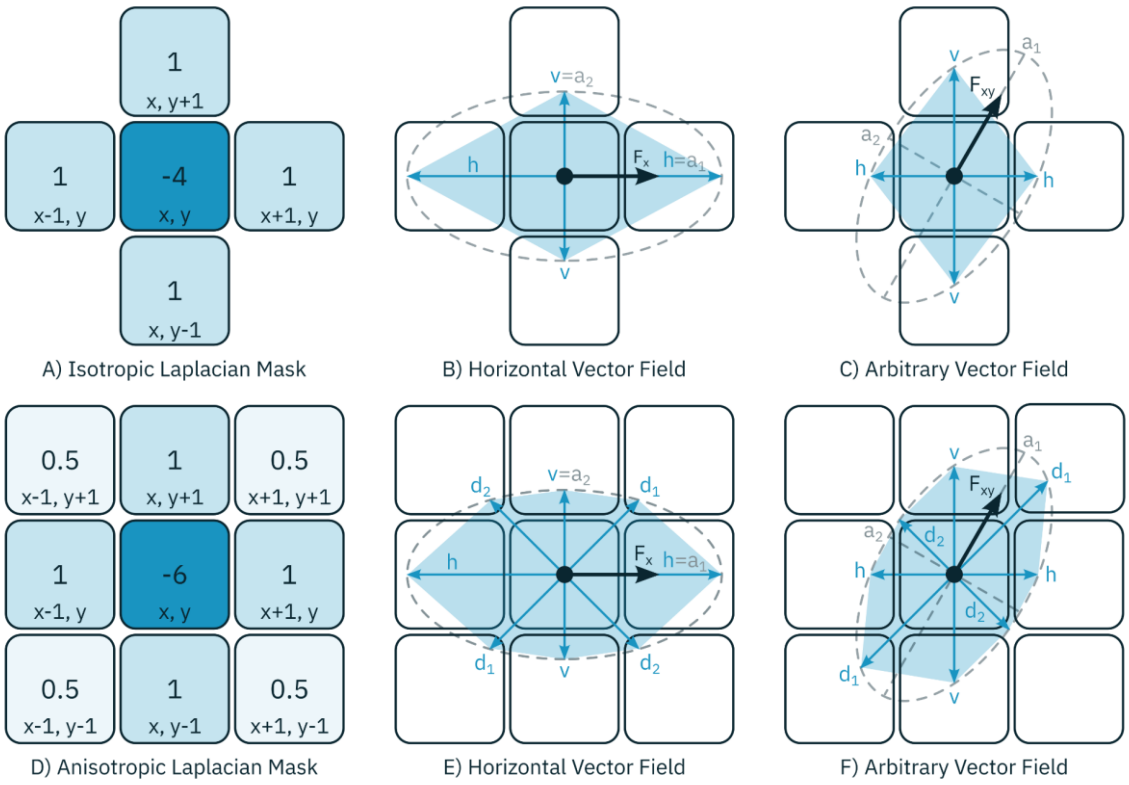

Figure 2. Comparison between 4-neighbours and 8-neighbours Laplacian masks in defining the anisotropic behaviour of diffusion

2.3 Controlled pattern generation

The intensity of the anisotropic behaviour can be controlled by turning off parameters a_1 and a_2, affecting the diffusion respectively in the parallel and perpendicular field direction. When $a_1=a_2$, a simple isotropic diffusion occurs (Figure 3A). When $a_1=1$ and $a_2=0$, the pattern exhibits anisotropy along the field

direction. When $a_1=0$ and $a_2=1$, the anisotropic behaviour is perpendicular to the direction of the vector field. When the proportion a_{A1}/a_{A2} for substance A is the same as a_{B1}/a_{B2} for substance B, the pattern has an isotropic distribution but is stretched in shape along the field direction (Figure 3B). A different behaviour occurs when $a_{A1}/a_{A2} \neq a_{B1}/a_{B2}$. For instance, if the behaviour of substance A is purely isotropic, then the pattern is not stretched but developed along the direction of the vector field (Figure 3C).

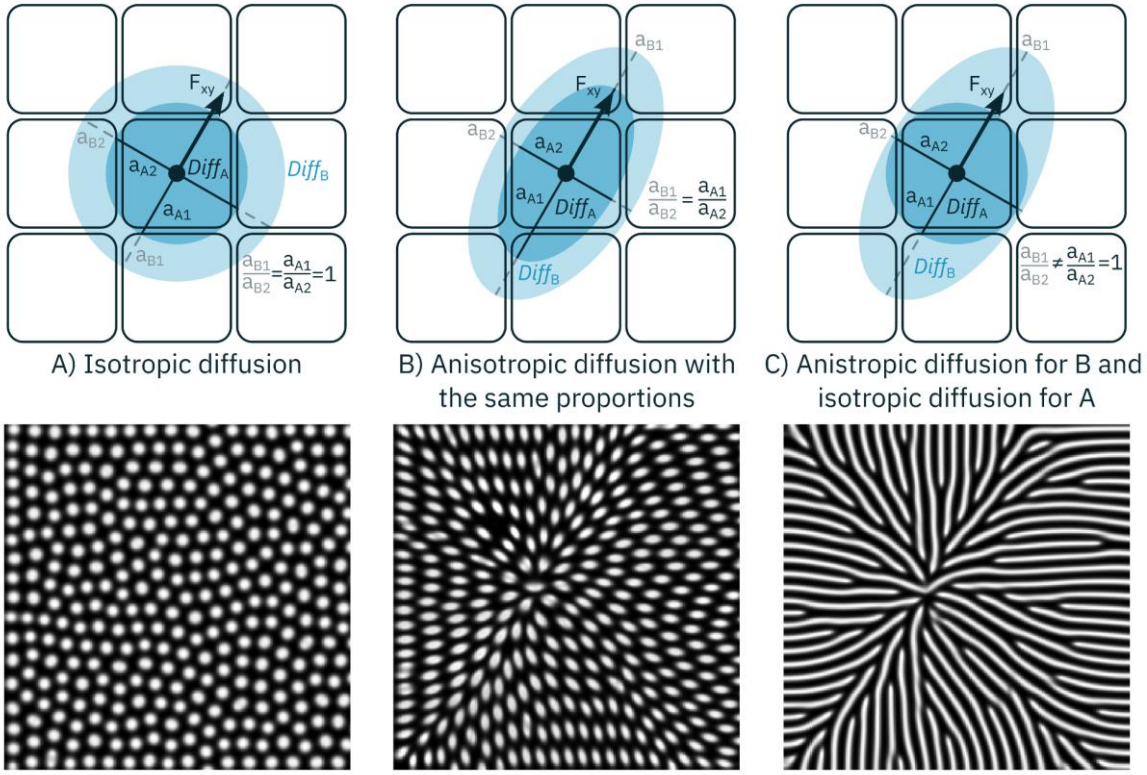

Figure 3A. Isotropic diffusion for the substances A and B.
Figure 3B. Anisotropic diffusion for both A and B.
Figure 3C. Isotropic diffusion for A and anisotropic diffusion for B

Figure 4 shows the behaviour of the anisotropic RD for a given vector field. The pattern is aligned to the vector field on the left while it follows the perpendicular direction on the right. Compared to the isotropic case, the pattern appears more stable, exhibiting uniform features for a broader range of f and k variation parameters. Similar phases can be observed compared to the isotropic case (Figure 1).

These patterns can be easily transformed into 3D geometry to obtain geometrical features with various structural properties. The bottom part of Figure 4 shows a few cases of surface thickening based on anisotropic RD patterns provided by a vector field. These ribbed geometries are obtained by directly transferring the value of substance A into a thickness height map. In addition, the patterns generated parallel to the vector field can be combined with those generated along the perpendicular direction (crossed patterns) to obtain a two-way ribbed layout.

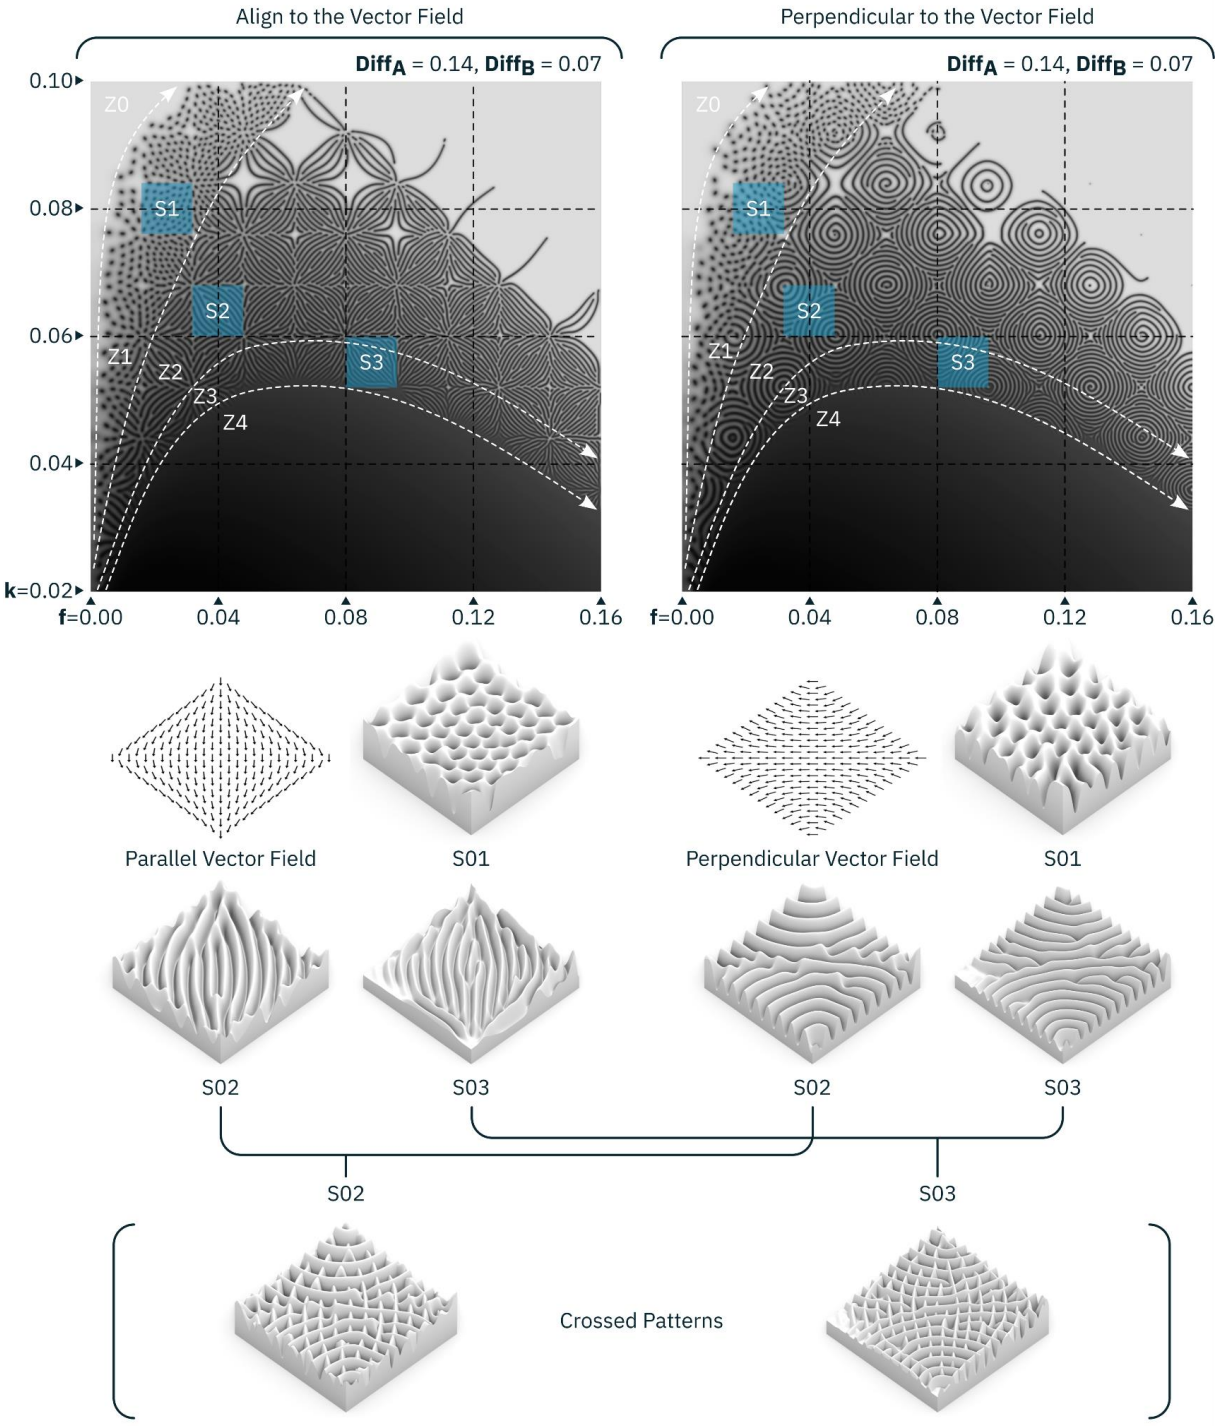

Figure 4. Phase diagrams for anisotropic RD. On the left side, the pattern is generated parallel to a given vector field. On the right, the pattern is generated in the perpendicular direction.
In the lower part, a set of displacement tiles is extrapolated to visualise the patterns in 3D. At the bottom, two crossed patterns for S02 and S03 are overlapped to obtain a two-way configuration.

3. Software implementation

Available RD implementations that allow an interactive tuning of parameters have been developed for graphic representation [15,16] and therefore lack integration with modelling software. To make this a tool for designers, the field-based anisotropic RD system described in this work has been implemented within Tissue, an open-source Blender add-on. In its current form, pixel-based and vertex-based modes are available. The pixel-based method was used in this work. It uses image textures as fields for A and B. The input vector field for controlling the anisotropic behaviour is an image where the channel *Red* and *Green* represent, respectively, the x and y components of the vector remapped from -1 and 1. Furthermore, additional grayscale images can be used as input to control the parameters F, k, scale, DiffA, DiffB, and Anisotropy. The vertex-based method processes the RD along an arbitrary mesh surface, using the Blender´s vertex groups as input fields to define height maps, where a value from 0 to 1 is assigned for every vertice. The vector field can be computed as a gradient function of a scalar field or by using the vector attributes.

4. Application case of isostatic path generation for ribbed slabs

The above-described method and implementation are deployed into a design-engineering computational pipeline, which is applied to proof-of-concept ribbed slab prototypes. Researchers and students developed these during SDU CREATE´s Summer School on Experimental Architecture in 2022. The following sections describe the modelling process and physical outcomes and illustrate a concrete application case for our method. The software pipeline encompasses the subsequent phases: (1) FEA-generation of scalar and vector structural fields; (2) generative design of isostatics patterns with RD; (3) Multi-field compositing of ribbed slabs.

The pipeline was applied onto two different slab cases of a rectangular shape, both measuring 20m x 10m, (RD-01) used four-point supports placed at the angles, with a slight offset from the perimeter; (RD-02) was based on two diagonal linear supports evenly placed in the longitudinal mid axes. Both elements were calculated with self-load and a distributed load equivalent to 6 kN/m^2. For this study, the prototypes were built in scale 1:10, and some construction details were tuned accordingly.

4.1 Modelling pipeline

A breakdown of the modelling pipeline blocks is described below:

(1A) Generation of structural fields - Starting from provided mesh shell elements representing the intended slab plan geometry, supports, loading conditions and material properties were applied into a linear FEA using Karamba for Grasshopper. The analysis includes primary and secondary principal moments, moment intensity, and sign information. Moment principals show the direction of the highest and lowest moment of inertia along the analysed surface.

(1B) Generation of fields maps - Through a custom exporter which translates mesh face properties into RGB colours, 2D maps were exported for the following steps of the design pipeline: (i) two maps of primary and secondary moment vectors directions, where the red (R) and (G) channels correspond to X and Y directions of the vectors; (ii) two grayscale scalar maps showing the absolute values of the moment intensities; (iii) two grayscale scalar maps outlining the sign of the principal moments, i.e. whether it is positive or negative.

(2) RD generation of isostatic structural patterns - In this phase, structural patterns for ribbed slabs were generated with the anisotropic RD system previously described, using the input fields from the preliminary FEA. Using a Graphical User Interface (GUI), designers controlled the pattern directionality according to the field of principal moments. They regulated the scaling of individual rib elements according to construction and fabrication constraints by scaling the pattern locally. The real-time behaviour of the RD simulation allowed us to preview results quickly and manually interact with its diffusion using Blender's brush tools to force the regeneration of critical parts, such as supports. In RD

Slab 01, the process was applied for both primary and secondary principal moments to generate a network of perpendicular ribs treated with two distinct scaling factors. In RD Slab 02, it was used to generate rib stiffeners only in the direction of the dominant principal moments, using local scale variations according to the moment intensity (Figure 5).

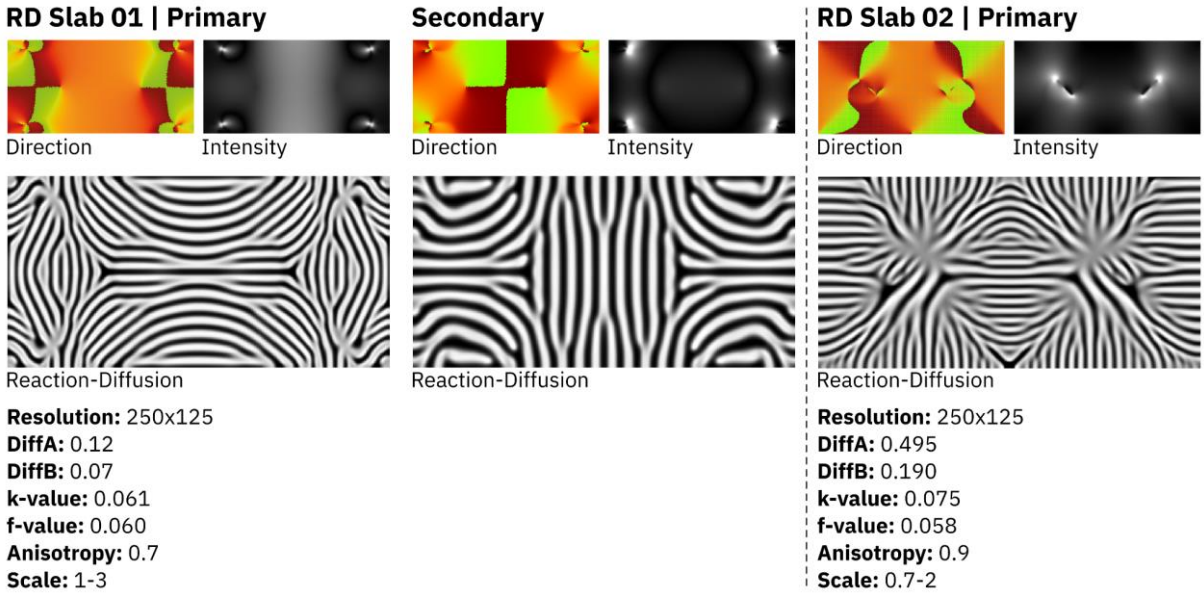

Figure 5. RD patterns were generated for the two slabs starting from the structural input fields. For RD Slab 01, both principal directions have been considered working with two scales for the primary and secondary directions. For RD Slab 02, a single rib orientation has been used, emphasising the scale varies according to the moment intensity.

(3A) Multi-field Compositing - In this phase, the three-dimensional geometry of ribbed slabs were obtained by combining the previously collected information layers. Scalar 2D maps representing design elements, structural data, and RD patterns were combined into a single height map with a compositing method for generating the slab geometry. The RD pattern was thickened to obtain ribbed elements that stiffen the tensional areas induced by the bending moment. The ribs´ cross-section shape was tuned mathematically through function curves according to the reinforcement rebar´s size and needed concrete cover. The ribs´ sectional height (H) for the primary ribs was parameterised according to the moment intensity (I) to obtain the required moment of inertia for any given moment value in the slab without the structural need for additional steel reinforcements. This is achieved with the following formulation *H=RD'*I*T*. For the case of RD Slab 01, a two-way ribbed slab, the secondary ribs´ sectional height was parameterised on a different layer. Afterwards, the information on the cross-section height for primary and secondary ribs was combined using the maximum value at every point of the slab: *h=max(h1,h2)*. The field-based compositing for the supports provided a mathematical control for the transition among the various slab parts (Figure 6).

(3B) Local Model Editing - The output geometries from the multi-field compositing were then analysed and prepared for fabrication. In this phase, additional geometric requirements can be introduced, for instance, to ensure integrated connection interfaces and construction details. Mesh sculpting tools are conveniently used to accommodate such needs and mitigate the transition between the generated ribbed geometries and the support areas.

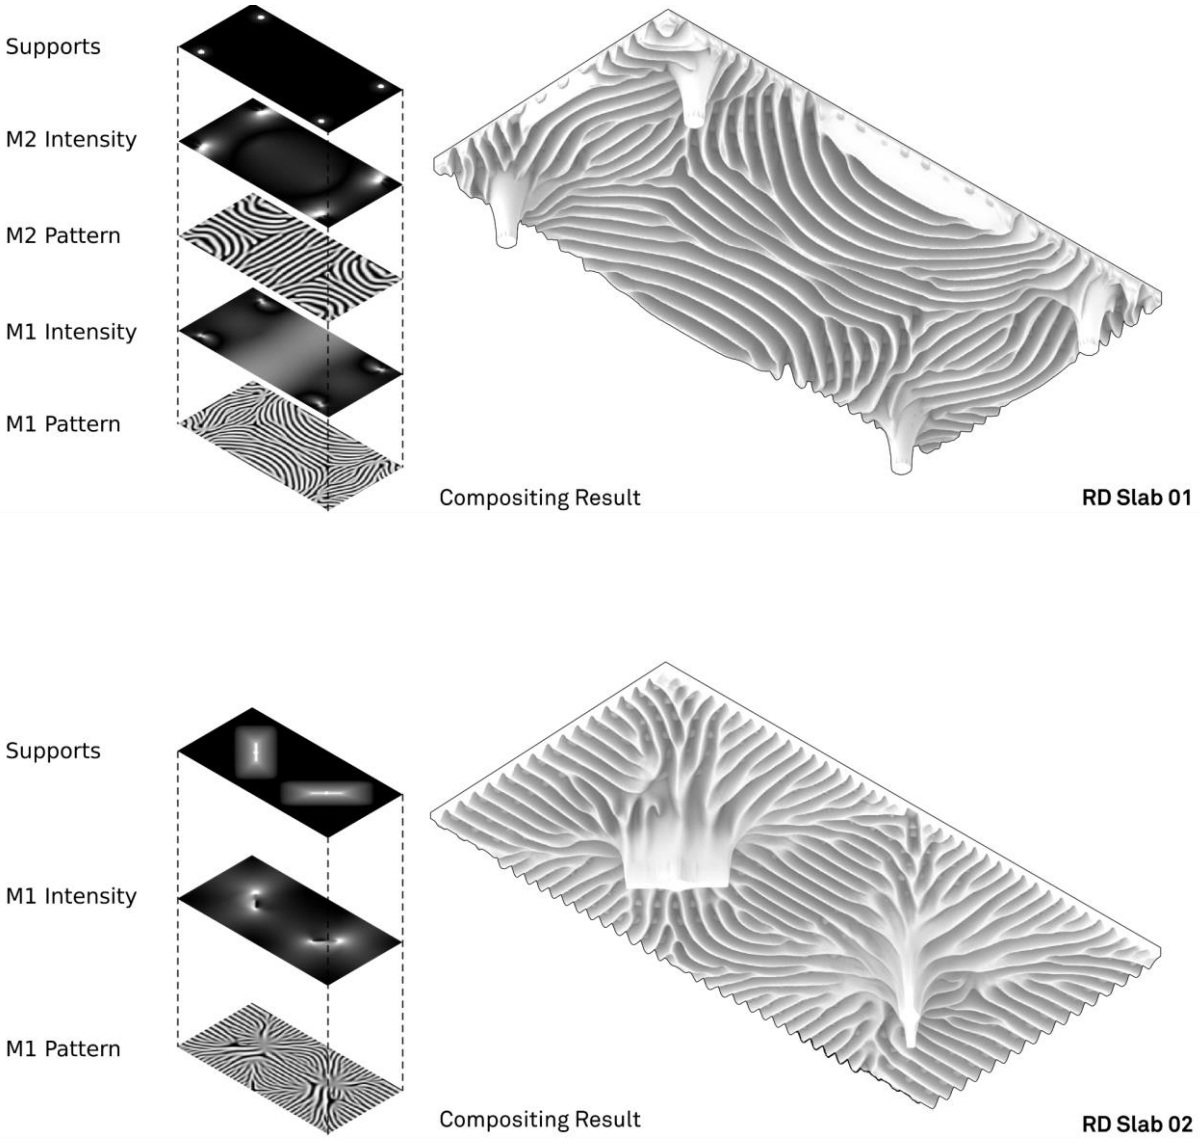

Figure 6. Multi-field Compositing process and generated 3D geometries for both slab prototypes.

5. Results

The RD-driven modelling pipeline for ribbed slab structures was successfully applied to the design and construction of two proofs-of-concept ribbed concrete slabs, realised in scale 1:10. These were fabricated through the use of 7-axis robotic milling of styrofoam moulds combined with Mixed Reality-assisted rebar bending, where Ultra-High-Performance Concrete (UHPC) was cast. A comprehensive overview of the fabrication process is provided in [17].

Two fully functional slab prototypes were built, verified using a non-linear FEA in Abaqus, and physically tested using non-destructive loading methods. The ribbed slabs confirmed their intended structural behaviour showing a bending high-stiffness despite their minimum thickness. The innovative design approach provides a new perspective from both computational and morphological viewpoints, resulting in a novel language for densely ribbed concrete slabs, virtually flexible to any boundary condition (Figure 7).

The presented RD pipeline allowed users to easily engage with the design of isostatic ribbed slabs, solving complex topological conditions in the path generation of the structural patterns without the need for establishing laborious parametric models. Designers could generate options using relatively intuitive tuning operations on the bi-dimensional RD patterns.

The use of the field-based anisotropic RD system proved to be particularly effective in the following:

(i) generating quickly structural patterns with a user-controlled scale where the rib stiffeners and their in-between spacing are semi-constant;

(ii) solving regions of largely variable proportions, where stress and moment principal vector fields quickly converge/diverge - often near supports. Our system generates seamless bifurcation and interactions that are coherent with the intended stiffening direction;

(iii) providing dimensional control in the individual ribs' width and height, particularly relevant in areas where stresses and support have a significant variation

(iv) providing opportunity for quick manual editing of unsatisfying configurations thanks to the interactive nature of the RD simulation.

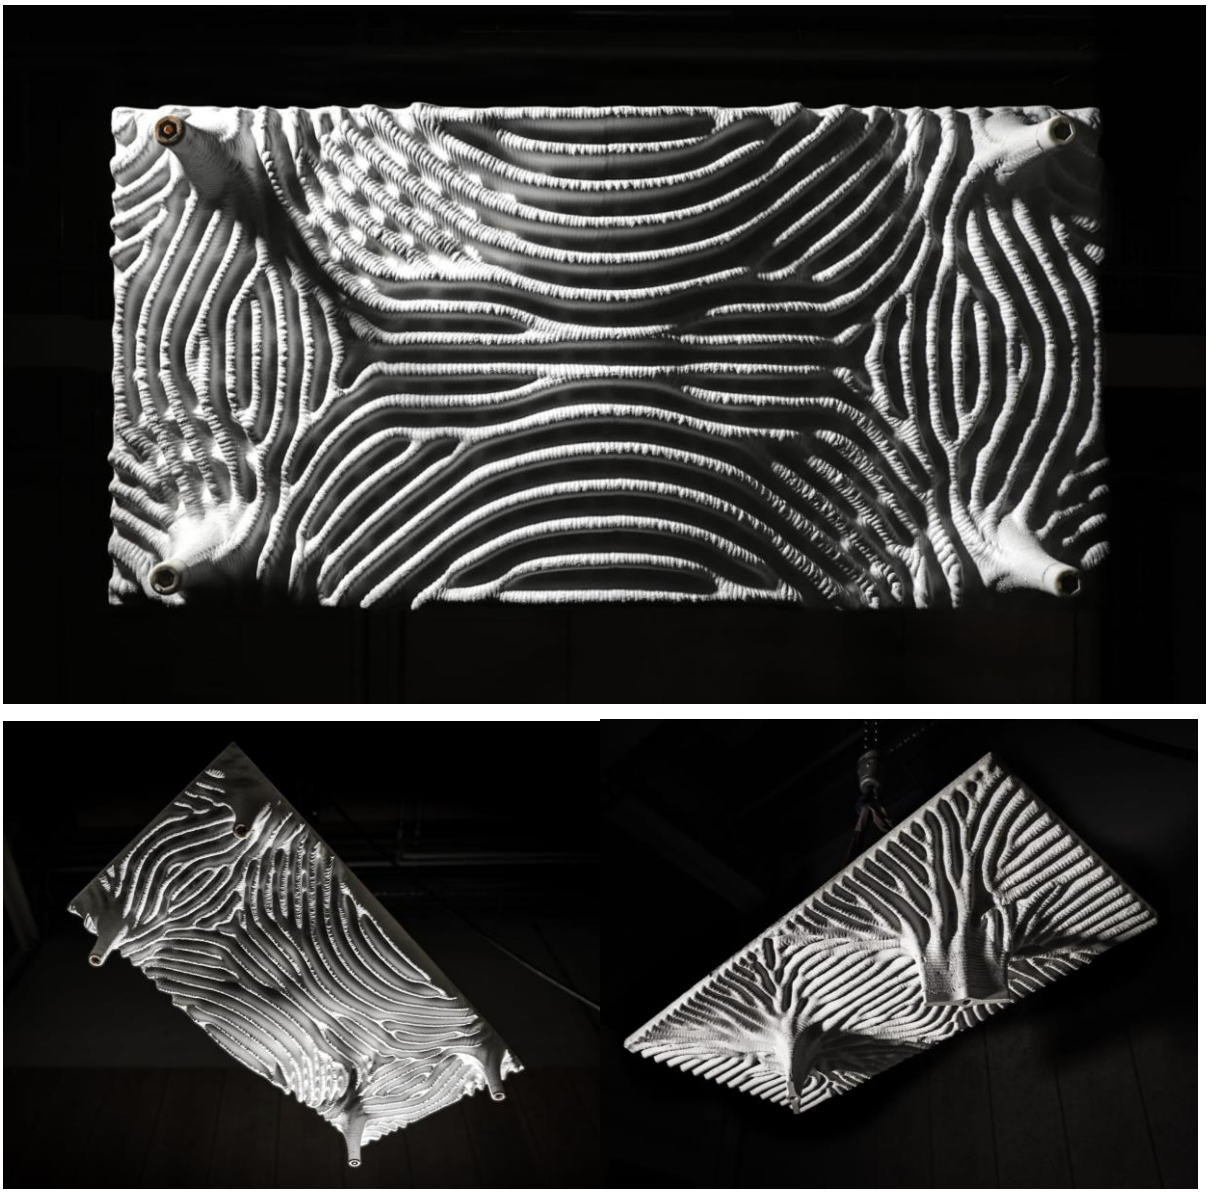

Figure 7. Pictures of the realised ribbed concrete slab prototypes.
RD Slab 01 (top and bottom left) and RD Slab 02.

6. Conclusion and future works

The paper discussed an unexplored development of anisotropic RD to generate ribbing layouts in structural plates subjected to bending. The approach successfully solves the geometrical and topological problems when exploring the design of isostatic ribbed slabs with different boundary conditions, offering a quick-to-use and interactive tool. Learning from this work, future upgrades of the current pipeline will focus on simplifying the user experience for non-advanced designers by introducing real-scale dimensional control of the patterns independently from simulation resolution and providing tunable presets for post-processing the stiffeners´ cross-section profile and relative dimensions. Furthermore, migrating the current implementation made in Numba to GPU computing will be considered to speed up the simulation. Future studies will extend the current 2D approach to the design of material-efficient 3D structures with a volumetric implementation of the RD system.

Abstract

In the rapidly changing world of construction and architecture, reassessing standard fabrication practices has become paramount, as they have been slow to adapt to increasingly prototypical requirements. Confronted with the unpredictability of non-uniform materials and uncertain site conditions, there is an evident lack of tools able to adapt to variable conditions during construction. Is it therefore possible to augment human tactical sensibilities with computerized form optimization to overcome these challenges [1]? In this paper, we demonstrate a highly adaptable construction process implementing concepts of feedback-loop generative design, continuous structural safety analysis, cloud-based data management, real-time spatial data acquisition, and builder guidance. Our process is underpinned by four key developments: (1) the on-site production of randomized branched cement geometries by pouring into organic-shaped channels directly drawn in soil, (2) the development of a novel macro-scale aggregate structural model [2] capable of performing continuous data analysis, (3) the integration of VR motion-tracking hardware with custom accessories for human-assisted cooperative real-time data acquisition and user guidance, and (4) the implementation of a custom cloud-based data interlink and visualization system for comprehensive remote multi-site construction management. The result is a closed-loop system where motion tracking equipment supplies XYZ coordinates for each stacked cement piece to a structural model that optimizes the target prototype and generates the allowed building volumes, which are then conveyed as instructions via LED-equipped accessories worn by each builder.

1. Introduction

This paper presents the development and application of an experimental construction process utilizing variable-form branched cement pieces derived from prescribed pouring guidelines, combined with a digitally guided assembly process. The pieces are stacked to achieve stability through friction from rough surfaces in direct contact while maintaining moderate porosity, as required by the client's design specifications. Balancing sufficient friction and maximizing voids between pieces is a challenging task due to the highly manual process of stacking pieces by hand.

During assembly, the builder exercises discretion in stacking pieces within the provided guidance volume, resulting in uneven stack density and shape deviations. Consequently, the final form remains unknown until completed. To ensure builder safety, fabrication guidance must be sequentially generated from structural analyses throughout the construction process.

The proposed construction method follows these operational steps:

i. Initial guidance is sent to the construction site, and pieces are stacked up to a certain stage.
ii. Stacked pieces are continuously scanned for position information.
iii. A point cloud derived from scanned pieces is merged with an automatically generated point cloud estimation of the completed structure, creating a structural model for static linear analysis (described in subsection 2.3)
iv. Structure safety is evaluated using the method described in subsection 2.4. If safe, the system proceeds to vi; if not, it proceeds to v.
v. Generate a new point cloud estimation of the completed structure and return to iii.
vi. Update the guidance volume and transmit the data to the construction site.

This paper comprises three sections: structural model development, construction system toolchain, and comments on the erected structures. The first section discusses the evaluation method for the construction system, covering construction material guidelines, material characteristic modelling, structural model schema, structural evaluation procedure, and optimization method. The second section details the hardware and software implementations, as well as the cloud-based construction visualization and management system. We conclude with an analysis of the erected prototypes and a commentary on the generated data for each structure.

2. Simplified modelling and evaluation of randomized branched cement geometries

With the rapid development of structural modelling in recent years, the precise analysis of complex geometries has been made possible. Nevertheless, structural analyses are commonly carried out prior to the construction phase and are based on given design characteristics where all variables can be exhaustively evaluated. Additionally, significant development costs are required to create new, high-precision material models. As such, it is extremely difficult to implement these conventional processes in unplanned construction situations. The structural evaluation method proposed in this paper is therefore based on the premise of ensuring continuous structural safety, which enables us to appropriately downscale the requisite analysis methods and simplify the overall material model. As a result, the evaluation of structural strength and structural optimization during construction can be performed nearly in real-time. We expect this novel process to not only serve as a solution for our specific fabrication research but also drive further technological developments in the construction industry.

2.1 Fabrication of randomized branched cement pieces

In an optimal scenario, builders would create construction materials on-site through a straightforward, freeform cement pouring process, producing randomized branched cement geometries. However, due to the potential for high variability in stacking ability of these geometries, we established a minimal guideline to maintain consistency between pieces without imposing excessive restrictions. We determined that each piece should have branches longer than 60 mm and a cross-sectional diameter of 50 to 80 mm. Although not indispensable, we also established a series of positive material shape characteristics to look for when pouring the randomized geometries.

The cement was mixed by weight with a ratio of 1.0:0.46:1.0 between water, mortar, and sand aggregate. In some cases, we tested an alternative cement type that replaced Portland cement with magnesium-based cement from desalination brine [3] which achieved comparable results. The cement was poured as a single object into organic-shaped channels drawn directly in soil near each construction site, and separators such as thin plywood were added to form the branch lengths according to our guidelines immediately after pouring, as illustrated in Figure 2.

Figure 2. Photographs of the material pouring process and diagrams of positive material characteristics.

2.2 Material modelling and analysis

To develop an effective material model and analysis method, we conducted a series of experiments to determine the structural properties of the randomized branched cement pieces. Test specimens were created by stacking six to eight fabricated pieces together and evaluating them through compression tests. The resulting load-deformation curve is shown in Figure 3. However, this approach has a limitation: it does not scale well with changes in material composition resulting from constructing in multiple locations using domestically poured cement. To account for these differences, compression tests must be conducted for each locally produced material.

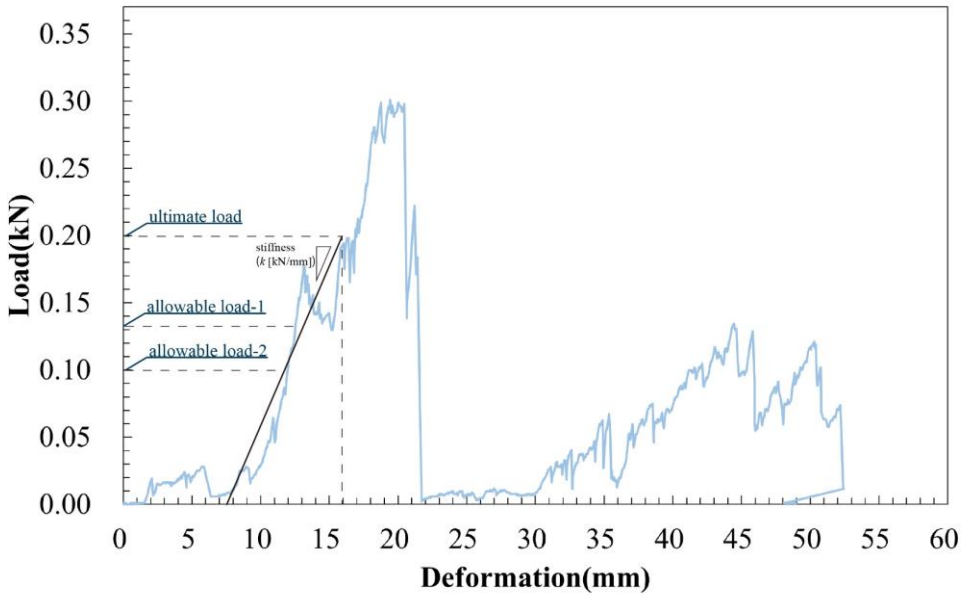

Figure 3. Load-deformation curve of material compression test

The analytical model is generated by representing the structure as a three-dimensional truss. Each piece's centre of gravity is represented as a node, and contacting pieces are connected by line elements of specific strength and stiffness, as illustrated in Figure 4, and further explained in Subsection 2.3. For the static linear stress analysis, we consider the maximum load and ultimate loads as follows: ultimate compression force N_{cu}, ultimate tension force N_{tu}, ultimate shear force Q_u, and ultimate bending moment M_u. Two load scenarios are examined: self-weight (Load-1) and self-weight plus horizontal load (Load-2, with a base shear coefficient of 0.05). The allowable stress is calculated from the ultimate load of the experiment:

$$\boldsymbol{Load-1}\text{: } [\mathrm{N_{ca1}}, \mathrm{N_{ta1}}, \mathrm{Q_{a1}}, \mathrm{M_{a1}}] = 1/2 \times [\mathrm{N_{cu}}, \mathrm{N_{tu}}, \mathrm{Q_u}, \mathrm{M_u}] \quad (1)$$

$$\boldsymbol{Load-2}\text{: } [\mathrm{N_{ca2}}, \mathrm{N_{ta2}}, \mathrm{Q_{a2}}, \mathrm{M_{a2}}] = 2/3 \times [\mathrm{N_{cu}}, \mathrm{N_{tu}}, \mathrm{Q_u}, \mathrm{M_u}] \quad (2)$$

The overall structure is designed to resist its own self-weight and horizontal force and is evaluated using allowable stress design.

Figure 4. Photograph of material compression test and truss modeling

2.3 General modelling scheme

To model the material stacking process, we developed a schema that generates a simplified representation of the structure based on a three-dimensional truss model. This schema comprises the following steps:

i. Populate a point cloud of nodes by acquiring the approximate centre of gravity of each stacked cement piece as a single point in 3D space.
ii. Set z-coordinates (height) less than 120mm to 0mm. This is to ensure that the first layer of cement pieces is placed on the ground plane.
iii. Classify nodes by XY-planes at z=n*H (for n=0 to N), where H is the vertical distance between planes.
iv. Link each node in the nth group to three nearest points in the n-1th group, if the distance is less than 400mm.

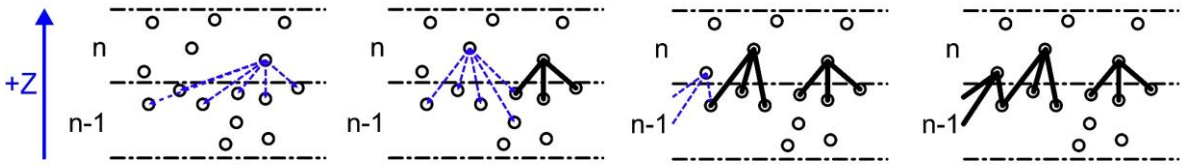

Figure 5. Section diagram of generating a three-dimensional truss.

Base parameters of the model, such as the vertical distance (H) between planes are established during mock-ups tests and adjusted according to the average size and shape of the cement pieces. This modelling schema, however, omits specific character information normally found in distinct-element modelling methods [4] such as points of contact between each piece and the shape of the piece itself. While necessary for a precise evaluation of the mechanical condition of each piece, this level of detail becomes insignificant in active construction site conditions, where pieces may break apart or shift positions. Furthermore, in the absence of reinforcement, such as rebar, cracking is not expected to significantly impact the structure's strength. While such cracking may initially cause load reductions, the load continues to increase subsequently, indicating the structure's resilience despite minor crack formation. Instead, the schema solely models the total number of stacked pieces and approximate contact density between them to ensure an adequate safety factor.

This contact density, defined as the number of truss links per unit volume, serves as a key robustness indicator of the structure's ability to withstand horizontal forces due to human contact and geometry displacements from significant material breakage. The greater the value, the more contacting frictional forces are expected. Additionally, the volume occupied by a piece per unit volume indicates the structure's ability to withstand its own weight.

The model considers two load scenarios: the long-term load due to the structure's weight (load 1) and the short-term horizontal load from human contact (load 2). We perform static linear analyses for each scenario and calculate the safety ratio (R) for each truss as a percentage of allowable stress:

$$R = max\{max\{N/N_{a1} + M/M_{a1}Q/Q_{a1}\}, max\{N/N_{a2} + M/M_{a2}Q/Q_{a2}\}\} \leq 1.0 \qquad (3)$$

N, M, and Q represent axial force, bending moment, and shear force in the truss member, respectively. N_a depends on whether N is compression (N_{ca}) or tension (N_{ta}). N_{a1}, M_{a1}, and Q_{a1} correspond to load scenario 1, while N_{a2}, M_{a2}, and Q_{a2} correspond to load scenario 2.

Static linear analysis offers near real-time calculation speed and sufficient insight into the overall safety of the structure. The simplification of the structure model is considered acceptable, based on realistic constraints on the overall shape of the structure, sufficient weight, small horizontal forces, and the absence of lifting or other problems. Analysis results are visualized by mapping safety ratios.

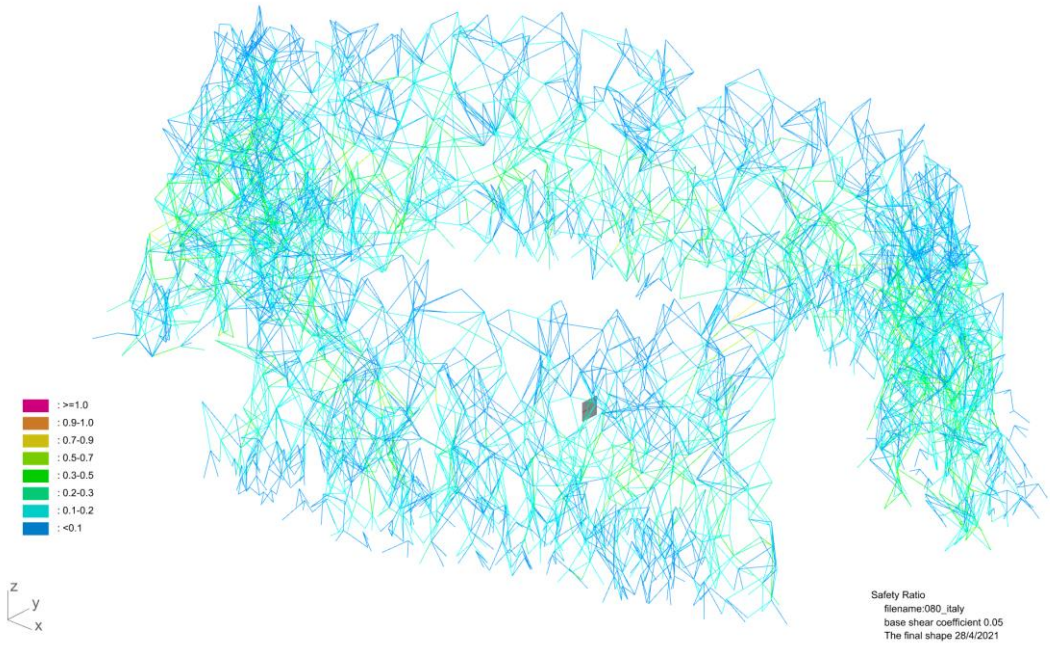

Figure 6. Analysis results mapped by safety ratio.

2.4 Real-time structural optimization and feedback during construction

During the construction phase, structural optimization is achieved by adjusting the target shape to minimize the highest calculated safety ratio value. The input variables of the optimization process consist of control points on multiple cross-section curves representing the target shape. By modifying the control points in the unconstructed volume, an optimized shape is continuously generated. The following automated operations are proposed for adjusting the target shape:

A. Deform the top of the cross-section curve horizontally (XY) by a certain distance in any direction.
B. Deform the top of the cross-section curve vertically downward (-Z) by a certain distance.

Operation A results in a more even weight distribution on the bottom of the structure by shaping the cross-section to resemble an isosceles triangle, reducing the load on lower pieces. Operation B reduces the number of stacked pieces, leading to an overall stress reduction. Utilizing these two operations, the structural optimization is performed using the following method:

i. Provide a target shape based on construction site conditions, and stack pieces up to a certain stage.
ii. Generate a truss model using already stacked pieces and randomly generated points in unconstructed areas. Perform static linear analyses and calculate the safety ratio. If structural issues arise, proceed to step iii; otherwise, skip to step v.
iii. Perform Operation A and return to step ii. If no solution is found before the peak cross-section curve reaches the middle of the base, move to step iv.
iv. Perform Operation B and return to step ii. If no solution is found before reaching the height of already stacked pieces, manually evaluate if it is safe to continue with the construction process.
v. Complete the optimization. If the construction is not finished, update the target shape and resume construction. Return to step i.

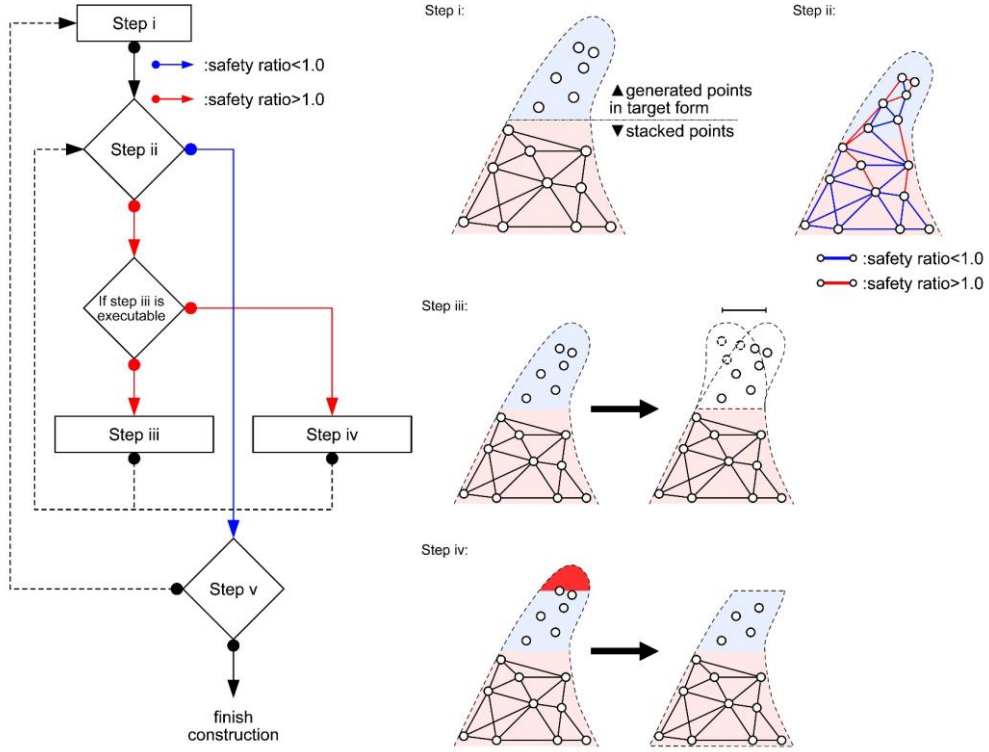

Figure 7. Optimization logic diagram along with sectional diagrams of each step.

3. Construction system toolchain

Deploying a digital fabrication system on a site that is completely inaccessible to project researchers and designers is challenging, especially without a dedicated assembly team that can be deployed in multiple construction locations. The fabrication system must therefore provide user guidance for piling and balancing randomized concrete shapes while also serving as a management platform to minimize inherent construction risks and hazards. By enabling real-time data interoperability, continuous collaboration among engineers, designers, managers, clients, and the general public is facilitated, ensuring a resilient construction system that can adapt to design changes while maintaining structural safety.

3.1 On-site hardware implementation

SteamVR [5] and its accompanying hardware, commonly used in industries such as digital fabrication, virtual production, and VR gaming, offer a cost-effective solution for acquiring precise 3D position and orientation data at around 50Hz [6]. However, challenges such as tracker occlusion, coordinate discrepancies between real and virtual environments, and long-term tracking system drift need to be addressed.

To mitigate tracker occlusion, an offset virtual origin is established using the local orientation of tracked devices. In the case of the VIVE controllers (deployed as point scanners), this virtual origin corresponds to the equipped pointer extension, positioning the virtual scan at -525 mm on the Y axis and 330 mm on the Z axis. For each builder, a VIVE tracker incorporating a blue LED and armband is mounted just before the elbow. An offset virtual origin is positioned at the palm of the user's hand. Some concessions had to be made in terms of positioning precision to ensure accessibility. The implemented offset factor is therefore based on the average forearm length of 269 mm [7].

Both coordinate parity and long-term tracking system drift are resolved by employing a continuously tracked world origin. The coordinates and orientations of all VIVE devices reference a base VIVE tracker representing world space and its corresponding rotation. This referential coordinate system creates a self-correcting tracked space resilient to external perturbations and ensures alignment between the physical environment and digital systems for structural analysis, visualization, and construction.

Figure 8. From left to right: reference origin tracker with 3D printed XY axis pointer, user guidance tracker with LED attachment, scanning controller with added pointer.

3.2 On-site software implementation

The on-site software implementation consists of straightforward tasks for users. Wherever the blue LED on the VIVE tracker lights up, stack up the cement material. After balancing a selection of pieces, scan each stacked piece by pointing at the centre of gravity position with the modified VIVE controller. These tasks are managed by a Unity Engine [8] application deployed on a gaming laptop. To process incoming guidance volumes, the application deserializes mesh data [9] and generates a collection of collision boxes using a volume-capable voxelization script [10]. Although this leads to a nominal loss of resolution, it allows real-time assessment of the user's virtual tracker position within the buildable area.

We developed a web app, accessible on a user's smartphone, to manage the scanning system within the Unity application. Users can select from three point types: Main points (centre of gravity of each concrete fragment), Blue points (tie points of the safety wire), and Red points (verification of virtual environment positioning and structural displacement evaluation). Selecting a scanning type generates a new session ID and forwards it to the Unity application.

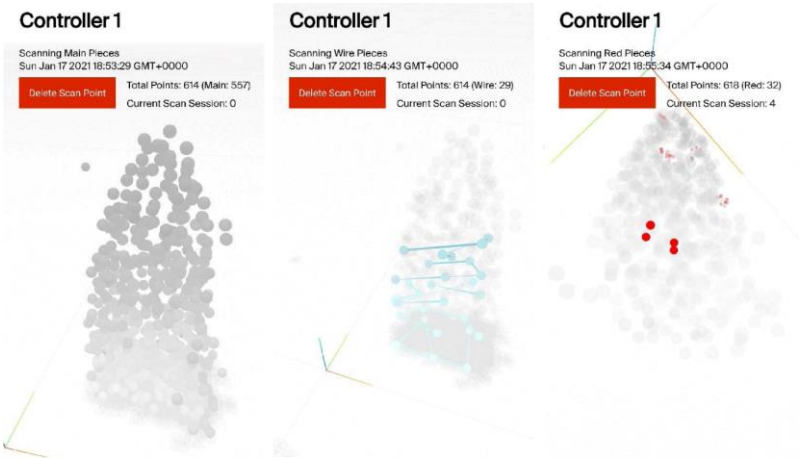

Figure 9. Screenshot depiction of mobile web app. From left to right: main scan points, blue points, red points.

Users can scan required points by actuating the trigger on the VIVE controller, while simultaneously monitoring the ongoing scan session on the web app. This app displays descriptive information such as the number of points scanned in the current session and the total number of points scanned throughout the fabrication process, along with a real-time 3D visualization of the generated point cloud. If a mistake occurs, the web app provides a delete button with immediate visual and audible feedback.

To complete a scan session, users tap the "Finish session" button within the web app. Sessions are automatically closed if a loss of connection occurs or if the web page is closed abruptly, ensuring a scanning lockout to prevent unforeseen scan points from appearing.

For each scanned point, the Unity application generates a JSON-compatible string containing the sessionID, controller actuated (to support multiple scanners), point type (command), individual pointID, point position in meters, and the layer (corresponding to the construction day). The format is as follows:

```
{"sessionID":"fdbc36c0-9125-11eb-bb11-fd31f66d0264","controller":"controller1",
"command":"red","pointID":"a9d4cbc6-fc9a-4d26-b8b6-f12afeb5d312",
"positionedPT":"(5.301707,-0.09540617,1.038687)","layer":"1"}
```

(4)

3.3 Cloud-based management and visualization deployment

We deployed a Raspberry Pi 4B single board computer [11] as a lightweight server to relay data between the construction site and the structural analysis system using Node-red flow-based JavaScript development platform [12]. The server manages three main components: real-time data sharing using websockets [13] and REST APIs [14], a RAM-based database with persistent backups utilizing Node-Red's 'Context Data' feature, and coordinate conversion of scan data between the right-handed (Z-up) coordinate system of Grasshopper, left-handed (Y-up) coordinate system of Unity Engine, and the right-handed (Y-up) coordinate system of ThreeJS [15]

To address potential misuse of equipment and incorrect data, resulting in a potentially dangerous construction environment, we created a real-time interactive visualization with ThreeJS, allowing all parties to monitor the construction and correct any miss-scans. The digital twin is accessible on various mobile devices from any location. On launch, the visualization interface fetches the latest database point cloud via the REST API and establishes a websocket connection for real-time updates. An optional live view of the on-site VIVE controller positions is available to minimize errors for the on-site users in charge of scanning the construction.

We integrated the Meta Quest 2 [16] and webXR capabilities for an immersive experience with true 3D depth perception, enhancing remote management and reducing the burden on users. Advanced locomotion options provide a more accurate assessment of the structure's 3D geometry, further reducing the chances of errors during remote management.

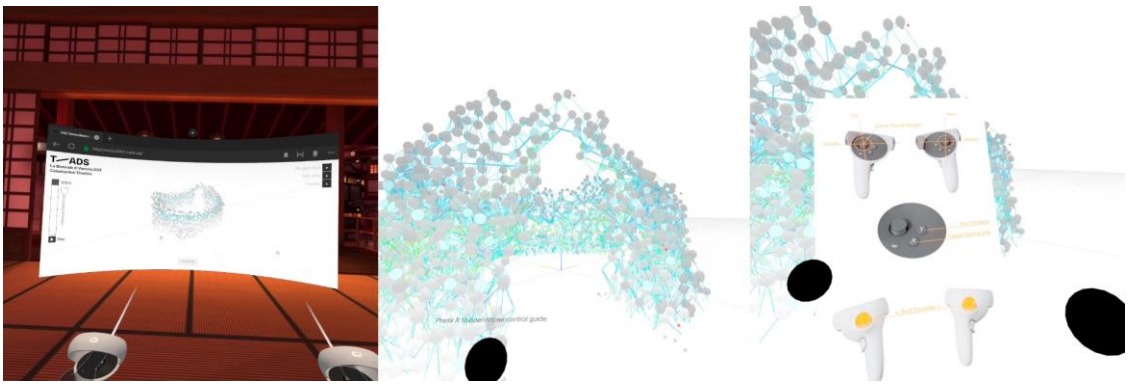

Figure 10. Screenshots of 3D visualization web app accessed via Meta Quest 2.

4. Comments on the constructed architectures

To evaluate our construction system, we erected three mock-ups with similar dimensions to test the structural model and scanning and guidance system. The first two mock-ups were towers (1.5m x 1m base, 2.7m height), and the third tested arching with a steel support frame. A large-scale pavilion (7m length, 5.2m width, 2.7m height) was constructed incorporating prior test elements. The second and third mock-ups and pavilion were remotely managed.

4.1 Standalone tower in Tokyo, Japan

Constructed in a local and controlled environment, the goal of this standalone tower was to achieve an approximate stack height of 2.8 meters. This was considered the structural limit of the material. Without guidance, previous tests achieved only 1.7m height due to tapering. With guidance, the planned height was achieved in a week. After achieving the target height, it was decided to continue stacking until overcompression. This led to collapse, but with controlled toppling.

Figure 11. From left to right: safety factor of 3D truss model, 3D scan of completed mock-up, 3D scan of collapsed mockup due to overcompression.

4.1 Construction tests in Dubai, UAE

Two prototypes were built in Dubai using a new team and domestically produced stacking material. The first prototype, a copy of the Tokyo tower, achieved the target 2.8m height in three days with minimal tapering. The second prototype tested arched stacking assisted by prefabricated steel arch frames. The arched structure was completed in two days.

Figure 12. From left to right: safety factor of 3D truss model (arch), photograph of completed arch, photograph of Tokyo tower analogue.

4.2 Large-scale pavilion construction in Venice, Italy

The structure's initial stacking area is an elliptical torus of an external length of 7 metres and width of 5.2 metres, and an internal length of 4.6 metres and width of 2.8 metres. In elevation, the pavilion gently varies in height between two peaks of a maximum of 2.8 metres and a minimum of 1.7 metres. Arched stacking from the Dubai mock-up was utilized for the two 2.2-metre-high openings that allow passage for people. The torus has a roughly triangular cross-section with the upper part slightly inclined inward. This inward portion is compressed by gravity from both sides, similar to a masonry dome structure. The pavilion took six days to construct utilizing a local construction team and two representatives from the Dubai team.

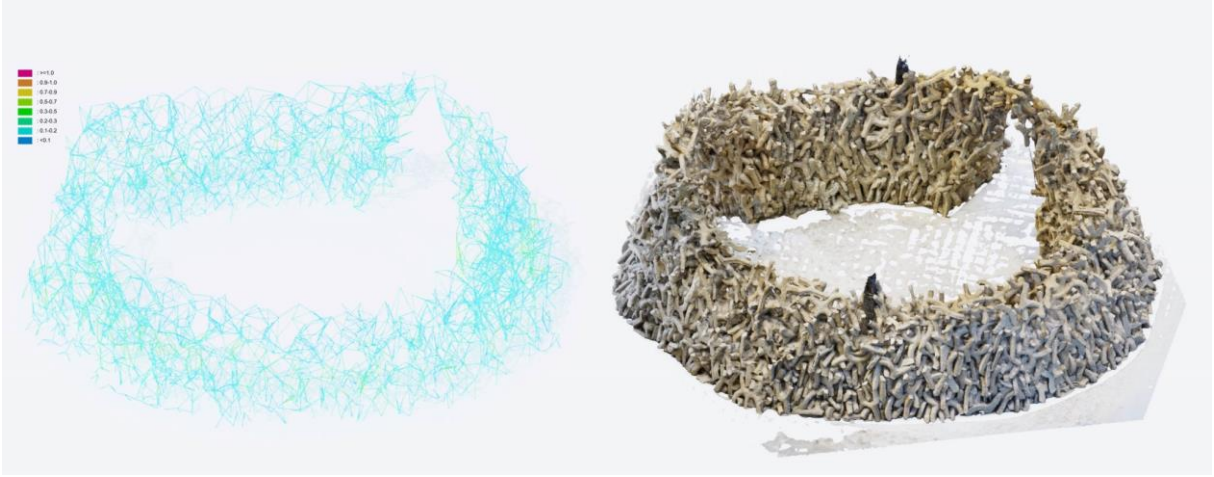

Figure 13. From left to right: safety factor of 3D truss model, 3D scan of completed pavilion.

We conducted a long-term creep evaluation of the structure via comparative photogrammetry analysis at the start of the exhibition and 6 months later near the end. This showed a 1.5 to 2 cm inward displacement on one of the facades. The cause of this displacement however remains inconclusive as we are unable to make a distinction between a slow movement and a single event.

Figure 14. Long-term creep analysis of overall pavilion

5. Conclusion

The paper demonstrates an innovative construction process both in terms of material modelling and construction site management. By adopting a simplified structural analysis method, we are able to rapidly model complex material interactions, thus ensuring near real-time analysis during construction. The practical applications of this system, as demonstrated through the construction of various mock-ups and a large-scale pavilion, attest to its effectiveness in diverse scenarios. Moreover, this approach also illustrated the relevance of a cloud-managed construction system for rapid and flexible deployment in multiple construction sites, enabling continuous collaboration among builders, engineers, designers, managers, clients, and the general public. As a result, we believe that adopting more responsive and adaptable construction processes can scale, allowing rapid adaptation while ensuring the safety of builders and users. Looking ahead, this construction system implementation offers promising opportunities for innovation in the industry by facilitating construction management, increasing efficiency, and accommodating a wide range of architectural designs.

Abstract

In the article, the challenges associated with traditional timber lattice shells are discussed. Despite their high efficiency, their manufacturing requires significant expertise and assembly effort, making them difficult to enter the industry. The research explores alternative irregular lattice shells based on geodesic patterns, which are suitable for low-tech manufacturing and limited budgets. The paper focuses on the method of transferring complex digital data to building elements using a low-tech tool, explaining the design process for multilayer geodesic grid shells and discussing the advantages and challenges of this approach. Furthermore, the design principle with individual connections is explained in detail, followed by an explanation of the transfer of data from the design and construction process to the lattice shell. To facilitate this, a low-tech tool was developed from conventional available components, which transfers data on assembly to the construction elements. The article concludes with a report on the experiences of building an elastically bent lattice shell made of timber using this concept.

Keywords: lattice shell, digital fabrication process, timber construction, computational design, structural design, digital process chain, digital tool, man machine interface, low-tech approach

1. Introduction

1.1. Overview

The Chair of Structural Engineering and Building Construction deals with the topic of lattice shells in teaching and research within the framework of digital timber construction and novel wood technologies. The aim is to use digital tools and optimized planning processes to design, construct and build efficient and sustainable lightweight structures. In the related course, the students dealt with the static properties of shell structures and created their own designs with digital tools on the basis of these laws.

1.2. Motivation

The advent of computational tools in design and architecture has opened up areas of architectural geometry that now enable design, optimisation and fabrication for complex geometries. However, the optimised symbiosis of form and fabrication often requires exclusive multi-axis numerical control, which is not always accessible and usually very cost intensive. With the construction of the "In A Knotshell" pavilion, the aim is to show how manufacturing processes can be simplified with efficient, universal tools without sacrificing complexity. The main goal is to efficiently inform the building elements with the necessary data for handcrafting.

1.3. Boundary conditions

The main constraints for the fabrication are a limited toolset (chopsaw, drill stand, drilling machine for slotted holes) and an overall low budget of 3000 € for materials and tools. Since multi-axis CAM was not available for the project at that time, the decision was made to use a low-tech approach. This meant that most of the manufacturing will be done by hand and the geometric complexity had to be broken down for humans.

For the remainder of the project, only structural elements that are planar in their initial state were considered. There was also a desire to realise a sophisticated geometric form that works with a grid without constant node spacing and with different meshes.

Figure 1. (a) The finished ‘Knotshell’ pavilion.

2. Concept design

2.1. Geometric description

The final geometry of the 'Knotshell' pavilion was developed using the shape of a torus. More precisely, it is a section of a torus that represents an anticlastic surface and is reminiscent of a hyperbolic paraboloid. The advantage of using a torus, however, is that the shape is easily reproducible from a simple set of parameters and additional offset surfaces can easily be derived.

The section of the torus with the ground plane leads to the fact that the support points are not lined up on two parallel lines. Consequently, the contact area with the ground is increased.

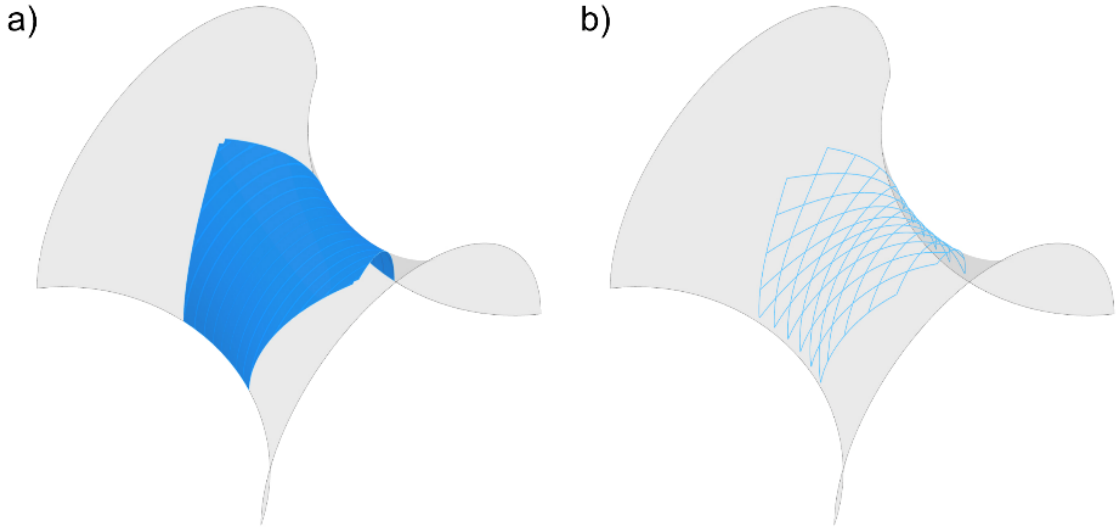

Figure 2. (a) The section of the torus as a basis for form-finding, (b) The geodesics based on the torus section.

2.2. Geodesic grid

The grid of the lattice shell consists of geodesics, the shortest path between two points in a surface. [1] Those two points are equal to the support points and are uniformly distributed on the boundary of the section. All intersection points of the geodesics will later be the points of the connections but with the addition that, strictly speaking, they lie on different offset surfaces. Overall, they form a distorted regular grid of quadrilaterals with smooth transitions due to the changing curvature and mirror symmetry.

For finding the geodesics the native Grasshopper algorithm was used.

2.3. Active bending and layering

The reason geodesics are chosen as grid lines is because they allow torsion and bending in the weak axis of the laths [2]. This is a requirement for the use of active bending, which significantly simplifies the fabrication process, because the geometry is encoded in 1D. A disadvantage though is that the bent state introduces pretension on the elements and therefore reduce their total load bearing capacity. The minimal bending radius has to be considered carefully in combination with the material thickness to preserve a certain amount of residual load capacity.

2.4. Software tools

The pavilion was designed and planned using digital tools such as 'Rhino' and the plug-in 'Grasshopper'. The structural analysis was done with the plug-in 'Karamba3D'[3] and the FEM software 'SCIA Engineer'. G-Code will be generated inside Grasshopper and executed via open software.

3. Conflicts and design strategies

The following describes the design factors on which the design, construction, choice of materials and choice of connections depended. It also describes what influence the decisions had on the development of the fabrication tool.

3.1. Complex geometry and fabrication

3.1.1. Design conflict

Building a lattice shell out of timber can be a demanding task that requires a high degree of pre-planning. This is mainly because such a structure consists of a multitude of laths, joints and nodes that must be precisely coordinated. In the construction of the Knotshell Pavilion, this was compounded by the fact that, due to its complex geometry, it has an alternating grid with different angles and nodes at different positions. Such a geometry can be very costly and time-consuming to produce.

3.1.2. Design strategy: Low-tech tool for fabrication process

In order not to compromise on the design of the lattice shell, it was decided to build a tool that allows the geometry data to be applied to the individual laths. This tool was developed from conventional components and simply guides a pen which conveys the information to the individual elements at the right place. With the precise definition of the geometric data, it becomes possible to manufacture the laths and joints and ensure that they have the required dimensions and tolerances.

3.2. Bended structure vs. planar fabrication

3.2.1. Design conflict

Making a curved support structure, such as that of the lattice shell of the "Knotshell" pavilion, from planar laths is a difficult task. Because of the restoring forces, any bending that is applied to the laths will result in the structure quickly losing its shape and stability.

Another reason for the difficulty of making a curved support structure is that the laths have to be bent in a continuous curve. This requires a high degree of precision and craftsmanship to ensure that the laths remain in the correct position and that there are no gaps or kinks.

3.2.2. Design strategy: Active bending

One possible solution to the problem of producing a curved supporting structure from planar material is the principle of active bending [2]. This is a technique in which the curved shape of the supporting structure is approximated by fixing elements in a bent state. Choosing the right fixture points the desired curve can be created [3].

In the design of the "Knotshell" pavilion, the individual elements were pre-curved using the active bending principle by precisely marking the nodes using the developed pen-plotter. The 3 layers have a minimal deviation in the position of the node points.

3.3. Flexible connections vs. achieving a fixed geometry

3.3.1. Design conflict

Due to the alternating grid, it was important to prefabricate the position of the nodes as accurately as possible in order not to have to compensate for too many inaccuracies in the overall construction of the shell. Therefore, it was decided not to use slotted holes for drilling. In some projects with lattice shells [7], slotted holes were chosen in order to be able to vary the structure afterwards. This had to be done because it was not possible to determine the exact nodes beforehand. We could not afford the inaccuracy caused by slotted holes in the project, as this would have made the fabrication on site much more

complex and it would hardly have been possible to erect the alternating grid as planned. So we were faced with the problem of making the nodes flexible only to the extent that the angles of the individual laths could change among themselves, but not the position of the nodes.

3.3.2. Design strategy: Exact determination of the nodes

With the low-tech tool developed, called a pen plotter, it is possible to determine the position of the nodes so precisely that it was possible to prefabricate segments. The prefabrication in turn made it possible to achieve an actively curved pre-curvature. This made it possible to dispense with further equipment on the construction site, such as a crane to lift the structure, as was the case with the truss shell of the Multihalle in Mannheim [8]. The actively pre-bent modules could only be joined together at the joints on site using a ladder and appropriate conventional tools.

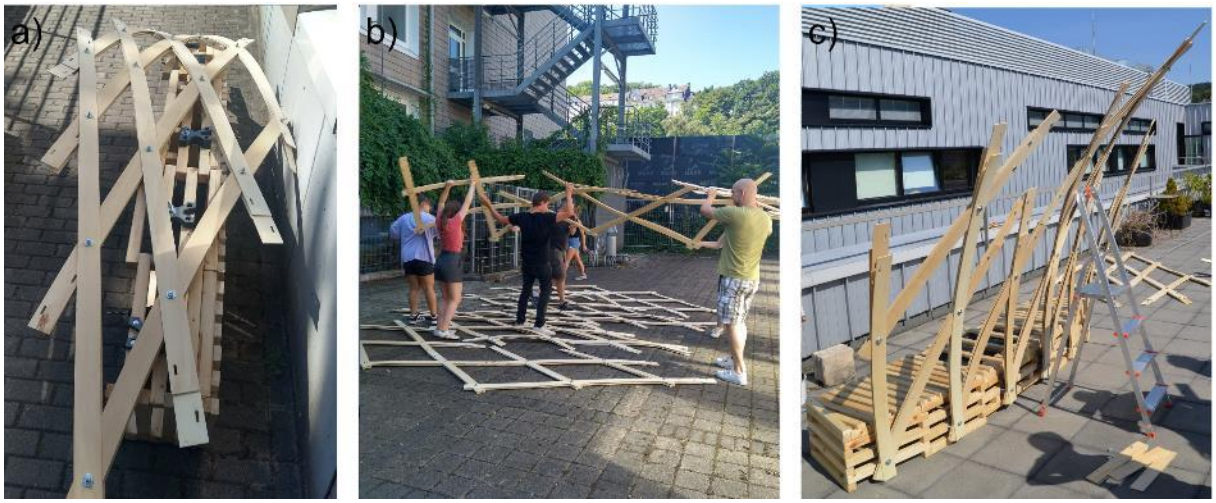

Figure 3. (a) a ready-assembled module for the lattice shell, (b) the planar assembly of the individual modules to test whether everything has been assembled correctly, (c) the installation of the first module in connection with the support module.

3.4. Erection process

3.4.1. Design conflict

The construction of timber lattice shells already reaches its limits on a small scale. At larger scales, the lack of a standardised and cost-efficient assembly method means that the technique has to be reinvented each time. Lattice shells are therefore only affordable for exceptional projects such as the Weald and Downland Museum or the Multihalle in Mannheim [7], where the costs and time required vary depending on the context. One reason for this is that the construction phase is an exceptional load case for an elastic timber lattice shell. This is due to high bending stresses caused by deformations during transport and erection, which also depend on the type of assembly and the shape and size of the shell. They have to be avoided where possible to prevent pre-damage and fractures.

In a review of elastic grid shells and their erection methods, Quinn and Gengnagel identify five viable means of elastic gridshell erection, which can be used in combination if needed. These include "pull up", "push up", "ease down", "inflate", and "by constraint"[9]. However, all of these methods require a grid that is made in the planar plane and is actively bent using these different strategies. These methods have the disadvantage that, on the one hand, they require a lot of space, since the planar development of the shell is usually much larger. In addition, the individual laths are subjected to alternating stresses during erection, which often lead to fractures [11]. This can make the building of complex geometries very costly. Those methods were not feasible for this project.

3.4.2. Design strategy: Prefabrication of bended structure

To avoid a costly erection process, a method of sequential construction was chosen. For this, the shell was divided into 6 modules which were prefabricated. This way, a substantial amount of pre-bending could be done in advance. In contrast to other [11] lattice shell projects, no breaks were recorded here.

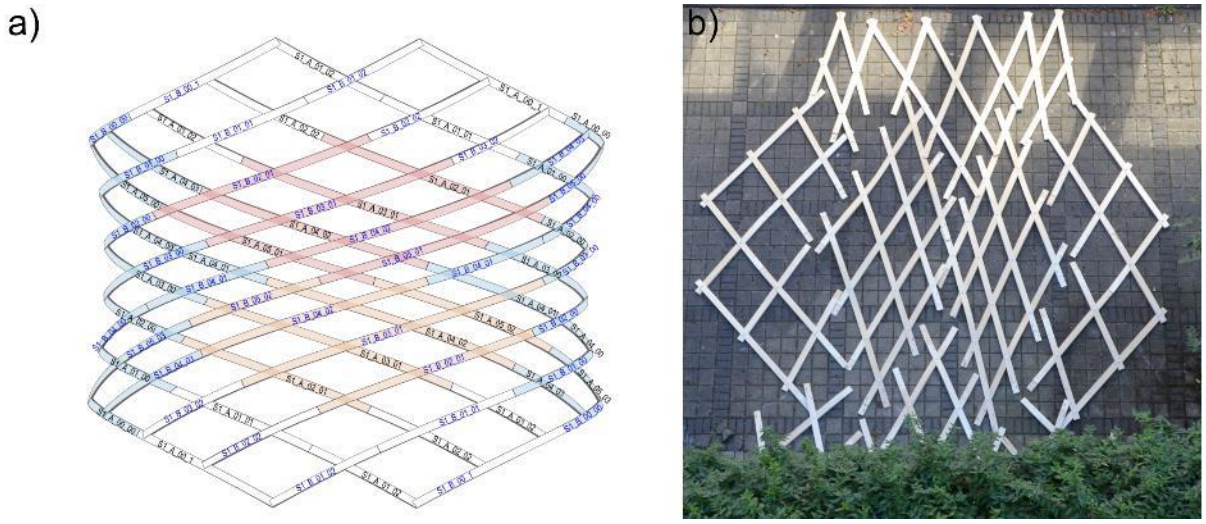

Figure 4. (a) top view with marking of the 6 modules needed for the assembly, (b) all completed modules are placed next to each other for inspection before erection.

4. Construction and joints

4.1. Material

For the active bending to work properly without breaking the laths, it was critical to carefully select the right material thickness. The choice was between plywood panels made of poplar (4 mm and 6 mm) and birch (6 mm). A reality check was the most practical approach, so breaking test were carried out with samples of the different wood panels. The minimum radius of curvature was of great interest here and as a result the 4 mm poplar plywood was picked, as it was better to go with a thinner material and use more layers. The plywood was delivered in panels measuring 2.5 m x 1.5 m. For an optimal usage of the material, the panels were cut into strips of 7.5 cm (20 pcs per panel). The length of 2.5 m was also optimal to match the size of the segments and modules. In total approx. 333 m of the strips were used (volume: 0.1 m^3, weight: 45 kg).

4.2. Nodes and layers

At the crossing points of the laths, the 3 layers of one direction are interlocked with the 3 layers of the other direction. They are connected with an M10 bolt, two washers and a nut. The connected laths can still be pushed together or apart in the plane and thus be stored in a more compressed way. However, since the geometries of the laths have already been adapted to the curved shape of the lattice shell and no slotted holes but ordinary holes are drilled according to the curved shape, they have a slight bend in the plane and are not as flexible as a lattice shell with slotted holes. At the nodes the layers meet and the 3 layers of one lath and the 3 layers of the other lath interlock. So at the nodes there are 6 layers on top of each other.

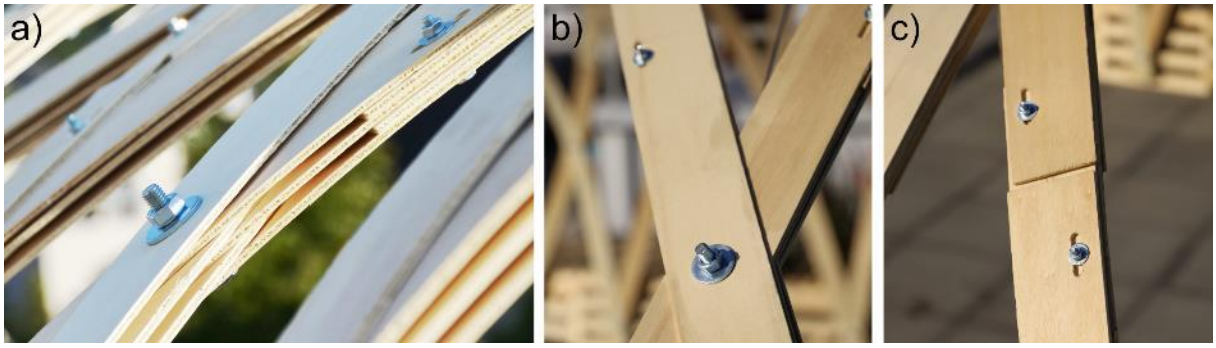

Figure 5. (a) Typical connection point, where all 6 layers of the laths are connected, (b) a node in the frontal view connected with a m6 screw, (c) a typical joint of the modules in the frontal view .

4.3. Joints between modules

The modules divide the shell into 6 segments, making it easier to erect on site. Therefore, a solution for the joint between the modules is mandatory. Overlapping the boards would result in a height offset in the individual layers and thus a change in the geometry of the lattice shell and all its elements. To prevent this, the boards in one layer are not overlapped but laid against each other. The cuts of the first and third layer are each on top of each other, while the cut of the second layer is shifted. This allows the 40 cm long connecting boards between the layers to be joined with only 3 screws instead of four. Due to the low loads of the lattice shell and the number of screws, M6 screws are used so that material and weight can be saved. In each layer, one of the meeting laths has two screws that firmly connect the connector against twisting, while the other lath is only fixed to the connector board by one screw. All 3 layers are connected by 3 screws and kept apart by the connecting pieces. To compensate for minor inaccuracies in the material, planning and machining of the boards, the laths are prepared with slotted holes at the predefined screw points. Any errors or small deviations in the lengths of the laths can thus be compensated for in this way.

4.4. Supports

The supports are special nodes (12 pcs in total) that are mounted to a bench on each side of the pavilion. They differ in shape and are also 3d-printed to connect to the structure at the correct spatial angle and height. The connection is also made with an M10 thread and nuts. The benches also serve as a foundation. As they support planters with soil, the benches have a certain weight and cannot be easily moved.

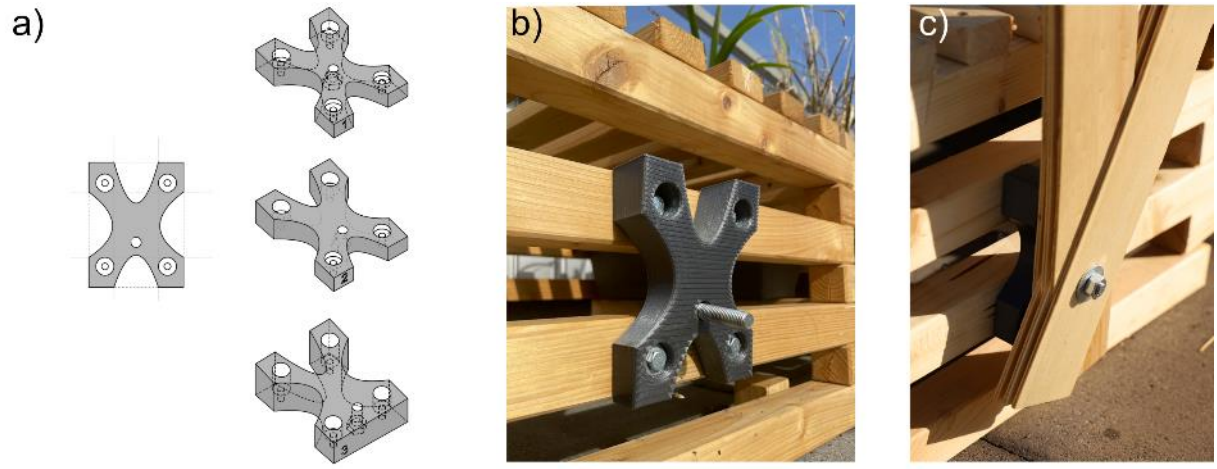

Figure 6. (a) axonometric representation of the typology-optimised support elements, (b) 3d printed support element for connecting the support to the lattice shell, (c) the finished assembly of a support node.

4.5. Bracing

The lattice shell is stiffened by a row of compression laths (red) in the longitudinal direction (= passage) on the vertex of the lattice shell. In transverse direction, two tension cables (blue) connected to the supports of the lattice shell take on this task.

4.5.1. Compression lath

Since the nodes of the lattice shell are only in a row on the vertex in the longitudinal direction, the compression laths are attached here. They fix the nodes on the vertex at the measured distances of the planning. The laths have pre-drilled holes at the appropriate distance and are placed on the nodes from above and screwed together. Due to the fixed distances, the lattice shell is contracted at the top and curves more upwards at the ends according to the planned shape.

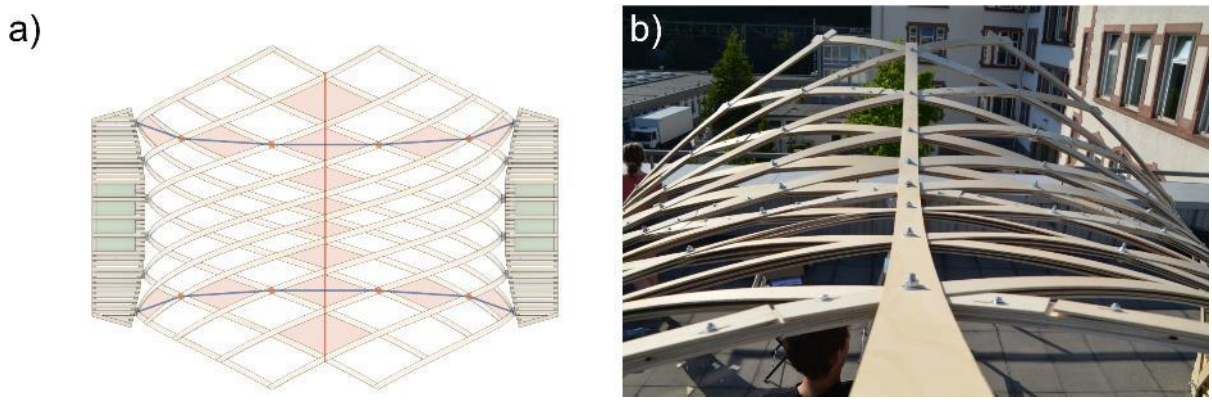

Figure 7. (a) elevation view of the bracing system, (b) view along the apex line (compression lath).

4.5.2. Tension ropes

To attach the tension ropes to the crossing points of the nodes, special clamps for fastening were developed and printed with a 3D printer. They consist of two flat discs that can be placed on top of each other and are attached to the screws of the crossing points. Two semicircular cut-outs on both discs allow the steel cable to pass through. When the nuts are tightened, the discs are pressed together. Small protrusions in the bushings prevent the rope from slipping through.

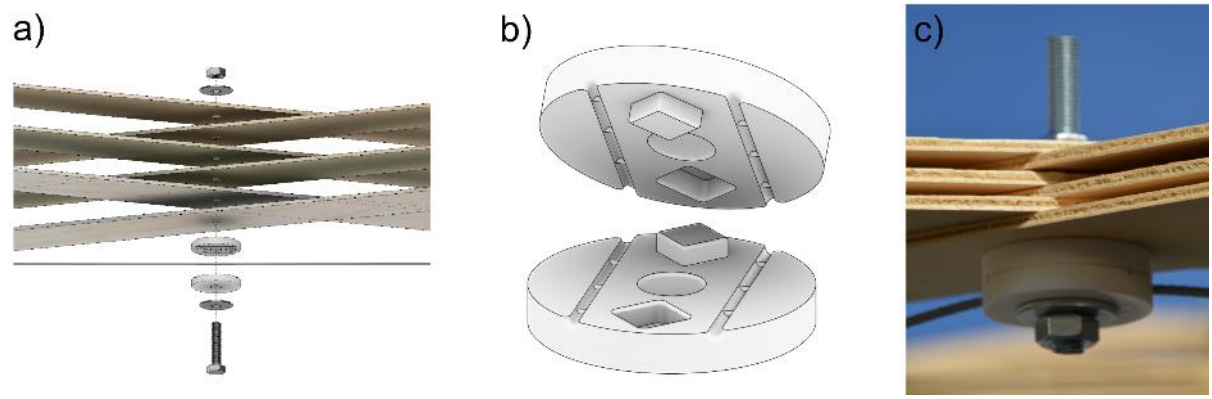

Figure 8. (a) exploded view of a node in connection with the 3d printed clamp for the tension rope, (b) axonometry of the clamp consisting of two discs with semicircular cut-outs for the steel cable. , (c) assembled node with the 3d printed clamp and steel cable.

5. Low-tech tool as interface

5.1. Fabrication approach and necessary data

The design decisions mentioned earlier reduce the complexity and the amount of fabrication data which has to be transferred to the wooden laths. All manufacturing steps will be executed by hand and need to be simple. Furthermore, all of the necessary information must be available at first glance and are directly tied to the component. These requirements led to the decision to use a custom large-format pen plotter. The plotter doesn't have to be built very sturdy, because there are little to no forces acting on the wooden laths in the process. The workflow is completely 2D and is comparable to laser cutting. The following information should be put on the components:

- Labelling/numbering of the laths
- Markers for drilling holes (both, connections and joints)
- Marker for cutting the lath to length

5.2. Customized low-tech tool: large format pen-plotter

The frame of the pen plotter was built from 2020 v-slot aluminium profiles. In combination with ball bearings and rubber wheels they also act as rails for the linear movement, so there is no need for expensive linear bearings. Movement is possible in 2 axes on a 500 x 3000 mm working space that is sufficient for labelling the laths. The frame is mounted on wooden base plates which in turn rest on 3 fixed tables. All connectors and mechanical parts are 3D-printed in FDM/FFF. 3 NEMA17 stepper motors drive the tool head via gears and timing belts. A small servo motor is responsible for lifting the pen, downward force during drawing is provided by a small spring. The controller is an Arduino Uno with a CNC shield. It is running the free GRBL firmware (GPLv3) which translates G-Code sent from a PC over a USB connection into movements. The cost of materials for the pen plotter is about 350 €.

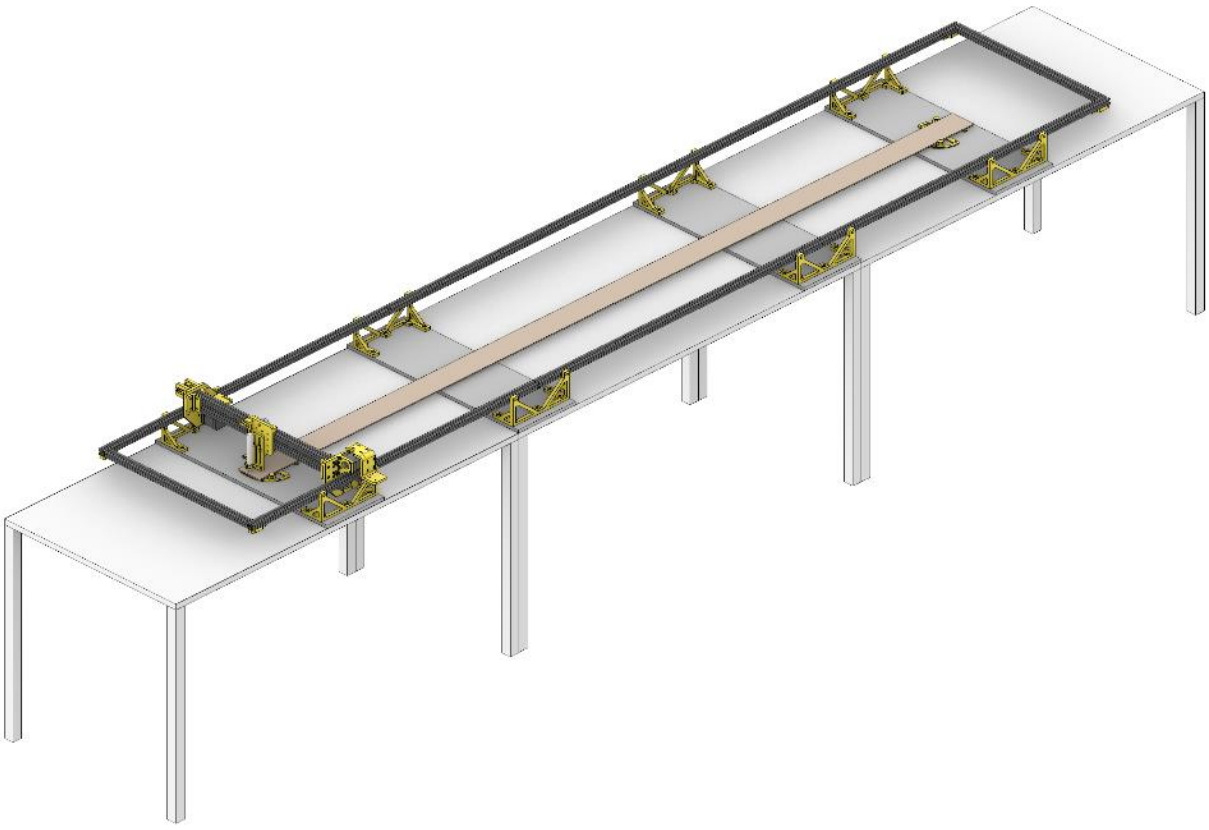

Figure 9. Isometric view of the custom large-format pen plotter.

5.3. Data transfer and conversion

The G-Code commands can be sent directly to the controller through a serial connection. For more precise control and manual commands, the open-source software 'Universal Gcode Sender' was used to load and execute the G-Code files. These are generated through a custom script in Grasshopper, which takes the previously generated drawings for each lath and translates them into movement commands. This also involves a quick optimization to minimize the amount of travel moves (= empty movements between the drawing of labels): The curves are sorted in ascending order according to the x-value of their starting point.

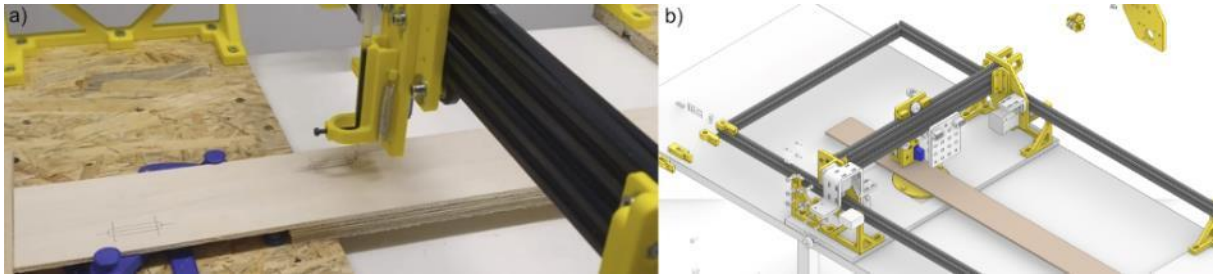

Figure 10. (a) developed pen-plotter in action, (b) exploded drawing of the pen plotter.

Each lath has a unique identifier which encodes its final location. It is readable and understandable for humans, at least it gives one a rough idea where the element is located in the structure. The labelling convention is as follows and is also used for the G-Code files:

S<layer>_<direction>_<row>_.gcode

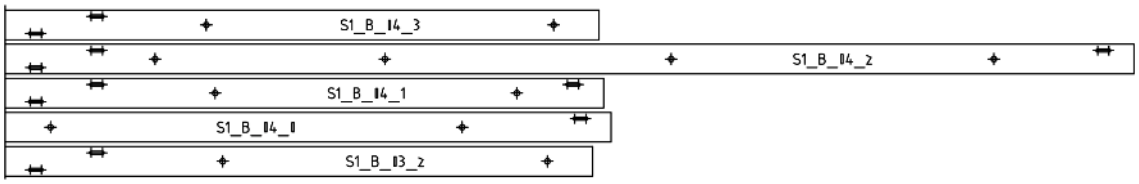

Figure 11. Automatically created drawings for the pen plotter.

5.4. Practical application and problems

The first practical problem to solve is the alignment of the laths in the machine. There was a total of 135 elements, which means that there is a substantial amount of manual interactions involved during the labelling process. Due to the manual cutting, the laths also vary slightly in width, so a conventional one-sided mechanical limit stop for positioning does not work for the y-axis. Instead a rotational spring bracket is used at both ends, which automatically centres the laths. Inaccuracies in the y-position while mounting the brackets are compensated for in the script by a one-time calibration. A deviation angle is measured and will be applied to all coordinates generated by the script. The best results for labelling were achieved by using regular pencils, which had to be exchanged and sharpened regularly. Gel pens or rollers were not suitable because of the rough and absorbent surface of the wood.

5.5. Full fabrication process

With the help of the pen plotter, the nodes and slotted holes as well as the cutting edge of the laths were drawn. The sticks were then cut to the correct length and the holes drilled accordingly with hand crafting tools in the following order:

1. Chop saw: cutting to length
2. Drill stand: drill the 10 mm holes for the connections
3. Drilling machine for slotted holes: prepare the slotted holes for the joints

All parts are then grouped together for the assembly of the modules.

6. Evaluation and conclusions

6.1. Overall precision of the fabrication process

The built result shows, that the achieved precision is sufficient to transfer the planned geometry into reality. When assembling the modules, the laths had to be bent in order to be able to push through the screws. The typical deviation in the distance between the holes related to the innermost and the outermost layer in one direction is about 4-6 mm.

The deviation between the planned and the built geometry was not determined, because the structural analysis was only limited to the active bending of individual laths and the minimal bending radius. The final geometry would deform under pretension and its own weight.

6.2. Time consumption and problems during assembly

It took two working days to label all laths. The machine time accounted for about half of the time (approx. 3-4 min per element), the rest was spent on manual activities (changing the laths, loading the files, changing/sharpening the pencils, keeping track of the parts).

The joints and support points were so precisely determined by the pen plotter that we were able to complete assembly of all modules within 2 hours.

The most difficult and time-consuming part during assembly was the screw joint between the modules. Originally, it was intended that the structure could be dismantled effortlessly if needed. The design of the joints originates from the decision to utilize active-bending to implement the geometry. Therefore, the butt joints must transmit bending moments and be stiff. Those requirements contradict each other to a certain extent and make it difficult to find an suitable solution.

The assembly of the whole structure on site took around 3 hours.

6.3. Disadvantages of the construction principle

A major disadvantage, which only became apparent in retrospect, was the very large overall surface area of the material (approx. 50 sqm) and the number of gaps that resulted from the layered structure. This makes it especially difficult to weatherproof the Knotshell pavilion. Moisture holds well in the gaps between the joints.

Acknowledgements

This template was adapted from the one used for IASS-IACM 2008 with modifications modelled after templates for recent IASS annual symposia.

Abstract

In recent years, computational methods have made it possible to design complex curved surfaces. Finding an easy and economical way to create desirable free-form surfaces is important for extending design possibilities. Based on a biomimetic approach, inspired by the mechanical force-induced morphological changes in floral development, this study developed a method for creating porous curved surfaces by applying auxetic structures. A free-form surface was obtained by suspending a thin metal plate with equilateral triangular repeated incisions under an equally distributed load. The form can be freely changed by changing the incision pattern. Material tensile tests were conducted to elucidate the mechanical properties, and it was observed that the material behaved elastically until the apex of the triangle buckled locally. After the load decreased, it gradually increased again up to the maximum load. The stiffness and strength depended on the length and angle of incisions. Based on the results, an incremental load analysis method was developed to find the form under a distributed load. The simulation was a geometric nonlinear analysis considering material nonlinearities. A mock-up was constructed to validate the simulation results. It is expected that the proposed method for creating free-form surfaces will be applied to various spatial structures in the future.

1. Introduction

In recent years, computational methods have made it possible to design complex curved surfaces. However, there are still few methods for manufacturing free-form surfaces, and in many cases, complex and uneconomical machining is required. Finding an easy and economical way to create desirable free-form surfaces is important for extending design possibilities.

During floral development in the floral meristem of plants, the tension distribution of epidermal cells becomes non-uniform, which is thought to be related to morphogenesis. Inspired by the cellular morphological changes of floral organs, this study developed a novel method for creating porous curved surfaces by exploiting the geometric properties of the auxetic mechanism [1] to create a non-uniform stiffness distribution in thin metal plates, and applying a load to the plates. Through the application of the geometric properties of the auxetic mechanism to thin metal sheet structures, this study developed a new method for the morphogenesis of free-form surfaces.

2. Morphogenesis system of floral meristem in plants.

Angiosperms have meristems, which produces organs at their tips. In most plants, a shoot apical meristem initially makes only leaves, which eventually transform into a floral meristem that forms flowers. The floral meristem continuously produces a dome-shaped floral primordium without floral organs (sepal, petal, stamen, and pistil). The floral organs, at first sepals, are subsequently initiated on the floral primordium in stages, and this process is called "floral development".

Typically, floral development is stable within a single species, and results in the formation of a uniform morphology of flowers in the species [2]. For example, in the plant *Arabidopsis thaliana*, four sepals are almost simultaneously initiated in every floral primordium, followed by four petals, six stamens, and one pistil to complete the floral development. The number of each floral organ is typically constant, and the arrangement of floral organs is stable. However, in the male flowers of the aquatic plant *Ceratophyllum demersum*, the number and arrangement of stamens vary with each flower, and various floral forms exist in the species [3], [4].

Morphological analysis suggests that, in the male flowers of *Ceratophyllum demersum*, the adaxial side of young floral primordium is pressed by a leaf primordium, and the mechanical forces between the two primordia suppress the initiation of floral organs (sepals) on the adaxial side [4], [5]. When the mechanical forces are released, different numbers of sepals are initiated depending on the degree of contact. It is hypothesized that various developmental patterns, from the early to the mid-stages of floral development, are caused by mechanical forces, leading to diverse floral morphology in the mature male flowers of *Ceratophyllum demersum*.

To verify this hypothesis experimentally, a previous study developed a novel experimental system to alter the floral morphology by artificially applying mechanical forces to the floral meristem of *Arabidopsis thaliana* [6]. In this experiment, a microdevice fitted to the shape of a young floral primordium was placed on the abaxial surface of another floral primordium and induced mechanical forces on it. The analysis of the results obtained by this experimental system revealed that the morphology or number of sepals occasionally changed at the site of contact (abaxial side) with the microdevice. This change in the floral development can be explained by considering the change of the stiffness distribution in the floral primordium at the abaxial side (Figure 1). Current studies are attempting to estimate changes in the stiffness distribution based on changes in the cell morphology and related gene expression in the floral meristem before and after the application of mechanical forces.

3. Framework of metal plate structures applied with auxetic mechanism

3.1. Auxetic mechanism

Based on a biomimetic approach, it is expected that a new form-finding method, which can efficiently create complex three-dimensional shapes such as those of plant flowers can be developed by generating materials with non-uniform stiffness distribution [7], [8]. As a method for fabricating panels with non-uniform stiffness distribution, this thesis proposes the application of an auxetic pattern of incisions to thin sheets.

Auxesis is a property where material expands in a direction perpendicular to the direction of the force applied to stretch it. The material can be endowed with the auxetic property by creating a pattern of many periodic incisions on a flat surface, like Japanese paper cut-outs known as "*kirigami*". In this study, an auxetic pattern with repeating equilateral triangles was used (Figure 2). A surface material with non-uniform stiffness distribution can be created by making periodic random incisions with different angles on a thin metal plate, which is then suspended by an equally distributed load to obtain a free-form curved surface. By controlling the incision pattern, a free-form surface can be obtained after the suspension (Figure 3).

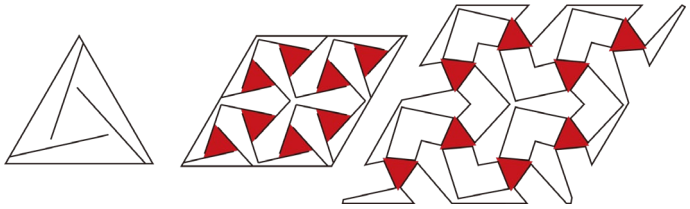

Figure 2. Auxetic mechanism: The process of expansion from left to right.

Figure 3. Image of a suspended form created by an auxetic pattern with various angles of incision (Kent paper model).

3.2. Paper model experiment

This study conducted a apaper model experiment to understand the correlation between the auxetic pattern and the curved surface shape after suspension. Four paper models with different patterns were prepared to observe the relationship between the incision angle (θ) and the sag after suspension (Figure 4), and it was found that the sag decreased as the angle (θ) increased.

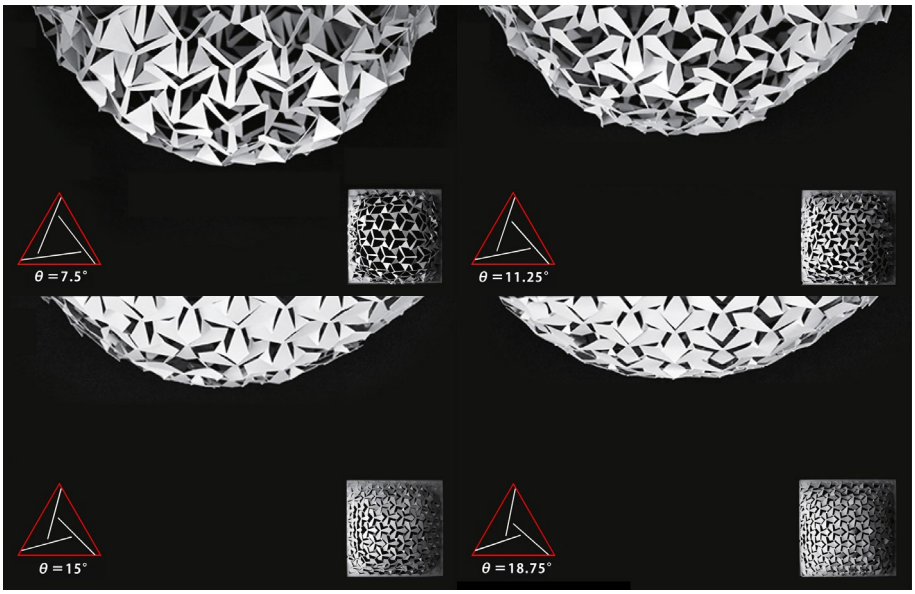

Figure 4. Paper model experiment: correlation between the incision angle (θ) and the suspended shape.

3.3. Framework of form finding method

A face material with non-uniform stiffness can be obtained by periodically arranging triangles with different incision angles. It is assumed that a free-form surface can be obtained by pulling down it with an equally distributed load. This study developed an algorithm to obtain an auxetic pattern from a given curved surface shape (target shape) using the Grasshopper visual programming language with the Kangaroo plug-in. The equilateral triangular unit that serves as the repetitive unit was conceptualised as three springs with equal stiffness (spring constants), and the springs of adjacent units were combined and converted into a wire model (Figure 5). First, a metal plate without incision was modeled as a triangular mesh, and geometric nonlinear analysis was performed by applying equally distributed loads to calculate the curved surface shape. Next, the convergence calculation was performed by varying the stiffness of each unit so that the difference between the obtained shape and the target shape was reduced (Figure6), and a stiffness distribution was obtained (Figure 7). Finally, the auxetic pattern was obtained by mapping the equilateral triangle units obtained from the stiffness distribution.

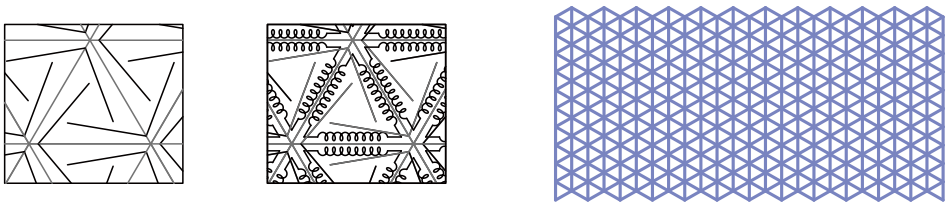

Figure 5. Replacement of wire model with spring and wire mesh model.

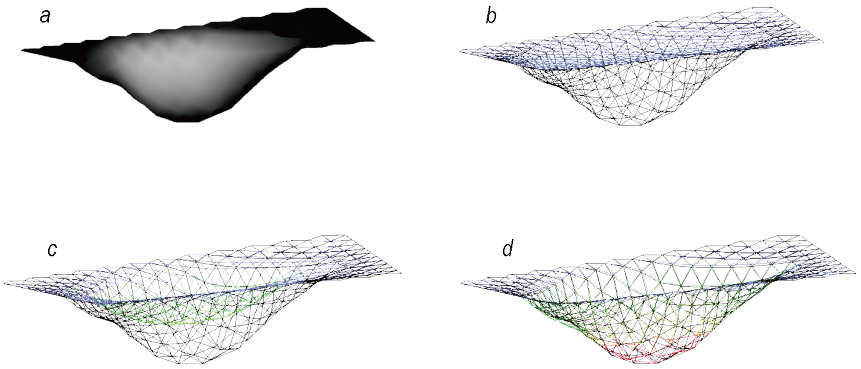

Figure 6. Convergence calculation: (a) target shape; (b) convergence calculation at step 0; (c) convergence calculation at step 1; (d) convergence calculation result.

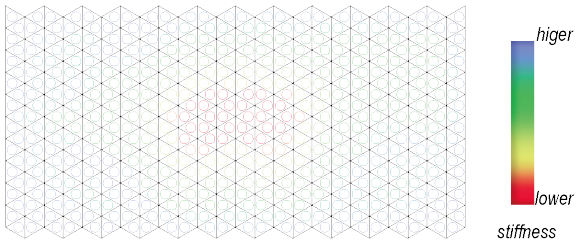

Figure 7. Stiffness mapping for target shape.

The results obtained by the paper model experiments suggest that the incision pattern changes the suspension shape and a framework for stiffness mapping that achieves the desired free-surface shape under an equally distributed loading was investigated.
Designing a free-form surface by introducing an incision pattern requires the detailed investigation of the actual incision pattern and mechanical properties. The geometric nonlinear analysis described in this section assumes that the material properties of the springs in the analysis models are linear elastic, and the quantitative relationship between the incision pattern and the stiffness in the actual material is unknown. It is thought that accurate calculations can be carried out by elucidating the relationship between the incision patterns and the stiffness and by considering nonlinear material properties.

4. Material properties of auxetic mechanism and application to design method

4.1. Material tensile experiment

Material tensile tests were conducted to elucidate the mechanical properties. A specimen with the geometry shown in the figure 8 was prepared by incising 1mm-thick stainless-steel plates of grade SUS304.

Figure 8 shows the shape of the tensile test specimen. The tensile test parameters are the remaining length after incision ($e = 5.0\text{mm}, 10.0\text{mm}$) and the incision angle ($\theta = 0°, 5°, 10°, 15°$). As shown in Figure 8(b), eight specimens were subjected to the tensile test.

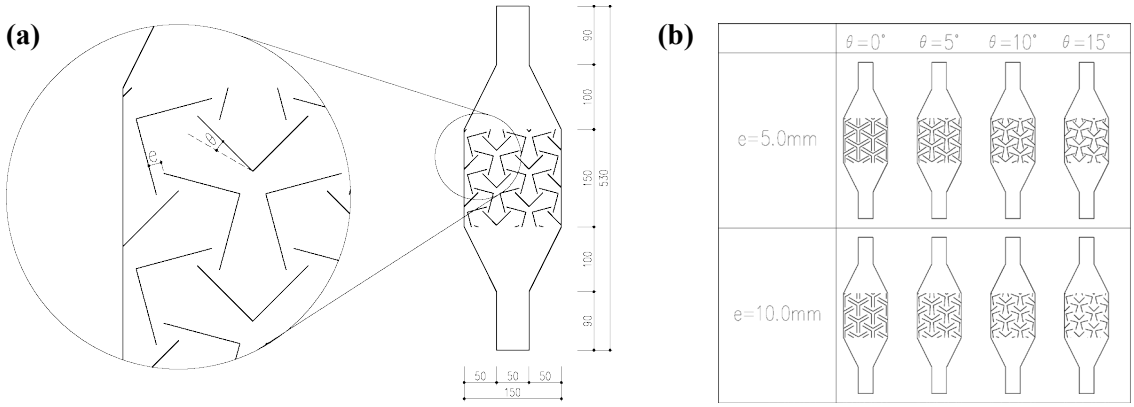

Figure 8. Tensile test specimens:(a) general diagram of the material tensile test specimen; (b) specimens subjected to tensile test.

The tensile tests were performed using an Amsler testing machine. Figure 9 shows the tensile test setup, and Figure 10(a) and (b) shows the load–deformation curves for each specimen, and the plot of the relationship between the vertical displacement of the Amsler head and the load during the tensile test. For the specimen with e=5mm and θ=0°, data were only available up to the point where the specimen was deformed to approximately 2/3 of its deformation at rupture due to a troubles with the testing machine.

The results reveal that, as the load increased, the equilateral triangle surrounded by the Y-shaped incision rotated while the incision opened. The material behaved elastically until the apex of the triangle buckled locally. After the load decreased, the load gradually increased again to show the maximum load, eventually leading to the fracture of the material. A trend was observed such that as the incision angle θ increased, the stiffness and the maximum load increased and the the extension after yielding decreased.

Figure 9. Material Tensile Test: The triangular pattern rotates, causing local buckling and out-of-plane distortion (left: e=5.0mm, θ=0°; right: e=5.0mm, θ=10°).

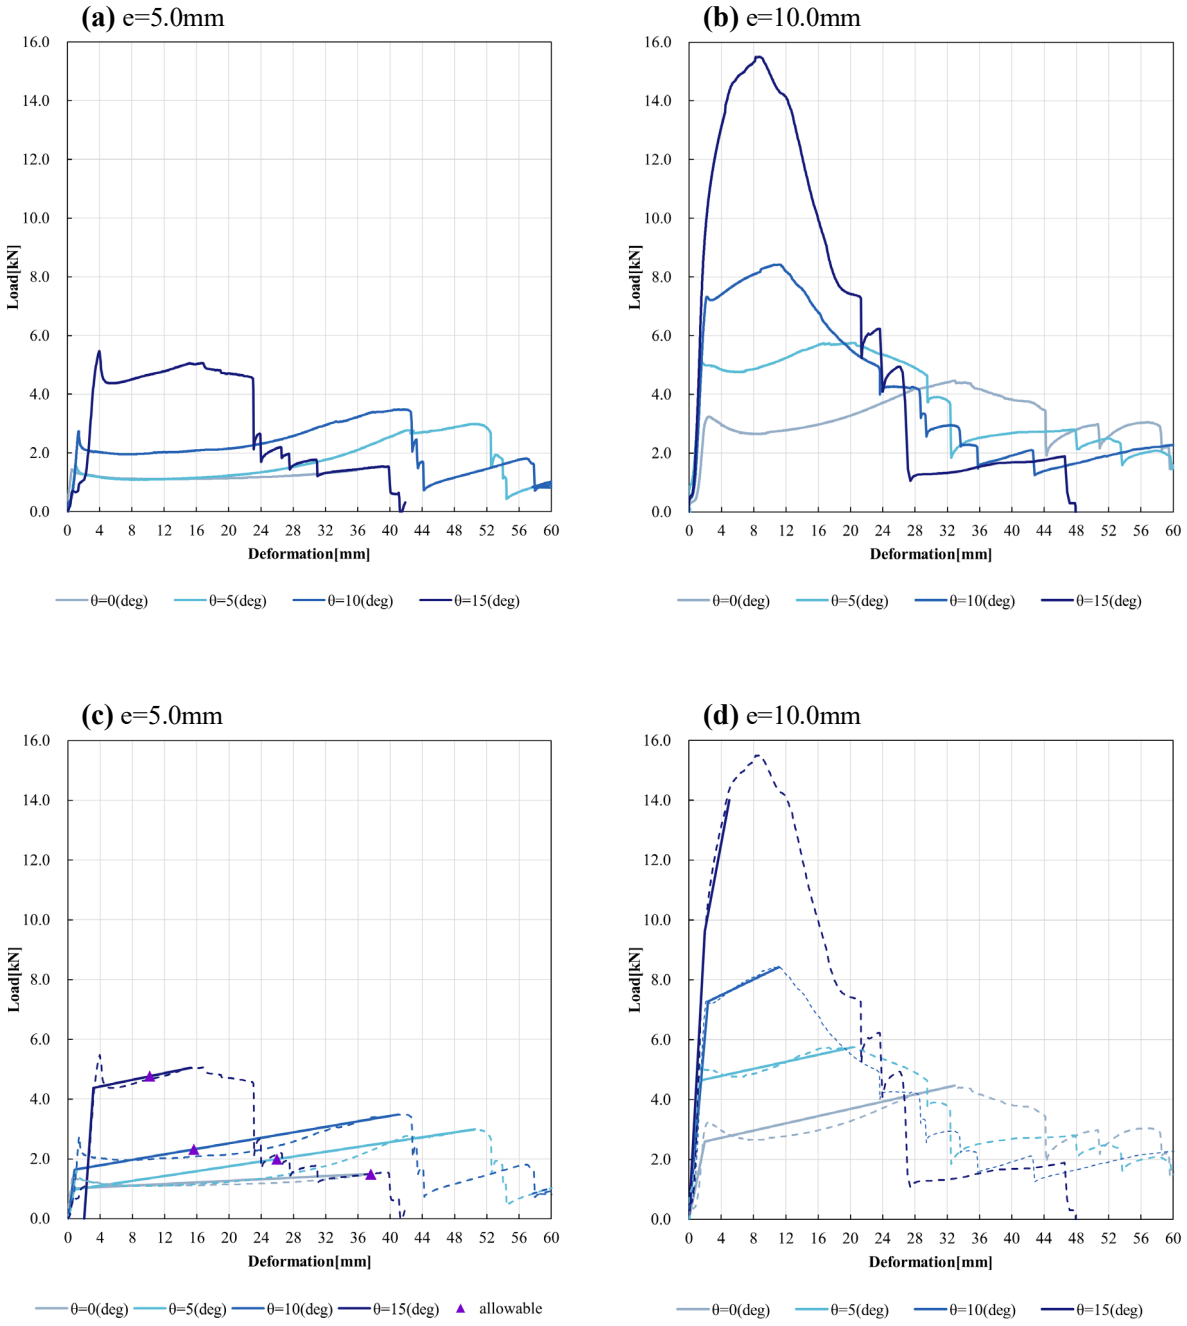

Figure 10. Experimental result and bi-linear model: (a) load–deformation curve (e=5.0mm), (b) load–deformation curve (e=10.0mm), (c) bi-linear model (e=5.0mm), and (d) bi-linear model(e=10.0mm).

4.2. Analysis method considering material properties of auxetic mechanism

Based on the experimental results, an incremental load analysis method was developed to find the form under a distributed load. The simulation was a geometric nonlinear analysis considering the material nonlinearities. The metal plate was mesh modelled with a bilinear model depending on the incision angle.

The bilinear model was created based on the load–deformation curves obtained from the tensile tests, as follows: the primary stiffness K_1 was approximated based on the stiffness obtained experimentally in the elastic range. It was assumed that, after yielding, it is assumed to the load increases linearly up to the maximum load, and the secondary stiffness K_2 is determined such that the integral values up to the maximum load point are equivalent. The intersection of the straight line between the elastic and plastic ranges is the yield point P_y (displacement δ_y), while the allowable stress P_a is the point corresponding to 2/3 of the maximum load P_2. Figure 11 shows the diagram of the bilinear modelling process and Figure 10(c) and (d) shows the actual load–deformation curve of the bilinear model obtained by the experiment.

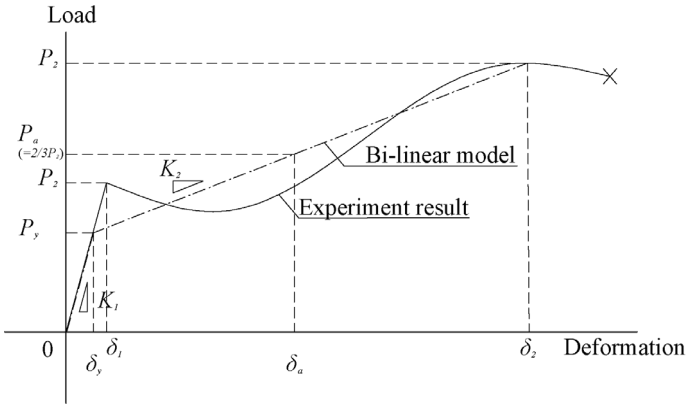

Figure 11. Diagram of bilinear modelling.

The load and deformation obtained from the tensile test were converted to the stress degree and strain, and the primary and secondary stiffness values were converted to the apparent Young's moduli E_1 and E_2.

$$\delta = \frac{P}{A}, \varepsilon = \frac{\delta}{L} \ (A = 150\text{mm}^2, L = 150\text{mm})$$
$$E = \frac{\Delta\delta}{\Delta\varepsilon}$$

In the incremental load analysis process, the curved surface shape is obtained by reducing the Young's modulus of a wire to the second-order stiffness once its tensile stress reaches the yield point. Assuming that the unloading stiffness is equal to the primary stiffness, the shape after unloading can be also obtained by geometric nonlinear analysis. It is assumed that similar auxetic patterns conform to the same bilinear model, and the Young's modulus and yield stress are equal to the experimental values.

An example of the application of the proposed analysis method is presented below. The analysis model is a stainless-steel panel with a thickness of 1.0 mm with an auxetic pattern incision; the effective width of the wires constituting the mesh is 50 mm.
The stiffness was mapped as shown in Figure 12(a), and Young's modulus is based on experimental results. The boundary conditions were fixed on four sides, and the proposed analysis method was applied for one cycle, that is, an equally distributed load of 9.8 kN/m^2 (1.0 tf/m^2) was applied and then removed. The load–deformation curves obtained by plotting the vertical displacements of the representative nodes A, B, and C (Figure 12(a)) on the horizontal axis, and the equally distributed load on the vertical axis

are shown in Figure 12(b). The deformation after applying the equally distributedload of 9.8 kN/m^2 (1.0 tf/m^2) and unloading is shown in Figure 12(c).

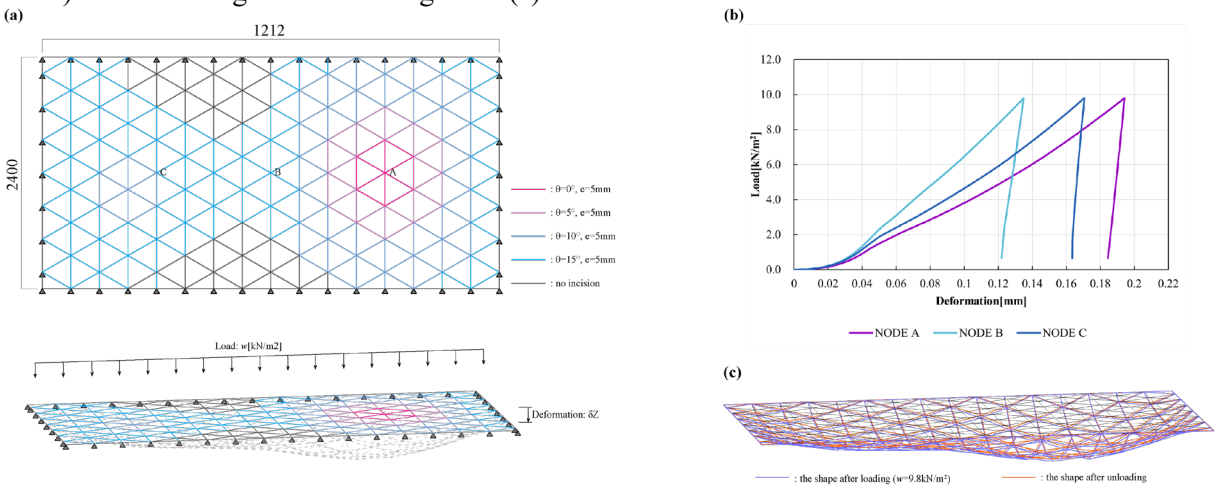

Figure 12. Example of analysis using proposed method: (a) analysis model diagram; (b) load–deformation curves for NODE A, B, and C; (c) deformation after loading and unloading.

4.3. Mock-up experiment

The roof surface of the mock-up consisted of two thin metal sheets with a width of 1.2 m and length of 2.4 m. The metal sheets were made of 1 mm-thick SUS2B stainless-steel, and different incision patterns were created on each sheet using laser processing. Side A has a uniform incision of 0°, and the side B has incisions of gradational angles in the range of 0° to 18.75°. These metal sheets were fastened to the four-way frame with bolts, and subsequently hung over a frame to form the roof. The overall shape of the mock-up is shown in Figure 13.

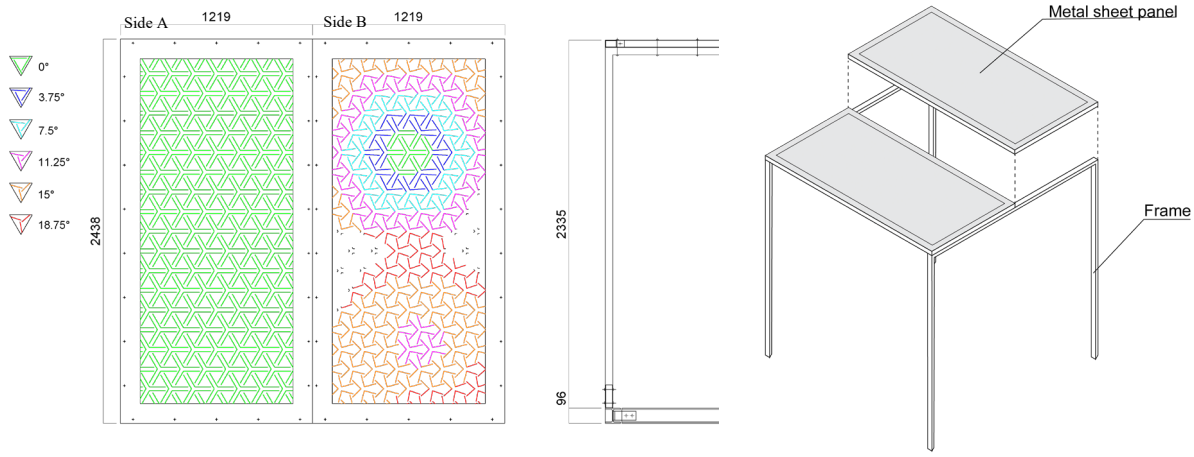

Figure 13. Overall shape of mock-up.

Loads of approximately 98 N (10 kgf) were applied by chain blocks installed at each loading point, and the values indicated by the spring weights attached to each loading point and the vertical displacements were recorded each time (Figures 14 and15). Figure 16 shows the final shape of the mock-up after loading.

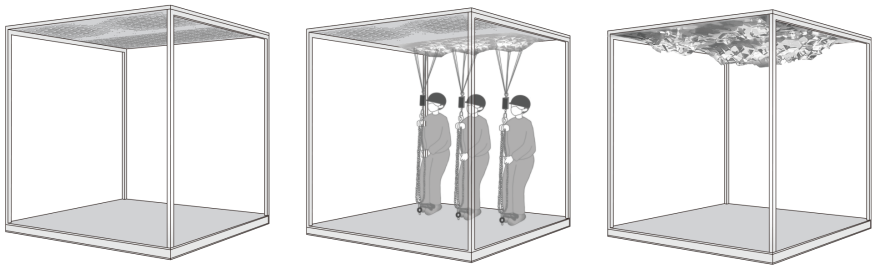

Figure 14. Diagram of mock-up loading and measurement process.

Figure 15. Mock-up: loading and measurement.

Figure 16. Mock-up after loading.

The analysis model and the results obtained using the procedure outlined in Section 4.2 are shown in Figure 17. The auxetic pattern is similar to the pattern of the material tensile test and the bilinear model obtained in this study was used. The incision angles in the mock-up patterns include angles that have not been experimentally verified. The analysis model maps the wires to stiffnesses values that are linearly complementary to the angles that have been tested, and that the stiffness is assumed to vary continuously with the incision angle.

The load-deformation curves and analytical results at each loading point of the mock-up are presented in Figure 17. The maximum displacement occurred at the loading point at the center of span for the uniform stiffness model, and at the loading point with the smallest incision angle for the non-uniform stiffness model; both exhibited the same trend as the analytical results.

For the uniform model, the error between the experimental and analytical displacement values after loading was 2.1%, 0.9%, and 2.1% for loading points 1, 2, and 3, respectively, and the error after unloading was 5.6%, 0.88%, and 7.8%, respectively.

For the non-uniform model, the errors between the experimental and analytical displacement values after loading was 13%, 5%, 5%, and 2.1%, respectively. The error after unloading was 6.3%, 4.4%, and 46%, respectively. The error after unloading was 6.3%, 4.4%, and 46%, respectively.

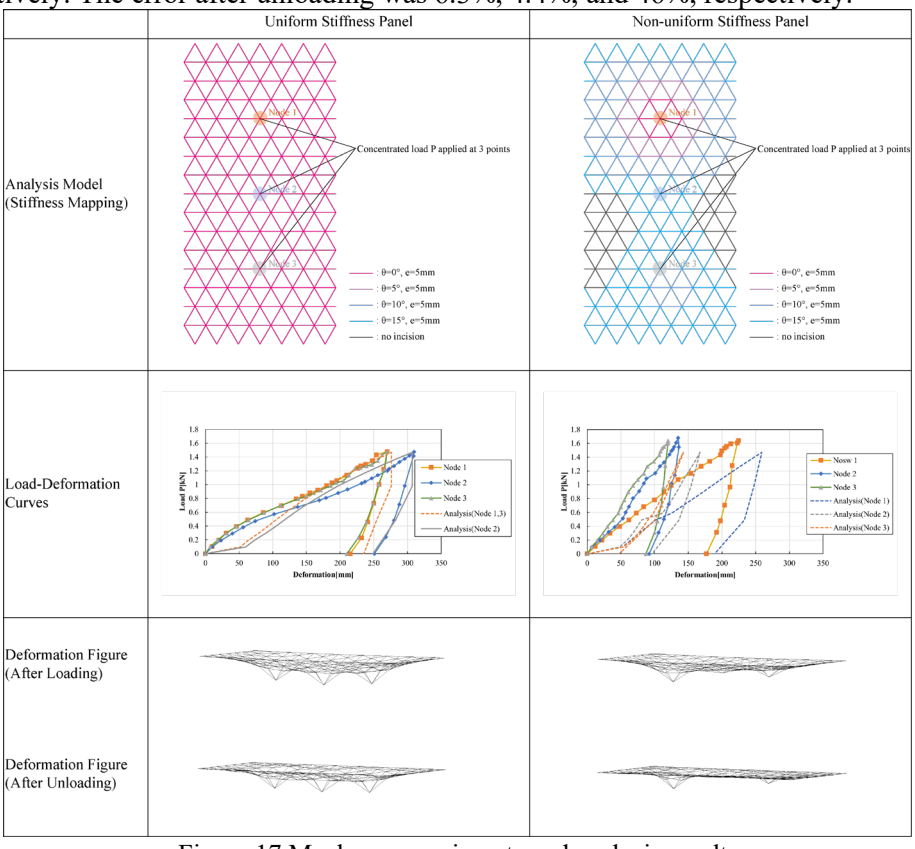

Figure 17 Mock-up experiments and analysis results

The following improvements can be made to the analysis:

1. The analytical model load was assumed to be at the center of each loading point, but in the mock-up, the load was distributed among three points within each loading point, so the surface shape obtained by the analysis was more deformation concentrated at the loading points compared with the actual mock-up.
2. All wire joint conditions were modeled as rigid for the convenience of solving large deformation problems, but modelling of the rigidity of the bolted joints may be considered.

3. More material tests should be conducted for more incision angles to investigate the relationship between incision angle and stiffness in detail.

5. Conclusion

This study found that a free form can be obtained by randomly distributing incision patterns. A mock-up was constructed to validate the simulation results. The research presented herein has potential for further development. For example, our innovative pavilion can be developed into spatial structures that adapt their form to control the heat radiation according to the climatic conditions at the structure's location. It is expected that the proposed method for creating free-form surfaces will be applied to various spatial structures in the future.

Abstract

Multi-scale simulation is a widely used method for balancing the accuracy and cost of numerical simulations of structures. This technique allows designers to obtain both global characteristics and local information of structures simultaneously. In this paper, we propose a coordinated distributing multi-scale coupling method based on the Finite Particle Method. The method aims at deformable interfaces. We first describe the basic theory of coordinated distributing coupling. Next, we present a calculation process which includes the following steps: the calculated interface force is distributed to the secondary particles based on the force balance relationship; the displacements of the secondary particles are obtained by calculating the motion equation; and the motion of the major particle is calculated through applying the displacement coordination relationship. This method enables the coupling of beam-plane, beam-shell and beam-solid, while avoiding stress concentration on the coupling interface. Numerical tests have been conducted to validate the stability and reliability of the proposed method in dynamic nonlinear problems. The calculation results indicate that this method is effective for the multi-scale fine analysis of structures.

Keywords: finite particle method, coordinated distributing coupling method, major-secondary particle coupling system, displacement coordination relationship, force balance relationship

1. Introduction

Accuracy and efficiency are critical concerns in the numerical simulation of structures [1]. There are three primary modeling approaches: structural modeling, refined modeling, and multi-scale modeling. Structural modeling involves building a global simplified model of the structure using low-dimensional elements such as beam elements. However, this approach cannot reflect the mechanical properties and failure mechanisms of the structure due to the lack of local information [2]. Refined modeling involves building a detailed model to examine the local response of the structure using high-dimensional elements such as shell or solid elements [3]. However, the reduced element mesh size significantly increases the computational cost of the model by requiring an excessive number of nodes and elements [4]. Multi-scale modeling is a combination of structural and refined modeling. It involves building a simplified simulation of the entire structure with low-dimensional elements and a refined simulation of key parts with high-dimensional elements. This approach not only describes the overall response of the structure but also captures the local fine behavior, achieving a balance between accuracy and efficiency [5].

Unlike the Finite Element Method (FEM), the Finite Particle Method (FPM) is based on the Vector Form Intrinsic Finite Element Method and employs particle description and the concept of path unit to describe the deformation and motion of the continuum [6]. It calculates the pure deformation of an element by inverse motion, which has better stability in geometric nonlinearity. FPM has achieved excellent results in structural dynamic behavior [7, 8], fracture behavior [9, 10], mechanism motion behavior [11], contact and collision behavior [12], buckling and failure behavior [13, 14]. Recently, a

computational platform of FPM based on GPU parallel acceleration strategy had been developed [15]. FPM is suitable for solving complex structural nonlinear problems, and the coordinated distributing coupling proposed in this paper is based on this method.

The deformable interface method in the multi-point constraints (MPC) has been studied and improved by many current scholars. McCune [16] used Reissner bending and assumed stress distribution to construct constraint equations to achieve beam-solid and shell-solid coupling under geometric linear conditions. Yan [17] established a multi-scale deformable interface model for a single-branch beam using the stress equation for rectangular cross-sections. Wang [18] derived force and displacement constraint equations of the interface through the principle of virtual work and proposed a multi-scale constrained construction method applicable to geometric nonlinearity. However, most of these studies aiming at deformable interfaces are based on implicit finite element methods.

Multi-scale methods for explicit finite elements have also been investigated. Meguid [19] proposed a coupling method applicable to explicit finite elements based on the assumption of a rigid interface, but neglected the contribution of local bending moments and moments of inertia at the nodes of high-dimensional elements. Based on the concept of Vector Form Intrinsic Finite Element Method, Zheng [20] proposed a physical quantity transfer method and displacement constraints suitable for FPM multi-scale connections, and realized three types of connections: beam-solid, beam-shell, and shell-solid. However, the above studies have the limitation of planar assumptions and do not solve the stress concentration caused by rigid constraints.

In this paper, we propose a coordinated distributing multi-scale coupling method applicable to the explicit solution of FPM. The method adopts the concept of force distribution and displacement coordination to allow the coupling interface to deform. Firstly, the calculated interface force is distributed to the secondary particles according to the force balance relationship. Then, the displacements of the secondary particles are obtained through the motion equation. Finally, the motion of the major particle is calculated by applying the displacement coordination relationship.

In the following sections, we introduce the basic principle of FPM, followed by the principle of the coordinated distributing multi-scale coupling. Finally, we verify the effectiveness and stability of the method through several typical cases.

2. Basic principle of finite particle method

The basic principles of the FPM include particle description, path unit, deformation description, and motion control equations [6]. The particle description refers to the discretization of the geometry and spatial location of the structure using a finite number of particles as the smallest basic cell. The path unit is the time trajectory of the particle motion discretised into microsegments, and the properties of the structure represented by particles are kept constant within any path unit.

The deformation description mechanism is the core feature of FPM. The deformation increment of the solid micro-element in the path unit $(t \sim t + \Delta t)$ contains the rigid body displacement and pure deformation $(V_t \sim V_{t+\Delta t})$. FPM makes the particle undergo a virtual inverse motion to reach an intermediate form V_a to deduct the rigid body displacement, and treats the remaining part $(V_a - V_t)$ as pure deformation.

The motion equation of particle i follows the Newton's Second Law in each path unit, i.e.:

$$\boldsymbol{M}_i \ddot{\boldsymbol{x}}_i = \boldsymbol{F}_i^{ext} + \boldsymbol{F}_i^{int} \tag{1}$$

where $\boldsymbol{M}_i$ is the generalized mass matrix of particle i, $\ddot{\boldsymbol{x}}_i$ is the generalized acceleration vector of particle i, and $\boldsymbol{F}_i^{ext}$ and $\boldsymbol{F}_i^{int}$ are the generalized internal force and generalized external force on particle i, respectively. FPM uses an explicit central difference algorithm, and the displacement of the particle at

the moment $t + \Delta t$ is obtained from the increment of moment $t - \Delta t$ to moment t, and sub-steps are iterated continuously to complete the calculation of the whole progress.

3. Basic principle of coordinated distributing multi-scale coupling

In contrast to the rigid interface method, which treats the major-secondary particle system on the interface as a rigid body for calculation, the coordinated distributing coupling algorithm allows the system to deform relatively under the satisfaction of the displacement coordination relationship and force balance relationship in this paper. In this section, the displacement coordination and force balance relationship for the major-secondary particle system are described.

3.1. Major-secondary particle displacement coordination relationship

The major-secondary particle coupling system is defined in the multi-scale connection interface. The coupling of beam element and hexahedral solid elements is shown in Figure 1. In this paper, the particles in the interface are distinguished according to their dimensions, the beam particle in the low-dimensional element is defined as the Major particle, and the solid particle in the high-dimensional elements is defined as the secondary particle. The low-dimensional element and the high-dimensional element at the interface jointly characterize the motion and deformation of the connection interface.

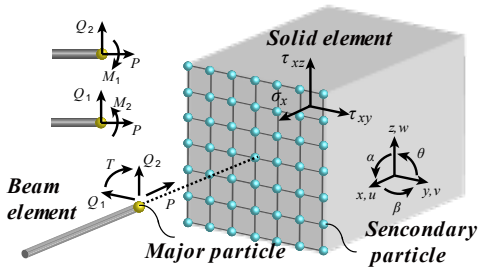

Figure 1. Major-secondary particle coupling system of beam-hexahedral solid

The linear displacement coordination relationship between the major and secondary particles can be expressed as:

$$f(\boldsymbol{x}_\alpha, \boldsymbol{x}_\beta) = \boldsymbol{x}_\alpha - \mathbf{C}\boldsymbol{x}_\beta = 0 \tag{2}$$

where $\mathbf{C}$ is the displacement coordination coefficient matrix of $6 \times 6n$, n is the number of secondary particles, $\boldsymbol{x}_\alpha$ is the 6×1 vector of major particle displacement, and $\boldsymbol{x}_\beta$ is the displacement vector consisting of $6n \times 1$ for each secondary particle. The form of imaginary displacement equation (2) , i.e.:

$$\delta f(\boldsymbol{x}_\alpha, \boldsymbol{x}_\beta) = \delta\boldsymbol{x}_\alpha - \mathbf{C}\delta\boldsymbol{x}_\beta = 0 \tag{3}$$

where $\delta\boldsymbol{x}_\alpha$ and $\delta\boldsymbol{x}_\beta$ are the imaginary displacement vectors for the major particle and secondary particle, respectively.

In large deformation problems, the coupling interface may rotate or produce non-negligible sectional deformation, and the displacement coordination coefficient matrix $\mathbf{C}$ is constantly changing between two adjacent path units, so the displacement coordination relationship is described nonlinearly, i.e.:

$$f(\boldsymbol{x}_\alpha, \boldsymbol{x}_\beta) = \boldsymbol{x}_\alpha - \mathbf{C}(\boldsymbol{x}_\beta)\boldsymbol{x}_\beta = 0 \tag{4}$$

Its imaginary displacement equation is expressed as:

$$\delta f(\boldsymbol{x}_\alpha, \boldsymbol{x}_\beta) = \delta\boldsymbol{x}_\alpha - \mathbf{C}^*(\boldsymbol{x}_\beta)\delta\boldsymbol{x}_\beta = 0 \tag{5}$$

$$\mathbf{C}^*(\boldsymbol{x}_\beta) = \frac{\partial \mathbf{C}(\boldsymbol{x}_\beta)}{\partial \boldsymbol{x}_\beta}\boldsymbol{x}_\beta + \mathbf{C}(\boldsymbol{x}_\beta) \tag{6}$$

where $\mathbf{C}^*(\boldsymbol{x}_\beta)$ is displacement incremental coordination matrix in the coupled interfaces.

3.2. Major-secondary particle force balance relationship

The force balance relationship between the major and secondary particles can be expressed as:

$$\boldsymbol{F}_\beta^I = -\mathbf{C}_f \boldsymbol{F}_\alpha^I \tag{7}$$

where $\boldsymbol{F}_\beta^I$ and $\boldsymbol{F}_\alpha^I$ are the vector of interface forces on the major particle and each secondary particle respectively, and $\mathbf{C}_f$ is the $6n \times 6$ force distribution matrix, which can be interpreted as the reverse of the interface forces on the major particle (i.e. $-\boldsymbol{F}_\alpha^I$) distributed to each secondary particle. the formulas for $\boldsymbol{F}_\alpha^I$, $\boldsymbol{F}_\beta^I$ are as follows:

$$\begin{aligned} \boldsymbol{F}_\alpha^I &= \mathbf{M}_\alpha \boldsymbol{a}_\alpha - \boldsymbol{F}_\alpha^e \\ \boldsymbol{F}_\beta^I &= \mathbf{M}_\beta \boldsymbol{a}_\beta - \boldsymbol{F}_\beta^e \end{aligned} \tag{8}$$

where $\mathbf{M}_\alpha, \mathbf{M}_\beta$ are the generalized mass matrixs of the major particle and the whole secondary particle set, $\boldsymbol{a}_\alpha$, $\boldsymbol{a}_\beta$ are the generalized acceleration vectors of the major particle and the whole secondary particle set; $\boldsymbol{F}_\alpha^e, \boldsymbol{F}_\beta^e$ are the element particle force vectors of the beam unit on the major particle and the element particle force vectors of all solid elements at the secondary particles, respectively. $\boldsymbol{F}_\alpha^e$ contains the axial force (P), the shear force in two directions (Q_1, Q_2), the torque (T) and the bending moment (M_1, M_2).

The force balance relationship between the major and secondary particles in implicit finite element method can be derived from the principle of virtual work [18]: the sum of the virtual work done by forces (stresses) of different types of elements in the interface should be equal to zero. For explicit dynamic calculations, the sum of the virtual work done by the forces (stresses) of different types of units in the interface should be equal to the work done by the unbalanced forces of the masses at the interface at the virtual displacement, i.e:

$$(\mathbf{M}_\alpha \boldsymbol{a}_\alpha - \boldsymbol{F}_\alpha^e)^T \delta \boldsymbol{x}_\alpha = -\left(\mathbf{M}_\beta \boldsymbol{a}_\beta - \boldsymbol{F}_\beta^e\right)^T \delta \boldsymbol{x}_\beta \tag{9}$$

Under the linear displacement constraint, substituting the displacement coordinated imaginary displacement in the form $\delta \boldsymbol{x}_\alpha = \mathbf{C}\delta \boldsymbol{x}_\beta$, and approximately removing $\delta \boldsymbol{x}_\beta$ as it applies to arbitrary imaginary displacements, we obtain:

$$\mathbf{M}_\beta \boldsymbol{a}_\beta - \boldsymbol{F}_\beta^e = -\mathbf{C}^T(\mathbf{M}_\alpha \boldsymbol{a}_\alpha - \boldsymbol{F}_\alpha^e) \tag{10}$$

Comparing equation (15) with equation (7), it can be seen that under the linear displacement constraint, the force distribution matrix $\mathbf{C}_f$ is a transpose of the displacement coordination matrix $\mathbf{C}$, i.e.:

$$\mathbf{C} = {\mathbf{C}_f}^T \tag{11}$$

Substituting $\delta \boldsymbol{x}_\alpha = \mathbf{C}^*(\boldsymbol{x}_\beta)\delta \boldsymbol{x}_\beta$, under the nonlinear displacement constraint and approximately removing $\delta \boldsymbol{x}_\beta$, the same can be obtained as:

$$\mathbf{C}^*(\boldsymbol{x}_\beta) = {\mathbf{C}_f}^T \tag{12}$$

The linear constraint is essentially a special case of the nonlinear displacement constraint, and the displacement incremental coordination matrix of Eq. (17) is degenerated to the displacement coordination matrix to obtain Eq. (16). It can be seen that there is a transposition relationship between

the force distribution matrix and the displacement increment coordination matrix for both linear and nonlinear constraints.

3.3. Force distribution for secondary particles

The interfacial forces can be assigned to each secondary particle based on the force balance relationship. The study of deformable interface method has proposed various ways to implement the interface force distribution, including temperature stress method [1], stiffness matrix method [18], and stress distribution weight method [16]. In this study, based on the local coordinate system $\boldsymbol{\Omega}$ of the coupled interface, the assumption that the components are independent of each other in the distribution of the interface force in the stress distribution weight method is adopted:

$$\mathbf{C}_{f_i} = [\boldsymbol{c}_{i,P} \;\; \boldsymbol{c}_{i,Q_1} \;\; \boldsymbol{c}_{i,Q_2} \;\; \boldsymbol{c}_{i,T} \;\; \boldsymbol{c}_{i,M_1} \;\; \boldsymbol{c}_{i,M_2}] \tag{13}$$

$$\mathbf{C}_f = [\mathbf{C}_{f_1} \;\; \mathbf{C}_{f_2} \;\; \mathbf{C}_{f_3} \;\; \cdots \;\; \mathbf{C}_{f_n}] \tag{14}$$

where $\boldsymbol{c}_{i,Y}$ denotes the vector of force distribution coefficients (6×1) from particle i under load component Y, corresponding to the six components of force distribution. According to equation (14), $\mathbf{C}_{f_i}$ of each secondary particle is integrated as the force distribution matrix $\mathbf{C}_f$.

3.4. Displacement solution for major particle

After obtaining the force assigned for the secondary particles, the displacement of the secondary particles and major particle can be solved. The displacement increments $\{d\widehat{\boldsymbol{u}}_{Si}, d\widehat{\boldsymbol{\theta}}_{Si}\}$ for secondary particles in the interface coordinate system can be obtained after the calculation by the central difference method of FPM. In order to solve the displacement of the major particle, it is assumed that the center of secondary-particle set is connected with the major particle by a rigid beam, and the displacement of the center of secondary-particle set is calculated according to the displacement increment of each secondary particle, and then the displacement of the major particle is solved according to the motion of the rigid beam.

Based on the transposition relation of equation (12), the force distribution matrix $\mathbf{C}_f$ is transformed into the displacement increment coordination matrix $\mathbf{C}^*$, and the displacement increments $\{d\widehat{\boldsymbol{u}}_C, d\widehat{\boldsymbol{\theta}}_C\}$ from the center of secondary-particle set in the interface coordinate system are calculated as follows:

$$\begin{bmatrix} d\widehat{\boldsymbol{u}}_C \\ d\widehat{\boldsymbol{\theta}}_C \end{bmatrix} = \mathbf{C}^* d\widehat{\boldsymbol{u}}_S = \sum_{i=1}^{n} \mathbf{C}_{f_i}^T \begin{bmatrix} d\widehat{\boldsymbol{u}}_{Si} \\ d\widehat{\boldsymbol{\theta}}_{Si} \end{bmatrix} \tag{15}$$

After obtaining the displacement $\{\boldsymbol{u}_{C,t+\Delta t}, \boldsymbol{\theta}_{C,t+\Delta t}\}$ from the center of secondary-particle set at the moment $t + \Delta t$, the displacement $\{\boldsymbol{u}_{M,t+\Delta t}, \boldsymbol{\theta}_{M,t+\Delta t}\}$ of the major particle at the moment $t + \Delta t$ can be solved according to the translation and rotation of the rigid beam:

$$\begin{aligned} \boldsymbol{u}_{M,t+\Delta t} &= \boldsymbol{u}_{C,t+\Delta t} + \boldsymbol{u}_{C,0} + \boldsymbol{d}_{M,t+\Delta t} - \boldsymbol{u}_{M,0} \\ \boldsymbol{\theta}_{M,t+\Delta t} &= \boldsymbol{\theta}_{C,t+\Delta t}\,, \boldsymbol{d}_{M,t+\Delta t} = \boldsymbol{R}\big(d\boldsymbol{\theta}_{C,t+\Delta t}\big)\boldsymbol{d}_{M,t} \end{aligned} \tag{16}$$

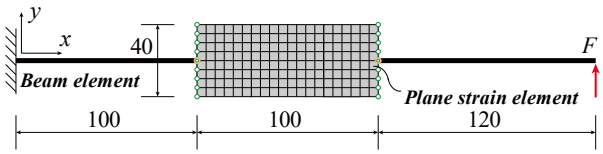
where $\boldsymbol{u}_{C,0}$ and $\boldsymbol{u}_{M,0}$ are the initial position vectors of the center of the secondary-particle set and major particle, respectively, $\boldsymbol{d}_{M,t}$ is the position vector of the major particle relative to the center of the secondary-particle set at time t, and $\boldsymbol{R}\big(d\boldsymbol{\theta}_{C,t+\Delta t}\big)$ is the three-dimensional rotation matrix.

Note that the interface coordinate system is updated by the rotation matrix $\boldsymbol{R}\big(d\boldsymbol{\theta}_{C,t+\Delta t}\big)$ between adjacent time steps, and the force assignment matrix $\mathbf{C}_f$ needs to be recalculated based on the position from the secondary particles in the new interface coordinate.

4. Numerical example analysis

4.1. Beam-plane element coupling

In order to verify the effectiveness of coordinated distributing coupling for beam-plane element connections, a rectangular cantilever beam as shown in Figure 2 is used as an analysis example (mm). The cantilever beam is unit thickness, using isotropic linear elastic material, $E = 2.1 \times 10^5$MPa, $v = 0.3$, $\rho = 7850\text{kg/m}^3$, and the free end is subjected to a vertical concentrated load F.



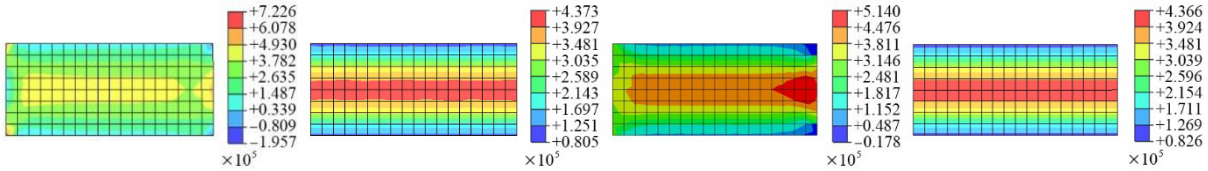


Figure 2. Coupling for beam-plane: geometric schematic

The time step is $\Delta t = 1 \times 10^{-6}$s. The stress distribution form of equation (17) is selected to build a coordinated distributing coupling model, and the fully refined model, FPM dynamic coupling model[20] and Abaqus distributing coupling model are established for comparison. The element number of fully refined model is 512, and the element number of the above three multi-scale models is 171.

$$\sigma_x = \frac{P}{A} + \frac{M_1 z}{I}, \tau_{xy} = \frac{3Q_2}{2A}\left(1 - \frac{4z^2}{h^2}\right) \tag{17}$$

where A is the interface area, I is the interface moment of section, z is the distance from the mass point in the interface to the central axis, and h is the interface height.

(a) (b) (c) (d)

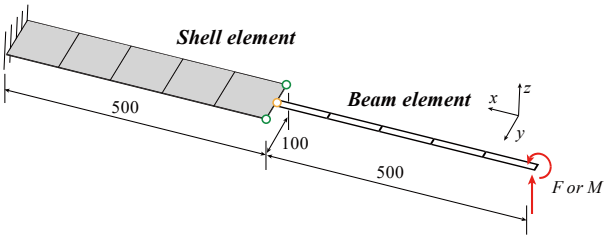
Figure 3. Coupling for beam-plane: shear stress distribution of plane element under small deformation: (a) FPM dynamics coupling, (b) coordinated distributing coupling, (c) Abaqus distributing coupling and (d) fully refined

The shear stress distribution results of the plane strain element when the free end $F = 12\text{kN}$ (small deformation) for each method are shown in Figure 3. It should be noted that compared with the fully refined model, the multi-scale model lacks half of the elements participating in the stress weighting of the particles at the coupling interface. Therefore, in order to ensure the effectiveness of the comparison, the stress cloud plot comparison area starts from the second row of elements closest to the coupling interfaces. The FPM dynamic coupling model has obvious stress concentration at the corners; the Abaqus distributing coupling model changes uniformly in the middle, but the stress concentration still appears near the interfaces; the shear stress of this method is basically unchanged along the beam axis direction, it has the highest degree of agreement with the fully refined model, and the relative error of the maximum shear stress is 0.16%. The comparison verifies the applicability of the method in beam-plane element coupling under small deformation.

4.2. Beam-shell element coupling

In order to verify the effectiveness of the coordinated distributing coupling for the beam-shell element connection, a cantilever thin plate example is shown in Figure 4. The left end of the cantilever thin plate is fixed, the shell element is coupled with the beam element at the middle interface, and the other end is

subjected to concentrated force or bending moment (dimensions are in mm). Isotropic linear elastic material is used, $E = 120\text{MPa}$, $v = 0.3$, $\rho = 5000\text{kg/m}^3$, and the thickness of the sheet is 10mm.



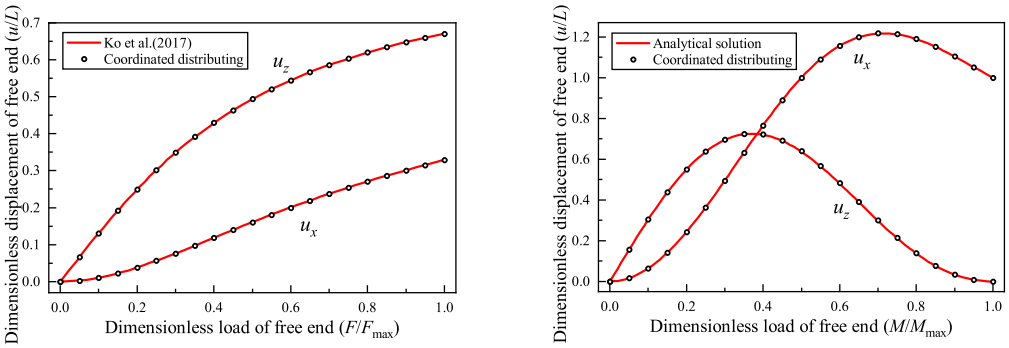


Figure 4. Coupling for beam-shell: geometric schematic

The model adopts FPM-S4 thin shell element, the time step $\Delta t = 3 \times 10^{-4}\text{s}$, and the force distribution matrix of the coupling part is calculated in the form of regular stress distribution. The maximum value of the vertical concentrated force F on the free end is set $F_{\max} = 4EI/L^2$; the maximum value of the concentrated moment M is set $M_{\max} = 2\pi EI/L$.

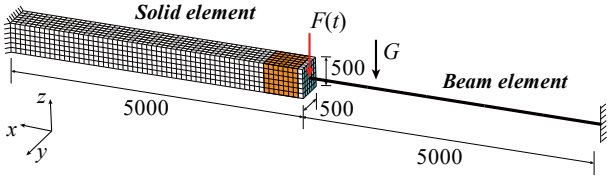
(a) (b)

Figure 5. Coupling for beam-shell: load displacement curve at the free end: (a) concentrated force along z axis and (b) concentrated moment in positive direction around y axis

The load-displacement curve of the free end under the vertical concentrated force is shown in Figure 5(a). It is in good agreement with the results of the fully shell model using MITC9 elements in literature [21], which verifies the effectiveness of the coupling method in beam-shell connection processing. The load-displacement curve of the free end under concentrated moment is shown in Figure 5(b). The matching effect with the analytical solution is also ideal, which further verifies that the method can effectively solve the connection problem of thin shells with large deformation.

4.3. Beam-solid element coupling

In order to verify the effectiveness of the coordinated distributing coupling for the beam-solid element connection, an example of a rectangular beam fixed at both ends (dimensions in mm) is used as shown in Figure 6, using isotropic linear elastic materials, $E = 2.1 \times 10^3\text{MPa}$, $v = 0.2$, $\rho = 7850\text{kg/m}^3$.



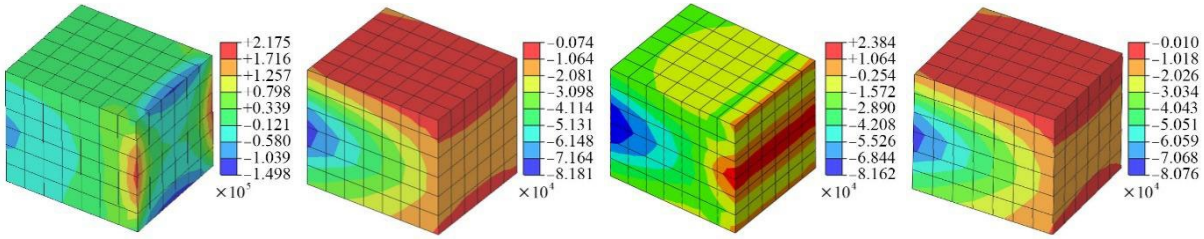


Figure 6. Coupling for beam-solid (bending): schematic

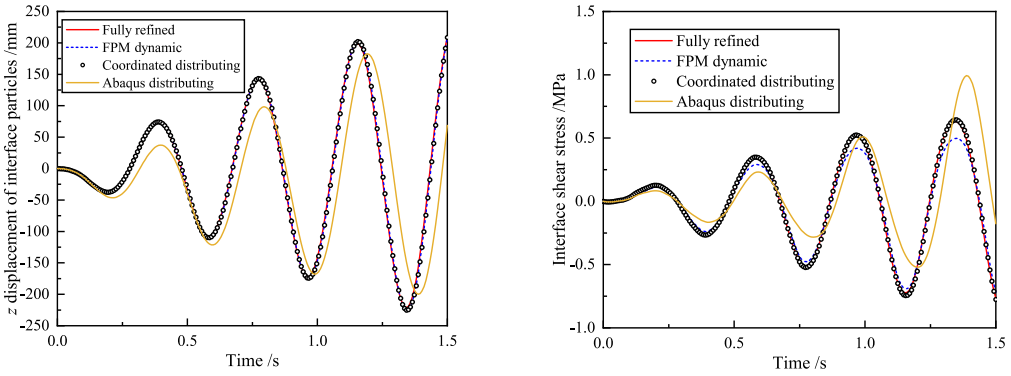
In order to consider the coupling effect of the method under the action of gravity, the gravity load is applied to the whole structure, the gravitational acceleration is taken as $9.8\text{kg} \cdot \text{m/s}^2$, the time step is

taken as $\Delta t = 1 \times 10^{-4}$s, the regular stress distribution form of equation (17) is chosen to establish the coordinated distributing multi-scale model. The fully refined model, the FPM dynamics coupling model and the Abaqus distributed coupling model are also developed for comparison. The element number of the fully refined model is 4320, and the element number of the multi-scale model is 2165.



(a) (b) (c) (d)

Figure 7. Coupling for beam-solid (bending): shear stress distribution at the interface under gravity: (a) FPM dynamics coupling, (b) coordinated distributing coupling, (c) Abaqus distributing coupling and (d) fully refined

Figure 7 shows the results of shear stress distribution of solid elements at the coupling interface (the highlighted area in Figure 6). The FPM dynamic coupling has a significant stress concentration at the outer boundary of the interface; the Abaqus distributing coupling has the same problem at the top and bottom boundaries and the neutral axis position; the stress results of the coordinated distributing coupling have a parabolic distribution at the interface, and the values are closer to those of the fully refined model, with the relative error is 1.30%. This comparison indicates that the method is applicable in the case of beam-solid element coupling.

In order to verify the coupling effect of the method in dynamic problems, the gravity load is changed to a vertical time history load at the mid-span position, $F(t) = 5 \times 10^4 \sin(5\pi t)$N, and the mass damping coefficient $\alpha = 0.05$, the calculation time is 1.5s. The time-history curves of secondary particle displacement and shear stress at the interface are shown in.

(a) (b)

Figure 8. Coupling for beam-solid (bending): z displacement and shear stress curve at the interface particle under time history load: (a) z displacement curve, (b) shear stress curve

It is obvious to find that the natural frequency of the Abaqus distributing coupling model is significantly smaller than that of the fully refined model from Figure 8(a), and the displacement error is remarkable, because Abaqus distributing coupling method may weaken the coupling stiffness at the interface. The displacement results of the coordinated distributing coupling model and the FPM dynamic coupling model are in good agreement with the fully refined model. For the interface shear stress curve shown in Figure 8(b), the stress results of the Abaqus distributed coupling model are also significantly different from those of the fully refined model due to the small natural frequency; The errors on the peak values

are 20.87% and 2.92%, respectively, reflecting that the method has a higher accuracy advantage in the stress calculation of beam-solid coupled dynamic problems.

5. Conclusion

Based on the basic theory of the Finite Particle Method, this paper proposes a coordinated distributing coupling method for explicit solution to create the interaction between major particle and secondary particles. Compared with other multi-scale explicit methods, the deformability of interface is considered and the displacement coordination equation is adopted instead of the averaging process in the proposed method, and the conclusions are as follows:

(1) In static problems, compared with FPM dynamic coupling and Abaqus coupling, the stress results of the coordinated distributing coupling method are closest to the fully refined model, especially in the direction of the shear stress, the stress concentration problem caused by the sudden changes at the coupling interface is effectively solved.

(2) In dynamic problems, the displacements and stress results of the coordinated distributing coupling model are consistent with the fully refined model, especially in the interface shear stress of the beam-solid coupling, the error is still controlled within 3.0%, which is obviously less than those of FPM dynamic coupling model and Abaqus coupling model. The comparison reflects the high calculation accuracy of the method in dynamic problems.

The coordinated distributing coupling method proposed in this paper can be applied to multi-scale modeling of actual engineering, so as to obtain more accurate local information while grasping the overall characteristics of the structure. Further research will conduct an in-depth discussion on the development of coupling interface plasticity.

Abstract

A guidance system for three-dimensionally accurate projections of timber frame construction elements was developed. Employing augmented reality (AR) glasses, interactive assembly instructions are projected onto the work environment of a timber construction company and integrated into their operational workflow. The purpose of this was to restructure the conventional assembly process utilising paper plans into a semi-digital, temporally relevant and accelerated process. The necessary geometry data was readily available and could be exported by current timber construction-specific CAD systems. The component information and layering sequence were configured for the glasses using an AR toolkit. Compared to preceding systems, the developed solution applies a successive relevant temporal filter as well as a fitting algorithm that refers to several localisation markers. Specifically developed software facilitates the levelling of the projection plane, measuring functions as well as approval and monitoring functions of individual components. According to practical trial runs of the assembly process, it was found that the project significantly improved the positioning of the individual timbers, the fastening of the sheeting and the insulation panels, while also reducing the extent of accumulative errors. Further development also managed to include non-conventional, free-form geometries. Tests revealed that the developed solution did not require any extensive training and its application could be considered intuitive.

Keywords: prefabricated timber structures, digital transformation, augmented reality, timber frame, design for manufacturing and assembly, precision, projection

1. Introduction

The duration of the manufacturing process of wooden panel elements strongly depends on the technical equipment of the respective timber construction company [1, 2]. The joint research project OptiPaRef (funded by the BMEL within the ZIM funding program 2021/2022) has therefore set itself the goal of increasing manufacturing efficiency and process reliability in the manual production of timber frame construction elements by making the low-investment technology of augmented reality (AR) usable for timber construction. To this end, the FLEX research group led by Prof. Dr.-Ing. Alexander Stahr has developed an assistance system for the holographic display of complex manufacturing information.

All relevant data is already defined by timber engineers; afterwards the information exchange takes place via a predefined interface from the CAD program [1]. The core idea of the project is to make the already existing planning data available to the carpenters in the workshop with the help of optical-parametric component referencing. To this end only the information required for the current work step is displayed and scaled directly in the carpenter's field of vision using AR glasses. At the same time, quality assurance in production is significantly simplified by the AR-based documentation of already placed elements.

2. Timber element construction in the SME sector

Traditional timber frame construction is based on prefabrication of large building elements, which are only assembled at the construction site. Due to the multi-layered requirements (statics, thermal insulation, sound insulation, etc.), wood panel construction has a high complexity in its overall structure as well as in its individual elements [1]. This requires a considerable manufacturing effort, which must be implemented in a secure production process. Within the market sector, a strong price competition can be generated by few companies that are automating their manufacturing in portal processing machines. Such large-scale equipment requires considerable investment, which is not manageable for medium-sized companies [2], In general, large production facilities and machinery are not necessary for the manufacturing process. In Germany the large majority of timber construction companies is employing less than 20 employees, who are joining timber elements manually in their workshops [3].

Factory planning for the manual production of wood panel elements takes place digitally with the help of wood construction-specific, menu-driven CAD software. This software is capable of generating the plans for the assembly of the panel elements as well as the control data for numerically controlled joinery systems or nailing bridges. In the company of the project partner Holzbau Lepski, ready-tied lumber and wood-based panels (see Figure 1) have so far been laid out and joined in a manual process. The information from the digital planning is stored on printed plans and transferred and checked from these analogously. For marking out complex geometries or free-form shapes, such as those found in bat dormers, it is necessary to print dimensionally accurate copies of corresponding partial sections of the construction drawings and to arrange them over the work piece. This analogous intermediate step is very time-consuming.

An existing solution for the paperless transfer of assembly information are laser systems permanently installed above the work table, which project the component contours onto the work surface in two-dimensional projections. However, the projections do not offer the desired possibility of information retrieval and are associated with a location-bound assembly, from which the research project would like to free itself [4].

Figure 1. Person mounting a timber frame

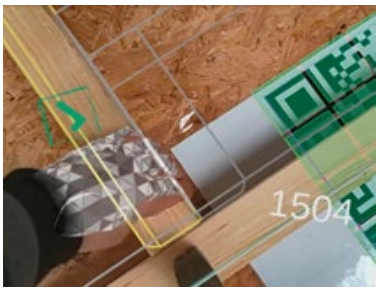

Figure 2. Positioning-outlines, localisation marker, release button and object ID

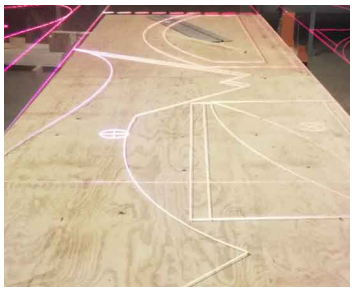

Figure 3. AR-Projection of free-form building parts onto LVL-boards

3. AR glasses instead of paper plans

In order to overcome these obstacles and to be able to offer an innovative, low-investment alternative, the project partners studied and further developed the application of AR glasses in the field of timber element construction [6, 7]. The overall goal was to extend the chain of digital planning data into the manufacturing process. The core of the work was therefore the description of a corresponding workflow and the development of interfaces, which ensure the availability of all information necessary for the assembly without time-consuming conversions.

This development was based on the HoloLens2 by Microsoft - AR glasses that use time-of-flight cameras to orient and locate themselves in space. With the help of a device-specific AR toolkit, special functionalities could be programmed to make the planning data already available in digital form directly

and intuitively available to the workers during the production of the panels. Based on this, an action-oriented information structure was developed, which is based on geometry projection.

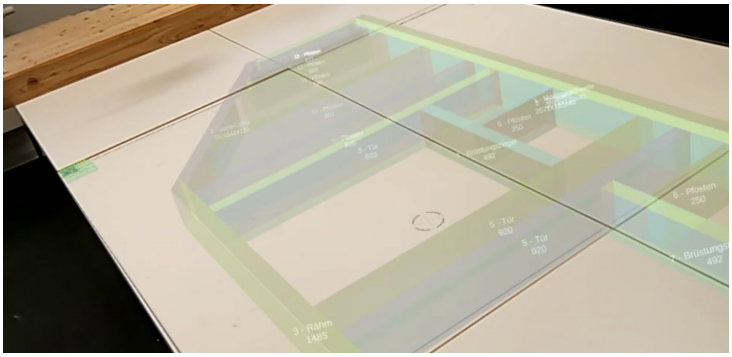

Figure 4. Geometry projection

In addition to the pure projection of target positions, a measuring tool was developed that processes information from the positions of a measuring marker (coordinates, lengths and angles) as well as an approval tool that enables paperless logging of the manufacturing process by means of gesture-controlled command input.

The multi-layered and written instructions that were initially envisaged proved not to be effective, as they severely restrict the worker's approach and his room for maneuver. Instead, the instructions are provided in purely geometric "information layers". Furthermore, it has proven useful to allow jumping back in the information sequences. This implies a shift from the term "instruction for action" to "possibility for action".

4. Setup and turning table

An element to be manufactured consists of a squared timber frame, which on both sides is clad with insulation, foils and boarding. This requires to turn the element. Due to the large dimensions, heavy weights and low stiffness of the unsheeted frame, a manual turning operation carries a high risk of damage or injury. Therefore, a butterfly turning table is used for this step, which consists of two adjacent assembly tables, a feeder table and a receiving table.

Figure 5. Butterfly turning table (feeder table)

The feeder table has a stop bar in the longitudinal direction and a clamping device in the transverse direction, by which the wooden frame is held in position. The individual parts of the wooden frame are positioned in it and joined together. This is followed by the planking and machining of the visible upper side of the frame with nailing or stapling machines; in addition, openings and holes can be cut in the planking.

Once the planking of one side is completed, the element is transferred to the receiving table by means of a hydraulically operated folding mechanism. To prevent collisions, the table has neither a stop nor a clamping device. These are not necessary for the dimensional stability of the element, as the frame is already connected. The second side can now be planked and machined here.

Figure 6. Sequence of butterfly turning table in action

5. Technical implementations

The FOLOGRAM toolkit (www.fologram.com) was used to control and program the HoloLens. FOLOGRAM is a mixed reality application that provides tools for processing 3D data and interpreting environmental data (e.g., QR markers, hands, spatial map, etc) on devices with autonomous location (e.g., smartphones, tablets, AR glasses). As its base, FOLOGRAM uses GRASSHOPPER, a node-based extension for parametric modeling under RHINOCEROS (www.rhino3d.com).

5.1. Precision of the Hololens

When switched on, the HoloLens generates a coordinate system from its current position. This means that the resulting coordinate system is unpredictable; however, the origin of the coordinate system can optionally be bound to a QR marker [4, 5]. From the sensor data, an environment model is created with respect to the coordinate system, the so-called spatial map, in which the HoloLens can locate itself. The spatial map is permanently updated. When changing the position of the glasses, minimal deviations in the assignment of the spatial map to the coordinate system occur due to the noise of the sensor data. This results in visible shifts and rotations of the coordinate system over time, the so-called drift. The longer and more widespread the movements, the more drift occurs [6, 7].

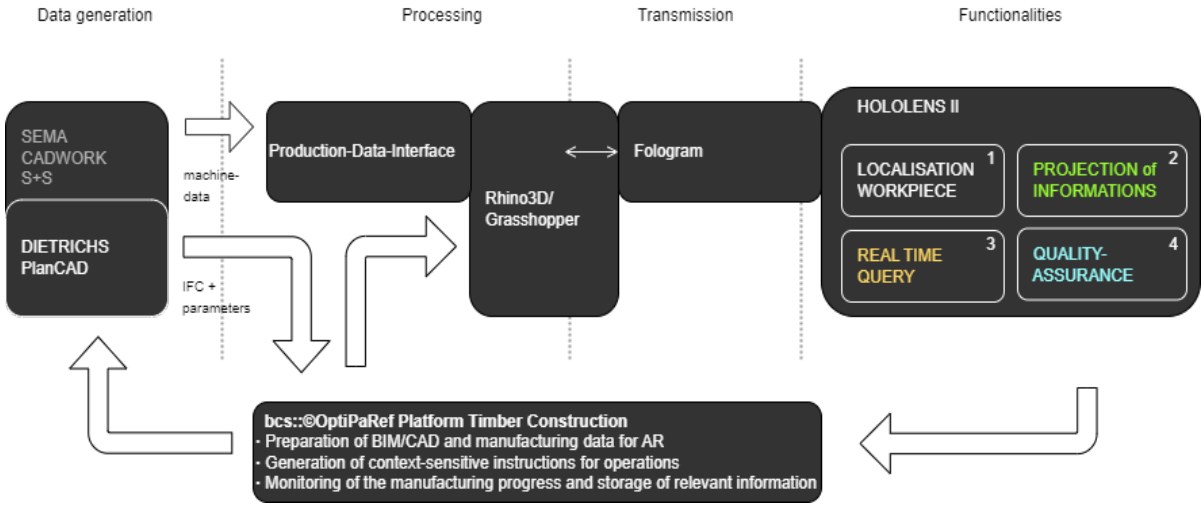

Figure 7. Data flow and required components

So the HoloLens-internal coordinate system is not suitable for millimeter-accurate positioning without a correction device (e.g. WLT tools for Unity) [8]. In addition, length measurements in space result in deviations of up to 1%. Measurements at different times result in different deviations. Therefore, precise position determination must be based on exactly defined reference points.

5.1.1 Positioning on the feeding table

Precisely measured, abrasion-resistant localization markers are attached to the feeding table, which are recognized by the HoloLens and matched with stored marker positions. Thus, the exact position and the scaling factor of the feeder table are unambiguous. Deviations from the target positions are displayed on a scale next to the marker. In this way, deviations caused by drift can be detected and corrected by re-reading the markers. The deviation of the projection to the physical components could be kept below 2mm over a length of the work table of 8 meters. This accuracy was considered sufficient for timber construction by project partner Lepski.

Figure 8. Abrasion-resistant localization markers

The markers are weighted in favor of the most recently read markers to account for the temporal effects of drift. To prevent all markers on the table from being covered by components, there are 2 markers placed on top of the stop bar at the end of the working area, which is usually never covered.

5.1.2. Positioning on the receiving table

After the turning process, the turned element rests in undetermined position on the receiving table. For integration into the digital workflow, however, its position must be precisely determined. This is achieved with the turning table markers that are placed on the corners of the turned element and read in. The lower corner closest to the stop bar of the feeder table defines the origin, the other corners define directions of the element. Since the four corners are oriented in different directions, the corresponding corner can be recognized from the marker orientation.

The positions of the markers on the receiving table are stored relative to the feeder table so that they can be removed again. This prevents the markers from being irreversibly buried under the plates mounted above them. To correct the drift, a marker could be read in at the encoder table.

5.1.3. Coordinate systems

The final positioning of the element takes place in relation to the clamping device integrated in the feeding table. The dimensionally accurate mapping of the element to be produced on the assembly tables requires the following coordinate spaces to be linked:

- HoloLens-internal (CS1), subject to drift
- CAD-related (CS2), origin of the geometry model
- Work tables (feeder and receiving table) (CS3), at a defined base point

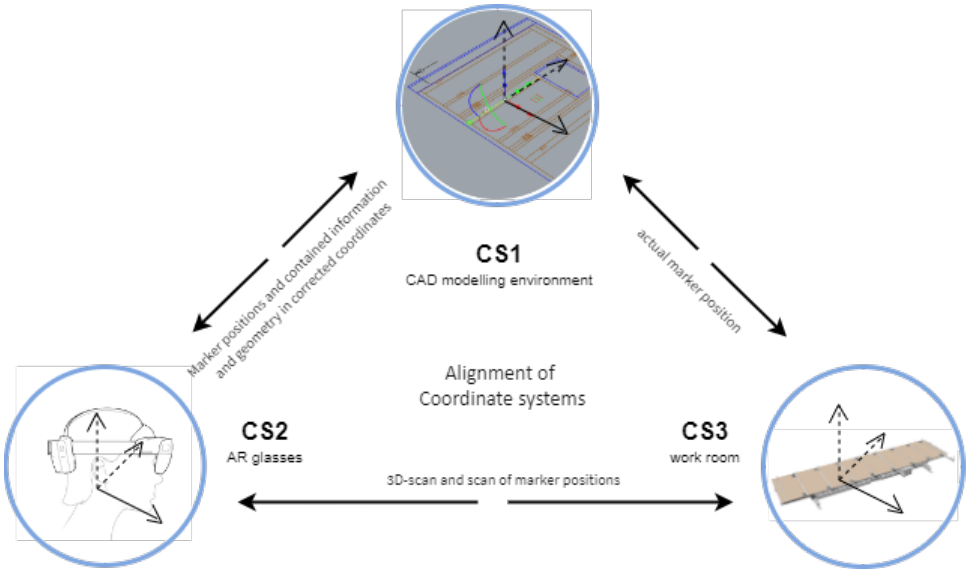

Figure 9. Relations between the coordinate

5.2. Interaction

The individual elements and functions that make up the system are shown below:

5.2.1. QR Marker Labels

A QR code ("Quick Response Code") is a two-dimensional barcode with integrated error correction, developed by the Japanese company Denso Wave in 1994. The HoloLens can determine the position of the markers in space as well as read out the information encoded in them. Depending on the strength of the error correction, even partially hidden markers can be read. The accuracy in determining the position of the markers varies with the environmental conditions (distance of the HoloLens to the marker, incidence of light, contrast). When observing a marker with the HoloLens, a wobbling of its image can be detected. This noise can be mitigated by calculating a mean value (median) from the last 25 marker positions determined.

Figure 10. Position marker, measure marker

Figure 11. Display of the user's hands

5.2.2. Control by hands

The HoloLens recognizes the user's hands and displays them in real time as a separate graphical element in the hologram. Coordinates can be extracted and processed from the geometry of the hand and the individual fingers, e.g. the position of the fingertip of a particular finger. If a fingertip comes close enough to a defined point, e.g. to the image of a control element, an action is triggered. To select an element, two fingertips are placed near the element in question.

5.2.3. Model Data

For the transfer of data from the element construction CAD program, an interface was casted which would fulfill the following requirements:

- universal, supported by as many CAD programs as possible
- complete, with all production-relevant information
- text-based for easier evaluation and, if necessary, extension

The WUP format from the Homag/Weinmann Company met all these requirements. It was especially developed for element construction systems. It is ASCII based and well documented.

Figure 12. 3D geometry of a bat dormer

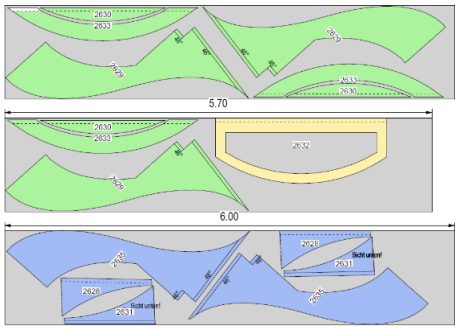

Figure 13. Placement of the curves within the measurements of the sheets

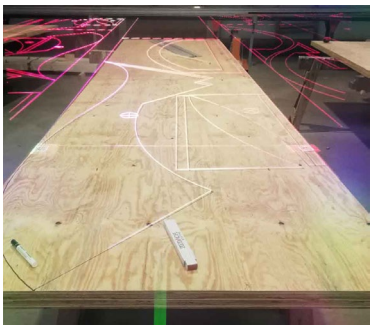

Figure 14. Projection of the outlines via AR device

In order to be able to use the positioning system for geometries other than wood-frame construction elements, a second projection interface was programmed which makes it possible to place any geometries from RHINOCEROS on the feeder table. It is designed only for tracing the outline of freeform geometries but not for interaction. For test purposes, the cut curves of a bat dormer were projected and drawn on raw boards (see Figure 14). The resulting measurements of the cut out building parts were all within the required range of precision.

6. Usage

6.1. Positioning and labeling

The original idea of displaying the element edges as lines along which the components can be aligned did not prove to be effective, since the line thickness must represent several millimeters for sufficient recognizability. Therefore, individual parts were broken down into their individual surfaces, which were colored differently. The component edges could thus be precisely positioned along the edges of the color transitions.

Figure 15. Coloured line display style

Figure 16. White line display style

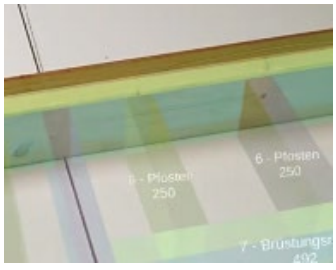

Figure 17. Surface display style

Since most of the individual parts have box geometry, 3 colors would be sufficient; i.e. one for each main plane. However, since there are also parts with oblique sections and individual parts connecting each other, 4 colors are used instead. Each part is randomly assigned 3 colors for the main planes and the fourth for slants. By using 4 colors, the probability that 2 coplanar faces of adjacent parts have the same color is reduced to 1:4. However, if situations arise where this is not sufficient, the random seed can be manually changed.

The component number and, if required, its designation are displayed to represent the individual part. It can be set whether the label is displayed only for the active part or for all parts. Machining operations are displayed with the values required by the operator, e.g. drilling diameter or setting values for the nailing machine.

6.2. Measuring

There is a separate QR marker for measuring lengths. It is placed at the point to be measured and read in with the HoloLens. As soon as the display has stabilized, a measuring point can be read in by touching the displayed measuring symbol with the hand (see Figure 18). By pressing the displayed reset symbol, the measuring points are reset and a new measurement can be performed. The quantity of read-in measuring points leads to different details:

- One measuring point shows the coordinates of the element origin (stop bar on clamping fixture).
- Two measuring points show the distance between these measuring points as well as the X, Y and Z distance in the coordinate system of the work table.
- Three measuring points show a triangle with distances and angles
- Four measuring points show a quadrilateral with distances and angles as well as the diagonal distances.

Figure 18. Measuring marker displaying set and reset-buttons

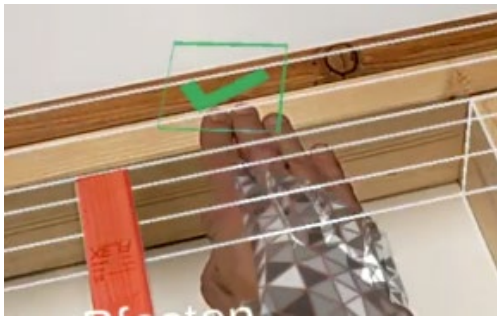

Figure 19. Selected element with approval button

6.3. Approval and documentation

After selecting a specific part with 2 fingers, it is highlighted and a detailed description is displayed. In addition, approval symbols are displayed, which can be activated with the hand. In this case the part gets documented in a text file. After the approval, only the outlines of the part are displayed and it can no longer be selected. The explicit selection of any part is intended to prevent individual parts or machining operations from being overlooked.

The text file with the documentation of the used parts also pilots the display of the parts to be processed. The work progress is laid out as follows:

- From the start of assembly, all parts of the wooden frame are displayed on the feeding table as long as at least one part of the frame is still not approved.
- Once the frame is finished, one side of the planking is displayed until the last part has been inserted or the last machining operation has been performed here as well.
- The element can now be turned. After the turning process, the position of the element on the receiving table must be read in with the turning table markers.
- Once the position of the element on the receiving table is determined, remaining machining operations and parts are displayed.
- After all parts and machining operations to be documented have been released, the element display hides and the next element can be loaded for machining.

6.4. Several HoloLenses

When using multiple HoloLenses, it must be taken into account that each HoloLens uses its own calibration as well as its own coordinate system. To work with the required precision, a separate FOLOGRAM computer must be set up for each HoloLens. If the text files that control the program progress are stored on a network drive that is accessible to all FOLOGRAM computers, they can be used simultaneously on the same element. This setup process could not be performed by the workers.

6.5. Ergonomics and practical use

In general, the use of the HoloLens was received with curiosity and positive feedback by the workers. The interactive control as well as the measuring and approval processes were immediately understood and applied. However, the setup process was found to be very complicated by the workers. The following peculiarities were documented:

1) Safety at Work: Particular hearing protection that can be worn together with the HoloLens is available for use in factory halls.

2) Power: The low battery power of the HoloLens was found to be problematic. However, this can be remedied with an additional battery worn on the body.

3) Robustness: When using tools with strong vibrations or large chip ejection, the HoloLens is irritated. In these cases, the contour to be produced was traced with a pen and then produced without HoloLens. After removing and putting away, the screen was occasionally forgotten to be folded up, after which the system was automatically put into sleep mode and then had to be restarted.

4) Wearing Comfort: For the duration of the test scenarios of a few hours, continued wearing of the HoloLens was not a problem. It was not tested how the wearing comfort develops during a whole day or over several days.

7. Evaluation of assembly times

To document the reduction in assembly time, 2 elements with similar dimensions and the same number of individual parts were manufactured by two workers; one in conventional manual joinery and the other with AR glasses. While the conventional paper plan guided assembly of a standard timberframe wall took 1,5h, the AR-projection based assembly of the identical wall took only 46 min from the moment of uploading the geometry until the wall was finished.

8. Results

After embedding abrasion-resistant QR markers into the surface of the worktable, the deviation of the projection to the physical components with an accuracy that was deemed to be sufficient for timber construction by the project partner Holzbau Lepski.

The intuitive approach proved to be successful during the test runs carried out. Test subjects who had no experience in using AR solutions were able to intuitively operate and use the developed system without extensive training periods. Short explanations were sufficient for the use of the measuring and approval tools as well as for the markers for the turning table. Only startup and setup of the AR glasses required extensive training.

Although the glasses are not technically mature at this point, time savings based on AR projections in the digital continuation of planning can already be demonstrated.

9. Future work

Recognition of components based on glued labels does not currently work because the markers required for recognition by the AR glasses do not fit on the slim surfaces of the wooden elements. In addition, the effort required to manually apply the labels (on multiple component sides) is not commensurate with the expected time savings. In a follow-up project, it would be recommended to investigate how a component marking generated with the help of numerically controlled joinery systems can be reliably read and recognized by the glasses. This way the correct placement of the marked component could be automatically identified. The development would result in additional quality control and further time savings. An additional increase in usability and simplification of the setup installation would be the renunciation of the proprietary software Grashopper and Fologram and to develop an open source app, which fulfills mentioned task steps.

Abstract

3D printing technology has ushered in a new era for the construction industry. It offers a new approach to manufacturing complex geometrical structures with numerous advantages over traditional construction methods, significantly increasing the value of parametric shape design. Nevertheless, because of gravity, structures with overhang features need support structures during the printing process. This significantly limits their printability and reduces the freedom of parametric shape design. From previous studies [16], Curvature-orient printing with an Additional-axis base seems a new solution to enhance Self-support printing to make the overhanging objects without any support structures. Rotating the Additional-axis base can reduce the inclination of the printing paths to reduce the effects of gravity. However, there are still three main failure phenomena for self-support printed objects with curvature-orient printing: (1) Overhanging collapse, (2) Slipping off from the Additional-axis base, and (3) Global deformation. If these effects cannot be predicted, it is impossible to calculate the failure limitations to generate optimized printing actions to enhance Self-support printability in Curvature-orient printing. These failure causes depend on the material, mechanical factors, the shape of objects, and so on. Thus, the failure limitations are dynamic during the printing process. Therefore, developing the process simulation for Self-support printing seems promising. Some current previous studies have developed simulation tools for triaxial printing, but the potential of the process simulation for Self-support printing has not been explored so much. This paper proposes a process simulation tool for Self-support printability of 3D Curvature-orient printing with an Additional-axis base. The proposed tool was developed based on Shaun Wu's work [18]. This research tried to fabricate it into a simulation tool predicting the Self-support limitations of the printing process, adapting to diverse materials and shapes. Additionally, the user can optimize the printing actions based on these predictions to enhance Self-support printability. To make the proposed simulation closer to reality, the parameters in this simulation program were generated from previous studies and numerous physical printing experiments. Ultimately, actual validation was done to show the potential of this proposed tool. The Grasshopper file of this tool is made freely downloadable for educational and academic use.

1. Introduction

Additive Manufacturing (AM), first introduced by Pegna [1], has revolutionized the construction field, enabling customization and flexible mass production. Robot-assisted construction, as discussed by Nycz et al. [2], offers numerous advantages, including increased quality, reduced mistakes, and faster work cycles. This technology, known as 3D printing (3DP), involves an extrusion-based manufacturing process and has been used in various projects such as the design of a topology-optimized 3D-printed bridge by concrete printing [4], topology-optimized concrete components [5], and the concrete funicular spatial structure [6].

3D printing can produce mass-customized architectural components quickly, accurately, and cost-effectively, transforming traditional building forms. Despite the prevalence of square buildings and furniture, curved forms are more common in nature. Ancient human housing, such as the Huts of the Matakam people, utilized curved forms. With increasing urbanization, high-cost curved buildings have become less prevalent due to traditional construction technology limitations. 3D printing technology can overcome form limitations and reintroduce curved buildings to the mass market. In a collaborative project, parametric shape design was explored, focusing on the potential of 3D printing in producing complex shapes. The design process considers mechanical performance, environmental factors, and topography, resulting in unique and intricate shapes. Thus, 3D printing is an optimal approach for complex architectural designs. 3D printing technology, while faster and more accurate for complex forms, faces challenges with overhang features such as shells and roofs. Common solutions involve support structures [5, 6], which can be wasteful and limiting (See Fig.1). Alternative methods to reduce support volume [7–9] have become bottlenecks in efficiency, precision, and cost reduction.

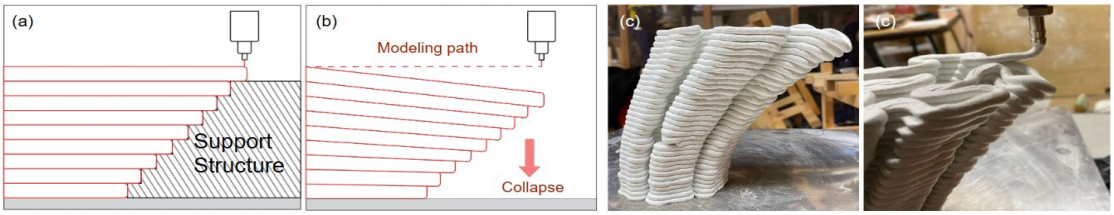

Figure 1. Self-support 3D printing in the triaxial printing way: (a) printing process with support structure, (b) printing process without support structure, (c) collapse occurring without support structure in triaxial printing.

Aiming to enhance self-supporting printability, the study takes advantage of Curvature-oriented printing with an Additional-axis base as an alternative to traditional triaxial printing [10, 11]. Curvature-oriented printing generates curved slicing layers, allowing greater kinematic freedom and smooth orientation adjustments during printing [12, 13]. This method supports new paths more effectively due to continuous extrusion direction changes based on curvature, enhancing self-supporting printability compared to triaxial printing. However, gravity-induced deformation remains an issue even with curvature-oriented printing and accelerated curing using a heat gun, as shown in Fig.2. This leads to increased global deformation and potential collapse.

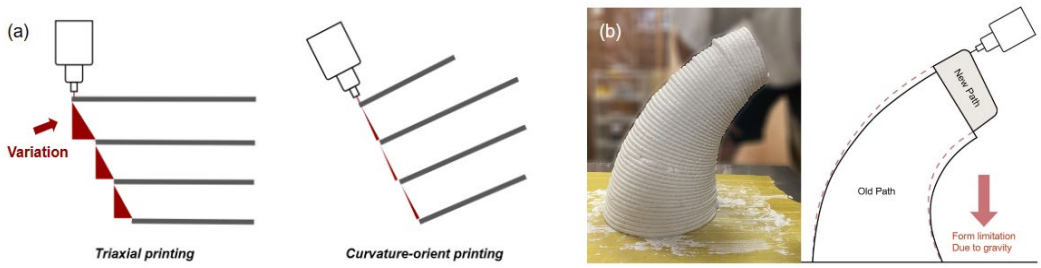

Figure 2. Curvature-oriented printing with an additional-axis base: (a) reduced path variations in curvature-oriented printing compared to triaxial printing, (b) global deformation occurring during the curvature-oriented printing process.

Gravity is inescapable, so I explored adjusting the printing path inclination to reduce gravity's effect by rotating the additional-axis base. The 3D curvature-oriented printing with an additional-axis base, consisting of a 6-axis robotic arm and a 2-axis base, was employed to improve Self-support printability of clay forms. Through numerous experiments, I identified three primary failure modes: (1) overhanging collapse, (2) slipping off the Additional-axis base, and (3) global deformation. Overhang collapse occurs when the printed model's shape isn't compatible with the printer's capabilities, causing global deformation and eventual collapse. Objects slip off the base because it rotates during printing without support structures to secure them, causing detachment if the object is too heavy or the base's inclination angle is too large. Global deformation arises from gravity, and if deformation isn't controlled within acceptable limits, accurate printing is impossible. Avoiding these failure modes and optimizing printing steps require understanding their boundaries during the printing process. Predicting these limitations is challenging due to their dynamic nature, relying on factors like shape and material properties. Developing a process simulation tool for curvature-oriented printing to enhance self-supporting printability appears promising (See Fig.3).

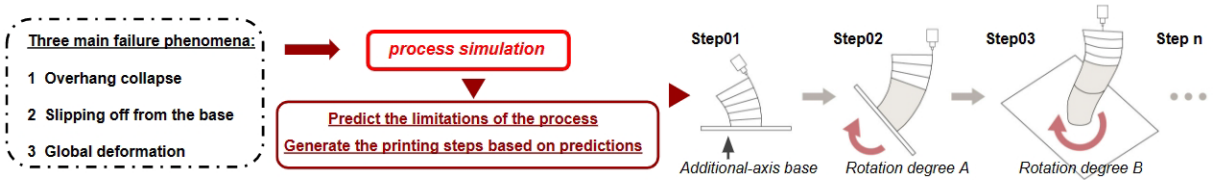

Figure 3. Objectives of the Process Simulation in Curvature-Oriented Printing with an Additional-Axis Base.

Some existing studies have developed simulation tools [14–16] for triaxial printing, but the potential of process simulation for self-supporting printing remains largely unexplored. In this paper, a process simulation tool was developed using Grasshopper (a visual programming language [17]) to predict self-supporting printing limitations and optimize printing steps to enhance Self-supporting printability of curvature-oriented printing with an additional-axis base. Global deformation simulation analysis was conducted using the Finite Element Analysis (FEA) software Karamba3D. Building on Shaun Wu's [18] study, my self-supporting global deformation simulation system was developed and was also created to predict overhang collapse and slipping off failure phenomena. All simulation analyses were combined into a process simulation system.

Although clay was used as the experimental material in this study, the proposed tool aims to predict a variety of materials and shapes. This paper thoroughly discusses the general methodology and simulation strategies for the three failure phenomena, and actual validations were performed to demonstrate the tool's potential. The proposed tool predicted the printing process of clay forms, generating optimal printing actions based on predictions and sending these actions to the self-supporting printing system. The Grasshopper file of this tool is freely downloadable for educational and academic use.

The paper's subsequent sections are organized as follows: Section 2 discusses the schematic overview of the general methodology, including numerical and validation methodologies. Section 3 presents the main simulation strategies for predicting the process limitations of the three failure phenomena. In Section 4, the actual validation results demonstrating the potential of the proposed process simulation tool for enhancing self-supporting printability are reported. Finally, Section 5 provides the conclusion and discussion.

2. General methodology

2.1. Numerical methodology

The proposed 4-step simulation system enhances self-support printability in curvature-oriented printing (Fig.4). It identifies three main failure phenomena from numerous experiments: (1) Overhanging collapse, (2) Slipping off from the Additional-axis base, and (3) Global deformation. The methodology predicts these limitations and generates printable paths and optimized actions. A robotic control system like FireFly [19] or Machina [22] sends these actions to the printing system. Step 1 predicts and optimizes printable paths. Step 2 predicts global deformation and organizes actions accordingly. Step 3 predicts slipping-off limitations based on step 2 actions. If slipping risks exist, actions are modified and re-analyzed in step 2; otherwise, the final optimized path is generated. In step 4, optimized actions are sent to the printing system to create objects. A changeable printing speed generation system is included to improve self-support printability, to be discussed later.

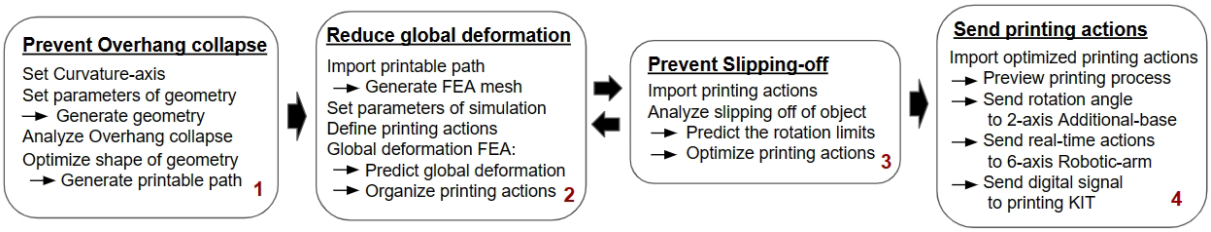

Figure 4. Overview of numerical methodology.

2.2. Validation methodology

The validation methodology involved testing various shapes, from simple curved cylinders to complex Liquid-rock geometries [23], demonstrating the potential of the proposed simulation tool and enabling parameter adjustments. Printing limitations depend on factors like material properties and mechanical performance. Paper-clay was chosen for its suitability, affordability, and ease of use, with a final density of 1.386 g/cm3. It was extruded using a StoneFlower Ceramic KIT [21], with signals sent from the KUKA Robot Controller (KRC) and an Arduino board. The curvature-oriented printing system includes a 6-axis robotic arm (KR6-16-20 from KUKA) and a 2-axis DIY additional-axis base. Robotic actions involve additional-axis base actions, robotic arm actions, and printing KIT switch signals. Additional-axis base actions were sent using FireFly [19], robotic arm actions via Machina [22], and printing KIT information was loaded into an external controller using Arduino programming. The controller, connected to the KRC, controls extrusion speed and receives switch signals using Machina. Fig.5 provides an overview of the validation methodology and the tools/connections for this printing system.

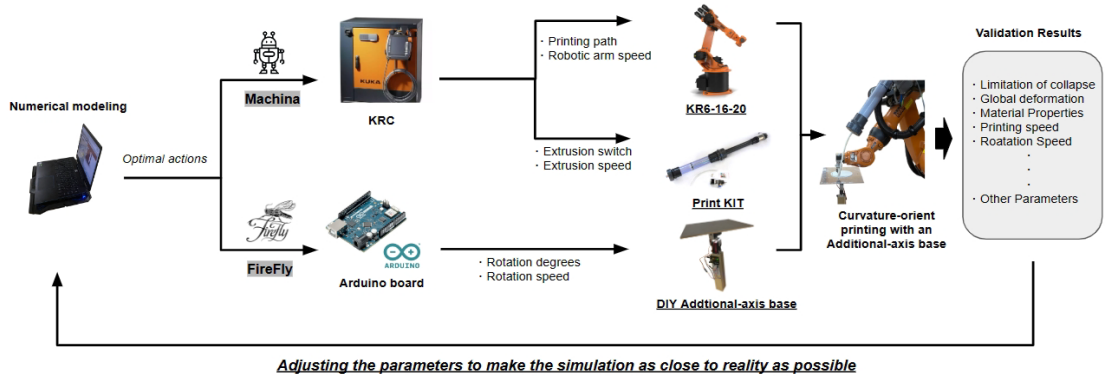

Figure 5. Overview of validation methodology.

3. Simulation Strategies

This section delves into the main simulation strategies of the proposed numerical methodology in the same order as the numerical methodology analysis: Overhanging collapse, Global deformation, and Slipping off. Additionally, a changeable printing speed generation system for enhancing self-support printability is discussed. An overview of the Grasshopper file and case examples of the proposed simulation results are presented at the end of this section. Numerous Grasshopper plugins, such as KUKA PRC, Machina, FireFly, Karamaba3D, as well as custom C# and Python scripts, were used to create the simulation system.

3.1. Overhanging collapse simulation strategy

The printable path generation is crucial as it directly affects printing results. Geometries have a Curvature-axis as a reference, and graphics along it form the geometry, varying in size and complexity. The simulation tool targets diverse shapes, but due to time constraints, two representative shapes were tested: Hollow curved geometries (simple) and Liquid-rock geometries (complex). Both have continuous, collision-free paths.The height range of the printing path is a crucial factor affecting print quality in Curvature-orient printing, as it constantly changes according to curvature and shape, unlike the constant value in triaxial printing. Incorrect path heights can lead to printing errors and, ultimately, overhanging object collapse. Using Self-support Liquid-rock geometry [23] as an example, the complex geometry generated through the Kangoo2 plugin from Grasshopper avoids path collision due to a 7mm nozzle diameter.

As shown in Fig.6(a), Layer 52 of the geometry is divided into 19 points (Ph0-18) with varying path heights (Ph). Through experimentation, a Ph range of 1.5 to 6.0 mm has been determined to result in successful printing. To prevent overhanging collapse, a function was developed to calculate the Ph range automatically, optimizing geometry shapes based on printable Ph values. As shown in Fig.6(b), the grey path is not printable due to its Ph range being outside the 1.5-6.0 mm limit. By adjusting the Curvature Axis, the geometry's shape changes, making the red path printable for the next FEA mesh generation.

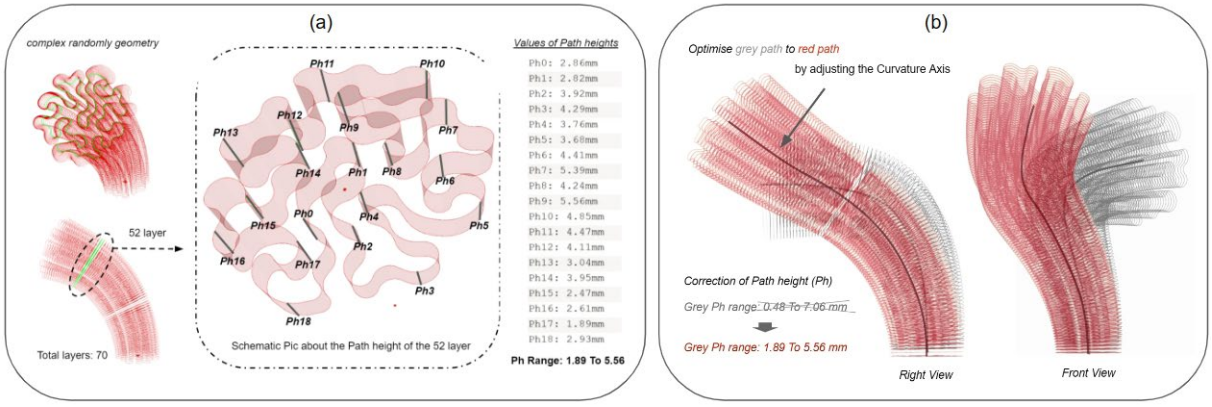

Figure 6. Overhanging Collapse Simulation Strategy: (a) automatic calculation of path heights, (b) Optimizing the shape of geometry based on calculation data to prevent overhanging collapse.

3.2. Simulation strategy for global deformation

Global deformation is a crucial reference for optimizing printing actions. However, it is dynamic during the printing process and depends on factors such as geometry shapes, and material properties. The mechanical performance prediction of global deformation in the 3D printing process follows the general methodology proposed by Shaun Wu [18]. A commercial FEA software, Karamba3D, was used for global deformation analysis through Grasshopper. In this study, a Self-support FEA system was developed to predict global deformation in the Curvature-orient printing process with an Additional-axis base.

3.2.1. FEA mesh generation for global deformation

Global deformation FEA requires an adapted mesh for the Self-support printing process. With the modified overhanging geometry shape and generated printable path from the previous strategy, a function was developed to automatically generate the FEA mesh. The mesh configuration is mainly based on six parameters (see Fig.7(a)): (1) Printing path, (2) Path width (***w***), (3) Path heights (***hi***) for analysis mesh, (4) Number of printed segments (ni) for each layer part, (5) Segment length (***ls***) in the direction tangential to the print path, (6) Perpendicular planes (***pi***) of each segment for the printing path. FEA mesh generation in this system requires inputting only the printing path and path width (***w***), while other parameters are automatically determined. A zero-thickness shell structure (see Fig.7(b)) was selected as the final FEA mesh, whose Values ***Phi*** of height are changeable, to accommodate Karamba3D's lack of volumetric element support. Only small global deformation needs to be calculated, so the Voxelization methodology[14][16] was not necessary for this simulation tool.

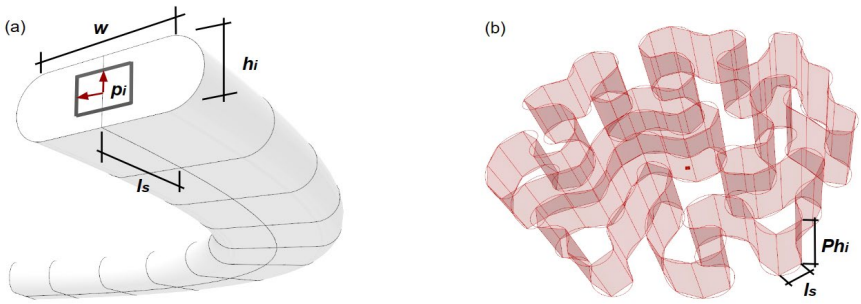

Figure 7. Printing Path Configuration: (a) general mesh configuration of the path, (b) a zero-thickness shell structure of the FEA path in Karamba3D.

3.2.2. FEA parameters setting for global deformation

To analyze global deformation limitations using FEA, material and mechanical parameters must be set. Most parameters were extracted from previous studies and adjusted through self-experiment validation.

FEA parameters setting:

1.	*Specific weight of material:*	*13.865*	*KN/m³*
2.	*Coefficient of thermal expansion:*	*5.6*	*1/C°*
3.	*Stiffness Module (t=min):*	*0.002 + 0.000013t*	*KN/m²*
4.	*Compressive Strength (t=min):*	*0.0015 + 0.000014t*	*KN/m²*
5.	*Curing parameters:*	*0.0056*	*KN/m²*
6.	*Rotation base degree A:*	*-90 ~ 90*	°
7.	*Rotation base degree B:*	*-90 ~ 90*	°

The material used was DAISO paper clay with a 35 ml water to 500 g clay ratio. The specific weight was determined through self-experiments, while the coefficient of thermal expansion is from Culbertson W. Ross's clay research [24]. The stiffness Module and Compressive Strength values were adapted from Xiyao Zheng's study [25] and adjusted with self-tests. A heat gun accelerated clay curing during printing, ensuring Self-support strength. Curing parameters were incorporated into Stiffness Module and Compressive Strength formulas. Other settings were based on Shaun Wu's study [18], and rotation degrees A&B were set according to the RDS5160 Torque Digital Robot Servo used for the DIY Additional-axis base.

3.2.3. FEA elements definition for global deformation

To reduce computational effort, the mesh model combines multiple printing paths into one layer for FEA (See Fig.8(a)). Elements in the mesh follow the FEA mesh generation method from Fig.7 and are affected only by gravity. Rotation force from the 2-axis Additional-axis base is ignored due to low speed and the heat gun's accelerated curing. The crucial setting in FEA elements definition is the changeable Supporting Points for the Self-support geometry, as the whole printed object undergoes dimensional rotation during simulation. The printing path is split into Old-path (no deformation analysis) and New-path (with deformation analysis). Supporting Points' position is determined automatically based on curing speed (5mm/s, according to the heat gun). The New-path, based on Supporting Points, is generated for deformation analysis (FEA). The Base path at the geometry's bottom predicts if the Self-support geometry slips off the Additional-axis base during rotation (Fig.8(b)). The simulation strategy for Slipping off will be elaborated later.

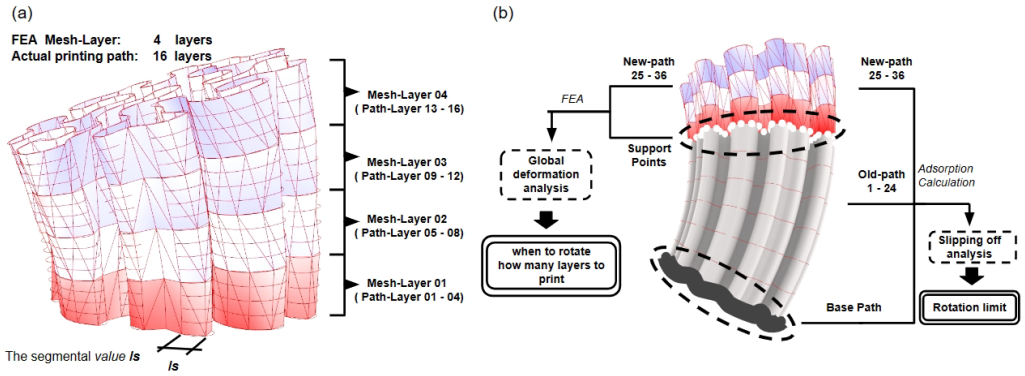

Figure 8. FEA elements definition for global deformation: (a) layer definition in FEA mesh, (b) defining Supporting Points between Old-paths and New-paths.

3.3. Simulation strategy for slipping-off

1. *Rotation base degree A:*	*-90 ~ 90*	°
2. *Extrusion speed of printing KIT:*	*0.35*	*g/s*
3. *Atmospheric pressure:*	*101,325*	*Pa*
4. *Security Factors:*	*0.029 ~ 0.021*	*(25° ~ 75°)*

This function aims to simulate Self-support 3D Curvature-orient printing clay with an Additional-axis base, making it crucial to predict if the Self-support geometry will slip off from the base during printing. Two causes for Slipping-off are: (1) object sliding on the base, and (2) object separating from the base. Experiments indicate that the primary cause is the latter: object separating from the base. Additionally, the Base path of the object and the surface of the Additional-base can form a vacuum-like condition, enabling the fixation of self-support geometries using air pressure instead of support structures. However, air pressure fixation has limitations. When the object's total weight exceeds the theoretical attraction value $\boldsymbol{w}$ (kg) or the Additional-axis base inclination is too large, the object's bottom will separate from the base (See Fig.9).

Figure 9. Slipping-off experiments: (a)(b) objects fixed on the base, (c)(d) objects slipping off from the base.

Fig.10 shows three main factors influencing the vacuum adsorption force's attraction value ***w***: object weight ***mg***, effective vacuum area ***A***, and rotation angle ***θ***. With known printing path length, machine speed, and extrusion speed, the object's weight ***mg*** (*Kg*) is calculated. Despite the DIY Additional-axis base's two-axis rotation, Rotation degreeA ***θa*** (See Fig.3) primarily affects tilting pressure. When calculating area ***A*** for pressure value ***P***, the actual printing path width is 5mm, not 7mm, due to bottom material evaporation and shrinkage. In calculating the Theoretical attraction value ***w***, multiply by the Security factor value ***F*** for better error tolerance, as the Base path bottom is not in a complete vacuum. The Security factor value ***F***, an empirical value from self-experiments, may need re-measurement if conditions change. If the final ***w*** value is greater than the object's ***mg***, the object meets Self-support conditions and won't slip off the base.

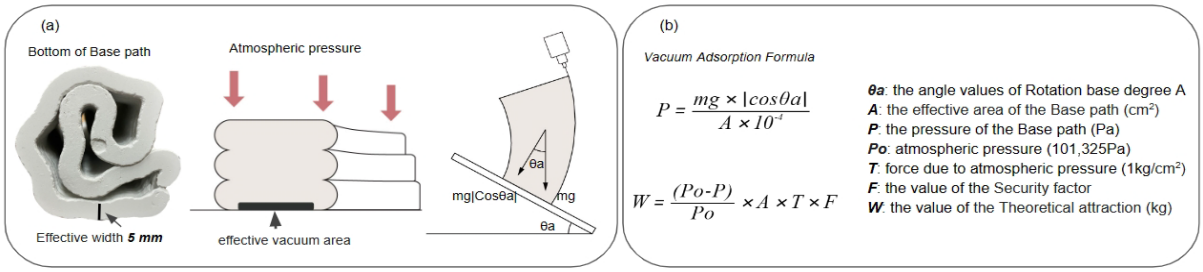

Figure 10. Vacuum adsorption calculation: (a) principle of vacuum adsorption during 3D printing, (b) formula and factors influencing vacuum adsorption during 3D printing.

3.4. Generation strategy for changeable printing speed

In the Self-support 3D printing system, path height values vary within the same layer (See Fig.6). To ensure a constant 7mm printed path width for different path heights, the robotic arm's speed is adjusted while maintaining a consistent extrusion speed (231 mm³/s), given the nozzle diameter is 7mm. Based on self-experiments, the printable path height range is 1.5-6.0mm, with corresponding robotic speeds of 720mm/min for 1.5mm height and 360mm/min for 6.0mm height (See Fig.11(a)). A comparison between objects printed with constant and changeable speeds is shown in Fig.11(b), demonstrating improved accuracy using changeable printing speeds. Changeable printing speeds (Ps) are generated based on path height (Ph) values. Using the printable Ph range (1.5-6.0mm) and the corresponding optimal robotic speed range (360-720 mm/min), the appropriate printing speeds are determined (See Fig.11(c)). These changeable printing speeds are inserted into the robotic action programming through the real-time robotic tool Machina [22]. The robot adjusts its speed based on variable path heights, ensuring the printed object is consistent with the analysis model and improving printing accuracy.

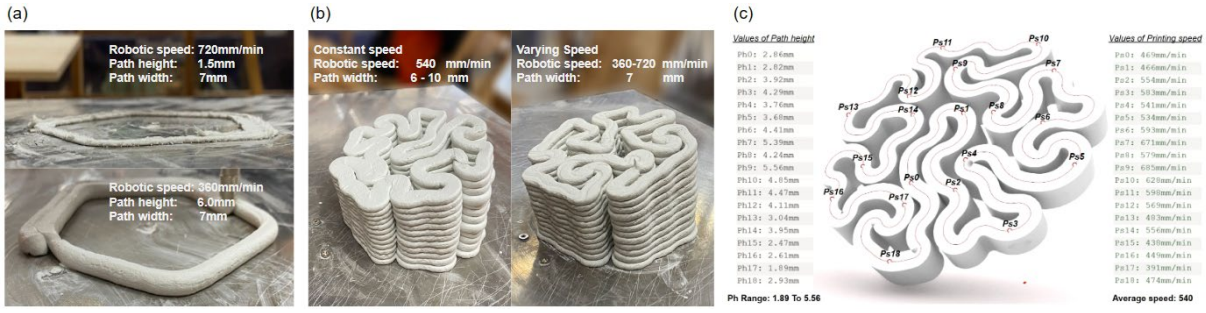

Figure 11. Changeable printing speeds: (a) the relationship between robotic speed and path height, (b) a comparison of objects printed with constant versus changeable speeds, and (c) a function for automatically generating optimized robotic speed according to various path heights.

3.5. The showcase of the Grasshopper file

Although the controller of the Printing KIT and DIY Additional-axis base requires hardware code programming in Arduino board, most of the programming is executed through Grasshopper [17]. (See

Fig.12&13) The Grasshopper file will be open-source and uploaded to GitHub. My YouTube video will explain the operation of the proposed tool and the steps of parameter adjustment. I hope this tool will be used and further developed by other researchers who are interested in Self-support 3D printing. Link of my video: https://www.youtube.com/watch?v=GJUpvVhbB4o&t=95s

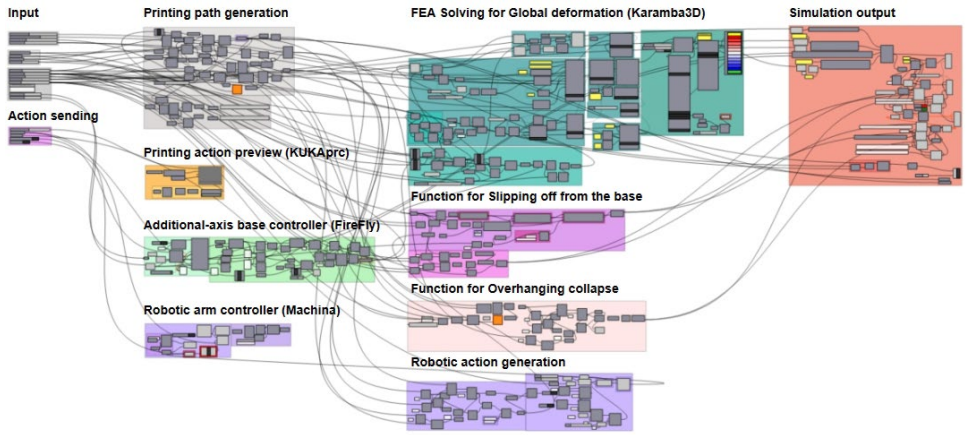

Figure 12. The overview of the Grasshopper file of the developed process simulation tool.

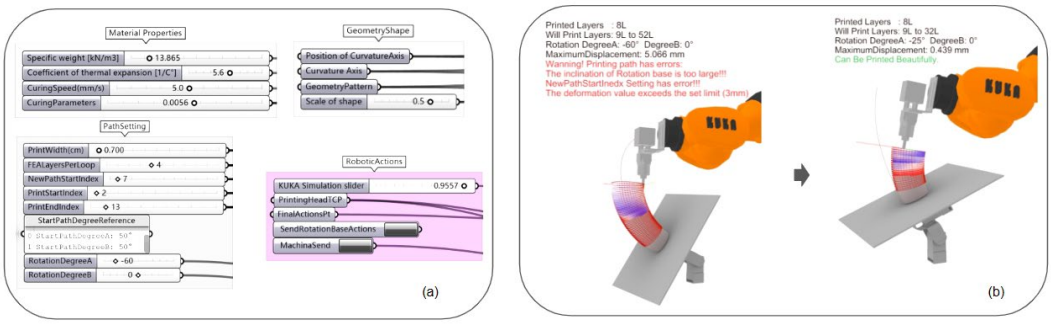

Figure 13. Process Simulation Showcase: (a) input factors for the process simulation system, (b) simulation results highlighting optimized printing actions to enhance self-supporting printability.

4. Validation

The validation phase involves two steps: (1) Training simulation - fine-tune parameters to align simulations with reality; (2) Potential validation - use the refined tool to optimize printing actions for two cases, print actual objects, and compare global deformation values between simulations and reality to verify the tool's effectiveness.

4.1. Training simulation

Building on Shaun Wu's work [18], this research focuses on simulating self-support limitations of 3D curvature-oriented printing with an additional-axis base. Adjustments are made based on self-experiments to closely match reality. First, predict self-support limitations of typical shapes and organize printing steps. Print the clay form step by step, following the simulation's steps. Set the same fixed observation view in both reality and simulation (See Fig.14), comparing the deformation value (*Dv*) of the global clay form. Measure the lowest and highest distance values from the top printing path to the additional-axis base to reduce errors. Finally, adjust simulation parameters based on global clay form comparisons until the process simulation closely resembles reality.

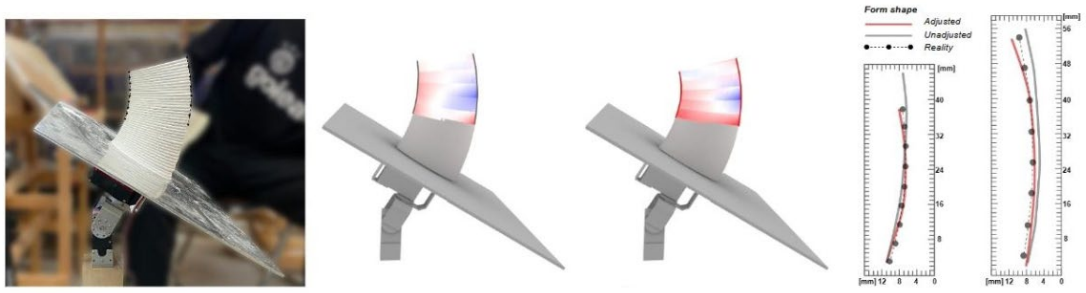

Figure 14. Parameters adjustment method: (a) The global self-support clay form in reality, (b) The simulation of self-support clay form with unadjusted parameters, (c) Comparing global deformation values to adjust parameters, making the simulation as close to reality as possible.

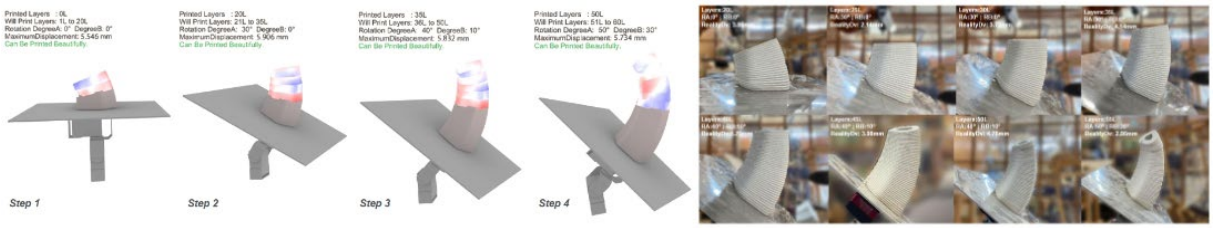
4.2. Potential validation

After adjusting parameters, the simulation results closely resemble reality. To verify the simulation tool's generalizability for diverse shapes, two self-support clay forms, Gradient polygon geometry (simple) and Liquid-rock geometry (complex), are used in the validation phase. The proposed tool predicts printing process limitations and generates optimized printing actions/steps. Actual clay objects are printed following these steps. A global *deformation limit* of 6mm is set. The differences between *Reality Dv*, *Simulation Dv*, and the *Deformation limit* are compared using line charts. If *Reality Dv* values remain below the *Deformation limit*, it suggests the tool can provide valuable predictions for self-support limitations, improving global clay form accuracy.

4.2.1. Gradient polygon geometry validation



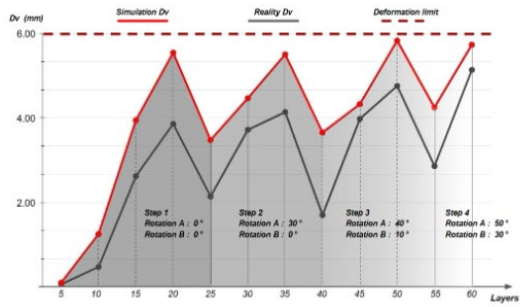


Figure 15. Optimized printing process for the gradient polygon geometry & actual deformation results during the Self-support Curvature-orient printing process.

Validation results show that *Reality Dv* for the gradient polygon geometry is controlled within 6mm, indicating improved global form accuracy using the proposed simulation tool's optimized printing process (See Table 1). While *Simulation Dv* overestimates global deformation compared to *Reality Dv*, the proposed tool still closely reflects the actual printing process, demonstrating its potential for predicting simple geometry printing processes.

Table 1. Comparing global deformation values of the gradient polygon geometry between reality and simulation.

layers	5	10	15	20	25	30	35	40	45	50	55	60

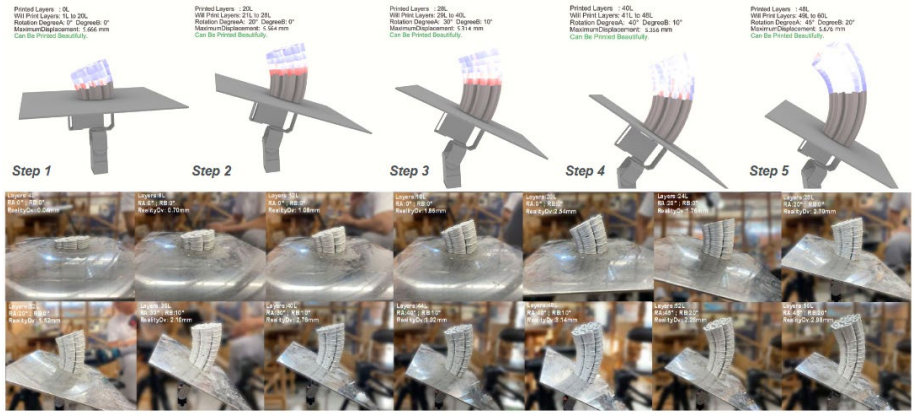
4.2.2. Liquid-rock geometry validation



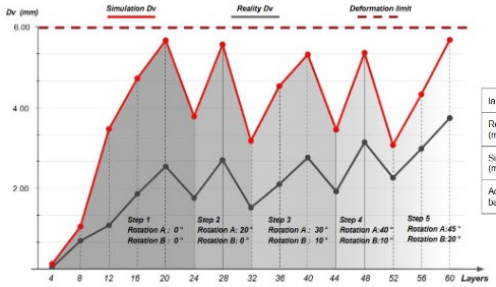


Figure 16. Optimized printing process for the liquid-rock geometry & actual deformation results.

In Table 2, Reality Dv for Liquid-rock geometry stays within 6mm, but the difference with *Simulation Dv* is greater than in Table 1. The discrepancy may result from the imperfect Curing rate setting. A heat gun accelerates clay curing, but curing is non-linear with printing time. Complex geometry has longer printing times, leading to more complex curing rates for the same layers compared to simpler geometries. Although the proposed tool improves Self-support printability for complex geometry, it can't accurately predict the printing process.

Table 2. Comparing global deformation values of the liquid-rock geometry between reality and simulation.

5. Conclusion and discussion

This paper introduces a Grasshopper process simulation tool designed to predict dynamic Self-support limitations and optimize printing actions in Curvature-orient printing with an Additional-axis base. The tool offers a versatile technique for diverse forms and materials, enhancing parametric shape design value while analyzing dynamic printing limitations of Self-support geometries. The primary objective is to predict printing process limitations and improve Self-support printability, taking into account factors such as geometry, material properties, and mechanical factors. The study emphasizes global form printability, excluding internal form considerations. However, based on validation results, the current simulation tool struggles to accurately predict printing limitations for complex Self-support geometries. Future research should incorporate randomized changes in FEA mesh node positions to simulate imperfections during the actual printing process of complex geometries.

The author plans to apply the tool to 3DP concrete construction projects in future studies, optimizing parametric shape design and printing actual structures based on the tool's dynamic predictions. The proposed process simulation tool is freely available for educational and academic use and can be downloaded from the following website: https://github.com/XuanyuL/Process-simulation-for-Self-support-printability-of-3D-Curvature-orient-printing-clay-form-with-an-A/blob/main/Self-supportPrintingSimualtion.gh.

Abstract

Development of new timber construction techniques has mainly focused on the hybridization of wood with other materials to improve the bearing capacity through integration with steel plates and fasteners. Advantage of embodied carbon in wood constructions are often threated by the burning demolishing process, e.g., if the wood is incinerated at the end of buildings' life. To remedy this, reduction in joint complexity increases the reusability of building components such as beams, as in our case short linear timber element, for disassembly. To do so, a functioning demonstrator reflects on how innovative structures are realized through synthesizing of interlocking joinery, and how augmented-reality assembly could enable the circular economy in wood. Nevertheless, the structural applications of timber construction are ever expanding, and it is of the utmost importance to broaden this essential dimension of industry and develop novel and acquisitive value-added design with high-performance application. We employ a design-fabrication-construction strategy to fill the gap between designers or engineers with local practitioners and advance wood machinery. This leads us to a certain knowledge on digitalized process and fabrication before being deployed in non-experimental and industrial applications.

Keywords: timber structures, interlocking joinery, augmented construction, structural optimization

1. Introduction

Mass timber constructions rely on hybrid joineries, most of which may be statically interlocked, but extensively use secondary material such as steel connections or fasteners. "Steel accounts for about 4% of global energy use" [1, p. 10], whereas renewable material of wood is manufactured by the sun, and its sustainable nature gives considerable environmental advantages. "Historic wood construction in different parts of the globe widely used interlocking joints before metal connections." [2]

Moreover, "while these hybrid materials have opened new markets such as multi-story housing, separating the component materials of such products is not economically feasible, and the reduction of carbon emissions from timber are largely negated by the high emissions of secondary materials. Solid timber is much more readily reused, recycled, or consumed as a source of compost or energy." [3, p. 425]

Advantage of embodied carbon in wood constructions are often threated by the burning demolishing process, e.g., if the wood is incinerated at the end of the buildings' life. To remedy this, reduction in joint complexity or material variety results in a simpler process for separating the wood components. The use of one material enables the building to be completed with a single dominant trade, which reduces the cost. We seek three main objectives for this investigation.

1. Upward scaling: exploration of optimal aggregation of short linear elements for upward scaling of free-form structures.

Copyright © 2023 by Nima ZAHIRI. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

2. Only-timber: consistent reduction of material joint complexity by adhering to material monotony of processed timber, by the possibilities that digital fabrication brings forward.
3. Reusability: examining the ease of assembly and disassembly throughout augmented reality for an easy installation, dismantling and future reuse.

To do so, a functioning demonstrator, serving as a case study, reflects on how innovative structures are realized through synthesizing of simple joint geometry, and how digital twin through sequential augmented assembly could enable a circular economy in wood construction. This represents a circular approach to maximize the reusability of timber elements by developing a new concept for disassembly.

This leads us to a certain knowledge on digitalized process and fabrication before being deployed in non-experimental and industrial applications. Herein, the paradigm of lightweight construction is thus interpreted in a more profound and comprehensive way. This serves as an investigation upon some other similar projects for further high-rise endeavors.

2. Experiment: finding tolerances

Before recessing the demonstrator elements, it is crucial to understand the optimum offset volume of intersection for interlocking joints through a simple mockup test. (Figure 1) The offset depends on the type of wood and accuracy of the machine. The experiment involves testing different offsets, and then measuring the dimensions through a CT scanner.

2.1. Testing

A simple setup, shown in Figure 1, examines different offset values. (The offsets from right to left are 0, 0.2, 0.5, 1, and 2 mm) Surprisingly, the 0 mm offset fitted perfectly fine in the mockup experiment. While, in theory we need a small gap in pockets. To realize this behavior, having the accurate dimensions will give a better insight.

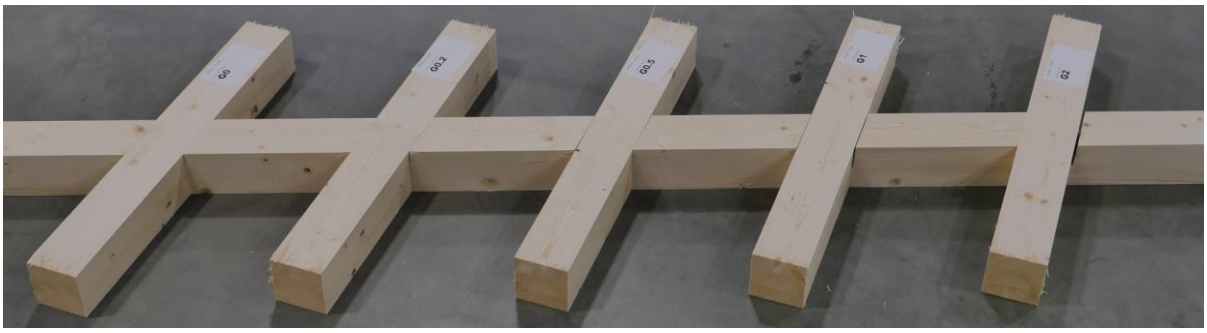

Figure 1. Mockup test for finding the tolerances.

2.2. Measuring

Industrial computed tomography (CT) scanning is used to inspect internal wood quality. In addition, our CT scanner can also be used for geometry measurements in line with a coordinate measuring machine. The CT scanner is part of MANULAB, the national manufacturing research infrastructure at NTNU.

The right image in Figure 2 shows a small, desired portion of the mockup sample in the scanner. As the dimensions indicate, the splinter tool of the Hundegger machine recesses slightly larger (approximately 80.06 mm) than the computer model. The cross section ought to be 80 mm, which is approximately 79.3 mm obtained from the planer machine. That is, the offset gap is 80.06 - 79.03 = 0.76 mm. The decision is to proceed with 0 mm offset in the computer design model.

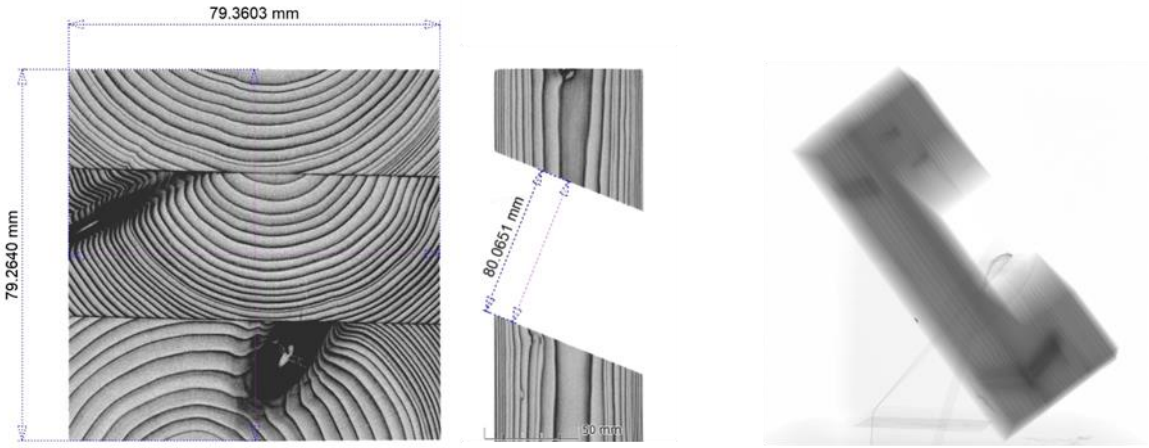

Figure 2. CT scanning

3. Demonstrator: design-fabrication-construction

The design-fabrication-construction strategy is employed to fill the gap between designers or engineers with local practitioners and advance wood machinery. According to Figure 3, the workflow could be fragmented into three recursive subsequences:

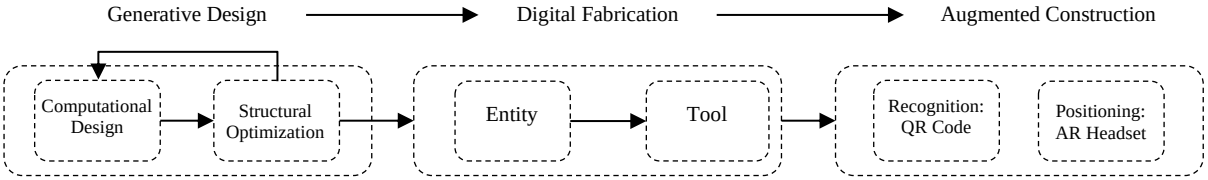

Figure 3. design-fabrication-construction diagram

In the following sub-chapters, each subsequence is investigated in an organized manner as Figure 3.

3.1. Generative design

In conventional design processes, "workflows are typically linear and have little opportunity for mutual informing or recursion between steps." [4, p. 93] However, we adhere to a recursive process, as illustrated in Figure 4, and embody integrative iterative sequences to overcome the limitation to a few, firmly established and recurring structural typologies.

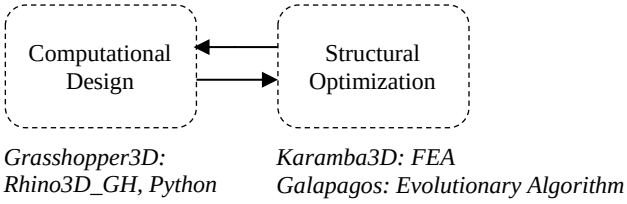

Figure 4. Generative design diagram

During the design process, the generative design plays a central role. "Evolutionary Algorithms, applying the biological principles of mutation, selection, and inheritance, reinterpret the parametric system that becomes the genome . . . and the architect's design goal becomes the fitness criteria." [5] It defines optimized solutions based on multiple variables and fitness criteria, exploring multi-objective genetic algorithms using Galapagos from Grasshopper for Design optimization.

A parametric model generates and examines different scenarios; n numbers of circles are stacked with the distance of z and variable radii between 0 and R with free rotation. To provide structural depth, the components are aggregated on two sets of circular configurations. (Figure 5)

The lines are then translated to timber beams and nodes are assigned as joints with translational and rotational stiffness. "The joint behavior is considered semi-rigid, or an intermediate between an idealized moment connection and an idealized pin connection." [6, p. 2] It creates a finite element model from given entities (points, beams, supports, loads, cross sections, materials), and calculates the deflections of a given model using first order theory for small deflections.

"The problem of high building design particularly concerns problems related to the limitation of horizontal displacements of the building and ensuring its spatial rigidity, proper foundation and resistance to dynamic wind action and seismic effects." [7, p. 2] So, the key design challenge associated with acting load is to minimize the horizontal displacement on the tip of the structure, while simultaneously optimizing the geometrical typology.

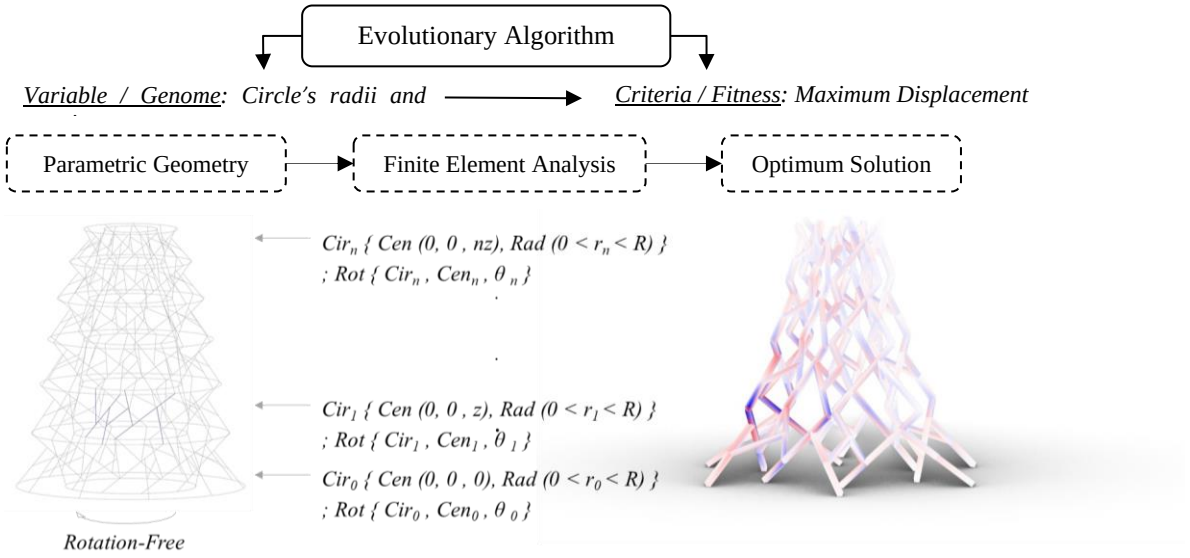

Figure 5. Evolutionary algorithm

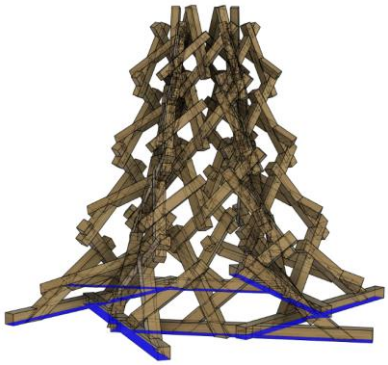
3.1.1. Computational design

The classic orthogonal setup is shown in (Figure 6a). It is shown how the connections sit on which proportion of the length. In this arrangement each two interconnections are planar, so interlocking joints could relate to the half lap joint, "one of the most basic joint types that is formed by simply removing half the thickness of each component of a pair and fit into each other." [8, p. 566]

(a) (b) (c)

Figure 6. (a) Basic logic of components placed in a rectilinear array. (b) Placement of components in a non-orthogonal pattern (c) axial rotation for the highest volume of intersection.



However, on a circular array, or non-orthogonal intersections, according to (Figure 6b), beams need to be slightly offset or rotated along their length axis to perform the highest volume of intersection solid. (Figure 6c) The aggregation of components has a repetitive pattern. These five beam types (named U, X, D, B, and C), as shown in Figure 7, embodies the whole structure.

Figure 7. Beam types

3.1.2. Structural analysis

In the previous section, multiple iterations investigated the optimum aggregation of short timber elements for upwards scaling. However, for more accurate finite element analysis, including contact surface tolerances in the interlocking joineries, nonlinear static analysis is employed in Autodesk Fusion 360 to guarantee that the stresses and displacements are in allowed boundaries. (Figure 8 and Figure 9) The outcome consists of 102 beams and 276 notches.

Density	1.38E-06 kg / mm^3
Young's Modulus	6890 MPa

Specific Heat	1464 J / (kg C)

Figure 8. 3D model and material specification

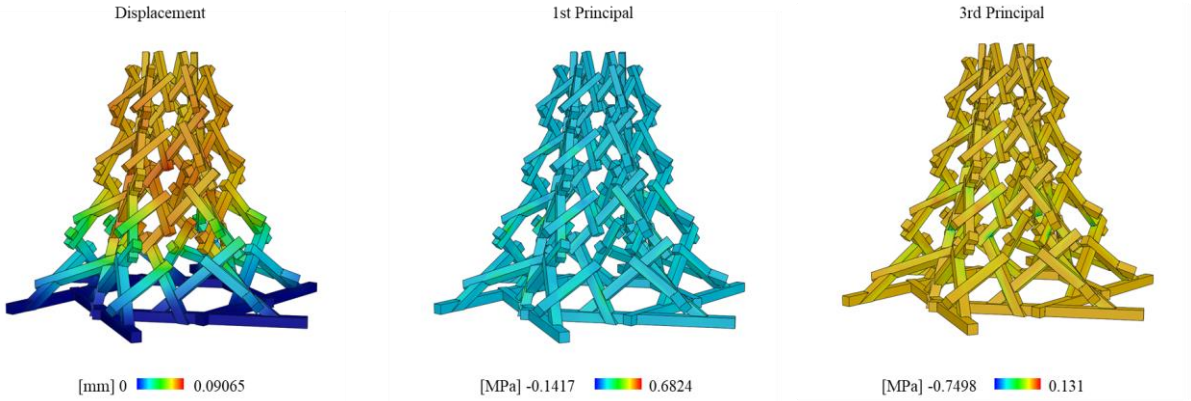

Figure 9. From left to right: displacement, 1st principal and 3rd principal theory.

3.2. Digital fabrication

New controlled timber-processing machine centers, such as Hundegger K2-Industry in this case, allow for the precise cut-outs with precision. The K2i sets a unique standard in performance and flexibility for industrial joinery. Unlike in mass timber construction which is mostly bounded to 90° or 180° angle cuts, we aim to study the use of conventional machines beyond their standard use and to reflect on contemporary fabrication technology for mass-customization.

First, the generated B-rep geometries in Rhino3D should be translated to information entities, using cadwork software to export .bvx format file. Then, it is possible to simulate our process and command the Hundegger with Cambium software. See the diagram in Figure 10.

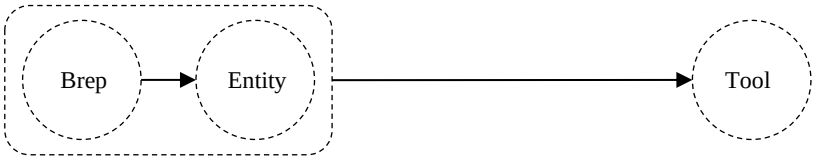

Figure 10. Fabrication diagram

3.2.1. Conversion

The cadwork software enables us to define all recessing across the beams and ending saw cuts as well. The defect parts could be found and checked. (Figure 11) The pocket connections are simple in terms of geometry, but complex in terms of the cutting plane. “The design of connections in timber structures is crucial to global structural performance.” [6, p. 1] In this respect, axial rotation to perform the highest volume of intersection is thus very efficient. These rectangular cross section beams could be intersected and subtracted simpler when they meet each other at almost right angles or when they receive perpendicular elements, otherwise specific rotation and positioning shall be maintained.

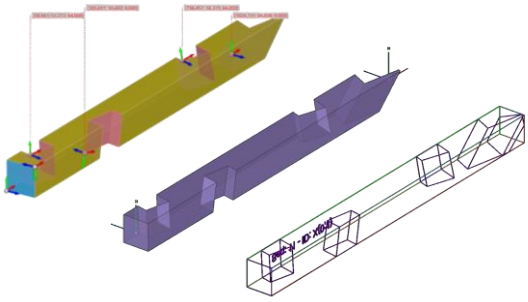

Figure 11. Conversion: from B-rep to .bvx format file, using cadwork

2.2.2. Fabrication

Wood is extensively machinable, brought by the opportunity to create precise operations, which converts this natural material to a digitalized one via interlocking joineries. Cambium simulation interface allows for checking the entire fabrication process in Hundegger K2i. Specific configuration of elements could be maintained, such as nesting the beams with the same cross-section. This hints us to purchase the optimum length and quantity of logs for each cross-section.

In fact, each floor or level has a different cross-section, which is indicated with color gradients, shown in Figure 12. The hierarchy of cross-section are 86, 80, 70, 60 millimeters, from bottom to top. Obviously, the lower levels have a greater cross-section to provide more structural stability. The reduced cross-sections of 86, 80, 70, and 60 mm are converted from 90 mm logs via planer machine.

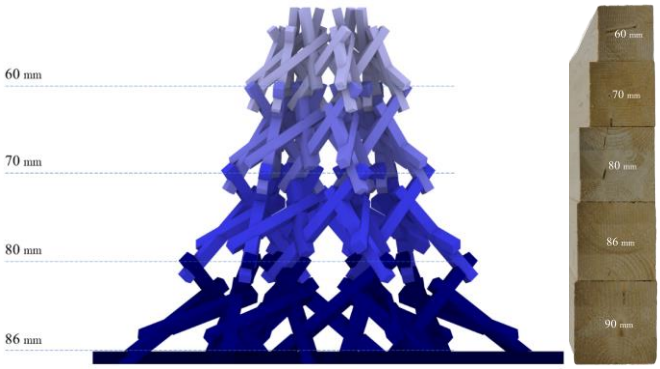

Figure 12. Hierarchy of cross-sections

The embedded tools in the planer machine take away from four sides of the logs, so the side dimensions are slightly different. To minimize this differentiation, the employed device is highly calibrated, and thus, the inaccuracy is very negligible. (Less than a millimeter) (Figure 13a) Then the output logs are transferred and automatically passed through on rails (Figure 13b) to the input of the Hundegger machine for recessing and saw cutting processes. (Figure 13c)

(a) (b) (c)

Figure 13. Chronological fabrication stages: (a) cross-section reductions with planer machine, (b) passing the logs automatically on rail to the Hundegger machine, and (c) process operation with Hundegger K2i

3.3. Augmented construction

Augmented construction facilitates the assembly-disassembly process via recognition and positioning of timber elements. This creates interactive and immersive augmented or mixed reality[1] presentations from existing 3D model. This interconnects the workflow from engineers (who makes the 3D model in computers) to constructors (who use the 3D model in augmented reality gadgets as fabrication instructions). While AR does not entirely eliminate 2D drafting, it can enhance the design process and improve communication between stakeholders or contractors by offering new ways to visualize and interact with construction designs. This section on augmentation has mostly focused on investigating the role of digital twins as an enabler for circular strategies. This strategy transits the construction from linear to circular process and bridges the gap between virtual 3D model and real construction.

As seen in Figure 14, for instance, an id: X beam has four front and back pockets every other interlocking connection. That means it cannot be assembled like a puzzle, but rather like bricks, it shall follow a sequential process, with an ability to reverse the process for disassembly, while keeping track of the status of elements. (Figure 15) The mixed reality serves as a reference to provide ease of assembly and disassembly.

[1] The difference between *augmented* and *mixed* terms derives from the ability to work in only the physical world or if the physical interactions have an impact in virtual mode.

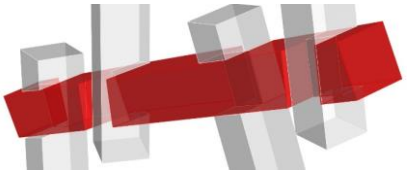

Figure 14. One element with front and back pockets every other interlocking connection

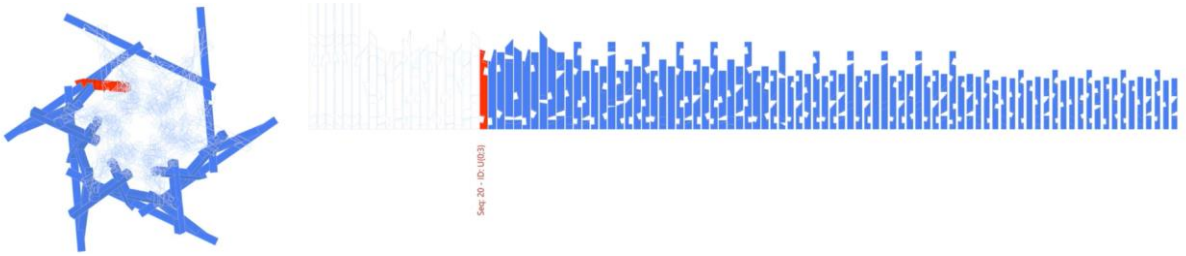

Figure 15. Sequential assembly

This starts with recognition or identification by scanning the QR code or Aruco marker and then follows up with positioning or placement using MS HoloLens 2 headset in augmented reality mode. (Figure 16)

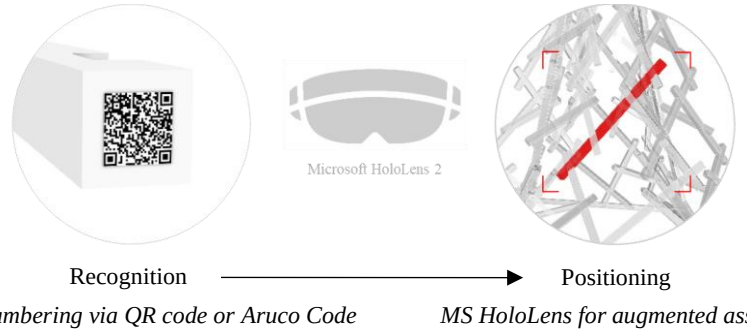

Figure 16. Two stages of assembly process; recognition via QR / Aruco and positioning via MS HL2

The Fologram software establishes an instant mixed reality experience between Rhino Grasshopper and the MS HL gadget. Geometry, layers, and grasshopper parameters can be edited in real time in Fologram to create powerful tools for design, communication, collaboration, and fabrication.

3.3.1. Recognition

The QR code or Aruco marker contains only a single number, which refers to the assembly sequence number. The QR code is printed on the main label along with all project information, using Cambium. (Figure 17a) However, since reading the Aruco marker is faster with installed Fologram in MS HoloLens 2, this has been used as well. A single Aruco marker is attached on the cross-section ends. (Figure 17b)

(a) (b)

Figure 17. (a) Main label, including project information and beam specification, printed along with a QR code. (b) Cross-section label, including single Aruco marker.

It is also possible to track a geometry via Aruco marker and save its location in Grasshopper. Then it becomes a digital twin model in which real-world interactions have a virtual reality impact in our computer interface.

Alternatively, we can identify the location of elements by using a customized menu with slider (Figure 18a), or we could toggle to another menu (Figure 18b) with next and previous button (Figure 18c), which could be used based on individual preference. This provides interactive instructions, presenting workers with visual arrows and cues, overlaid onto the physical environment to help them understand the assembly sequence.

(a) (b) (c)

Figure 18. (a) slider menu (b) toggle between menus (c) button menu

3.3.2. Positioning

It seems fair to report that the comfort and precision of HoloLens 2 is still questionable. The automatic placement is done by scanning a coordinate QR code, attached on the ground in the middle of the structure. Fologram fails to adequately orient it with the digital model, so some alignment is necessary. Nevertheless, the custom menu made by the author could effectively engage constructors with the virtual model to track the position and orientation of elements in real-time. (Figure 19)

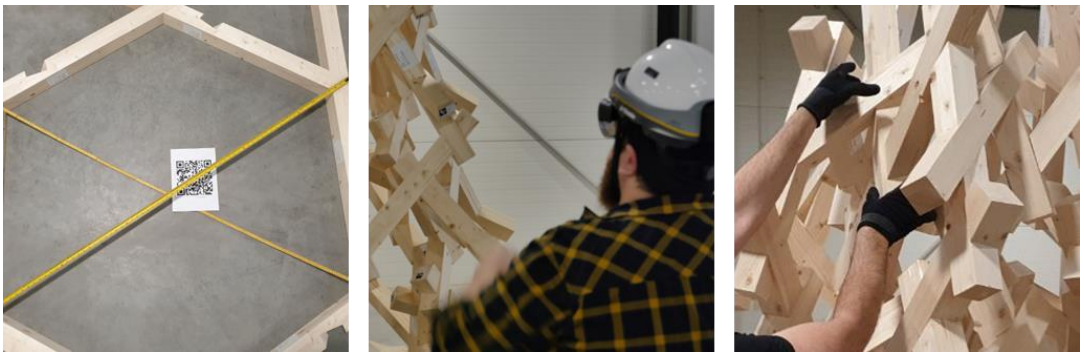

Figure 19. (a) coordinate placement; (b) collaboration; (c) manual-digital placement

As discussed, the assembly adheres to a sequential process, which is reversible. Figure 20 shows the assembly time lapse.

Figure 20. Sequential assembly of the structure

4. Discussion

Digital processes may allow for more complex and, if designed well, potentially performative high-rise structures. In this paper, we presented a tool-aware AR-assisted workflow which could be targeted for various timber systems e.g., CLT or hybrid floor decks in real construction. However, the experimental proposed structure employs short linear timber elements to create a mono-material structural system which is interconnected with interlocking joinery (Figure 21), since "structures made from linear elements required a large amount of material knowledge and technical skill to source and carve them, resulting in the emergence of extremely skilled craftsmen and a culture of wood fabrication". [9, p. 63] This leads us to a certain knowledge on the amount of computational design and digitalized fabrication before being deployed in non-experimental and industrial applications. As a further investigation upon some other similar projects, this research resulted in a functioning demonstrator which serves as a manifestation to unlock the possible futuristic trajectory in the evolving architectural typology of tall wood buildings.

Figure 21. Demonstrator

"The potential benefits of using joinery connections in mid-rise scale buildings are multifaceted. The elimination of metal joints could further drive down the embodied energy of structures. Using joinery connections may offer new implications in construction assembly speed of timber structures. Innovations in digital fabrication suggest that the cost of milling joinery could become competitive with that of fasteners . . ., [but the] analysis procedures for these unique wood-only joints are less standardized than those of metal connectors." [6, p. 1] "Their ecological and economic advantages make timber-only systems an interesting alternative for efficient and sustainable buildings." [3, p. 425] This helps us to realize how a single mono-material culture can inform all levels of performance from form to construction to disassembly.

5. Conclusion

This paper investigates the generative design of interlocking joinery timber construction and the potential implementation for upward scaling for future high-rise endeavors. The digital fabrication process incorporates automated manufacturing methods, but also from the construction sector point of view is still characterized by a high proportion of manual assemblies. The linked topic of disassembly is regarded as a vital factor of sustainability and long-term management of materials in use.

Figure 22 shows the general implication of design-production-construction approach.

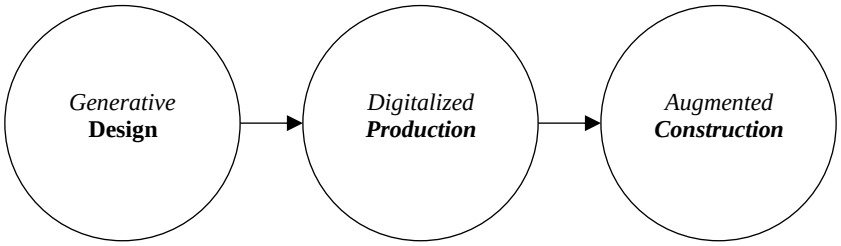

Figure 22. General implication of design-production-construction

To sum up, the whole process could be summarized according to Table 1.

Table 1. design-fabrication-construction process

Generative Design	1. *computational design* by parametric platform of Grasshopper inside Rhino3D. 2. *structural optimization*, utilizing a finite element model in Karamba3D
Digital Fabrication	1. *conversion* the B-rep geometries into legible entities, using cadwork. 2. *manufacturing* the element by Hundegger K2i, commanded by Cambium.
Augmented Construction	1. *recognition* by scanning the QR code / Aruco marker. 2. *positioning*, using augmented reality Microsoft HoloLens 2 headset.

The following conclusion are made:

- Simulation proves that shifting approach from orthogonal to free form twisted morphology possess better structural performance.
- Interlocking joinery is highly appreciated due to consistent reduction of joint complexity for ease of assembly and disassembly.
- Augmented construction, coupled by mixed reality, enables a digital twin mode for circular economy processes in wood construction.

This streamline construction process improves accuracy, reduces errors, enhances worker productivity, and expedites the assembly process for circular wood construction projects. The structural applications of timber construction are ever expanding, and it is of the utmost importance to broaden this essential dimension of industry and develop novel and acquisitive value-added design with high-performance application and fill the gap between engineers and local practitioners in complex design and construction. It is deliberately aimed to go beyond the framework of standard construction assumptions to excavate additional unusual aesthetic experiences, which are structurally more sensible, unfolded by wood.

Acknowledgements

This research was funded by the Department of Manufacturing and Civil Engineering (IVB) at Norwegian University of Science and Technology (NTNU). The fabrication is done in Innlandet Treindustri and Østlaft AS. I thank colleagues who provided insight, expertise, or practical knowledge that greatly assisted the research, although they may not agree with all the interpretations or conclusions of this paper.

Abstract

This paper describes the structural design and construction of a three-dimensionally curved '*circle truss*' and ETFE membrane roof, which is a key design element of the Haneda Airport (Tokyo International Airport) Terminal 2 expansion. First, the design conditions and constraints are discussed, explaining why such a structural system was adopted. Next, the construction and execution is described, including the use of BIM to manufacture the curved steel pipe members and unique solutions used to build the '*circle truss*'.

Keywords: EFTE, membrane roof, 3D curved truss, large space buildings

1. Project summary

The existing structure of Haneda Airport (Tokyo International Airport) Terminal 2 was completed in 2004. As this building was originally designed just for domestic operations and a significant increase in the number of flights was anticipated after as the scope expanded to international operations, a major terminal expansion plan was launched in 2016 with an anticipated opening date of April, 2020.

The design was conducted over a year and half from April 2016 to October 2017, with construction following over a 2.5 year period from October 2017 to March 2020. The enlarged terminal building features an international check-in lobby, duty-free shopping areas, airline lounges and government office areas, with the original 93,000m^2 total floor area enlarged by 65,000m^2 and separated by expansion joints into A, B and C zones. The new international check-in lobby in zone B (Figs. 1 and 2) required a large open space and long-span roof covering a 7,700m^2 plan area. This was achieved using a unique structural frame referred to as a "circle truss" and ETFE membrane. The circle truss is curved in three dimensions and is shown in Figs. 3 and 4. The membrane has three layers, including one opaque PTFE layer and two ETFE layers. This achieved a 1hr fire rating and blocks out strong sunlight, while giving the internal space the appearance of a general membrane roof.

2. Structural design challenges

A number of design challenges were overcome when designing and constructing the new roof, particularly with how it integrates with the existing structure, as shown in Fig.5.

1) The new structure is sandwiched between the existing terminal building and a viaduct, and had to span an existing common ditch. 2) The foundation used existing piles cast prior to designing the enlarged building. 3) The floor-to-floor height was limited to align with the existing building floors, while ducts and the baggage handling system had to fit within the structural depth, running through opening in the

truss beams. 4) The roof is supported by the existing building and foundations, and so it was imperative to minimize the roof self-weight. 5) The existing structure had to be locally retrofitted to integrate the expansion and support the increased loads.

Nevertheless, this paper primarily focuses on the roof structure.

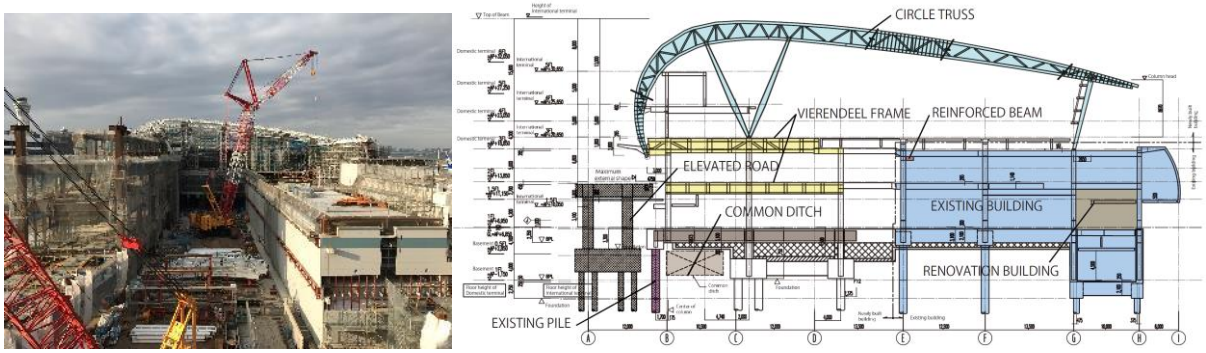

Figure 5: diagram of the structure plan

2.1 Structural design of the roof truss

The roof covers a 120m by 62m space, with a 59.5m main span (Fig.6). Additional loads imposed on the existing building were minimized by adopting lightweight roofing materials (ETFE) and by supporting the roof gravity load on the new structure as much as possible. This was achieved by

effectively cantilevering the roof from the new structure, with the far end supported by pinned-jointed struts so that bending moments are not transmitted to the existing structure.

Initial concept models created by the building designer with wire forming the roof frame are shown below. The circle truss concept is shown in Fig.7 and an alternative "triple beam" concept in Fig. 8. Both support about 65% of the roof gravity load on the columns of the new structure. However, time history analysis conducted during the final stage of design uncovered several vulnerabilities of the three beam concept in the event of a strong earthquake. The long direction of the existing structure experienced excessive deformations, the long roof chord members deformed about their weak axes like string of a guitar, while maximum vertical roof accelerations exceeded 4,000gal (40 m/s^2). The "circle truss" was instead adopted, as the three-dimensionally interlocking frame provided greater in-plane stiffness to the roof surface, reducing the earthquake demands on the existing structure.

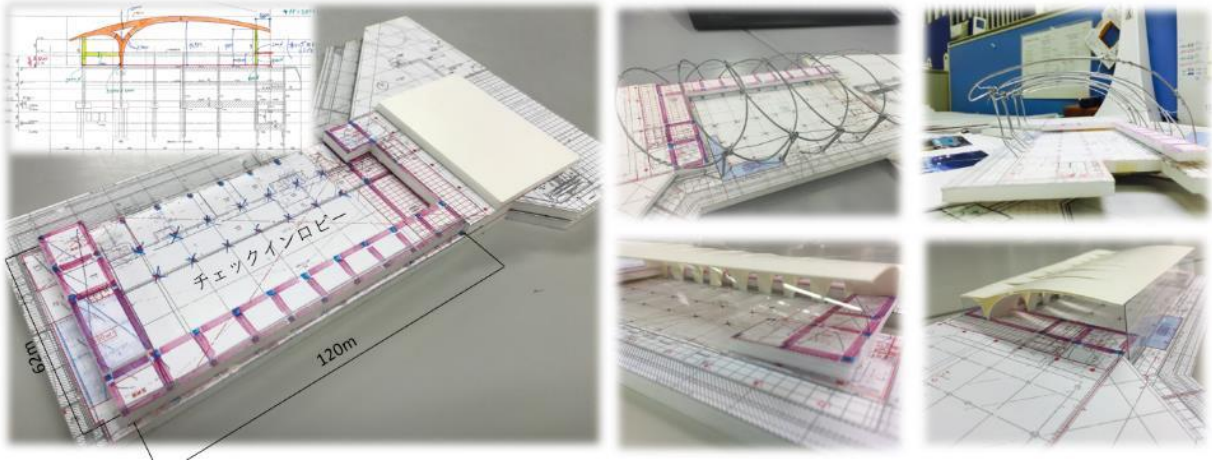

Figure 6: First sketch model of a large space building and the circle truss plan

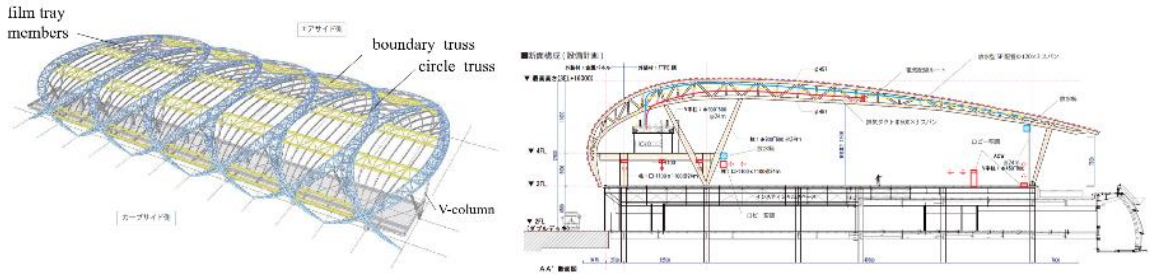

Figure 7: Circle truss concept

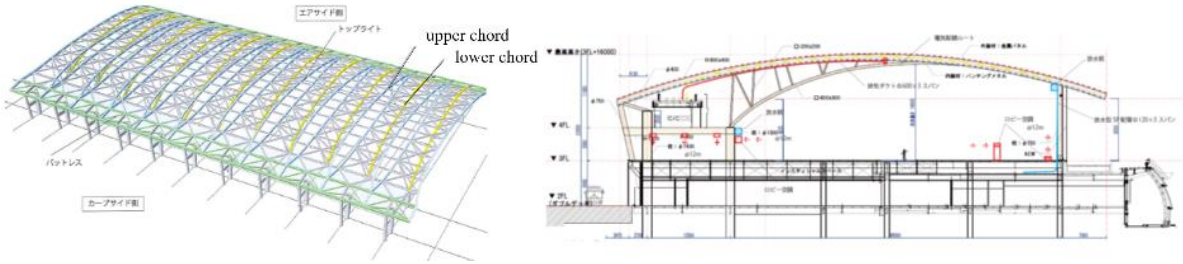

Figure 8: Three beam concept

2.2 Circle truss structure

The roof frame consists of five (later reduced to four) overlapping circles arranged in plan and then bent to arch over the check-in lobby and form one of the wall surfaces (Fig. 9). Each doubly-curved truss has two upper and one lower steel tube (STKR490, Φ400mm) chord. The internal clear height provides an open lobby space and maintains sightlines for the control tower, while the building height restriction ensures the airplane tails are visible from the control tower.

Three rows of boundary trusses were included in the longitudinal direction to brace and stiffen the circle truss. The primary columns of the three-pronged steel tubes taper down from φ900 to 600mm at the tip and are supported on cast steel plinth with ball joints. Although the curved steel tubes are clad, ring plate joints were adopted in preference to intersecting welded joints to simplify the fabrication and construction of the circle truss.

The circle truss was further optimized during the construction stage by eliminating a 12m half circle section of the roof and revising the truss members. First, the secondary beams were revised from box to tube sections, which are more effective in resisting torsion induced by the membrane tension. This permitted smaller sizes that reduced the roof self-weight and inertial earthquake forces. Next, the triangulated boundary trusses were changed to Vierendeel trusses, with fixed end beams connected into the secondary beams. These modifications reduced the roof frame steel tonnage from 230 to 200 kg/m^2 (Fig. 10). Note that this tonnage figure is highly conservative estimates, as it includes all steel (including secondary beams, fixings and columns) in the Tekla model, except for the curtain wall mullions, divided by the project plan area (even though the roof curves to form the land-side wall). A 3D printed model and final rendering of the roof structure are shown in Figs.11 and 12.

2.3 ETFE roof membrane

ETFE membrane was selected to minimize the roof weight. However, there are dimensional limitations when importing this material, and so the membrane framework was sized to have a width of less than 11m. The weight of the ETFE membrane and supporting steel members was about 70 kg/m^2, which is significantly lighter than the 100 kg/m^2 of conventional metal cladding. This reduction in imposed load further reduced the roof weight and influence on the existing building.

Although ETFE was codified for use in Japanese buildings in 2018, this material has low fire resistance and has difficulties satisfying domestic regulations for roofs to be fire rated. Therefore, a triple membrane was adopted that includes an inner flame-retardant PTFE layer with outer ETFE layers (Fig.13). The characteristic texture of the ETFE cushion gives a pleasing appearance, while the triple-layered composition helps to block the strong summer sunlight.

2.4 Curtain wall

The check-in lobby airside face features a large glass curtain wall supported by V shaped columns and wind-resistant box beams (Fig.15). The columns are located outside of the glass and the 18m long box beams cantilever a further 1m, providing a clean glass surface and direct view of the airplanes from the check-in lobby. Vertical members were intentionally terminated above the floor level to further open the field of view, and instead were suspended from the top floor to help suppress vertical deformations. These were arranged in either an A- or V- shape, with the compression members ■-60×60mm square bars and the tension members φ-25mm circular bars (Fig.14). A 75mm clearance was provided to accommodate the vertical roof deflections and avoid damaging the glass.

3. Fabrication plan/process

3.1. Geometry design for effective fabrication of circle truss

It is exceptionally challenging to accurately fabricate doubly-curved 3D trusses. While it is possible to bend pipe in two directions, that process would have exceeded the project's budget and construction schedule, given the limited number of suppliers with such specialized equipment. This situation was further compounded by the increased construction activity surrounding the Tokyo 2020 Olympics. This issue was avoided by rationalizing the circle truss geometry to achieve the double-curved global geometry from singly-curved individual pipes.

The solution was to combine and rotate multiple planar curves to approximately fit the complex original curve, as shown in Fig. 16. Each curve is circular with a different center and radius, and targets a different part of the 3D curve surface. These are then connected in a chain with tangent intersections, and were defined from three reference points to find the closest match the original curve. Further adjustments were made for ease of fabrication. Some points were defined up to 1m away from chord-diagonal intersections to provide straight segments at the connections, while the short elements at the circle truss intersections were straightened to minimize fabrication cost. Straight pipes were also used for the chord segments with large radius near the middle of the circle truss to minimize fabrication cost, as these near-flat segments still satisfied the architect's image and concept of the circle truss.

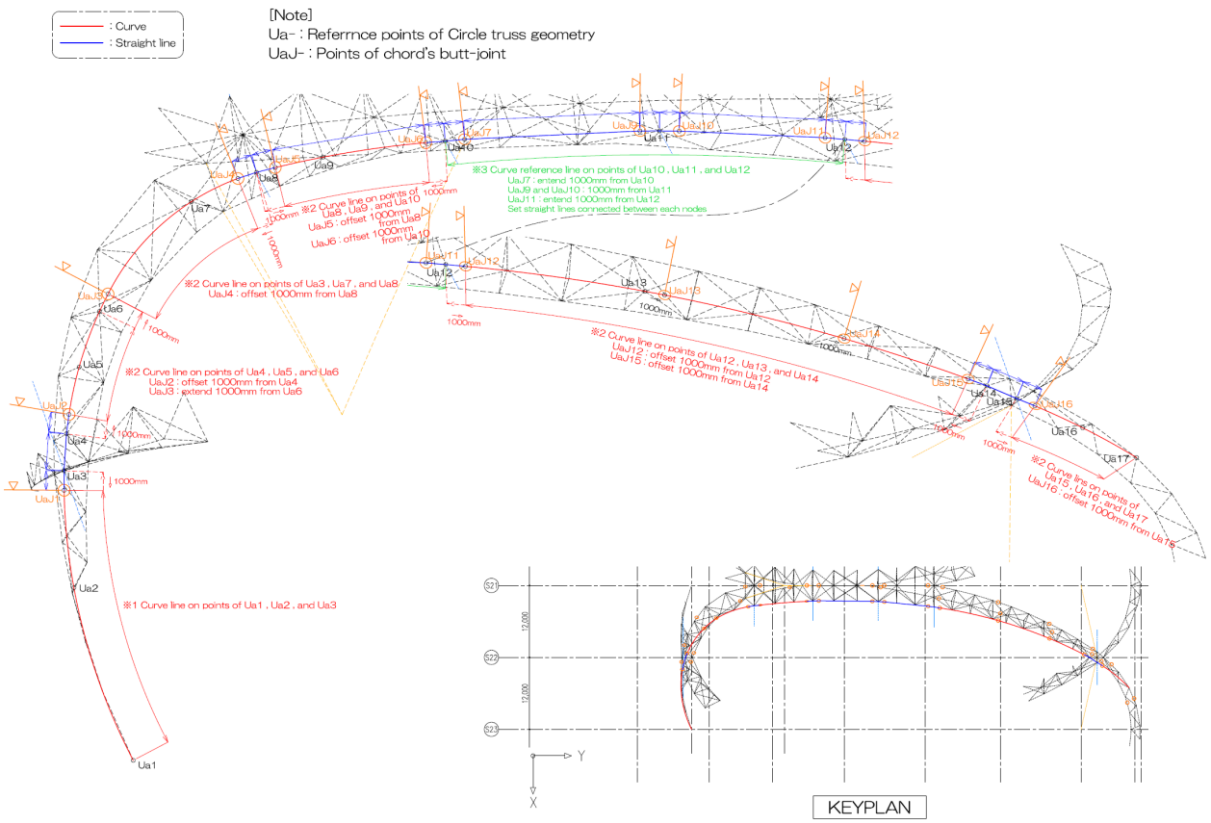

Figure 16: Geometric rationalization of the circle truss

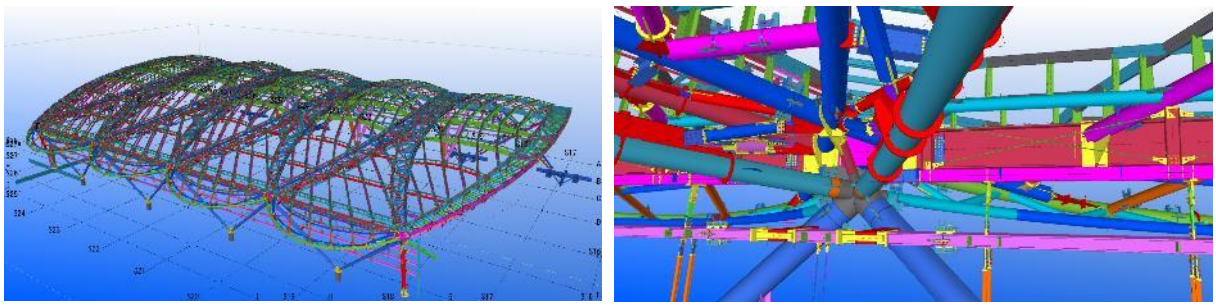
3.2. Fabrication of roof structure

Preparing the shop drawings and fabricating the steel structure was expected to take a considerable amount of time due to the complexity of the roof structure and circle trusses. Therefore, a detailed 3D BIM model of the entire steel roof structure was modelled in Tekla Structures (Fig.17). This was used to visual and review the fabrication and on-site construction, including member clashes, transportation sub assemblage blocks, site welding access.



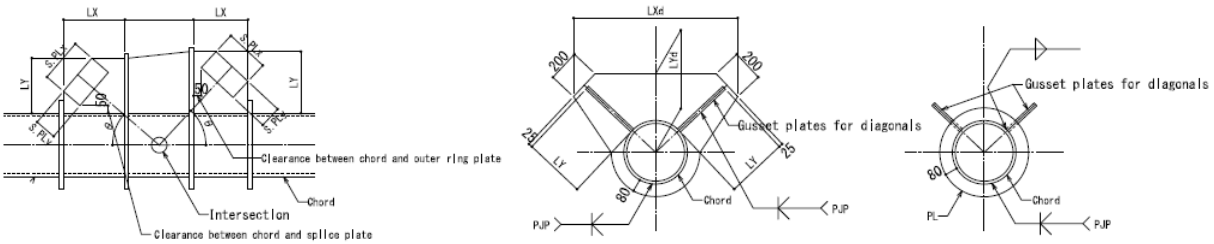


Figure 17: BIM model of roof structure

3.2.1 Circle truss connections

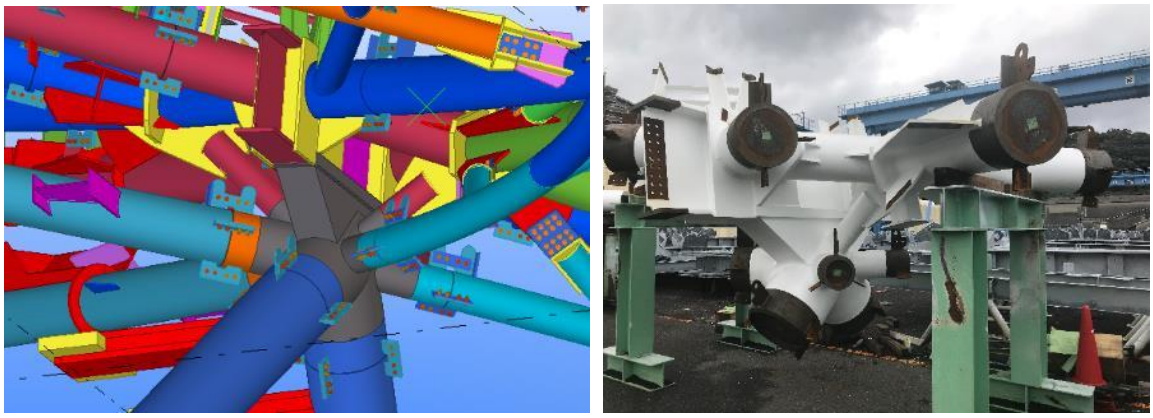
Representative connection details and fabrication photos of the circle truss are shown in Fig.18. The connections between the chords and diagonals consisted of outer ring plate reinforcement, gusset plates and slip-critical bolted connections to maximize onsite efficiency. The same type of connection was repeated throughout the roof structure, and were designed as follows:

- The shape and size of the gusset plates were determined from the clearance to the splice plates, ring plates and chords
- The joint design was automated, with only the weld lengths and sizes varied

However, several locations adopted prefabricated truss blocks, most notably the areas outside of the curtain wall. The diagonals within these blocks were factory welded to the chords. (Fig.18(c))

(a) Typical joint design

(b) Upper chords



(c) Circle truss with welded joints

Figure 18: Fabrication of circle truss

3.2.2 Cast steel connections

Beams running along the top of the curtain wall have joints connecting more than ten members of upper chords, lower chords and diagonals. These complex joints are located in a narrow space, but must provide moment fixity to the top of the columns to ensure redundancy in the out-of-plane direction. Therefore, large cast steel nodes were used to achieve a compact and cost effective joint design, with each featuring eight branches and two beam stubs. (Fig. 19(a))

The pin joints at the base of the primary three-pronged columns were also fabricated from cast steel. These connect members at a narrow angle and needed to be compact to minimize the bending moments transmitted to the frame under the bearing. (Fig. 19(b))

(a) Beam connections at the top of the curtain wall

(b) Three-pronged column base connections

Figure 19: Construction photos of cast steel connections

4. Construction plan

The construction had to meet a number of challenging criteria (Fig. 20, 21).

1) Height was restricted by the Aviation Law. This limited the construction staging yard to a narrow area surrounded by the existing buildings, elevated roads and runway.
2) Ensuring accurate construction despite the complicated roof shape.
3) A tight construction schedule.
4) Ensuring safety in the event of an earthquake during construction.
5) Coordinating the temporary supports and scaffolding.

These challenges were met using several strategies (Fig.22, 23).

1) A 350-ton crawler crane was used to minimize the height of the heavy construction equipment.
2) An accurate shape was achieved by first assembling all roof components on the ground.
3) The construction timeline was shortened by conducting a partial jack down after completing all welds for the respective section, instead of waiting until the entire roof was installed.

4) The temporary supports were designed for construction-stage earthquakes. The Japanese Level 1, (serviceability earthquake) seismic hazard was adopted, with a 0.2 G elastic short period horizontal acceleration. The vertical load was amplified to 1.2 to account for destabilizing eccentricity.

5) The temporary supports and scaffolding were laid out using BIM and carefully checked for clashes with permanent and existing structure.

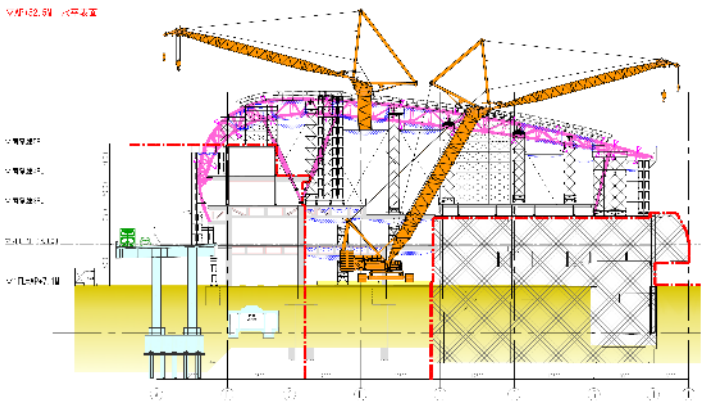


Figure 20: Construction plan

Figure 21: Surveying

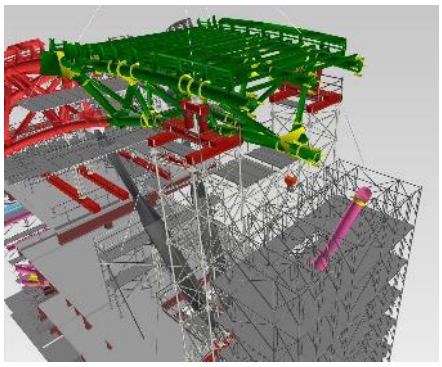

Figure 22: BIM modeling with scaffolding

Figure 23: Structural steel erection

4.1 Quality control

A survey was performed at chord positions that were pre-marked in the fabricator facility. About 5,000 coordinates were taken from the model to manage the accuracy of the temporary supports and construction. Although tight tolerances were specified, corrective action was only taken on site if deviations were anticipated to affect the subsequent section. Relatively large deviations were possible due to the jack down procedure, and so at these interfaces the level was compensated by raising the steel work 5 to 10 mm, or until it no longer interfered with welding.

4.2 Jack down

Jacking down was completed in 4 stages (Fig.24, 25), each corresponding to the welding and completion of a full circular truss. To add redundancy and improve accuracy, jacking down also waited until the adjacent circular truss was fully welded, but still supported. The second jack down stage is depicted in Fig. 24, with the previously lowered jacks in green, the jacks being lowered in purple and the completed welds indicated in orange.

Self-weight and construction stage deformations were analyzed and compensated in the roof geometry, and then closely monitored on site. As a point of comparison to the construction stage analysis, all monitored points with vertical deflections exceeding 50mm were compiled, and found to be 70% of the predicted displacements on average, with a 13% standard deviation. A maximum deflection of 60mm was recorded as the jack down loaded the self-weight into the roof structure, which compared favorably to the 58mm predicted displacement. This indicates that the partial jack down method offered accurate control of the roof geometry.

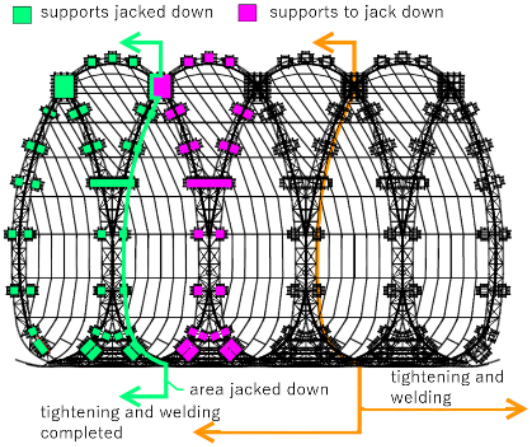

Figure 24: Second jack down stage

Figure 25: Hydraulic jack

4.3 Membrane roof installation

The roof membrane was separated into 318 units. On the steep land-side faces, sections were installed by hanging members from a Potain self-erecting situated on the elevated road (Fig.26, 27). However, none of the cranes could reach the steep air-side face, and so these membrane sections had to be manually transported and positioned. Since the membrane action of the ETFE cushions requires internal pressure, temporary blowers were activated immediately upon placing and until main blower was installed.

Figure 26: Installing the membrane roof

Figure 27: Lifting the membrane roof

5. Summary

This paper described the conception, structural design and construction of a unique “circle truss” roof as part of the Haneda Airport Terminal 2 expansion. This included the design process of the circle truss and triple-layer ETFE/PTFE membrane, integration with the existing building, and modifications implemented to reduce the cost. The use of BIM in the design and fabrication of the complicated steel structure was then described, followed by the membrane installation and partial jack down procedure. This challenging project was completed by clarifying and resolving unique challenges at each stage of the design, fabrication and construction with the entire project team (Fig. 28, 29).

Abstract

Membrane tensegrity shells use tensegrity structural principles to create self-supporting and wide-spanning spatial enclosures. These consist of a network of discrete struts pre-tensioning a single customised membrane surface, in place of multiple linear cables. While previous literature has documented the installation of occupiable pavilions, there are challenges in upscaling membrane tensegrity shells to be viable as larger outdoor shelters. Our research tackles these challenges in the ongoing development of an 8.0m span pavilion, entitled 'M-shell'. To achieve this, we implement our computational design-to-fabrication workflow consisting of four main phases: (a) determining optimal strut placement; (b) validating the model via finite element analysis (FEA); (c) extracting fabrication data; and (d) manufacturing and assembly. This paper documents the execution of this workflow for our half prototype 'M-shell' pavilion.

Keywords: membrane tensegrity shell, structural optimisation, design-to-fabrication

1. Introduction

Membrane Tensegrity Shells (MTS) are novel structural systems premised on the principles of tensegrity to create lightweight self-supported dome-like spatial enclosures. These systems consist of two main components: (i) a network of discontinuous discrete struts that act in compression and (ii) a large continuous membrane that acts in tension. The struts, arranged as crosses across the membrane, biaxially tension the elastic surface at localised areas. This interaction enables the formation of free-standing doubly curved envelopes. MTS also features several advantages over other conventional structural membrane systems, such as pole tents or frame-supported canopies. Specifically, these advantages include: (a) enabling large-spanning column-free enclosures to be created with a minimal number of linear elements, thereby minimising machining costs; (b) minimising their contact area on the ground by negating the need for tethering around its perimeter using cables; (c) relatively fast deployment with minimal skilled manpower in its set up.

MTS has been adopted as occupiable outdoor shelters with recent literature reporting several pavilion variations done by our team [1], [2] and Yang, et. al. [3], with the largest documented span achieved to date being the Bamboo Tensegrity Shell at 5.0m. While there is a potential for these shells to be viable as larger outdoor shelters, upscaling these systems poses several challenges. This is mainly due to the lack of understanding and formal engineering analysis of this non-trivial structural typology at larger scales. The complex interplay of tension and compression, coupled with the non-linear material

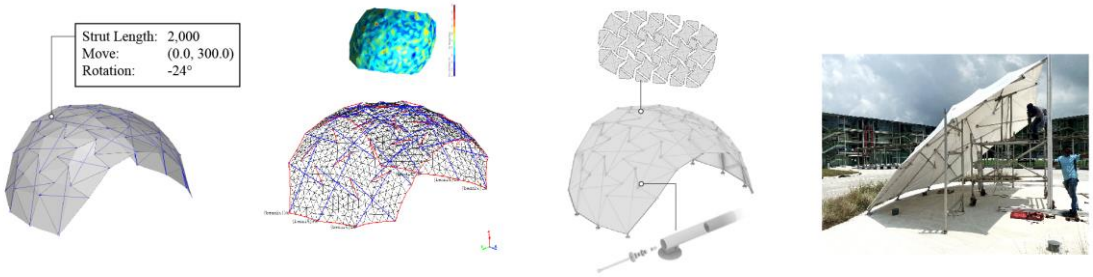
behaviour of the membrane and disconnected struts, makes modelling this system a challenging endeavour.



Moreover, there is a need to strike a balance between the mechanical properties of the struts and the membrane and their material weight. As there are no interim support elements, maintaining adequate pretension of the membrane is vital to create an 'inflated' dome geometry for the structure to be in structural equilibrium. This pretension also needs to be induced without causing the struts to buckle while ensuring that the struts do not excessively weigh down the membrane. Thus, making larger MTS structures would warrant stiffer components for both membrane and struts and possibly include other auxiliary support elements (e.g., internal cables) to achieve the required amount of stiffness in the system.

As such, upscaling MTS systems has to be addressed from both engineering and fabrication perspectives. This research tackles the challenge through an improved design-to-fabrication workflow for creating large scale MTS structures, specifically for making a half prototype that was partitioned from our intended 8.0m span structure, entitled the M-shell. This paper will document the various processes of this design-to-fabrication workflow. It will further share the challenges that we faced during the installation of this half prototype and suggest necessary improvements to address them. In short, the objectives for this paper are:

- To expand upon our computational design workflow by incorporating FEM analysis and design-to-fabrication scripts to obtain necessary fabrication data;
- To construct a half prototype pavilion to assess the viability of our fabricated components and assembly sequence.

2. Design-to-fabrication workflow

Our computational design-to-fabrication workflow consists of 4 phases: (A) Computational design of optimal strut mapping; (B) Validating using Finite Element Analysis (FEA); (C) Extracting fabrication data; (D) Manufacturing & assembly.

(a) Optimal Strut Mapping (b) Validating using FEA (c) Extracting Fabrication Data (d) Manufacturing & Assembly

Figure 1. Design-to-fabrication workflow in creating our 8.0m span membrane tensegrity pavilion.

This section is written with reference to the design and fabrication of our 1:1 scale half prototype. It is a segment of an asymmetrical arch that was derived from our full prototype of 18 crosses with a 45.3m^2 surface area coverage and mass of 345.6kg. The prototype is anchored to the ground at two edges with a total of 6 base footings. In this paper, the current prototype consists of 9 strut crosses, 2.6m average length, in a 3x3 configuration with 3 base footings. It also has a welded membrane with a surface area of 36.6m^2. Since it only has half its geometry, the exposed upper boundary condition was supported by a mobile scaffolding rig.

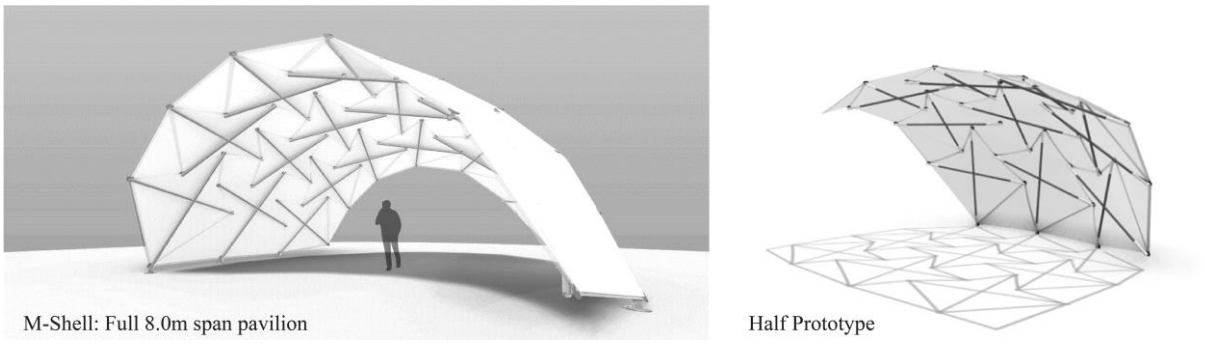


Figure 2. Renders of the full and half prototypes

2.1. Earlier prototyping using stiff components

Prior to executing this workflow on the half prototype, we created smaller 1:10 scale physical models to better understand the behaviour of the system as we were intending to use much stiffer elements compared to our previous iterations. Our models were made with cut-and-sewn ripstop fabric and aluminium tubes that were fitted onto the membrane using bolts and washers. This prototyping allowed us to decide on the elongation axis being the bias, 45 degrees of the warp/weft axis. Biaxially tensioning the membrane in the bias axis allowed the flat surface to deform into a curved surface with a grid of 2x2 strut crosses.

We later attempted this elongation strategy on a 1:1 scale strut cross made from two aluminium 6061 tubes that were pre-tensioning a polyester membrane laminated with a PVC coating. Thus, the pre-tensioning was decided to be up to 2.5% strain along the bias to ensure that the laminated membrane was adequately taut without causing either component type to yield.

Figure 3. 1:10 and 1:1 scaled models to determine the pre-tensioning strategy.

2.2. Computational design: Iterative conformal mapping

The computational design phase involves optimising the strut parameters to obtain an MTS geometry in structural equilibrium with minimal deviations from its intended geometry. The workflow includes a mix of procedures, namely strut mapping, conformal mapping, structural analysis, and optimisation. For more details and further application of this computational workflow, kindly refer to our recent published paper [4].

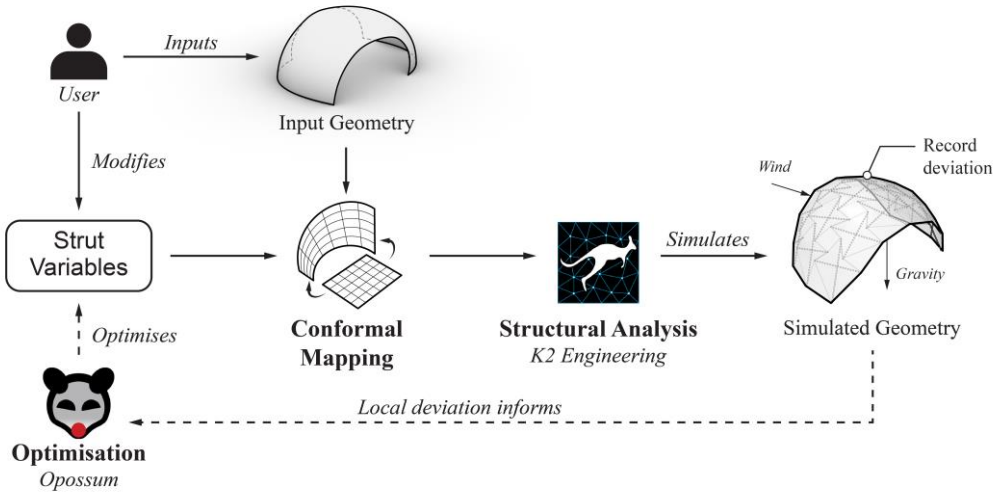

Figure 4. Computational design workflow.

Firstly, we input our intended shell geometry, as a mesh, into the Grasshopper script. The script generated a series of cross-like strut units in a grid-like formation based on the size of the mesh. Strut parameters, such as its position in x-/y-direction, average lengths, rotation, etc. can be adjusted to change the initial configuration of the struts. The script then implemented conformal mapping to mathematically position the struts onto the mesh faces while preserving their angles but changing their lengths [5]. This mapping ensures that the struts are always at 90 degrees regardless of their locations on the input mesh, which makes the struts pretension the membrane biaxially. Additionally, the struts with their endpoints closest to the bottom were extended so that these struts intersect the ground x-y plane. This ensures that the pavilion is always in contact with the ground. The script generates a Delaunay mesh from the end points of the struts to represent the membrane as a cable-net system.

Next, the script implements non-linear structural analysis on the newly created MTS digital model using the *K2Engineering* plug-in paired with *Kangaroo* [6]. The intention of this simulation is to give a sense of whether the given strut configuration is structurally feasible as a free-standing MTS system. The strut crosses were assigned as bar elements, specifically aluminium tubes, while the membrane was treated as a cable net with the interconnected mesh lines assigned as laminated polyester membrane material. These specifications can be found in Table 1. The strut endpoints at the ground plane (z = 0.0) were assigned as pinned supports that are free to rotate in any plane. Subsequently, the plug-in assigns gravitational and wind loads (20m/s in both x/y directions) to mimic the loading conditions in real life.

Table 1. Mechanical properties for the K2Engineering analysis

Type	Material	Cross-Section	Density	Young's Modulus	Pretension
Struts (Bar)	Aluminium 6061	Hollow Tube (50 x 45mm)	2720 kg/m³	68.9 GPa	N/A
Membrane (Cable Net)	PVC Laminated Polyester (700gsm)	Rectangular (50 x 0.78mm)	1.75 kg/m³	3.5 GPa	1000 N

Once the model converges, the deformation between each mesh face is extracted to quantify how much local deviation there is from the input mesh after loads have been applied. This compares the distance between the mesh faces between the simulated model and the input model. Both the average and maximum deviations will be fed into the optimiser in the next step.

The final step involves optimisation which uses the Opossum plug-in [7], a radial-based optimisation algorithm, that iteratively changes the strut parameters to obtain a structurally viable MTS structure with minimal local deviations from its input model. As Opossum runs, the Zombie Solver of Kangaroo is preferred to ensure that the simulated model has converged before it is assessed to generate new parameters for the next iteration.

2.3. FEA validation

While the computational design phase gives us an approximate digital model that is shown to be structurally viable, there is a need to validate this model using Finite Element Analysis (FEA). In this project, we worked with a local engineering firm that specialises in structural membranes, Multimedia Engineering, in the analysis of our pavilion. This analysis also takes into account building code regulations (Eurocode) in the modelling of the M-shell.

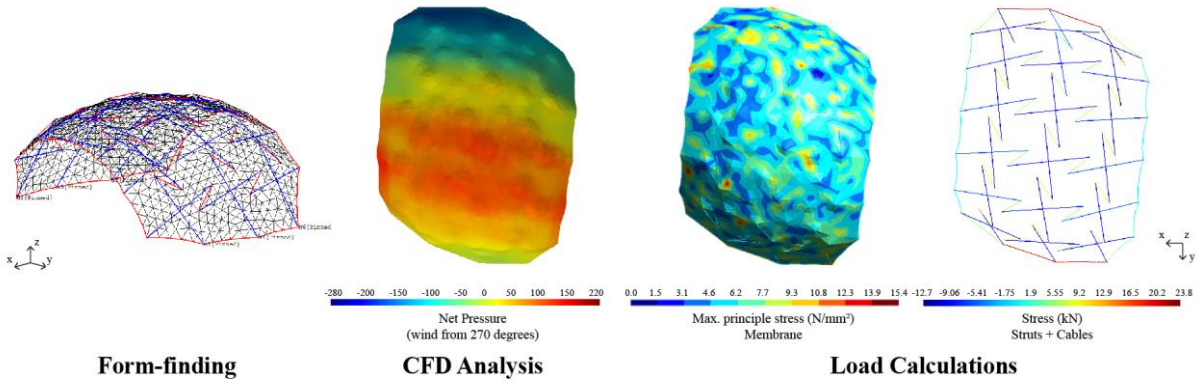

Figure 5. Structural analysis to validate the model.

Taking reference from our model, the engineering team performed a form-finding step to determine the natural shape of the MTS pavilion under its self-weight. This involved remeshing the Delaunay mesh to a finer resolution version and assigning the bases as pin support points. The form-finding step was carried out by changing the cross-section of the aluminium tube struts to ensure that the pavilion remains in structural equilibrium with no deflection from our given model. This converged model specified the aluminium tubes to be of 44.5mm diameter with a wall thickness of 6mm. Moreover, the form-finding step proposed the need for stainless steel wire rope cables at two main locations: (1) aligned along the perimeter edge of the membrane and (2) internally connecting the closest endpoints of the struts. These were 10mm diameter cables for the bottom-most perimeter edges and 6mm diameter cables for the internal connections and side perimeter edges respectively.

The next step involved a load analysis based on a combination of self-weight, rain load (0.1 kN/m2) and 8 different wind load scenarios (at 20m/s) using *Windas Tensinet*, a load incremental non-linear finite element analysis solver. Due to the asymmetrical geometry of the MTS pavilion, computational fluid dynamics (CFD) was performed initially to record the different amounts of pressure exerted across the membrane's surface before the non-linear finite element solver was used.

At each load scenario, deflections, stresses, and reaction forces from the support points were extracted from the pavilion. Stresses from the membrane, struts and cables were taken at the load scenarios where each component experienced maximum principal stresses. This data was assessed to determine whether these components were within their material limits. The assessment was inclusive of a 2.5 factor of safety for the membrane and 1.5 factor of safety for the struts and cables. Additionally, this load analysis helped us to determine the ideal orientation of the pavilion on the site to reduce the scenario of wind loading that will cause the maximum stress on the membrane.

2.4. Extraction of fabrication data

After the structure was validated, fabrication data of its constituent components were extracted from the model. These were categorised as data from the membrane, the struts and their end connectors, and the cables. The data was translated into working drawings which were used to communicate with fabrication specialists.

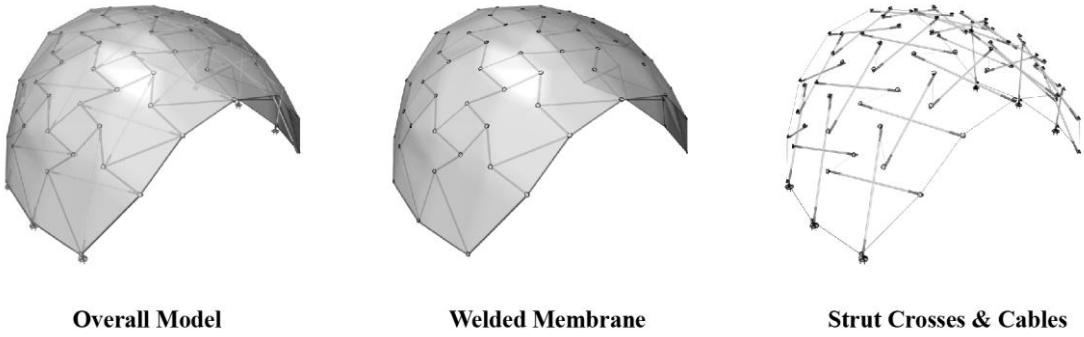

Figure 6. Various components of the M-shell.

2.4.1. Struts and connectors

To minimise buckling, each cross strut unit was modelled as an interconnected and in-plane component for the structural analysis steps. This property of the model was physically manifested by welding the tubes together to form an in-plane cross. Additional 6mm thick gussets were added at the intersection as triangular fins to further reduce the occurrence of buckling when the struts are pre-tensioning the membrane.

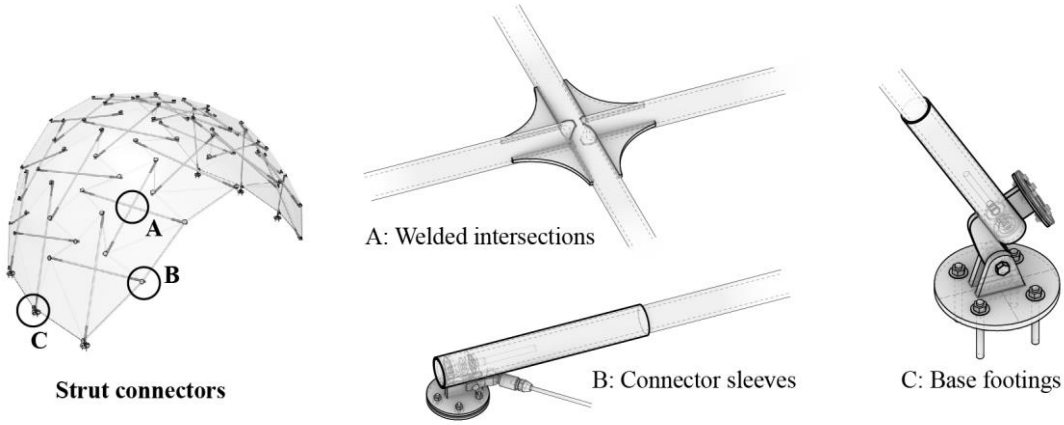

Figure 7. Various hardware connectors.

In addition to the struts, connector sleeves were also included to serve a dual function: (i) to connect the ends of the struts to the membrane, and (ii) to provide a way to mechanically elongate the struts to pretension the membrane. These aluminium connectors were designed as 350mm long tubes that were welded onto 4mm circular discs that could be bolted onto the membrane. The connector tubes were designed to be slightly larger than the strut tubes (50.8mm diameter with 2.8mm wall thickness) to house the ends of the crosses. These connectors also housed an extension mechanism where a hand drill with a hex adapter could be used to elongate the strut at each end.

As the connectors would interface the membrane at different angles, 100mm diameter circular discs were drawn at the end points of the struts in the digital model. This gave a reference surface to assess the number of different angles measured between the membrane mesh and the struts along the individual

planes of the struts' axes. These angles were all adjusted to be multiples of 5 degrees to standardise the connectors to a total of 5 variations of 90 to 115°, minimising the number of unique components needed to be made. This data was incorporated as a short vertical plate that was welded between the sleeve tube and the disc. 5 holes were also added to the discs to allow for the aluminium connector to be bolted onto the membrane.

The bases were also designed as 200mm diameter and 12.0mm thick aluminium discs that could be affixed onto the concrete slab of the site using anchor bolts. Each base had an aluminium fin mechanism that allowed the struts closest to the ground to rotate along their respective axes. This flexibility would provide room for adjustments during installation and allow for deflections to accommodate wind loads.

2.4.2. Membrane cutting patterns

The 3D membrane surface was segmented into cutting patterns for the fabricator, Advance Canvas, to cut and weld the pieces together. The segmentation of the membrane was based on the positions of the struts by creating and connecting lines between the closest neighbouring points. This led to the patches directly above the strut crosses adopting a star geometry; patches in between crosses adopting a diamond geometry; and patches along the perimeter having a triangle geometry. Due to the doubly curved nature of the membrane, each patch was made into a triangulated surface between the joined lines and later unrolled on the x-y plane. This created flattened 2D surfaces from the 3D mesh with minimal distortions.

Next, each patch was given an offset of 25mm from its perimeter edge as tabs for the welding of the seams. The tabs between neighbouring patches overlap and undergoes ultrasonic welding to connect the membrane pieces together. The 100mm diameter circular discs, used to interface with the aluminium hardware connectors, were added by laminating several layers directly on top of tabs added at these intersections. Furthermore, the seams along the perimeter were designated as wider 70mm and130mm offsets to accommodate the perimeter cables. These served as continuous channels to house the perimeter cables to further stiffen the membrane along its edges.

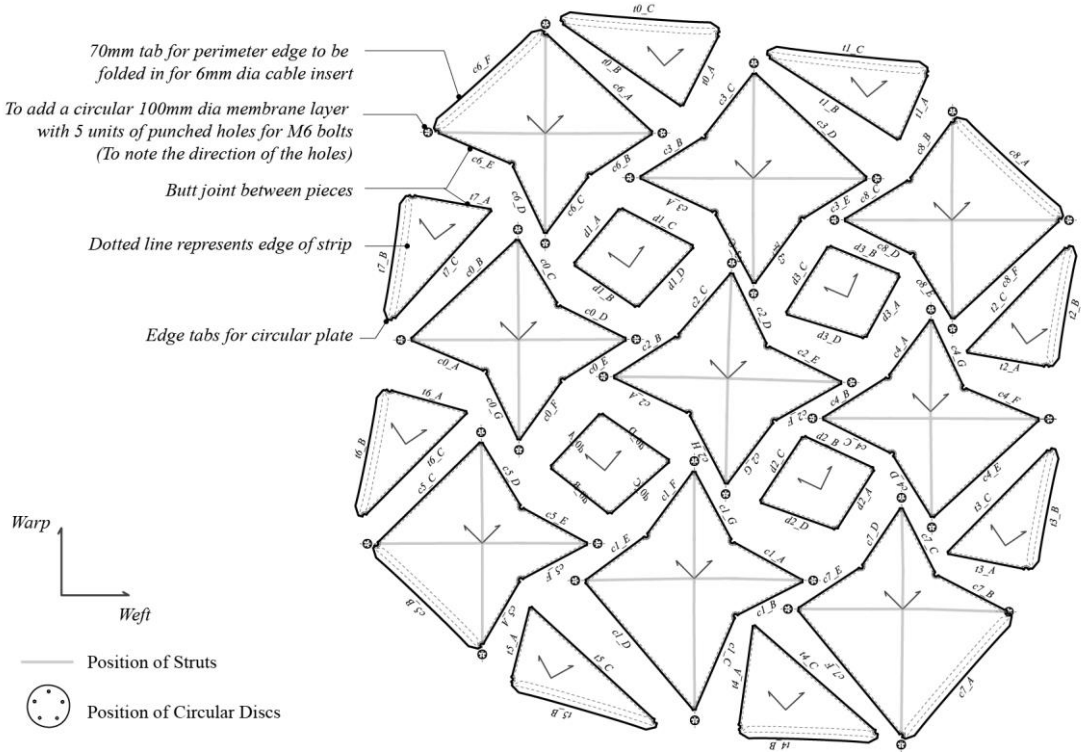

Figure 8. Cutting pattern of half prototype with 3x3 strut cross units.

2.4.3. Cables

Lastly, cable lengths were extracted from the model with consideration of the hardware dimensions (i.e., stud and turnbuckles). Internal connection cables were affixed onto the vertical plate of the connector and linked together using toggle end hardware. These allowed rotation in two axes, namely along and perpendicular to the length of the strut, to accommodate the different end points of the wire rope in 3D space. On the other hand, the perimeter cables were slotted through the perimeter channels of the membrane and their hardware was affixed onto special laser-cut pieces of the connectors.

3. Assembly and installation of the M-shell half prototype

The components were mass produced by multiple vendors and transported directly onto site. Before starting the assembly, the components were laid out and checked for their fit. Holes were also marked out on site and drilled into the concrete slab for the bases to be bolted onto the ground. The pavilion was then installed in the following sequence:

1. Fitting: The strut crosses were fitted onto the membrane by inserting the connector sleeves onto the struts and bolting them onto the membrane;

2. Flipping: A mobile scaffolding rig was brought to site and the un-tensioned membrane-strut assembly was flipped upwards using a pulley-rope system such that the assembly rests on the rig. This ensured that there was an empty space between the ground and the membrane to perform the next step;

3. Tensioning: The struts were elongated at every end using hand drills to their intended lengths to induce pretension within the membrane.

4. Repositioning: The tensioned membrane-strut assembly was hoisted up onto the scaffolding rig and shifted to the correct place. This involved aligning the end fins of the bottom most struts and locking them into the bases.

Figure 9. Assembly sequence.

3.1. Assessments and improvements

While the half prototype pavilion was able to be installed with relative success, we faced several challenges that led to the damage of the sleeve connectors and tearing of the membrane. We believe that these problems could stem from both the design of the components and our assembly sequence.

For the components, our extension mechanism needs to be improved to accommodate high torque drilling to prevent galling of the rivet nut of the extension mechanism. This led to jamming of the mechanism for certain sleeve connectors as the internal threads of the rivet nut were worn down by the drilling action. Thus, we are replacing the mechanism with lead screws which are more suited for high-speed applications. Additionally, the PVC membrane needs to be further reinforced with wider seams to resist tearing during installation. This has been implemented in cutting patterns of the final design of the full pavilion.

From the assembly sequence standpoint, we find that the membrane needs to be hoisted up to be in its final state as much as possible in step 2. We believe that this would minimise unnecessary overstretching of the membrane when elongating the crosses. This strategy would be implemented in the set up of the final pavilion by having the mobile scaffolding rig in the centre of the membrane-strut assembly. The rig would allow the propping up of the pavilion to be as curved as possible to target the final geometry of the intended pavilion.

4. Conclusion

In summary, this paper demonstrates a design-to-fabrication workflow for large-scale occupiable MTS pavilion using stiffer elements of aluminium tubes and a continuous welded polyester coated membrane. It showcased the design, analysis, and fabrication of half of the 8.0m span MTS pavilion which proves that these structures can be manufactured and assembled on a large scale.

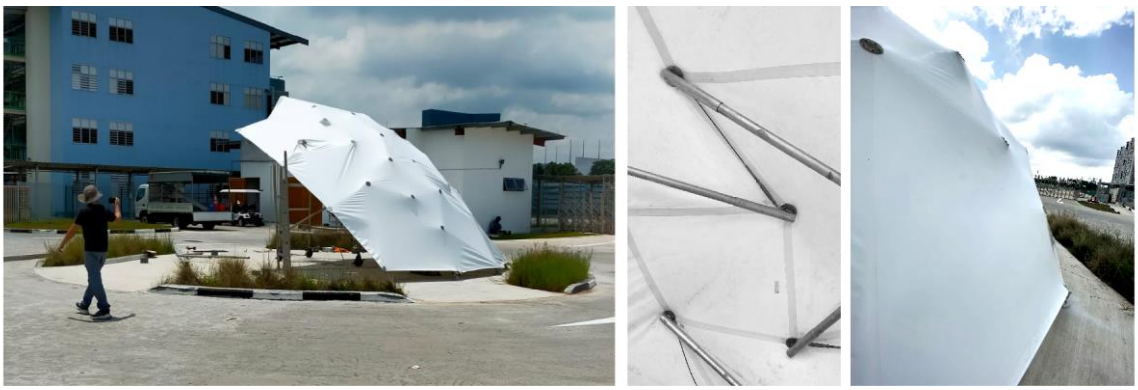

Figure 10. Half prototype with detail photos.

Currently, we are working towards making the full M-shell pavilion while making modifications to the design of the membrane and strut crosses. This would be assembled as the intended continuous arch that will serve as a self-supported outdoor shade pavilion. In the meantime, our team is also working with an engineering consultant to endorse this novel structural system with respect to the local building codes.

Acknowledgements

This research was supported and funded by the Decentralised GAP Funding project, Grant number: RGGAP20015, Tensile Ventures - Design Solutions for aesthetically unique, modular, quick assembly, event and recreation shelters. The authors would like to give their utmost gratitude to Dr. Phang (Multimedia Engineering), Mr. Larry Lim (Advance Canvas), Mr. Darren Mok (CutAnything) and Mr. Sam Vedanaigam (The Shelter Company), for their guidance and expert advice throughout this research. We also want to thank Chia Pei Zhi for copy-editing this paper and Sachin Gupta for developing the conformal mapping script. Lastly, we are grateful to Lance Macro Yu, Chung Zhi Xue, Lyvia Annabelle, Michelle Tan, Isaac Tan, Joy Liew, for assisting us as student helpers.

Abstract

The practice of off-site prefabricated construction dates back to the early 20th century. The advancement of information technology and the recent economic uncertainty may make this a new normal for the construction industry. The industry is composed of a number of players. Integrating information technology throughout the entire industry chain is essential. This will enable us to achieve the full potential of prefabricated construction in this large ecosystem, not just digitally but also intelligently. A cloud platform integrating artificial intelligence and cloud computing technology is presented in this paper and applied specifically to off-site prefabricated construction. AI generative modules shorten model creation and accelerate optimised solution finding, while cloud computing provides economical deployment with shared computing resources. In addition to global optimised prefabrication schemes generation in the investment or planning phase, this platform allows associative interaction between a standardised library and multiple disciplines and supports real-time spreadsheet calculation and IFC format export. These features facilitate further fabrication in the construction phase. With the use of a platform and factory production, off-site prefabricated construction has improved design efficiency and reduced loss in a hotel example project.

Keywords: construction industry, off-site construction, prefabricated construction, modular-integrated construction, BIM modelling, Xtect, global optimization, generative design

1. Off-site prefabricated construction

1.1. Introduction

As early as the 20th century, off-site prefabrication was practiced. In terms of design theory, we can see the emergence of this concept from Le Corbusier: “If houses were manufactured industrially, mass-produced like chassis, an aesthetic would be formed with surprising precision” [1]. As a matter of practice, the Sears Roebuck Company in the United States was able to transport prefabricated parts of buildings by rail to users before World War I, thus allowing the buyer to assemble the items on site [2]. Prefabricated semi-cylindrical buildings (Quonset huts), which had been imported from Britain, were used by American soldiers during the 1940s. Zachry Construction Company constructed a 21-story modular hotel in Texas at the end of the 1960s, which is currently known as the Hilton Palacio Del Rio Hotel [3]. Similarly, Kisho Kurokawa, one of the representatives of Metabolism in Japan, used prefabrication in the construction of the Nakagin Capsule Tower in the next decade, assembling all the prefabricated modules on site and anticipating their replacement if necessary.

Having a large carbon footprint, the construction industry has once again encouraged off-site prefabrication under the pressure of recent carbon emissions (in fact, the most critical factors during

Copyright © 2023 by Jackie Leong Shong YONG, Wanyu HE, Lei GU, Peiwen LI and Ying WANG. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

the epidemic were the high cost of manpower, building materials, and transportation). Recently, some countries and regions, including Singapore and China (including Hong Kong S.A.R.), have introduced proactive and incentive policies related to prefabricated construction, vigorously promoting the adoption of this green construction method. As opposed to conventional on-site construction methods, off-site prefabrication reduces carbon emissions during construction as well as upgrading the construction industry over time.

In general, off-site prefabrication can be divided into two categories: non-modular/volumetric prefabricated construction and modular/volumetric prefabricated construction [4]. The latter is also known as "Modular Integrated Construction" (MIC) [5].

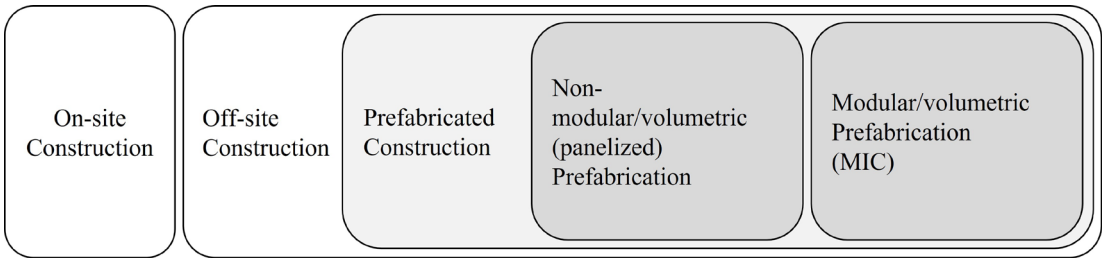

Figure 1. Concept of off-site prefabricated construction.

Non-modular/volumetric prefabrication refers to the fabrication of specific elements within a factory, such as walls, floors, stairs, decorative elements, etc. Alternatively, modular prefabricated construction involves the installation and assembly of various prefabricated components, including structures, mechanical, electrical, and plumbing components, as well as furniture and other components, in a single box-shaped unit. Depending on the degree of integration and the size of the unit, the unit can generally be divided into pods (smaller units with specific amenities, such as bathrooms) or modules (larger units with more comprehensive utilities). The modular units are transported to the construction site and linked and assembled to form the building units. Having completed the roof finishing and facade detail on site, the construction is basically complete and ready for review and delivery.

Off-site prefabricated construction also differs from conventional on-site construction in its design process. It adheres to the design principle "Design for Manufacture and Assembly" (DfMA), which stresses the need to take into consideration additional factors during the design process, such as factory manufacturing, logistics, and installation sequence. As a result, this mode of construction requires a higher level of design expertise. Designers must not only develop architectural designs, but also plan how they will be manufactured, transported, and assembled on site. As a result, the design stage schedule will also be extended [6].

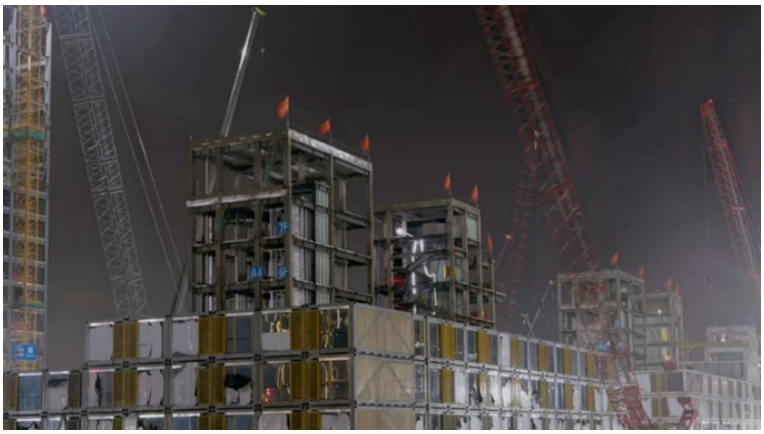

Figure 2. The assembly of prefabricated module on site [Courtesy of China Construction Science and Industry Co., Ltd].

1.2. Industry bottleneck

It is common for on-site construction to require outdoor work. Open working environments are susceptible to environmental factors such as rainfall, snowfall, high temperatures, and even less daylighting areas such as the Arctic Circle. The construction schedule on site is therefore difficult to control. Furthermore, due to the limited flexibility of the construction team to switch or relocate as the project changes, ensuring the quality of available labour is challenging. In addition to the scattering of the construction site management and the difficult conditions of the construction site, safety hazards are also present. There are often negative situations such as accidents during operations and large amounts of construction waste.

As off-site prefabricated construction is largely carried out in a controlled operating environment and standardized process flow, and even enjoys a more controllable procurement channel, it has the advantage of being less affected by the outdoor environment, providing a higher quality construction, and reducing emissions and waste during construction on-site [7]. The epidemic has made this method of construction a viable alternative for many projects such as temporary hospitals and affordable housing that require high construction standards and a controlled schedule [4]. However, there is still resistance to off-site prefabricated construction.

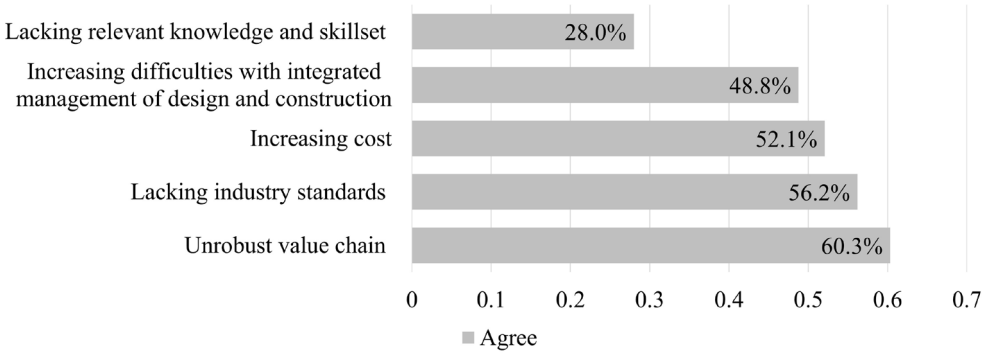

Figure 3. Examples of resistance to off-site prefabrication in China [8].

1.2.1 Supply

Prefabrication has not yet been fully adopted throughout the value chain, particularly upstream, where developers, designers and engineers, and suppliers of materials are involved. A common practice among designers is to produce a "modular key plan" after the architectural design, that is, without considering off-site fabrication processes at the outset of the design process. It is therefore difficult for developers to determine the feasibility of a project at the investment stage, such as calculating the cost and revenue. Due to the absence of geometric information in this phase, a calculation or compliance check is not possible. The recent turmoil in global politics and the economic situation, however, has also resulted in a lack of stability in the supply of building materials and parts, causing delays and affecting the completion of projects. Most on-site construction participants do not yet possess sufficient knowledge of this construction technique [9].

A lack of sound standards leads to a lack of unified standards for supervision and control throughout the entire project process. Developers, designers, and construction parties work independently. It is difficult to integrate and manage multiple terminals, and a strong prefabricated construction ecosystem cannot be established.

All of these factors contribute to the fact that the average cost of prefabricated construction is usually not lower than that of conventional construction, and is sometimes even higher. As an example, in modular prefabricated construction, each module is an independent box structure. If the module adopts a steel framework, the amount of steel used in modular prefabricated construction will be 1.5 to 2

times greater than that of traditional steel framework construction. In this regard, it is important to be able to estimate the amount to be procured and the costs involved.

1.2.2 Demand

As with any project, the owner generally has a variety of needs and objectives, and construction projects have different constraints and compliance requirements. It is no longer feasible to prefabricate off-site using traditional construction drawings or BIM models of LOD 200-300. In order to bridge the production and construction phases after design, off-site prefabricated construction requires a higher level of accuracy at the design stage, including the BIM model that reaches LOD400.

It may be possible to resolve the above problems through the "more combinations with fewer products" design approach [10]. The development of industrialized products requires not only a sound collaborative value chain, but also the ability to meet a wide range of market demands in order to attain economic scale. It is possible to achieve this by producing fewer types of parts, components, and modules to satisfy a larger market, thereby reducing unit costs. Furthermore, prefabricated modules can be used to construct some parts of a project to reduce construction time, whereas another part can be built with standardized components to suit individual needs. These different combinations of prefabricated components, modules, and on-site construction methods will result in a variety of possible solutions.

As a result, manual design adjustments for off-site prefabricated buildings and excavation of multi-combination design schemes will result in double the workload. The role of information technology in off-site prefabrication is therefore critical, as it contributes to finding a balance between standardization and individualization.

2. Digitalization and intelligence in construction

With information technology advancement and recent economic uncertainty, it may become a potential new normal for the construction industry [9]. The industry consists of multiple players. It is essential that information technology is deeply integrated throughout the entire industry chain. This will enable us to achieve the full potential of prefabricated construction in this large ecosystem, not just digitally but also intelligently.

2.1. Existing digitalization as basis: BIM

Industrialization of construction requires an integrated information platform covering the entire life cycle of construction projects. Information regarding the design, cost, and progress of all industry stakeholders must be coordinated simultaneously. In recent years, parts of the construction industry value chain have also adopted BIM for the purpose of interoperability of data.

Because prefabricated construction requires high levels of accuracy, it is a natural fit for BIM technology. By applying BIM to prefabricated construction at the investment or early design stage, one can not only evaluate the feasibility of prefabrication proposals early on but also estimate procurement or simulate construction more accurately. Although BIM requires a great deal of information processing, it remains essentially a manual modeling process. The prefabricated construction design stage brings more challenges for designers because they need to explore “more combinations with fewer products” and “multi-objective optimal solutions”.

However, the development of digital and intelligent information technology seems to bring a potentially effective solution to this problem, that is, the modeling process is simplified through intelligent computing, and computers can replace human beings to complete a large number of tedious repetitive labor and information processing tasks.

2.2. Integration of advanced information technology: AI and cloud computing

Using the AI generation, BIM model creation will be shortened and the search for optimal solutions will be accelerated. In the context of artificial intelligence-assisted architectural design, artificial intelligence does not refer to a specific algorithm or results from a training set, but rather to a series of intelligent systems which integrate multiple models that range from rule-based to data-driven models, including deep learning, machine learning, and operational research with computational optimization.

The cloud computing model offers a more economical deployment solution due to the sharing of computing resources. Using the cloud, not only is the requirement for local hardware reduced, but multiple terminals can collaborate simultaneously and efficiently.

2.3. The platform, Xtect

By integrating the aforementioned technologies, this article introduces a cloud platform designed specifically for off-site prefabricated construction: Xtect. It utilizes AI technology as well as cloud computing technology to simplify the production process of BIM models for prefabricated buildings, as well as its further construction.

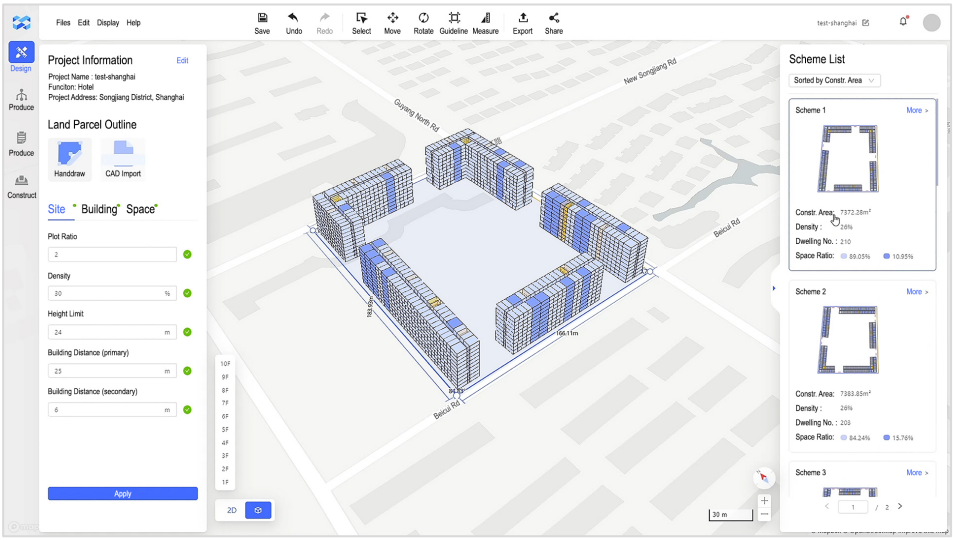

Figure 4. Screenshot of Xtect.

Three key features of the platform are as follows:

2.3.1. Generative design for multi-objectives

Due to the limitations of manual design, there are few comparative design alternatives to meet the project requirements, the design cycle is long, repeated communication is required, and it is difficult to reuse previous projects' design results in subsequent projects. In contrast, this platform performs multi-objective design optimisation and generates a number of design schemes that meet a project's goals and constraints by simply inputting some significant parameters. As a result, developers and designers are able to evaluate the feasibility of a project in advance based on the architectural form, parameters calculation, and compliance checking result of the generated scheme in the early stages.

Take for instance a modular prefabricated building project. Initially, the user sets up the configuration of the project. CAD files can be uploaded, or approximate geometric outlines can be drawn on the webpage to indicate the project's property line. Next, the user enters the project's goals, such as floor area ratio, building coverage, housing types ratio, etc. Afterwards, the user selects the appropriate module (housing or hotel) from the library and sets up the generation parameters to proceed with the layout and massing. The platform generates a number of modular prefabricated building schemes

based on the stated objectives and constraints, such as embedded compliance rules. A comparison is then possible between the generated proposals based on the parameters, allowing users to compare them side-by-side.

The module library described above stores the information about the module in a BIM-like data structure, which enables the library to be flexibly queried or adjusted according to the needs of various projects. The data structure of the modules consists of a number of parts that work together to facilitate the process of purchasing, production and installation. Additionally, some of the key components are based on associative design logic that may undergo certain variations depending on the requirements. By doing so, it can offer both standardization and customization to a certain degree of controllability, thereby making mass customization even more feasible.

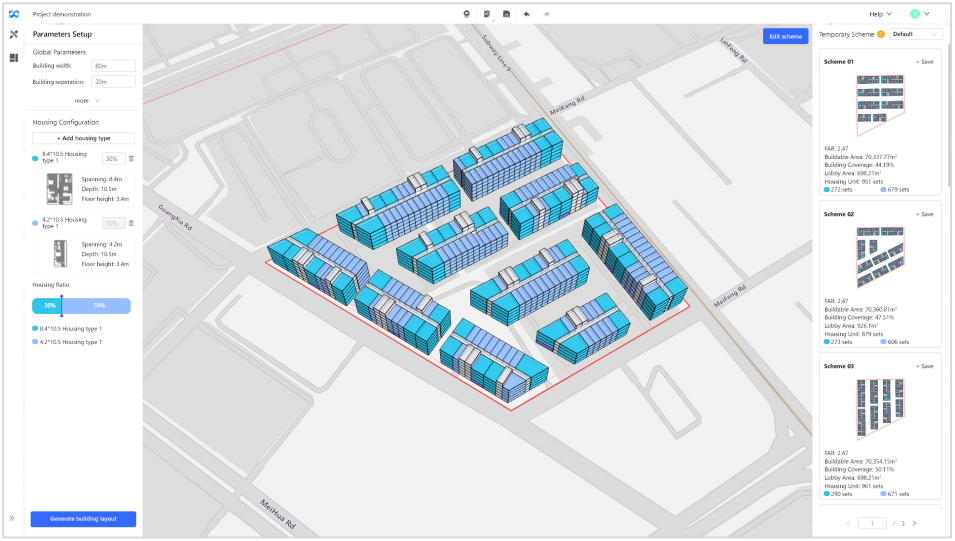

Figure 5. The layout schemes generated on Xtect.

To generate building layout schemes that are suitable for different actual projects, the "land division template" is employed initially. To accommodate different scenarios, project types, and land characteristics, this template is composed of several division rules and adaptive algorithm.

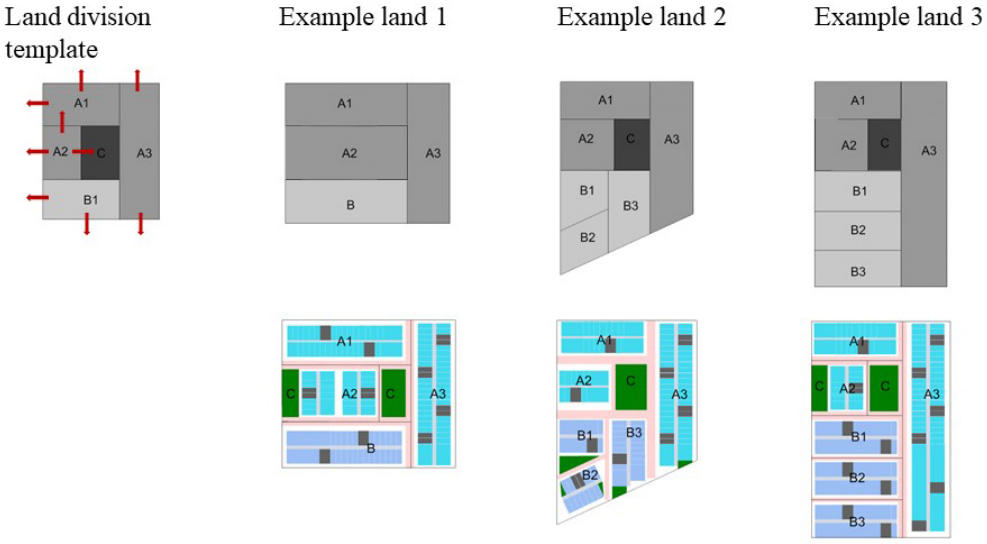

Figure 6. The adoptive application of the "land division template".

Please refer to Figure 6 as an example. The arrows indicate the possible direction of extension to suit various land scenarios. During template adjustment, the internal partitions of the template will undergo adaptive changes. If partitions such as A1, A2, A3, etc., are changed, the number of buildings and layout will also be altered. There are some divisions, such as B, that will be further subdivided in accordance with their size. Meanwhile, some divisions, such as C, represent public spaces such as parks or squares. A method such as the one described above can be used to turn a complex and difficult-to-solve building layout problem into a combination of labelled, modularized, and template-solvable problems.

2.3.2. Associative design of multi-disciplinary

Since prefabricated construction entails a closer relationship between design and production, it is imperative for various engineering disciplines to be integrated into the design process, which includes structural, MEP, and HVAC. The problem is that there are technical barriers between different disciplines. It is often the case that designers who control the whole must spend considerable energy and time coordinating between disciplines, which increases the difficulty of designing and the likelihood of inadequate consideration. Furthermore, it is inevitable to encounter situations where the design needs to be adjusted more or less during the process of developing the design scheme for prefabricated buildings. It is possible that a slight adjustment in one part of the situation may have an impact on the entire situation at this time. This will lead to the architectural design and engineering professions collaborating on a number of occasions.

The platform incorporates the architectural and engineering design logic of various disciplines and combines it with compliance audit logic in order to form associative design algorithms. With the integration of the associative generation algorithm of this platform, users are not only able to adjust the module size by modifying the parameters of the module building, but the change of size will also affect the relevant engineering professional components therein. For example, when the user adjusts the module layout by dragging the exterior wall, the algorithm will make linkage adjustments to the interior decoration, structure, and mechanical and electrical pipelines based on the new wall position, take into account avoidance, and update and transmit to the display interface.

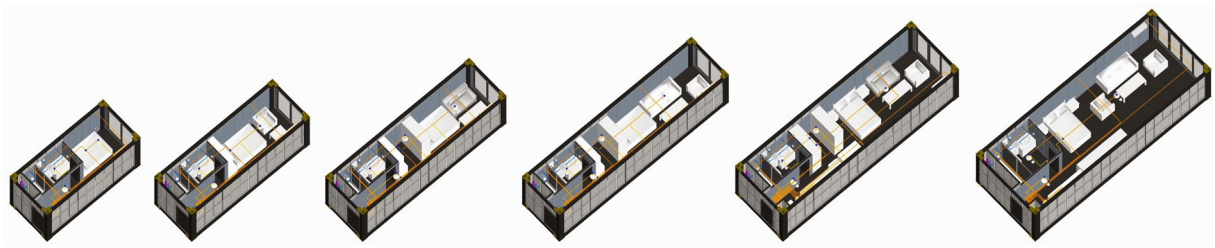

Figure 7. Component size and position changes due to module resizing on Xtect.

To achieve the aforementioned standardized and modularized interior layout scheme, the generation design for each module size is realised by a large number of structured data of modules with detailed interior information clustered into a controllable number of layout unit templates. To meet the interior customization requirements in projects with standardized methods, each unit template has a corresponding interior layout and configuration, which may include various engineering systems, furniture, and even the paving settings of modular panels.

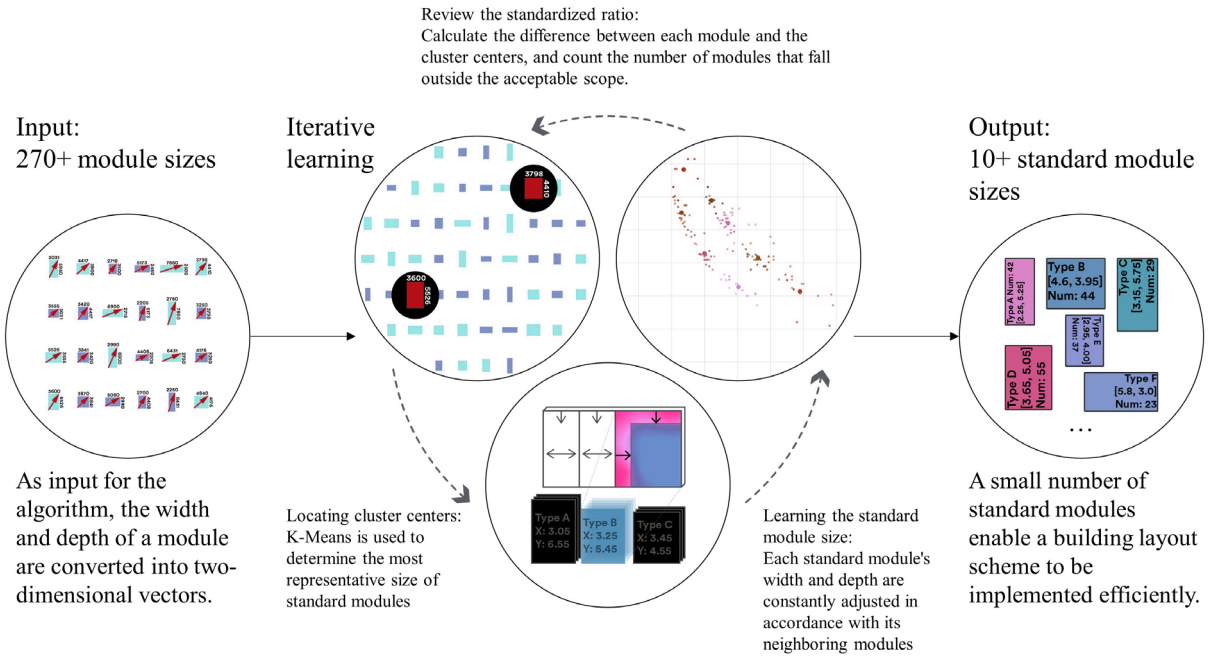

Figure 8. Iterative clustering and estimation of standard modules based on structured data.

Currently, this platform can support BIM models up to LOD400, so that the ceiling, hanging ribs, joists, air valves within the plumbing, and even some detailed components, such as screws, will be displayed simultaneously on the platform. Consequently, the designer's intuitive feeling is that when the building space is manually adjusted, the engineering professional components corresponding to the space can be adjusted automatically in real-time and reflected in the BIM model of the modular prefabricated building immediately.

2.3.3. Spreadsheet calculation and IFC format export

This platform generates a BIM model with semantic and attribute information, which acts as the connector for the various functions of the platform. Consequently, changes to the BIM model in different phases are transmitted through the entire platform. Through the reading of the model and the identification of components, the calculation module of the platform can automatically calculate various data statistics and indicators for the scheme. As a result of these standardized building components, several spreadsheets are automatically generated corresponding to the entire design in real time, containing information such as specs, quantity, price, etc. Additionally, users can choose to export the model in IFC format, so that they can edit and deepen the scheme in other BIM applications. In this way, real-time calculations greatly enhance the ability to control construction costs during the design phase, making it easier for the results of the design to be implemented during production and construction.

Technically, we have developed a centralized plan for the internal modeling algorithm and model storage structure, so that the front-end web rendering, 3D modeling, and IFC model generation can all use the same model storage structure. As a result, the model built by the algorithm engineer can be conveniently displayed on the front-end web page and verified and debugged in dedicated 3D modeling software. IFC format export is implemented using several SDKs and a core algorithm library. The SDKs correspond to applications that involve web page, 3D model, or IFC format generation, and the instructions of the core algorithm library can be converted into instructions for model generation under these applications.

3. Case study

This paper presents a case study of the platform in a hotel project in Shenzhen, in which China Construction Science and Industry Co., Ltd. (CSCEC) is the principal contractor.

Figure 9. Aerial rendering of the project

3.1. Module set up in library

In the module setup phase, the platform recognizes the uploaded components such as structures, interiors, and engineering. These recognized components later support associative regeneration with manual module adjustment. The regenerated modules can also be restored in the module library for future use. Meanwhile, the model depth of LOD400 allows for the calculation of the construction spreadsheet, which facilitates the efficient connection between the design, suppliers, and production ends. This reduces the grey area in cost estimation.

Figure 10. The various disciplinary components on Xtect.

3.2 Multi-objectives optimised design generation

The architectural design stage involves generating the layout based on the property boundary and the modules selected from the module library. Building setbacks and separations are met in the generated scheme in compliance with the local code requirements. The data for these several schemes can be viewed in real-time in the right display column to help the user select the scheme that best meets their requirements, such as comparing the economic parameters of various schemes.

As a result of scheme generation based on the module library, the basic information associated with the model is efficiently exported to the list of components required for the prefabricated hotel, and a

direct data interchange is established between design and production. In addition, each component will be assigned a unique ID, making it possible to inspect the model in a comprehensive manner and identify the problem in a timely manner. This ensures consistency in information for the site, building, module, and components, as well as future connections to production.

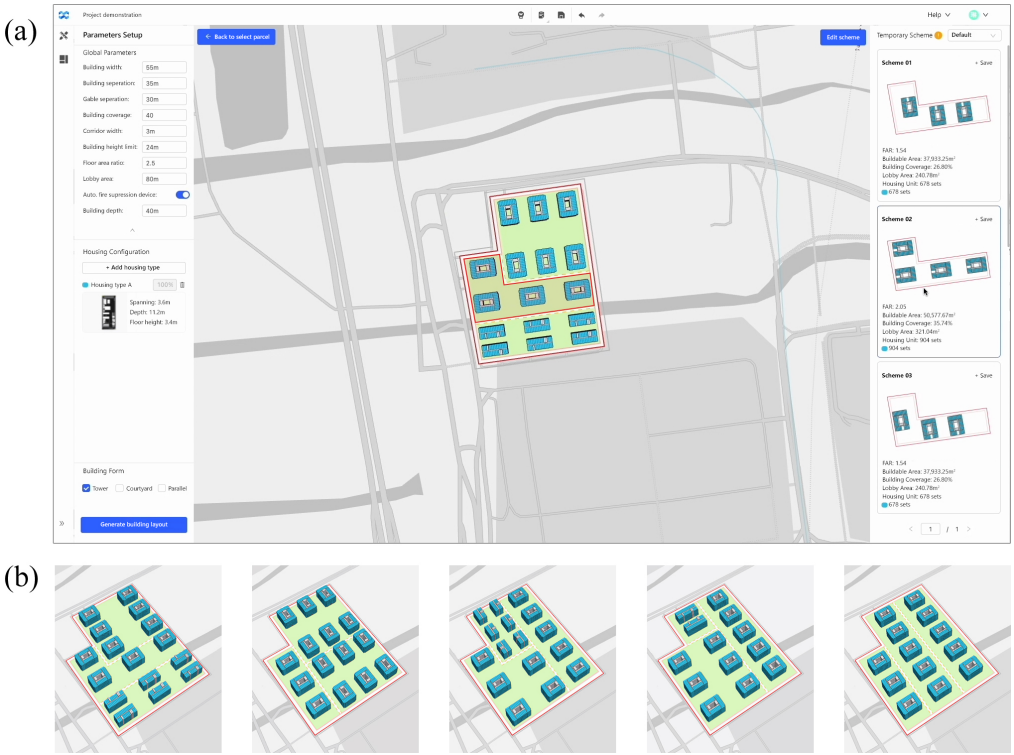

Figure 11. The development process of the building layout scheme for the case study on Xtect: (a) modular prefabricated building layout for a specific land parcel after land division, (b) overall building layout schemes on several land division strategies.

3.3. Prefabricated production

With the integration of this platform into the production line management system, it will be possible to order, monitor, and produce the components found in the designated scheme on the production line. For the construction of modules, CSCEC has developed an intelligent production line. This module production line is based on the concept of non-standard automation engineering equipment. The system utilizes high-precision servos, screw rods, and other structures, along with an automated control system, which improves the overall efficiency by more than 50%. Modules manufactured by it are variable in length, width, and height, covering more than 85% of the mainstream market's specifications and sizes.

Most of the work has been completed in the factory, so only the assembly of module and seam processing remains to be done on-site. As a result of the precision of the manufacturing process, the total size error can be controlled within 0-2 mm, and the module can be installed on-site within 20-30 minutes. As production volume increases, the cost of modular units processed at the later stage is often lower than that of modular units processed at the early stage, and a reduction in the construction schedule is achieved.

With the use of a platform and factory production, off-site prefabricated construction has improved design efficiency and reduced loss in this hotel project. Moreover, by using modular buildings, most of the on-site construction operations can be carried out in advance, thereby reducing more than 90% of the carbon dioxide emissions during the construction phase. It is also possible to reuse modular

units under certain circumstances. When turnover and reuse are taken into account, the overall carbon emissions of a building will be significantly reduced.

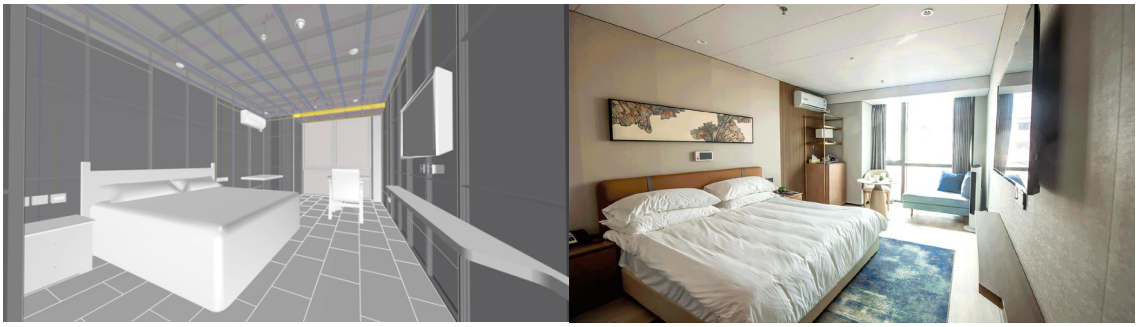

Figure 12. The before (BIM on the platform) and after (built) of hotel module.

4. Conclusion

As part of the general trend of reducing carbon emissions and reducing energy consumption, prefabricated off-site construction offers several benefits. Utilizing digital and intelligent technologies, it attempts to resolve the standardization-individualization conflict. Further research and development are needed to verify and deepen the research, as well as to explore the platform's application value in other regions. The platform can also be expanded to include other industrial value chains, such as building material supply management, project management, and green operations.

Abstract

Aluminum alloys have been increasingly used in civil engineering due to their favourable properties, such as high strength-to-weight ratio, high corrosion resistance, very good processability and recyclability. Many aluminium alloy single-layer latticed shells with span larger than 100m have been built in China over the past two decades. In order to study the seismic performance of aluminum alloy latticed shells, the material properties, the cyclic behaviour of H-section aluminium alloy members under axial and eccentric loads have been studied, and then two shaking table tests of a cylindrical and a spherical single-layer latticed shells have been carried out. The nodal displacement and acceleration and member forces of the shells were studied under frequent and rare earthquakes, when both models keep in elastic stage. And then, the collapse tests have been conducted to both model shells under severe earthquakes, and the whole collapse processes were studied. Finite element models have been established and verified to simulate the shaking table tests, and the seismic performance and the failure mechanism were studied. The results indicate that the aluminium alloy single-layer latticed shells have excellent seismic performance, but the lower elastic modulus leads to bigger displacements than that of steel shells, which should be considered thoroughly in the design of this kind of shells.

Keywords: aluminum alloy, single-layer latticed shell, shaking table test, collapse mechanism, seismic design

1. Introduction

Aluminum is the most abundant metallic element in the earth's crust. Aluminum alloys have many favourable properties, such as high strength-to-weight ratio, high corrosion resistance, and very good processability and recyclability[1]. And thus, there are more and more aluminium alloy single-layer latticed shells built in China over the past two decades, many of them have the spans larger than 100m[2]. There are many research on the static stability of single-layer latticed shells and found that the static stability behavior of aluminum alloy latticed shells is quite different from that of steel shells [3–6]. The seismic design of aluminum alloy latticed shells follows the code for steel latticed shells, but there are many differences between aluminum alloy and steel structures, such as different Young's Modulus of the materials, different member profiles and different connections.

The constitutive model of the aluminum alloy have been studied, and the parameters of Chaboche hybrid reinforcement model of aluminum alloy under cyclic load have been obtained[7],[8] , which are essential to the seismic response analysis of aluminium alloy structures. The hysteretic performance and failure modes of H-section members with different slenderness ratios under axial and eccentric cyclic loads have been studied [9],[10]. The mostly used joints in aluminum alloy latticed shells are gusset joints, the hysteretic performance and failure modes have been studied by experimental and analytical methods [11–14].

For the seismic performance of aluminum alloy latticed shells, Yu analyzed the seismic performance and failure mechanism of a single-layer cylindrical latticed shell using numerical analysis[15]. However, the only shaking table tests on aluminum alloy latticed shells were conducted by the Wu et al[16][17]. In this paper, based on the constitutive model of the aluminum alloy material, the hysteretic performance and failure modes of H-section members will be introduced. Based on the shaking table tests and numerical analysis, the seismic performance and collapse mechanism of a cylindrical latticed shell and a spherical latticed shell are studied and the seismic design of this kind of structure is suggested.

2. Hysteretic performance of H-section aluminium alloy members

2.1. Material property

To study the constitutive model of aluminum alloy, the material samples are taken from the flange and the web of the H-section members. The low cyclic loading test was completed on the QBS-300 dynamic and static universal material testing machine in the laboratory of Beijing University of Technology [9],[10]. The Chaboche hybrid strengthening model is used to describe the mechanical properties of aluminum alloy materials under cyclic loading, and the parameters of the model have been obtained. The comparison of the analytical and test values are shown in Figure 1. The hysteretic curve of the specimen obtained based on the Chaboche hybrid strengthening model is in good agreement with the experimental results, and the calibrated aluminum alloy material parameters have good accuracy, which can be applied to the seismic performance analysis of aluminum alloy energy dissipation components.

2.2. Performance of H-section members under axial and eccentric cyclic loads

H-section members are widely used for aluminium alloy latticed shell structures. Both the axial and eccentric cyclic loading test objects are three H-section 6061-T6 aluminium alloy members[9][10]. The section size of the members is H250mm×125mm×5mm×9mm, different lengths are used for different slenderness of the members. The load-displacement curves and the skeleton curves of the three axial loaded specimens are shown in Fig. 2. The load-displacement curves of the three eccentric loaded specimens are shown in Fig. 3, in which λ is the slenderness ratio of the. The comparison of failure modes between the FEM and experiment is shown in Fig 4 and 5.

(a) (b)

(a) (b)

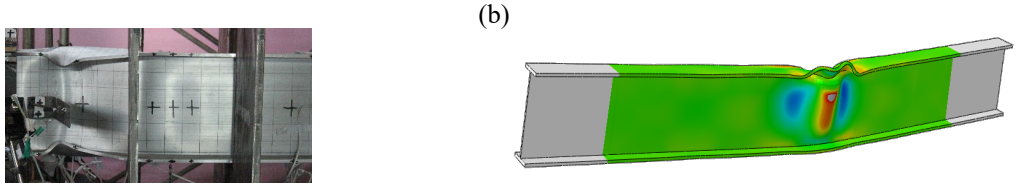

Figure 4. Failure mode of the axial loaded member with the slenderness ratio of 80: (a) test, (b) FE model.

(a) (b)

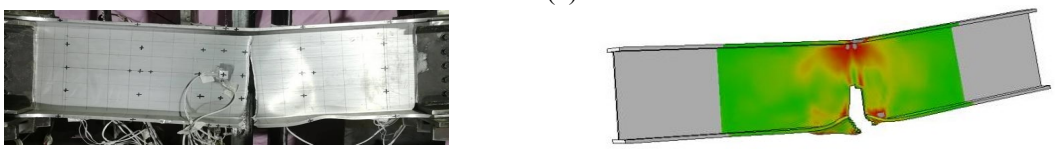

Figure 5. Failure mode of the eccentric loaded member with the slenderness ratio of 80: (a) test,(b) FE model.

For the axial loaded members, the load-displacement curves show that the members experiencing in-plane buckling with a small slenderness ratio have better seismic performance. Among them, the member with a smaller slenderness ratio and in-plane bending has a larger fracture load due to higher material utilization rate. After local buckling under compression, the stiffness of the member on the compression side reduces significantly, so the area of the hysteresis loop increases suddenly when most of the member reach plasticity, meaning that the energy dissipation of the members after local buckling

is more obviously reflected in the compression stage. Comparing the skeleton curve of members with different slenderness ratios, the bearing capacity degenerates more significantly with the increase of slenderness ratio. This means that limiting the slenderness ratio of members can improve the energy dissipation capacity of the structure, and this should be considered carefully in the seismic design of the latticed shells.

For the eccentric loaded members, with the same eccentricity, smaller the slenderness ratio leads to fuller the hysteresis curve of the members. The Skeleton curve shows that at the initial stage of increasing loading displacement amplitude, the tensile bearing capacity shows a strengthening trend, and the tensile bearing capacity with a large slenderness ratio is slightly lower. When the eccentricity is the same, the increase in the overall slenderness ratio decreases the energy dissipation capacity of the aluminium alloy member.

3. Shaking table tests of single-layer aluminum alloy latticed shells

3.1. Experimental models

The prototype structures used in the two tests is a 21.6m × 21.6m single-layer cylindrical latticed shell and a 60m span Kiewit-6 (K6) aluminum alloy single-layer spherical latticed shell. Referring to the similarity theory[18], the span and length of the cylindrical latticed shell model are both 3.6m, with a rise-span ratio of 1/4 and the length similarity ratio of 1/6, as shown in Fig. 6a. The spherical model is simplified to a spherical latticed shell with a span of 4.0 m and a rise-span ratio of 1/7, in which the length similarity ratio is 1/15, as shown in Fig. 6b[16][17]. The member sections are shown in Fig. 6. The pictures of the two test models are shown in Fig. 7.

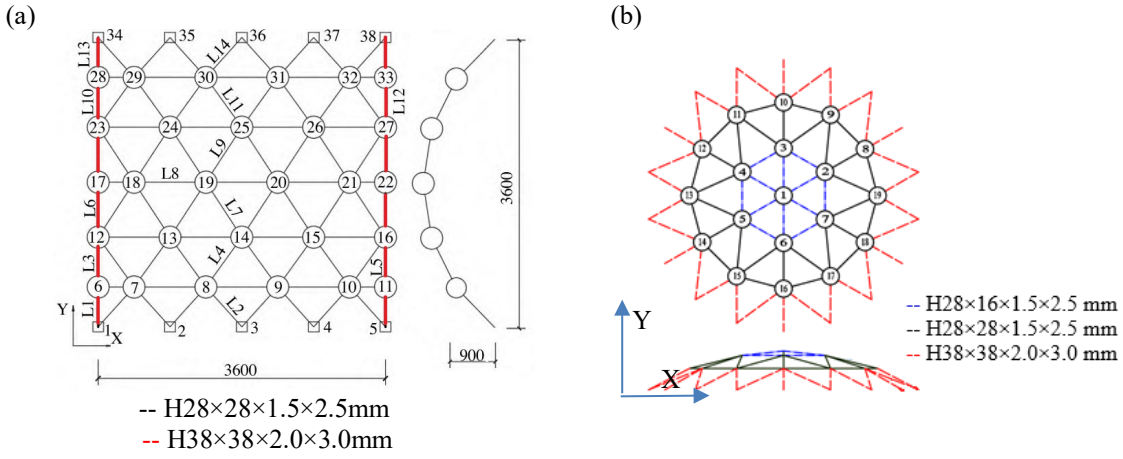

Figure 6. Layout of shell models and member sections (mm): (a) Cylindrical shell test model, (b) Spherical shell test model.

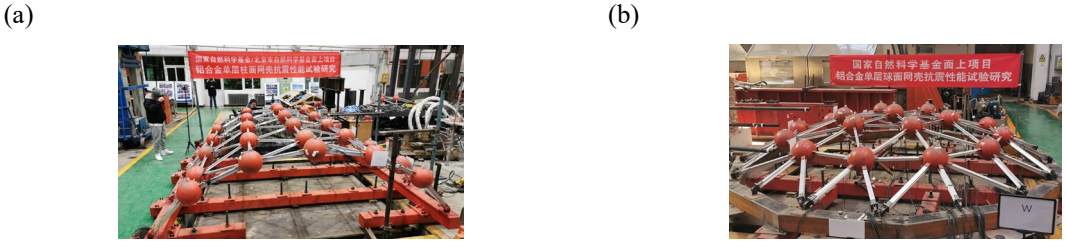

Figure 7. Pictures of shell models: (a) Cylindrical shell test model, (b) Spherical shell test model.

3.2. Distribution of measuring points

The displacement responses, acceleration responses and dynamic strain responses of the model are measured during the experiments (Fig. 8). The loads are applied to the models along Y-direction. The label AY6 is accelerometer of joint 6 along Y direction, and the other accelerometers are labelled in the same way. The label DZ1 is the displacement measuring point of joint 6 along Z direction.

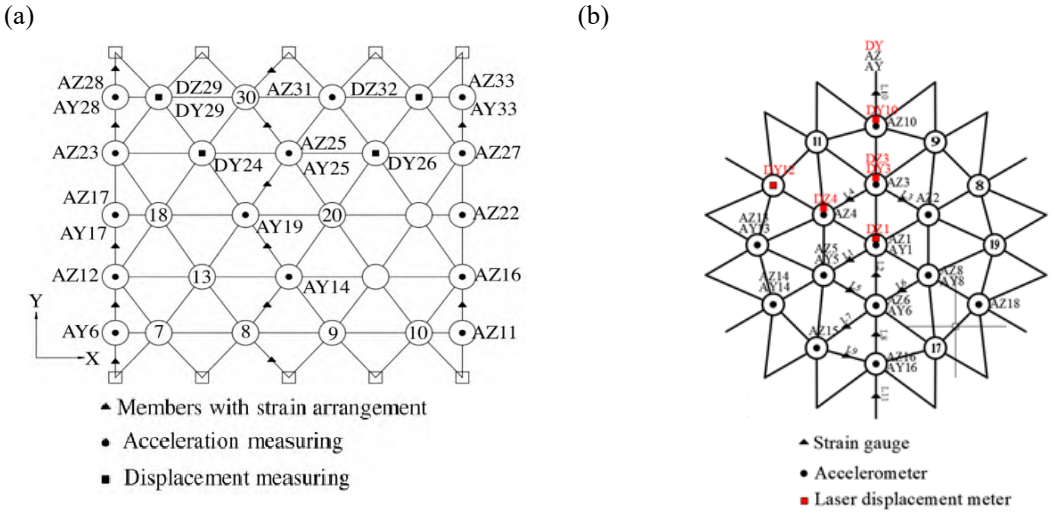

Figure 8. Arrangement of measuring points: (a) Spherical shell test model, (b) Cylindrical shell test model.

3.3. Experimental phenomena and results

3.3.1. Single-layer cylindrical latticed shell

The Taft, El Centro and CHY058 seismic waves are selected as the input ground motions for the cylindrical latticed shell along Y direction. The test is divided into three stages, i.e., elastic stage, elastoplastic stage and collapse stage.

Before the shaking table test, the first six natural frequencies of the model were tested, which are 2.20Hz, 5.37Hz, 6.34Hz, 9.03Hz, 9.77Hz and 11.71Hz respectively.

(1) Elastic stage test

The shell keeps in elastic stage when the peak ground acceleration (PGA) of the input waves less than 0.6g. The accelerations and displacements response are shown in Fig. 9. The maximum stress is 106Mpa, which appears at the end of L10, in which the bending stress is 98Mpa. This means that the bending moment is the main force for the members of the cylindrical shell subjected to horizontal lateral earthquakes.

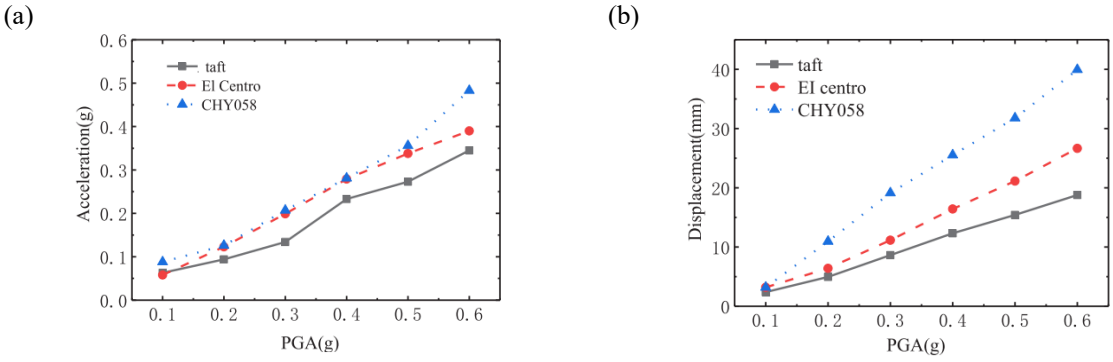

Figure 9. Responses of the cylindrical shell: (a) X-accelerations of joint 28, (b) Y-displacements of joint 29

(2) Elastoplastic stage test

The peak accelerations and displacements under Taft wave from 0.6g to 2.0g are shown in Fig. 10. It can be seen that the responses become nonlinear after the PGA of 1.8g. There are slightly plastic bending deformation on the flanges at the ends of member L3 and member L10. The maximum Y-displacement is 79mm at joint 24, equal to 1/11 pf the height of the shell. This means the displacement is too large for proper use of the roof.

(a) (b)

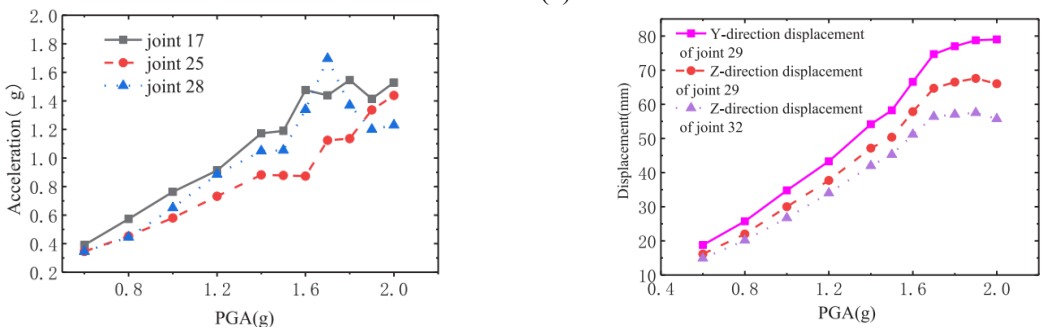

Figure 10. Responses of the cylindrical shell: (a) X-accelerations of joint 28, (b) Y-displacements of joint 29

(3) Collapse test

The CHY058 seismic wave leads to largest response to the shell. When the PGA reaches 0.9 g, the ends of member L10 breaks suddenly. The vertical displacement of joint 28 increases substantially, the slant members around it twist one after another, and a pit appears in a part of the latticed shell. As loading continues, the vertical displacement of the adjacent joints of joint 23 continues to increase, and the area of the pit further increases. Since the other member connected to joint 23 in the edge arch of the latticed shell breaks, the vertical displacement of joint 23 increases suddenly, and one side of the latticed shell collapses completely, as shown in Fig. 11.

(a) (b)

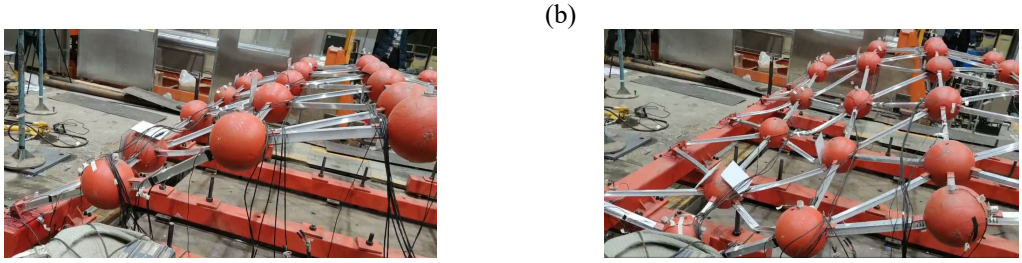

Figure 11. Collapse test of the cylindrical shell: (a) member broken, (b) Local collapsed

When the PGA is 2g, the displacement of the shaking table has reached its maximum limit. During the loading process, the maximum horizontal displacement of joint 29 is 79.06 mm, which is 1/45 of the model span. Besides, the vertical displacement is 62.02 mm, which is 1/53 of the model span (see Fig 9). When the PGA is 2.0 g, the proportion of members in the plastic stage is less than 5%, and the plastic development is concentrated in the four main stressed members at the edge arch of the latticed shell.

3.3.2. Single-layer spherical latticed shell

The Taft, El Centro and Manjil seismic waves are selected and applied to the model horizontally along Y direction. The test is divided into three stages, i.e., elastic stage, elastoplastic stage and collapse stage.

Before the shaking table test, the first six natural frequencies of the model were tested, which are 16.11Hz, 16.49 Hz, 16.60 Hz, 17.58 Hz, 18.07 Hz and 18.63 Hz respectively.

(1) Elastic stage test

The PGA of each seismic waves applied to the model increases from 0.1g to 0.6g by a step of 0.1g, during this stage all the members keep elastic. The acceleration and displacement responses of the latticed shell under Taft wave are shown in Fig. 12. It can be seen that the maximum acceleration is 1.5g, at joint 16 along Y direction. The vertical displacement of top joint is about 2.0mm, a very small value equal to 1/2000 of the span of the shell. The maximum stress is 42Mpa appearing on the member of the first top ring.

(2) Elastoplastic stage test

The peak accelerations and displacements under Taft wave from 0.7g to 2.0g are shown in Fig. 13. It can be seen that the responses increase nonlinearly, especially the displacement of joint 3, which increased greatly after the PGA of ground motion larger than 1.5g. The measures natural frequencies have also decreased than those of elastic stages. There are very slightly plastic bending deformation at the flanges of the ends of the outer members parallel to the Y direction. These mean the structure has entered the elastoplastic stage. But we have to say that this shell has have a very good seismic performance. The maximum vertical displacement under PGA of 2.0g is only 17mm, which is equal to 1/235 of the span.

(3) Collapse test

Because the shell is so 'strong' that there are only slightly plastic deformation under 2.0g. In order to study the how the latticed shell collapses under severe earthquake, some members of the shell are removed, as shown in Fig. 14.

(a) (b)

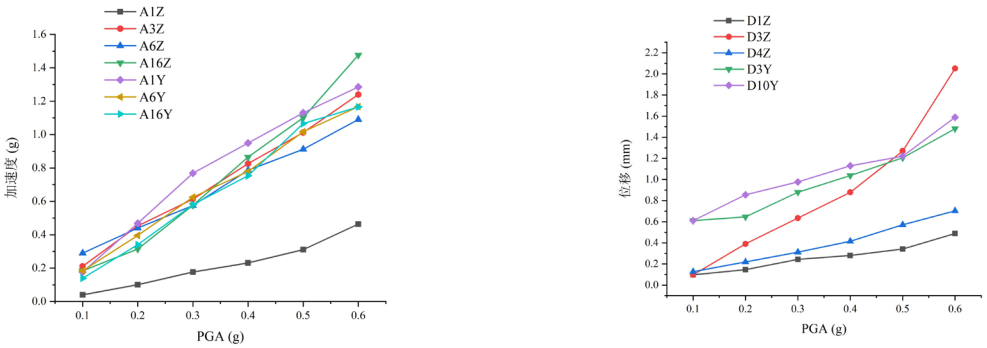

Figure 12. Seismic response of the shell in elastic stage under Taft wave: (a) Accelerations, (b) Displacements

(a) (b)

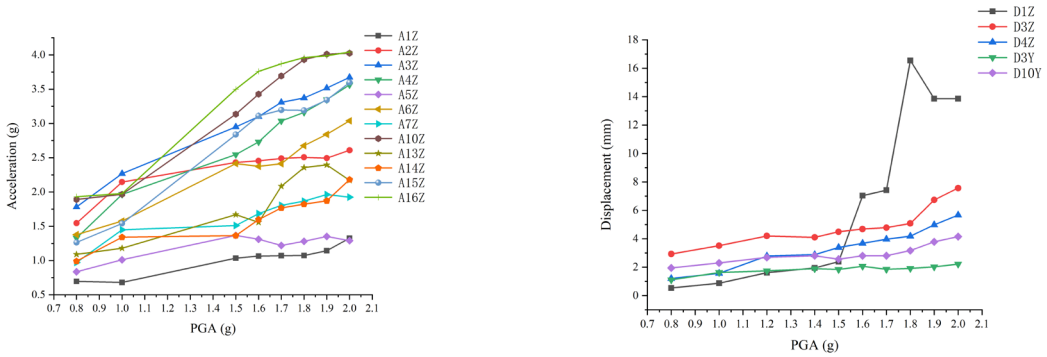

Figure 13. Seismic response of the shell in elastoplastic stage: (a) Accelerations, (b) Displacements

(a) (b)

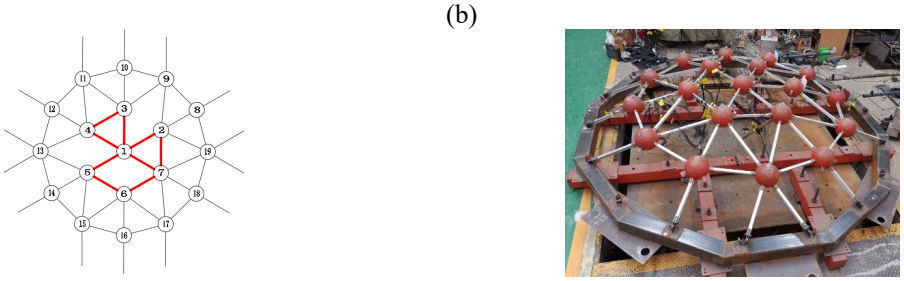

Figure 14. model with members removed for collapse test: (a) Plan, (b) model with members removed

The measured first natural frequency of the modified shell is 7.08Hz, and a sine wave with the frequency of 7.0Hz and PGA of 2.0g is applied to the model. Under the action of 2.0g ground motion, the lattice shell undergoes very significant deformation. Due to the instability of the top rib around the weak axis, the vertex torsion is caused, which in turn drives the six joints on the first ring to rotate; Under the combined action of axial force and weak axial bending moment, due to the significant difference in the moments of inertia between strong and weak axes and the cross-sectional form of the opening, a ring rod buckles in the plane of the shell, and the central flange of the rod is warped; Subsequently, the displacement of the vertex and the first ring joint diverged, causing the region to collapse. In view of the problem that H-shaped open sections are prone to buckling under compression and bending, it is recommended to pay attention to the slenderness ratio of the lattice shell members in engineering seismic design.

(a) (b)

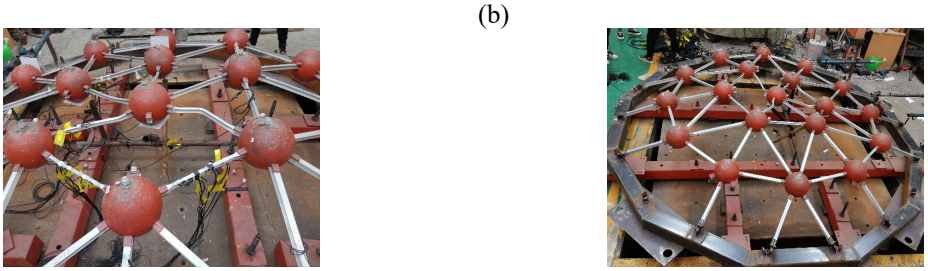

Figure 15. Collapse test of the shell: (a) member buckled, (b) Local collapsed

4. Numerical analysis of the seismic performance of single-layer aluminum alloy shells

4.1. FE model

A multi-scale modeling method combining the shell and beam element is adopted in ABAQUS software, the solid elements are used for connections . The constitutive parameters of the aluminum alloy material, considering the damage accumulation, are fitted by the material test, as shown in Fig. 15. The fitting of the stress-strain curves is compared with the material test data, as shown in Fig. 15b and 15c.

(a) (b) (c)

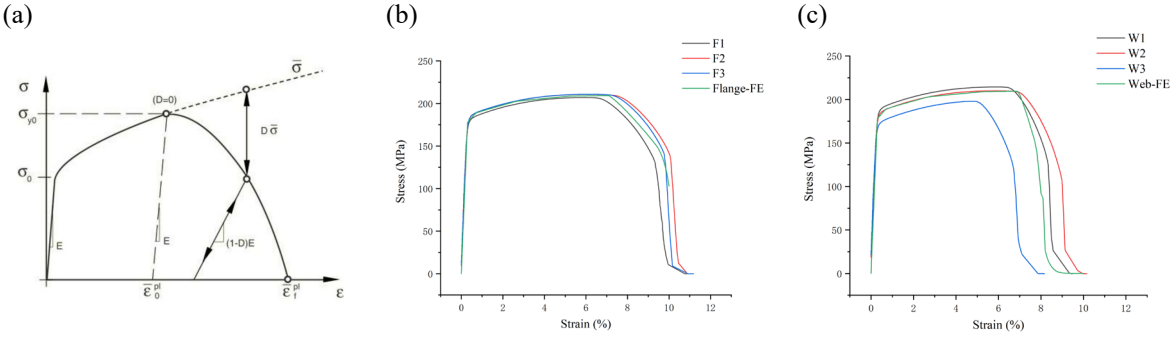

Figure 16. Numerical simulation of material test: (a) Stress-strain curve, (b) Flange sample, (c) Web samples.

Since the first ring in the latticed shell is the region with significant dynamic response, the radial members and ring members, here, are modeled using the shell element S4R. Moreover, the shear deformation beam element B31OS is applied to model the members except in the first ring, which considers the warpage of the open thin-walled cross-section. For steel ball joint, a discrete rigid body is used to simulate. In view of the tightness of the rivet connection, the connection between the members and the ball joint is regarded as a rigid one.

The shear deformation beam element B31OS is selected for component modeling. The joint sphere is modeled by a shell element, which is convenient for mesh generation and adopts a discrete rigid body simulation. The bearing connection is considered to be hinged. Rayleigh damping is implemented. According to the modal mass participation coefficient, the frequency and modal damping ratio of the first and fifth order are selected to calculate Rayleigh damping. The key members of the latticed shell model are L3, L5, L10, and L12. The material parameters and boundary conditions of the model are the same as those of the FE model based on the beam element. Only the above four members are modeled with the shell element.

4.2. Analysis of single-layer cylindrical latticed shell

The measured frequencies and mode shapes are in good agreement with the numerical results, with the maximum error is only 4%, as shown in Table 1.

Table 1. Frequencies and damping ratios of the latticed shell model

Order	1st	2nd	3rd	4th	5th	6th
Measured model frequency /Hz	2.20	5.37	6.34	9.03	9.77	11.71
Numerical model frequency/Hz	2.26	5.29	6.37	9.35	9.38	11.91

The displacement results of joint 29 of the latticed shell model in the severe earthquake stage obtained from the experiment and simulation are shown in Fig. 17a and 17b. Fig. 18 shows the comparison between the simulated and measured horizontal displacement of joint 26 and the stress of point 1-5. The results are in good agreement, and this means the FE model is accurate enough.

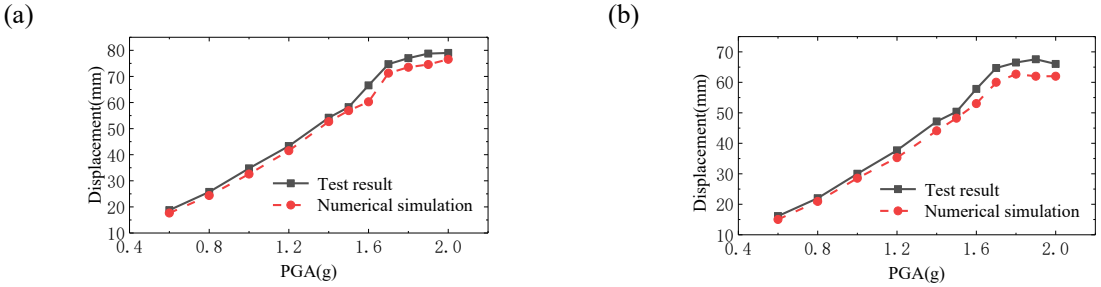

Figure 17. Displacement response comparison of joint 29: (a) Horizontal displacement of joint 29, (b) Vertical displacement

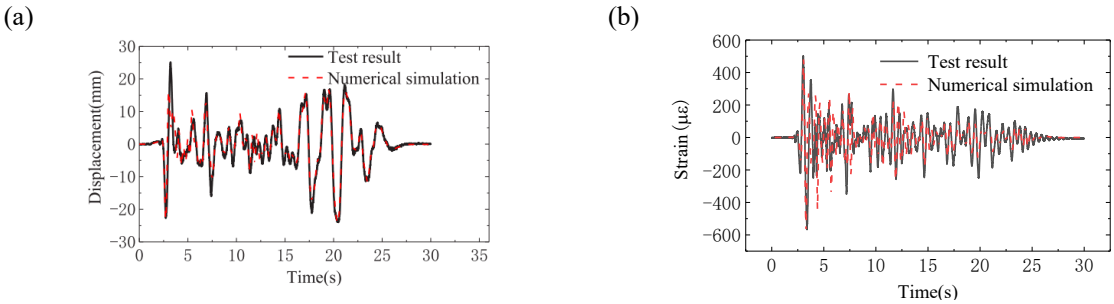

Figure 18. Time history response comparison: (a) Horizontal displacement of joint 26, (b) Strain of point 1-5.

Fig. 19 shows the calculation results of the FE model of the beam structure. The red line indicates that the member element has reached plasticity. The results show that the plastic development of the members is consistent with the test results. Before the first member broke and the lattice shell began to collapse, only four reinforcing members at the end of the lattice shell were monitored to enter plasticity, and the proportion of members entering plasticity was only 5% of all members. The rod with a relatively large cross-section undergoes end failure, while the rod with a smaller cross-section undergoes torsion failure. It is recommended to pay attention to the weakening of the member joint area and the influence of the member section on the member failure and the bearing capacity of the latticed shell during the seismic design of the latticed shell.

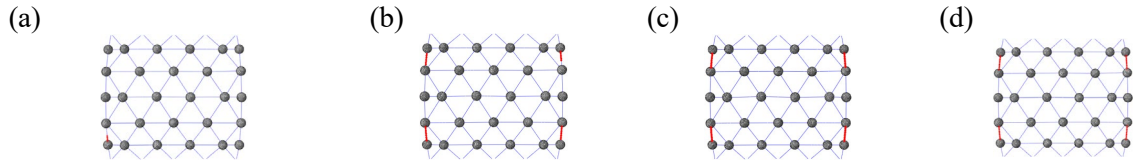

Figure 19. Plastic development: (a) PGA=1.3g, (b) PGA=1.4g, (c) PGA=1.6g, (d) PGA=2.0g。

4.3. Analysis of single-layer spherical latticed shell

The first six natural frequencies of the test and FE are listed in Table 2, the maximum error is about 2%.

Table 2. The first six order vibration frequencies of the test and FE

Order	1st	2nd	3rd	4th	5th	6th
Measured frequency (Hz)	16.11	16.49	16.60	17.58	18.07	18.63
Simulated frequency (Hz)	16.18	16.45	16.56	17.75	18.43	18.71

The displacement results of joint 3 in the elastoplastic stage, which are obtained from the experiment and simulation, are shown in Fig. 20a-b. Fig. 21a-b present four acceleration time-history comparison curves between numerical simulation and experiment under the Taft seismic ground motion with a PGA of 2.0g. Although the arrangement position of the accelerometers causes a measurement error, the simulated curves as well as the experimental curves are conforming in amplitude and shape, verifying the validity of the simulation method in the elastoplastic stage.

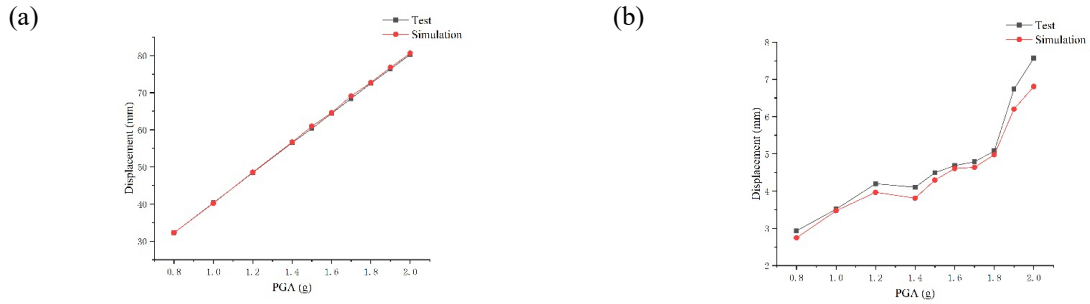

Figure 20. Displacement responses of Joint 3: (a) horizontal displacements, (b) vertical displacements.

(a) (b)

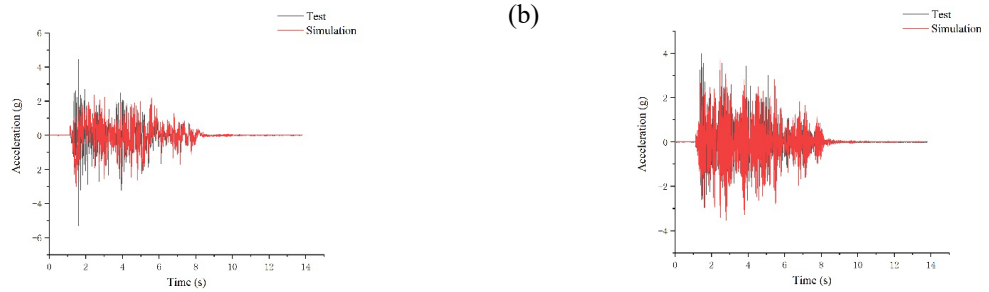

Figure 21. Acceleration measured and simulated of Joint 16: (a) horizontal acceleration, (b) vertical acceleration.

The time-history analysis in full load domain, is carried out on the FE model of test shell, whose plastic development process under the action of Taft seismic ground motion is listed, as shown in Fig. 22. The first ring of the latticed shell model is the region of plastic development.

(a) (b) (c) (d)

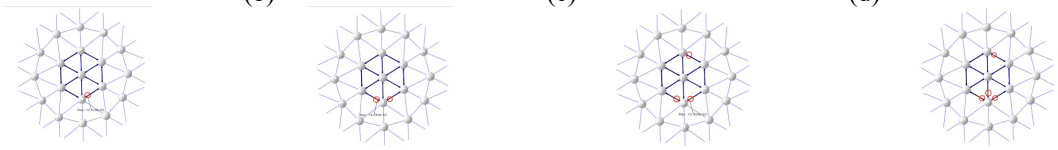

Figure 22. Plastic development process: (a) Taft-1.7g, (b) Taft-1.8g, (c) Taft-1.9g, (d) Taft-2.0g.

As can be seen from the figure, the deformation of the rod in the first ring of the model is the most obvious, manifested by the in-plane bending of the H-shaped rod and the in-plane rotation of the joint ball. Due to errors such as initial eccentricity and initial bending of the rod in the test model, the simulation results are inconsistent with the vertex rotation direction in the test phenomenon, but the plastic distribution and deformation of the simulation results are basically the same as those in the test.

(a) (b)

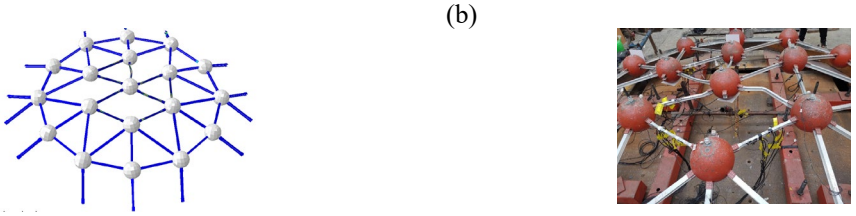

Figure 23. Failure mode comparison: (a) Finite element simulation, (b) Test model.

5. Conclusions

The seismic performance of single layer latticed shells was studied, especially the shaking table tests have been conducted. The following conclusions are drawn:

(1) The Chaboche hybrid strengthening model is reasonable to be used for the seismic analysis of aluminum alloy materials.

(2) The results of the shaking table tests indicates that aluminum alloy latticed shells have good seismic performance. But the displacement of the cylindrical shell is very big, due to the low Young's modulus.

(3) The multi-scale FE models are accurate enough to simulate the response of the shells, and the plastic development in the shells, and thus can be used to analyse the behaviour of the aluminum alloy latticed shells.

(4) the large displacement if the cylindrical shell suggested that besides the strength and stability of the structure, the displacement of the aluminum alloy cylindrical shells must be considered carefully during the design.

Abstract

Recently, aluminum alloy circular tubes have been widely utilized in the field of the grid, latticed shell, tubular truss, and bridge for its advantages of high strength–mass ratio, excellent corrosion resistance, and great durability. To improve the impact resistant performance of these aluminum alloy components, aluminum foam is employed as energy absorption filler in this study. Moreover, it is worth noting that the aluminum tubes are usually subjected to axial loads and the impact direction is perpendicular to the axis of the tube in practical engineering applications. Therefore, an impact test system which can realize the coupling of the lateral impact and axial force is developed to investigate the dynamic response of the aluminum foam-filled aluminum tubes. The failure modes, impact force histories, displacement histories, energy absorption, and permanent deformation of the foam-filled tubes were obtained and compared with those of the empty tubes under the same impact loading. In addition, the finite element (FE) model was also established via the software ANSYS/LS-dyna and the accuracy of the FE method was verified against impact test results. Based on the FE method, the influence of the axial force on the dynamic behavior of the aluminum foam-filled composite tube was analysed by consideration of the direction of the axial force (tension or compression) and the axial compressive ratio. The results show that axial tension benefits the impact resistance of the tube while the impact resistance of the tube is reduced by applying the axial compression. Furthermore, the adverse effect of the axial compression was weakened when the aluminum foam was employed.

Keywords: aluminum foam-filled, thin-walled tube, lateral impact resistance, energy absorption, axial compressive ratio, numerical simulation

1. Introduction

Aluminum alloy structures have the advantages of light weight, beautiful appearance, corrosion resistance, good processability, and high recyclability. Therefore, aluminum alloy is more widely used in the construction fields such as large-span space structure and bridge structure these days. However, these aluminum alloy structures are at the risk of accidental impact, which seriously threatens personal safety, property safety, and even social stability. Aluminum foam, which has the advantages of low density, high porosity, and high energy absorption ability, is widely utilized as filler in the field of protective structure for the purpose of energy dissipation [1]. Thus, to improve the impact resistant performance of the aluminum alloy tube employed in the construction field, filling aluminum foam is an effective way without significantly increasing the self-weight of the component.

The energy absorption performance of the aluminum foam-filled aluminum tube subjected to lateral loadings and bending has been widely studied [2-4]. However, all the above existing research on

mechanical properties, dynamic response, and energy dissipation of thin-walled metal tubes filled with aluminum foam is limited in the crashworthy structure utilized in the automobile, aircraft and astronautic, and military engineering, etc. Nowadays, study on the impact resistance of aluminum tubes utilized in the field of civil engineering under lateral impact has been carried out [5], whereas, in practical engineering applications, aluminum alloy members are usually subjected to axial forces (axial stretching or compression), which are ignored in the impact tests. Moreover, some researches on the influence of the axial preload on the dynamic response of the mild steel tubes have been published [6-9]. Zeinoddini et al. [6] carried out the impact tests on the cold drawn steel tubes, and the axial force was applied to the pipe before impact as a preload. Both the experimental and numerical results indicated that the axial force had a significant influence on the response of the pipe under the impact. Zhang et al. [7-8] conducted lateral impact test research on Q235 steel tubes with circular hollow section under axial preloads. "three plastic-hinge modes" were observed and the empirical formula for predicting the relationship between the displacement and impact force is proposed. Cui et al. [9] studied the dynamic behavior of the axially pre-loaded high-strength steel circular tubes under the lateral impact loadings, and detailly discussed the effect of the impact energy, diameter-thickness ratio, axial compression ratio, axial force direction, and shape of the hammerhead. However, the lateral impact resistant performance of the aluminum foam-filled aluminum tubes with axial preload have not been studied. Hence, in order to fill the gap in related research, the dynamic response of an axially preloaded aluminum alloy composite member under lateral impact is investigated in this paper.

In this study, lateral impact tests on 8 axially preloaded tubes and 2 tubes without axial preload are carried out to explore the dynamic behavior of specimens under the combined loadings. The deformation modes, impact force–displacement histories of the specimens were also investigated. Subsequently, an FE model based on ANSYS/LS-DYNA is established to reproduce the entire response process of the specimen. Besides, the simulation results of the specimens were compared with the test results to verify the accuracy of the FE model, and then the parameter analysis was conducted to investigate the influences of direction of axial force and axial compression ratio on the impact response performance of the axially preloaded empty tubes and composite tubes.

2. Materials and specimens

6082-T6 aluminum alloy and closed-cell aluminum foam are employed in this study, and the corresponding engineering stress–engineering strain relationships of the materials utilized is obtained based on the tensile tests on the aluminum alloy coupons and the uniaxial compression tests on the aluminum foam, respectively. In addition, the stress–strain relationship of the 6082-T6 aluminum alloy is described by the modified Johnson-Cook constitutive formula as follows [10]:

$$\sigma_{\mathrm{y}} = \left(A + B\bar{\varepsilon}^{\,p^{n}} + \sum_{i=1}^{2} Q_i \left(1 - \exp\left(-C_i \bar{\varepsilon}^{\,p} \right) \right) \right) \tag{1}$$

where σ_{y} represents the true stress; $\bar{\varepsilon}^{\,p}$ represents the effective plastic strain; A, B, n, Q_1, C_1, Q_2, C_2 are the material parameters. Furthermore, the stress–strain relationship of the closed-cell aluminum foam can be calculated by the equation as follows [11]:

$$\sigma = \sigma_{\mathbf{P}} + \gamma \frac{\varepsilon}{\varepsilon_{\mathbf{D}}} + \alpha \ln\left(\frac{1}{1 - \left(\varepsilon / \varepsilon_{\mathbf{D}} \right)^{\beta}} \right) \tag{2}$$

where σ and ε represent the true stress and the true strain of the aluminum foam, respectively; σ_{p} represents the foam plateau stress; ε_{D} represents the foam true complete compaction strain, which is obtained by Eq. (3); α, β, and γ are the fitting parameters. The material parameters of the aluminum alloy and the aluminum foam are listed in Table 1.

$$\varepsilon_{\mathbf{D}} = 1 - \rho_{\mathbf{f}} / \rho_{\mathbf{Al}} \tag{3}$$

where ρ_{f} and ρ_{Al} represent the density of the aluminum foam and its base material, respectively.

In the experimental study of this work, 10 specimens with axial preload are lateral impacted to investigate the dynamic performance of the empty tube and the composite tube under the combined axial compression/tension and lateral impact load. Besides, to obtain the dynamic response of the specimen with various parameters which include the direction of the axial force (tension or compression), axial compressive ratio, and impact energy, numerical studies are also carried out. The span of all the specimens is 900 mm, and the impact position is located at the mid span of the tube. A wedge hammer with a weight of 147 kg is utilized for all the tubes. The code of the specimens and the corresponding load condition are given in Table 2 and Table 3. The contents "ET" and "CT" in the first part of the codes represent the empty tube and composite tube, respectively. And the number "1" and "2" in the first part of the codes represent different section sizes of the aluminum tube, i.e., the specimens with number "1" have an outer diameter of 89 mm and a wall thickness of 4 mm, and the specimens with number "2" have an outer diameter of 89 mm and a wall thickness of 5 mm. The letters "C" and "T" in the second part of the codes represent the axial compressive preload and the axial tensile preload, respectively, while the number "0.2/0.4/0.6" indicates the ratio μ of the axial preload to the axial bearing capacity N (calculated by Eq. (4)) of the fully plastic section of the tube. Moreover, the number "4.8/6.8/9" in the last part of the code represents the initial impact velocity.

$$N = \frac{\pi D^2}{4} t\sigma_{0.2} \tag{4}$$

where D and t are the outer diameter and the wall thickness of the tube, respectively; $\sigma_{0.2}$ represents the yield stress of the aluminum alloy.

3. Experimental and numerical method

A drop hammer impact system is employed to carry out the local lateral impact tests on the aluminum foam tube, as shown in Fig. 1. The loading device can be divided into two parts: axial loading device

and lateral impact device. A 100 t jack is utilized for the axial preload, while a wedge drop hammer with a weight of 143 kg is applied for the lateral impact. It is worth to point out that the axial force may suddenly drop during the impact process, which is because that axial compression deformation of the tube occurs after the drop hammer contacts to the tube. Therefore, to provide a more stable axial load during the impact process, an energy accumulator is utilized. With regard to the boundary condition of the tube, fixed end is applied for one side of the tube, and a sliding boundary is applied for another side of the tube. Both the impact force and the static axial force are recorded by the load cell, as shown in Fig. 1. The sample frequency of the axial force and the impact force are set as 10^3 Hz and 10^5 Hz, respectively, because that the duration of the axial force was much longer than that of the impact force. Moreover, the whole impact process was recorded by a high-speed camera with a sample frequency of 3200 Hz.

A half finite element (FE) model is established based on the ANSYS/LS-dyna considering the computing efficiency. The modified Johnson-Cook model and the crushable foam model are respectively utilized to simulate the aluminum alloy and the aluminum foam in this FE model, and the corresponding material parameters are listed in Table 1. Considering the low-velocity impact is used for the drop hammer impact tests, the strain rate effect of the aluminum alloy and the aluminum foam is neglected in the numerical simulation. The rigid mat is employed for the other part of the FE model, including the holding device, the end plate, the wedge hammer head, and the counterweight. With regard to the aluminum alloy tube, shell element is employed, while solid element is used for the other part of the model. The mesh size of the aluminum foam tube wall is set as 2×10 m^2 and refined to 2×2 m^2 in the part of the composite tube which is near the impact position. Furthermore, the same densification area of the mesh size is applied for the aluminum foam, and the mesh size of the aluminum foam filler is determined as $10 \times 2 \times 2$ m^3 and refined to $2 \times 2 \times 2$ m^3. To simulate the fixed boudary of the side of the tube and the sliding boudary of the another side, the nodes of the holding device and the end plate are constrained. And the tied contact is utilized to simulate the contact between the tube wall and the end plate, while the surface to surface contact is employed to simulate the contact between the tube wall and the aluminum foam, the contact between the wedge hammer and the tube wall, the contact between the holding device and the tube wall.

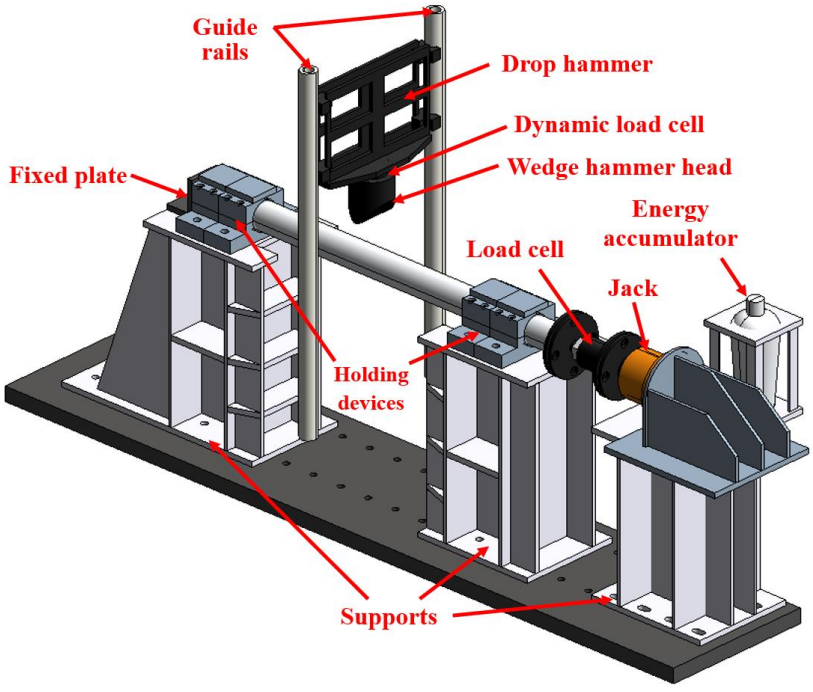

Figure 1. Test setup.

A two-step loading method is applied in the FE model to simulate the static axial load and the lateral impact loading. Firstly, the axial tension or compression is simulated via the implicit analysis module in ANSYS. The node coordinates and the stress state of the elements are recorded in a 'drelax' file for the next step. Secondly, the corresponding file is read in the explicit code ANSYS/LS-dyna the impact load is simulated by applying initial velocity to the drop hammer via the keyword *INITIAL_VELOCITY. Figure 3 shows the comparison of the permanent deformation of the specimens between the experimental and numerical results, and the comparison of the impact force–displacement curves between the experimental and numerical results is plotted in Fig. 4. In addition, the calculated average ratio of the FE results to the test results for F_{max} and D_{max} are 1.031 and 1.059, respectively Therefore, the numerical method proposed in this work can accurately predict the dynamic response of the composite tube under the combined load.

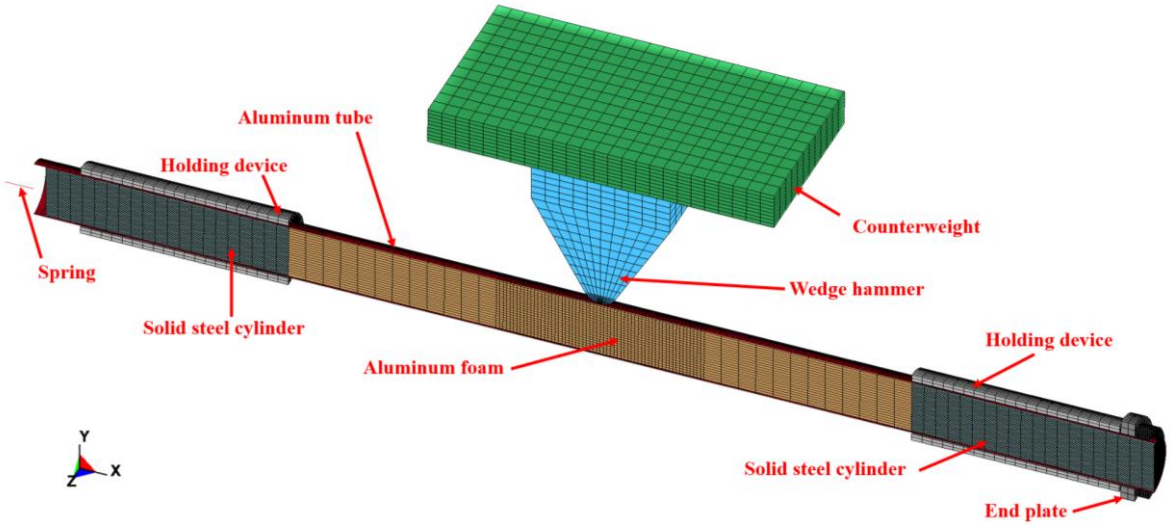

Figure 2. Half FE model.

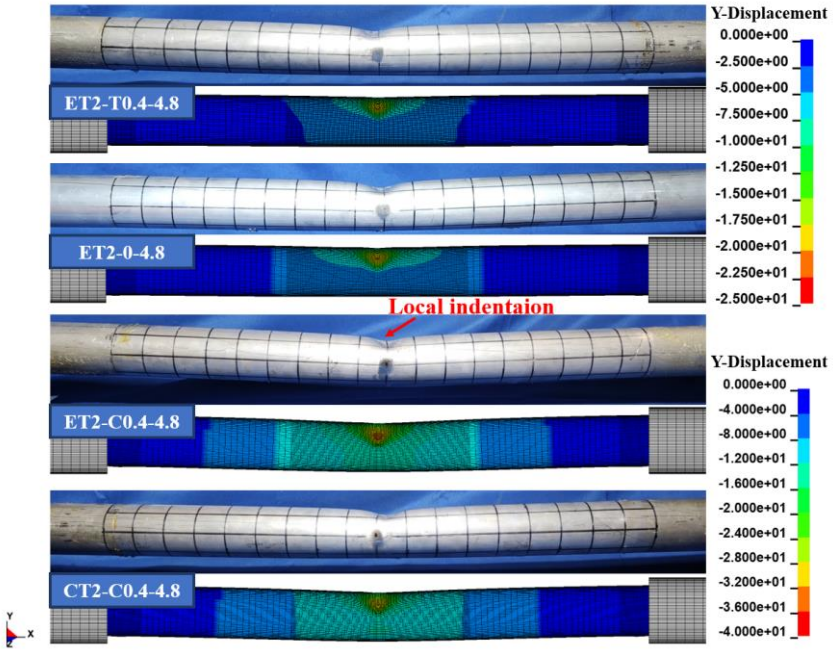

Figure 3. Permanent deformation of the specimens.

4. Influence of axial preloads on the dynamic behavior of the tubes

The permanent deformation of the tested tubes is shown in Fig. 3. It can be observed that the deformation of the tube is composed of the local indentation near the impact position and the global bending of the whole span of the tube. Moreover, the impact force–displacement of hammer head curves are recorded, as plotted in Fig. 4. The results show that the empty tube and the composite tube exhibit the similar impact process under the combined load. The impact force quickly rises at the beginning of the impact process, as well as the displacement of the hammer head is limit at this stage. At the following stage, the growth rate of the impact force–displacement of hammer head curve gradually decrease. When the velocity of the drop hammer reaches zero, the total initial kinetic energy (*KE*) of the hammer is transmitted to the tube, and then the elastic recovery of the tube occurs. The influence of different axial forces on the deformation is detailed discussed in the following subsection.

To investigate the effect of the direction of the axial force (tension or compression) and the axial compressive ratio on the dynamic response of the composite tube and the empty tube under the combined loadings, the parameters analysis is carried out by the numerical method. The results of the numerical study are given in Table 3. Besides, the response of the composite tube and the empty tube discussed in the following subsections are described as follows: the impact resistance of the composite tube and the empty tube can be compared by their maximum displacement $D_{\max}$ at the same impact energy; the depth of the permanent local indentation of the tube ΔD_{per} can be obtained by Eq. (5); the energy absorption ability of the composite tube and the empty tube is evaluated by integrating the impact force–displacement curves, while the integral interval is [0,40], as given in Eq. (6).

$$\Delta D_{\text{per}} = \left| D_{\text{h-per}} - D_{\text{b-per}} \right| \tag{5}$$

where $D_{\text{h-per}}$ and $D_{\text{b-per}}$ represent the permanent displacement of the top and the bottom point of the cross section at the impact position, respectively.

$$\text{EA}_{40\text{mm}} = \int_0^{40} F \text{d}\delta \tag{6}$$

where F and d represent the impact force and the corresponding displacement of the hammer head, respectively.

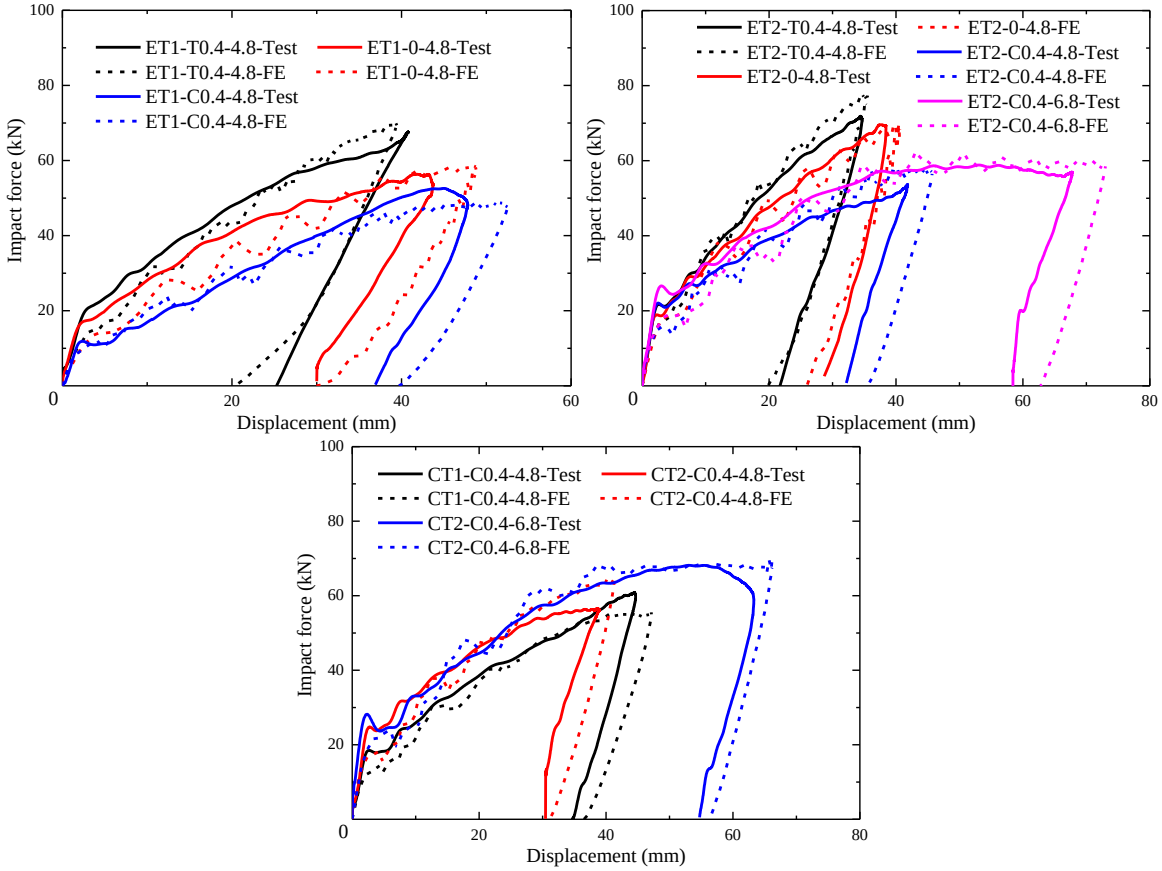

Figure 4. Comparison of the impact force–displacement curves between the experimental and numerical results.

4.1. Effect of the direction of the axial force

Both the axial tensile and axial compressive preloads are applied to the aluminum foam-filled tubes and the empty tubes before the beginning of the impact process in this discussion. In addition, the tubes without axial preload are also considered. All the tubes discussed in this subsection have the same section size, and the outer diameter and the wall thickness are 89 mm and 5 mm, respectively. The initial impact velocity of the hammer for all the tubes is set as 6.8 m/s. Furthermore, the ratio μ of the axial force to the axial bearing capacity N is 0.4 for the tubes with axial preload (T0.4 and C0.4 in Fig. 5 represent the axial tension and axial compression, respectively).

Figure 5 shows the comparison of the dynamic response of the composite tubes and the empty tubes with different axial force directions. It is observed that the influence law of the axial direction force on the behavior of the composite tube and that of the empty tube is similar. As shown in Fig. 5, the D_{max} of the composite tube increases from 56.71 mm to 66.18 mm when the axial force changes from 0 to C0.4, while the D_{max} decreases from 56.71mm to 50.17 mm when the axial force changes from 0 to T0.4. Therefore, it can be indicated that the axial tensile preload benefits the impact resistance of the tube while the impact resistance of the tube is reduced by applying the axial compression. Moreover, the depth of the local indentation is also improved by 15.8% (changed from 25.35 mm to 29.36 mm) after the axial compressive preload is applied, which leads to a more serious defect at the impact location, thereby further affecting the axial bearing capacity of the tube member after impact. The energy absorption EA_{40mm} of the composite tube decreases from 2434.6 J to 1757.8 J when the direction of the axial force changes from tensile to compressive, as shown in Fig. 5(c). In addition, the effect of the aluminum foam filler is also investigated, as plotted in Fig. 5. It can be found that filling the aluminum foam will reduce the deformation of the tube under the lateral impact loading, i.e., the reduction of D_{max}

and ΔD_{per} are 4.11 mm and 3.37 mm after the aluminum foam is filled when the axial preload is not applied. Moreover, the reduction of the deformation by filling the aluminum foam is more obvious when the axial compressive preload is applied, while little change in the reduction of the deformation is observed compared with the corresponding value of the tube without preload for the tubes which are axially tensile. In addition, the effect of filling aluminum foam into the empty tube on the EA_{40mm} is almost unchanged for the tubes with various axial preload.

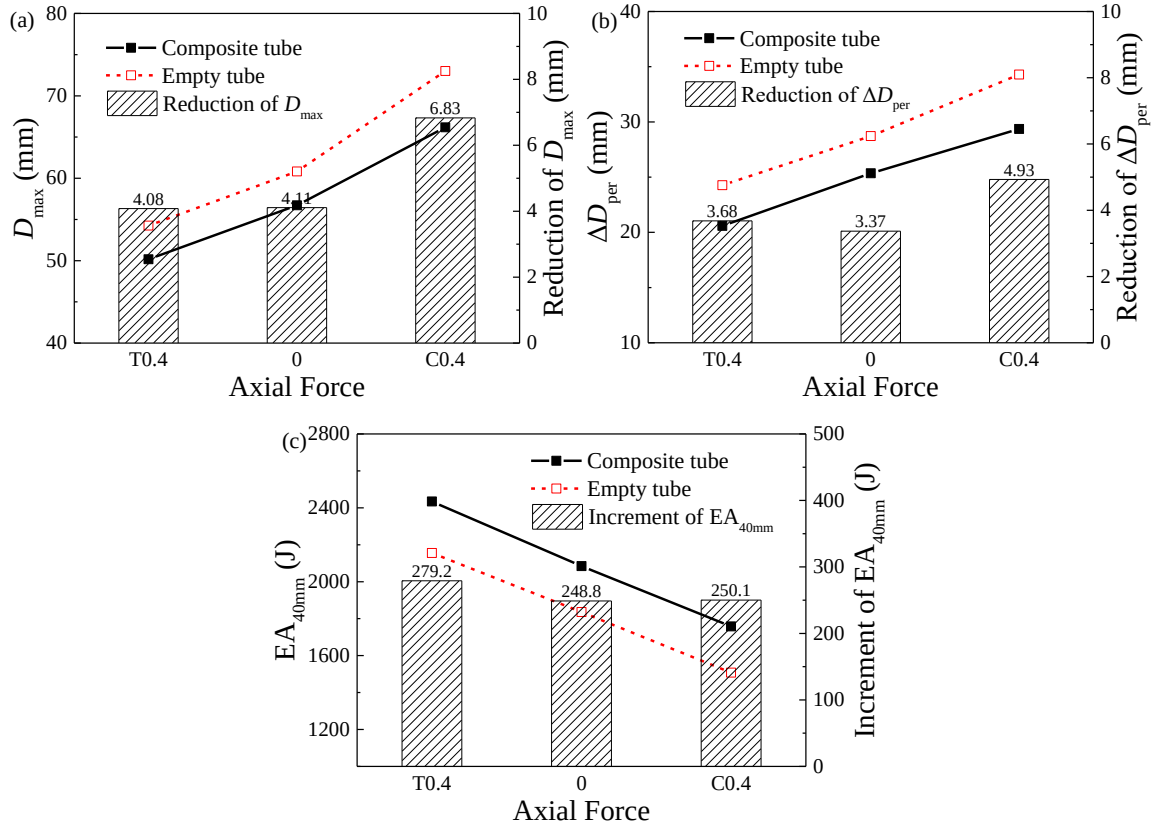

Figure 5. Effect of direction of the axial force on the dynamic response of the composite tube and the empty tube: (a) maximum displacement D_{max}, (b) permanent local indentation depth ΔD_{per}, and (c) energy absorption EA_{40mm}.

As shown in Fig. 6, the X-stress contours on the composite tube surface at the moment of impact completion are used to investigate the effect of the axial force on the residual stress. Compared with the axially tensile preloaded tube, the compression zone appears in the span and near the clamp for the tube subjected to axial compression preload. For all the tubes, the tensile stress concentration area mainly appears at the impact location. In addition, the tensile stress area of the tube under axial tension is larger than that of the tube under axial compression.

4.2. Effect of the axial compressive ratio

It is found in the above subsection that the combination of the axial compression and the lateral impact loading is the most unfavorable state, and the effect of filling aluminum foam on the axially tensile preloaded tube is close to that on the tube without axial preload. Thus, only the tubes which are axially compressive are discussed in this subsection. Three different axial compressive ratios (0.2/0.4/0.6) are employed to investigate the influence of the axial compressive ratio on the lateral impact resistance of the composite tube and the empty tube. All the tubes have an outer diameter of 89 mm and a wall thickness of 5 mm, and the initial impact velocity is 6.8 m/s.

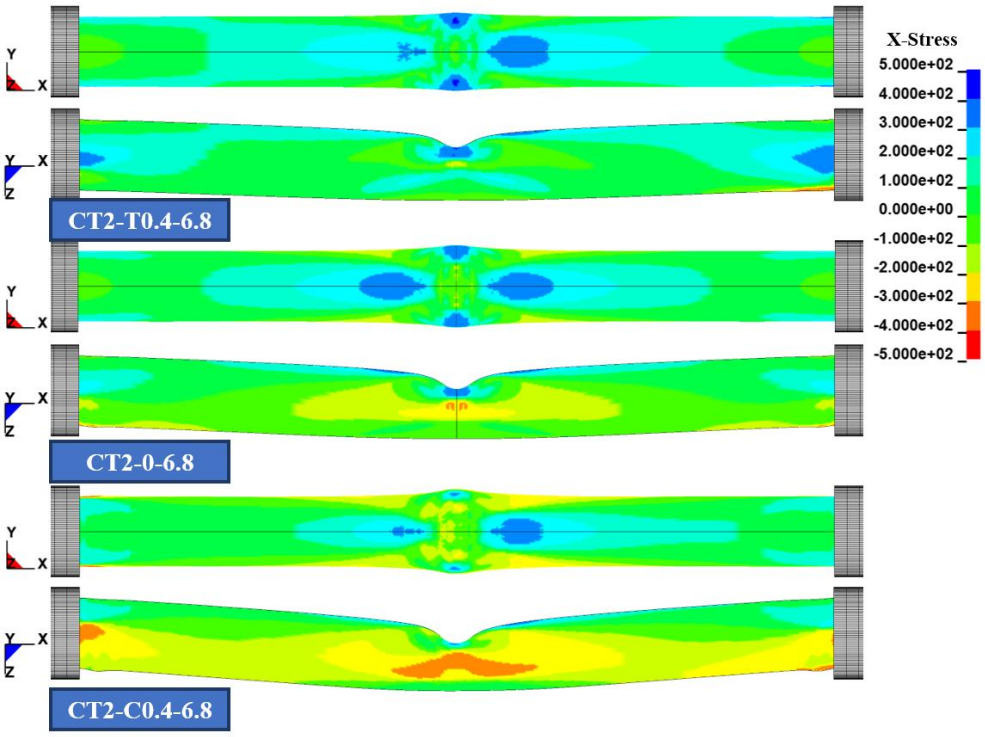

Figure 6. Contours of the residual stress of the composite tubes under different axial preloads.

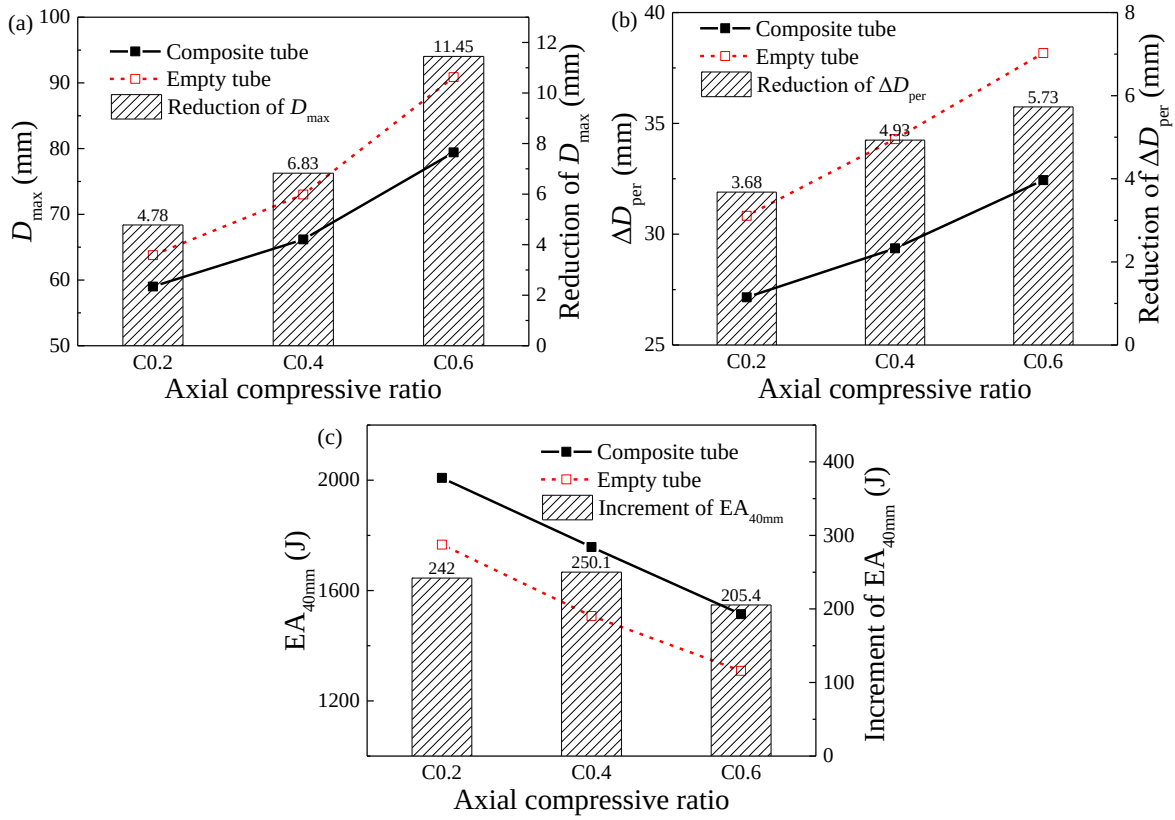

Figure 7. Effect of direction of the axial compressive ratio on the dynamic response of the composite tube and the empty tube: (a) maximum displacement D_{max}, (b) permanent local indentation depth ΔD_{per}, and (c) energy absorption EA_{40mm}.

As shown in Fig. 7(a) and 7(b), with the axial compressive ratio increases from 0.2 to 0.6, the maximum displacement D_{max} of the composite tube is improved by 34.6% (changes from 59.01 mm to 79.43 mm), and the local indentation depth ΔD_{per} is improved by 19.5% (changes from 27.15 mm to 32.44 mm). Furthermore, the influence by filling the aluminum foam into the empty tube also becomes more obvious with the increment of the axial compressive ratio, i.e., the reduction of D_{max} increases from 4.78 mm to 11.45 mm when the axial compressive ratio increases from 0.2 to 0.6, and the corresponding reduction of ΔD_{per} increases from 3.6 mm to 5.73 mm. The energy absorption EA_{40mm} of the tube decreases with the axial compressive ratio increases, which indicates that higher axial compressive preload will reduce the energy absorption of the tube subjected to lateral impact loadings.

In addition, as shown in Fig. 8, with the axial force changed from T0.4 to C0.6, the effective plastic strain of the tube wall with large deformation at the impact position significantly increases (the area of the dark red part increases). Furthermore, the filled aluminum foam shows an obvious influence on the plastic strain of the tube wall at the impact position, the value of the effective plastic strain decreases in the large deformation region of the tube wall, which can explain that filling the aluminum foam can inhibit the initiation and propagation of cracks near the impact region of the aluminum tube.

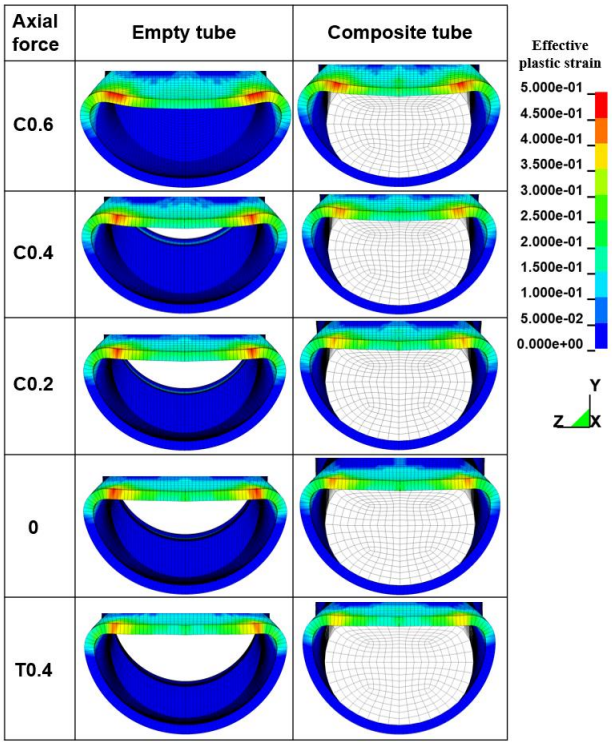

Figure 8. Contours of the plastic strain of the aluminum tube wall under different axial preloads.

5. Conclusion

In this work, the dynamic behavior of the axially preloaded empty aluminum tube and aluminum foam-filled composite tube were investigated by the experimental and numerical studies. The following observations and conclusions can be extracted from this study:

(1) The axially preloaded composite tube and the corresponding empty tube subjected to the lateral impact loading exhibit a combined deformation mode, including the local dent near the impact position and the global bending of the whole span of the tube.

(2) The maximum displacement of the tube D_{max} and the permanent local indentation depth ΔD_{per} decrease when the axial tensile preload is applied, indicating that the impact resistance performance of

the specimens with axial tension is improved. Instead, the axial compressive preload weakens the lateral impact resistance of the tube. Furthermore, filling aluminum foam can reduce the adverse effect of the axial compression force, i.e., both the D_{max} and ΔD_{per} decreases by filling aluminum foam into the empty tube.

(3) With regard to the axially compressive preloaded tube, its impact resistant performance decreases with the axial compression ratio increase, and the D_{max} and ΔD_{per} are improved by 34.6% and 19.5% with the axial compressive ratio increases from 0.2 to 0.6. Besides, the supporting effect of filled aluminum foam on the tube wall is more obvious with the increase of axial compression ratio.

(4) Compared with the empty tubes, aluminum foam-filled tubes exhibit better energy absorption capacity, whereas the improvement of energy absorption by filling aluminum foam is slightly affected by the direction of the axial preload and axial compression ratio.

Abstract

With the increasing demand for isolated long-span spatial structures, we proposed a type of curvature-consistent frictional pendulum isolation system that may induce notable seismic isolation effects in long-period and long-span spatial structures during rare earthquakes in this study. Taking the isolation system as the research object, a series of mechanical performance tests were carried out. The hysteretic characteristics and energy dissipation mechanism of the isolation system were analysed, and a refined numerical simulation method was established. The accuracy of the simulation method was verified by comparing the simulation results with experimental results. The isolation system was applied to a double-layer spherical reticulated shell structure, and the dynamic time history response of the structure was analysed. The results indicated that compared with classical friction pendulum bearings, according to the mechanical properties of the isolation system, the proposed curvature-consistent friction pendulum isolation system has excellent isolation performance and energy dissipation capacity, and the isolation system is more suitable for long-span structures. It has a good isolation effect for double-layer spherical reticulated shell structure, and the isolation effect is more effective when subjected to large earthquakes and rare earthquakes.

Keywords: curvature-consistent frictional pendulum isolation, double-layer spherical reticulated shell, mechanical performance tests, isolation performance, energy dissipation

1. Introduction

The classical friction pendulum bearing, a type of sliding isolation bearing, prolongs the natural vibration period of superstructures by adjusting the slider on the sliding surface of the chute, thereby weakening the seismic response of the structure under the action of external excitation. Considering the FPB characteristics of low sensitivity to seismic input frequency range, strong self-reset ability, and excellent isolation energy dissipation [1], it has become one of the most widely used and technologically mature isolation devices in the construction of buildings and bridges worldwide. Considering its mechanical properties, the FPB exhibits good hysteresis ability [2]. In previous studies, FPBs have typically been used in traditional multilayer and bridge structures [3-5], and the seismic response of structures is significantly reduced [6,7].

The isolation performance of the classical friction pendulum bearing is primarily determined by the friction coefficient and radius of curvature of the sliding surface. However, because the classical friction pendulum bearing is limited by its own size parameters, the seismic isolation effect of a structure with the characteristics of a long natural vibration period and encountering rare earthquakes is limited. Therefore, researchers have proposed some improved friction pendulum bearings [8-10]. If the curvature radius of the sliding surface or the number of sliding surfaces of the chute is increased to improve the isolation of a structure, the self-resetting ability of the isolation layer decreases, and the superposition of the residual displacement of the isolation layer affects the isolation performance of the classical

friction pendulum bearing. In this study, we developed a curvature-consistent frictional pendulum bearing (CC-FPB), which is suitable for long-span spatial structures. An isolation system composed of an annular array of CC-FPBs can afford sufficient seismic isolation and has short self-resetting time, as illustrated in Figure 1. Under static force, the outermost ring members of the upper shell structure primarily act to balance the outwards horizontal thrust of the structure. Conventional isolation bearings have low stiffness and thus reduce the horizontal restraint force of the outermost ring members. When the friction surface of the CC-FPB is mounted on a spherical surface with the same large radius of curvature as the friction surface, each slider of the CC-FPB is initially mounted at a certain angle. The sliders have a horizontally constraining effect on the superstructure, thereby causing the structure to slide on the spherical surface during strong earthquakes.

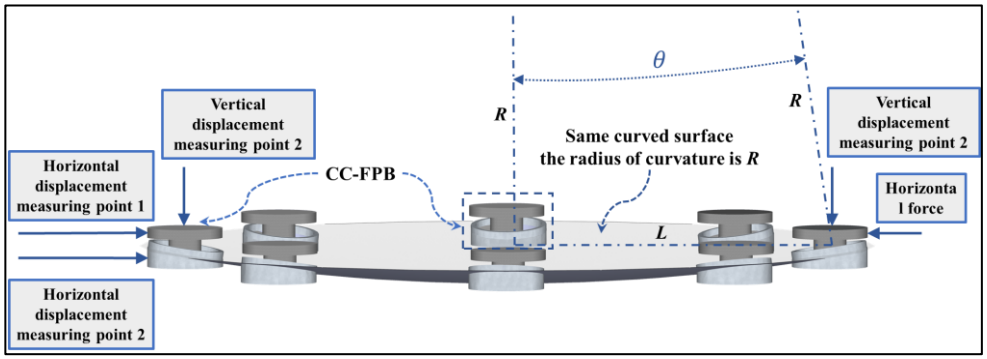

Figure 1. Arrangement of CC-FPBs.

The hysteresis curve of the CC-FPB was obtained by performing hysteresis tests and combining it with the theoretically deduced restoring force formula. The hysteresis characteristics and isolation energy dissipation mechanism were analysed. In addition, the variation of various mechanical performance indexes of the CC-FPB with loading conditions were characterized. To validate the accuracy of the hysteresis test and the feasibility of subsequent research, we developed a refined simulation method for 3D solid element modelling. According to the proposed refined simulation method, we applied CC-FPBs to a long-span spatial structure and analysed the seismic isolation effect and mechanism in the long-span spatial structure.

2. Hysteresis test of CC-FPB

In this study, a hysteresis test of a group of CC-FPBs was carried out to verify the hysteresis performance of the proposed bearing and to explore the variation of various mechanical performance indexes with vertical pressure, loading frequency, and displacement amplitude.

2.1. Test model design

The test model consisted of two CC-FPBs and a loading beam. The loading beam was used to connect the two CC-FPBs, and the loading beam was used to apply vertical pressure and caused loading displacement to the two CC-FPBs (Figure 2.). The total length of the loading beam was 3600 mm, and the loading beam was welded with the two CC-FPBs. The jack was located at the centre of the loading beam and moved and rotated with the loading beam. The jack moved when the loading beam moved along the direction of the actuator, and the pressure head rotated by 360° with the loading beam. The CC-FPBs were lifted by the ground beam to the horizontal position of the actuator. The height of the ground beam was 400 mm, and the height of the centre of the actuator was 1000 mm. The CC-FPB was fixed on the pedestal by using ground anchors that were separated by a distance of 1000 mm. The actuator and the loading beam were connected using a connector. The actuator was extended by half in the initial state to ensure normal reciprocation. During the test, different degrees of vertical pressures were applied through the jack, and various loading frequencies and displacements were applied through

the actuator. The overall test model is displayed in Figure 3. During the test, the lateral support ensured that the loading beam did not sway or twist.

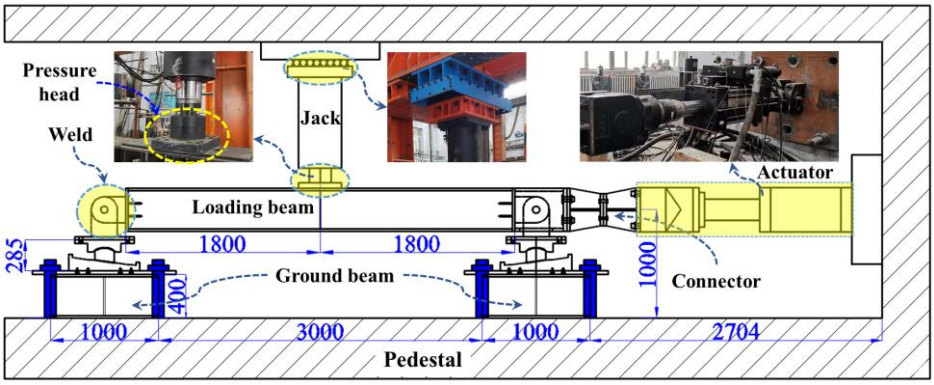

Figure 2. Test device diagram.

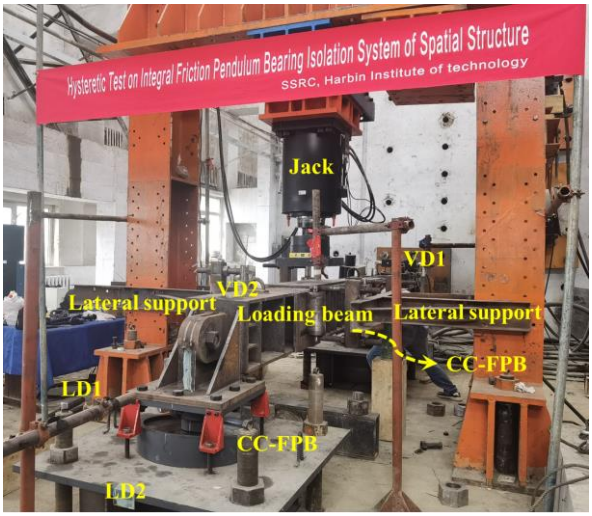

Figure 3. Overall test model.

Linear variable differential transformers (LVDT) were used to measure the horizontal and vertical displacements of the chute and cover plates of the CC-FPB. The layout positions are shown in Figure 4. To eliminate the slight displacement of the loading beam caused by the loosening of the ground anchors, the horizontal displacement of the cover plate and the ground beam were measured by horizontal displacement meters LD1 and LD2, respectively, and the vertical displacements of the left and right bearings were measured using vertical displacement meters VD1 and VD2, respectively.

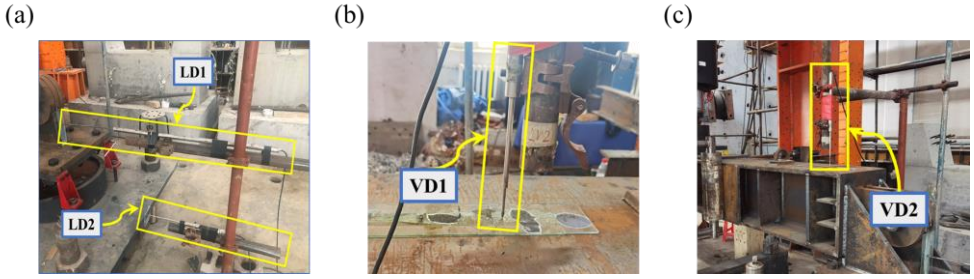

Figure 4. Location of the points of measurement: (a) LD1 and LD2, (b) VD1 and (c) VD2.

The loading system follows the sine wave loading, and the horizontal displacement was loaded according to Equations (1) and (2), respectively. The loading conditions are shown in Table 1, which is represented by vertical pressure-displacement amplitude-loading frequency.

$$d(t) = d_x \sin(2\pi f_0 t) \tag{1}$$

$$f_0 = v_0 / 2\pi d_x \tag{2}$$

Table 1. Loading conditions.

Number	Condition	Number	Condition	Number	Condition	Number	Condition
1	200-67-0.01	9	400-67-0.05	17	600-50-0.09	25	600-100-0.01
2	200-67-0.03	10	400-67-0.07	18	600-50-0.1	26	600-150-0.01
3	200-67-0.05	11	400-100-0.01	19	600-67-0.01	27	800-67-0.01
4	200-67-0.07	12	400-150-0.01	20	600-67-0.03	28	800-67-0.03
5	200-100-0.01	13	600-50-0.01	21	600-67-0.05	29	800-67-0.05
6	200-150-0.01	14	600-50-0.03	22	600-67-0.07	30	800-67-0.07

2.2. Hysteresis curve

The theoretical model of the bearing can be obtained according to the working principle of the CC-FPB (Figure 5), where K_{eff} denotes the equivalent stiffness, K_{fpb} denotes the swing stiffness, R denotes the radius of the curvature of the spherical surface, D denotes the horizontal displacement of the bearing, L denotes the offset distance of the slider, μ denotes the friction coefficient and G denotes the vertical gravitational force acting on the slider.

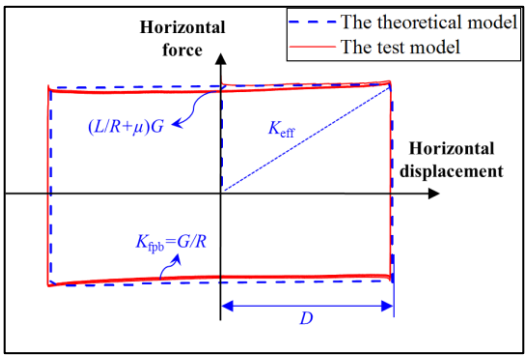

Figure 5. Theoretical model and experimental hysteresis curve.

3. Analysis of test results

The average cycle energy consumption (ACEC), average equivalent stiffness (AES), equivalent dynamic friction coefficient (EDFC), and equivalent damping ratio (EDR) were used as the main indexes to analyse the mechanical performance of the CC-FPB. The average value of the area enclosed by each hysteresis curve was the ACEC, the average value of the antilateral movement of each hysteresis curve was the AES, the EDFC was obtained by calculating the initial restoring force and vertical pressure, and the EDR was calculated according to the ACEC and AES. The mechanical performance indexes were normalised using Eq. (3).

$$V = \frac{x_i}{x_{\max i}} \tag{3}$$

where V is the normalised mechanical performance, x_i is the corresponding parameter value in Group, and $x_{max \cdot i}$ is the maximum parameter value under all working conditions in this group. Based on Eq. (3), the normalised ACEC is V_W, the normalised AES is V_K, the normalised EDFC is V_μ, and the normalised EDR is V_ζ.

3.1. Variations in mechanical performance indexes with vertical pressure

Considering the loading conditions listed in Table 2 as an example, the variation of various mechanical performance indexes with vertical pressure was studied, while the loading frequency and displacement amplitude remained constant

Table 2. Loading condition A.

	Group 1	Group 2	Group 3	Group 4
Loading frequency (Hz)	0.01	0.07	0.01	0.01
Displacement amplitude (mm)	67	67	100	150
Vertical pressure (kN)	200, 400, 600, 800	200, 400, 600, 800	200, 400, 600, 800	200, 400, 600, 800

The hysteresis curves obtained from the four groups of tests under loading condition A were processed, and the normalised mechanical performance indexes are shown in Figure 6. With an increase in vertical pressure, AES increased significantly, and the maximum increment was 60%; ACEC increased significantly, with a maximum value of 57%; EDFC decreased significantly, with a maximum decrease of 48%; and EDR changed little. In conclusion, the vertical pressure significantly influenced the isolation performance and energy dissipation capacity of the CC-FPB. The friction force of the slider was proportional to the vertical pressure, and the external force required for the slider to slide increased with the increase in the vertical pressure. Therefore, the equivalent stiffness and cycle energy consumption of the bearings increased. When the same excitation was applied, the isolation performance decreased with an increase in vertical pressure. Therefore, in the actual engineering isolation design, to ensure that the isolation bearing can give full play to its seismic isolation effect, it is necessary to consider setting a sufficient number of isolation bearings in the isolation layer to ensure that the vertical pressure acting on a single bearing will not affect the normal operation of the entire isolation system.

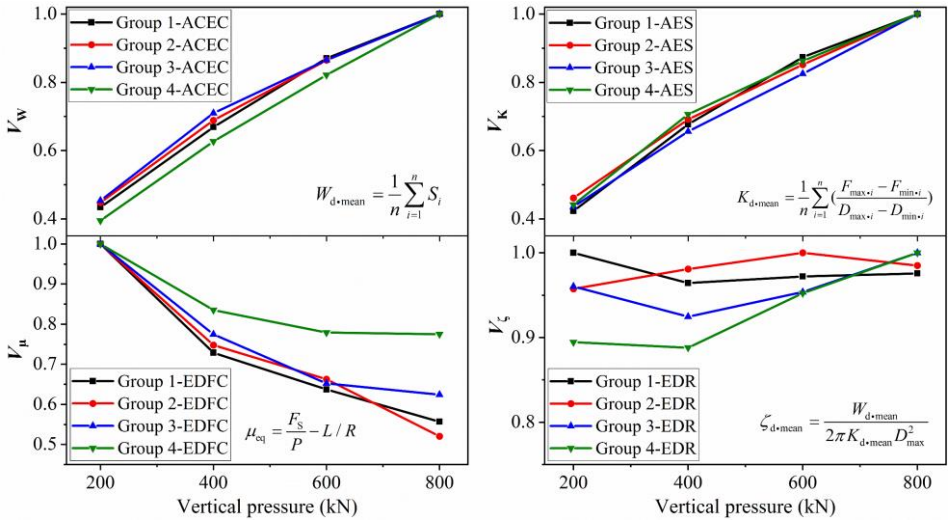

Figure 6. Variations in various mechanical indexes with vertical pressure.

3.2. Variations in mechanical performance indexes with loading frequency

Considering the loading conditions listed in Table 3 as an example, the variation of various mechanical performance indexes with loading frequency was studied, while the displacement amplitude and vertical pressure remained constant.

Table 3. Loading condition B.

	Group 1	Group 2	Group 3	Group 4
Displacement amplitude (mm)	67	67	50	67
Vertical pressure (kN)	200	400	600	800
Loading frequency (Hz)	0.01, 0.03, 0.05, 0.07	0.01, 0.03, 0.05, 0.07	0.01, 0.03, 0.05, 0.07, 0.09, 0.1	0.01, 0.03, 0.05, 0.07

The normalised mechanical performance indexes for loading condition B are shown in Figure 7. With the increase in loading frequency, the change in the AES was small, indicating that the isolation performance of the CC-FPB was less affected by the loading frequency. However, the ACEC increased significantly, with a maximum increase of 20%; EDFC increased, with a maximum increase of 21%; and EDR increased, with a maximum increase of 27%, indicating that the energy dissipation capacity of the CC-FPB increased with an increase in the loading frequency. When the input excitation frequency was high, the bearings had low sensitivity to the input frequency range and demonstrated a stable and excellent seismic isolation effect. Simultaneously, the energy dissipation capacity due to the friction between the slider and the sliding surface of the chute improved.

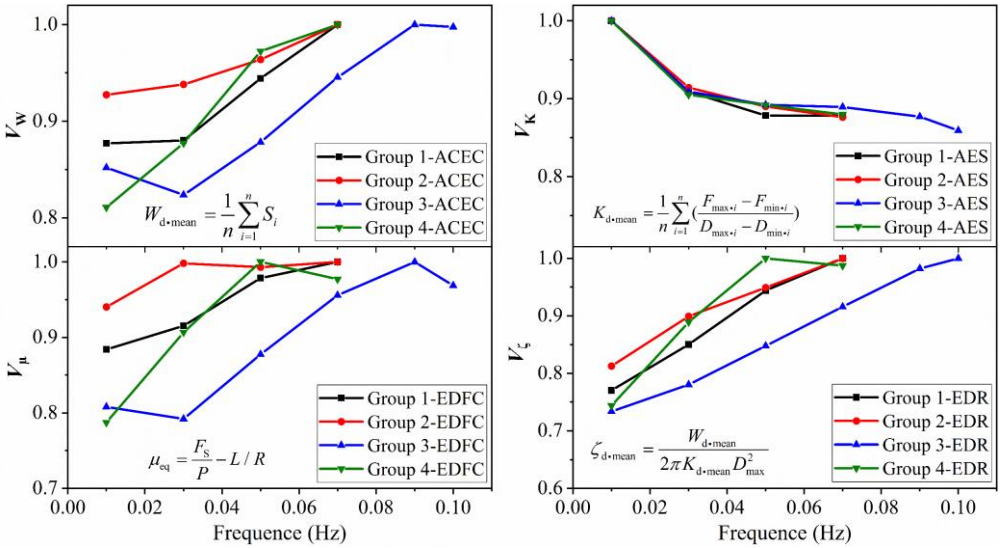

Figure 7. Variations in various mechanical indexes with loading frequency.

3.3. Variations in mechanical indexes with displacement amplitude

Considering the loading conditions listed in Table 4 as an example, the variation of various mechanical performance indexes with displacement amplitude was studied, while the vertical pressure and loading frequency remained constant.

Table 4. Loading condition C.

	Group 1	Group 2	Group 3	Group 4
Vertical pressure (kN)	200	400	600	800
Loading frequency (Hz)	0.01	0.01	0.01	0.01
Displacement amplitude (mm)	67, 100, 150	67, 100, 150	50, 67, 80, 100, 150	67, 100, 150

The normalised mechanical performance indexes under loading condition C are shown in Figure 8. With an increase in the displacement amplitude, AES decreased, and the maximum decrease was 59%; ACEC increased significantly, with a maximum increase of 68%; EDFC decreased by 16%, and EDR decreased by 19%. These results show that the isolation performance and energy dissipation capacity of the CC-FPB increased with an increase in the displacement amplitude. During a rare earthquake, the isolation layer of the isolation structure would produce a large displacement, the large displacement of the isolation layer would promote the large relative movement of the slider and chute, isolating most of the earthquake transmission to the superstructure and improving the amount of seismic energy consumed to overcome the friction.

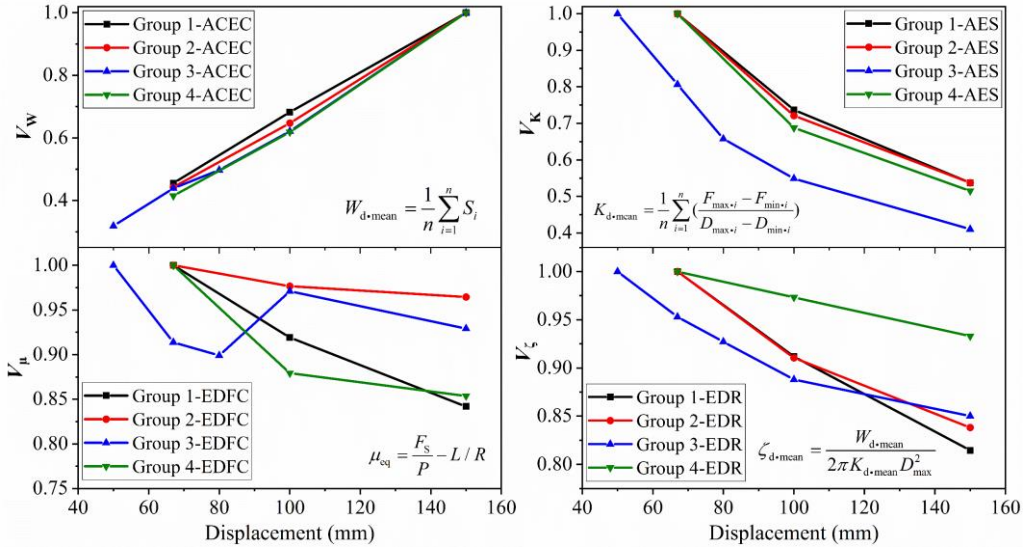

Figure 8. Variations in various mechanical indexes with displacement amplitude.

4. Refined numerical analysis model and test verification

The size of the numerical model was consistent with that of the test model, and the bearing and loading beams were modelled using solid elements. The entire model adopted eight-node hexahedral linear reduced integral elements (C3D8R), suitable for elastic-plastic analysis and contact analyses. The CC-FPB consists of two materials. The cover plate, slider, and chute are made of Q345 steel, and the PTFE plate is made of polytetrafluoroethylene (PTFE)-modified ultra-high-molecular-weight polyethylene. The two materials were assumed to be in an ideal linear elastic stage under all working conditions. The properties of the materials are listed in Table 5.

Table 5. Material property parameters.

Material	Q345	PTFE
Modulus of elasticity (MPa)	2.06E+5	1020
Poisson's ratio	0.3	0.4
Density (kg/m3)	7850	950

The chute was set as a fixed connection, and the upper load was applied at the midpoint of the loading beam to restore the test conditions. The loading beam was defined as a rigid body to improve the calculation efficiency. The hysteresis test model of the CC-FPB is illustrated in Figure 9. The refined simulation method described above was used to reproduce the numerical value of the hysteresis test with CC-FPB. ACEC and AES were calculated from the simulation results and compared with the test values (Table 6). The maximum error of the ACEC was only 5.1%, and the maximum error of the AES was only 7.05%, suggesting that the refined numerical simulation method is reasonably accurate.

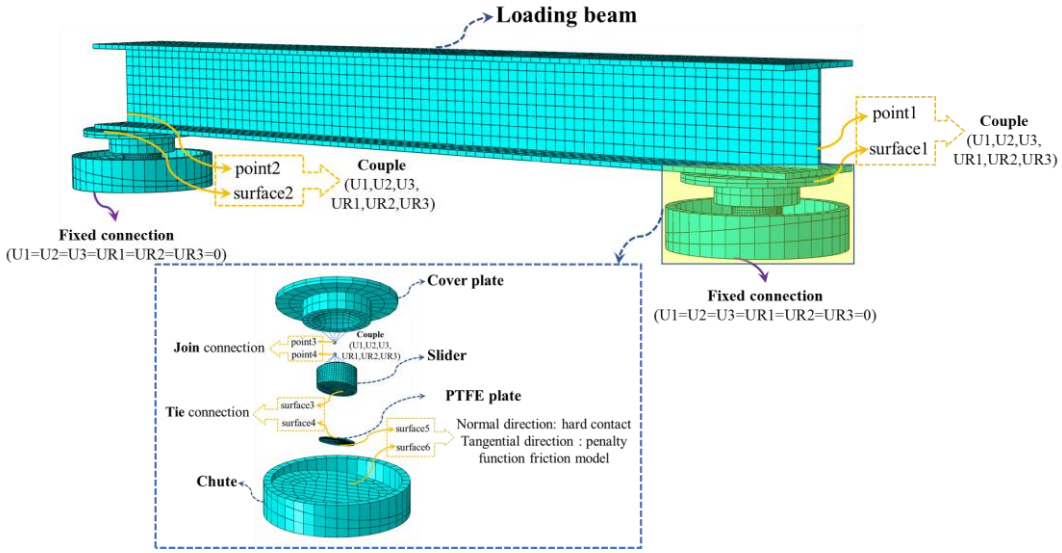

Figure 9. Hysteresis test model of CC-FPB.

Table 6. Test and simulated values.

Condition number	ACEC (kN•m)			AES (kN/m)		
	Test value	Simulated value	Error (%)	Test value	Simulated value	Error (%)
2	4103.982	4163.514	1.45	0.261	0.247	5.36
8	5574.463	5858.979	5.10	0.375	0.349	6.93
20	7195.711	7468.316	3.79	0.482	0.448	7.05
28	10081.54	9795.891	2.83	0.628	0.592	5.73

5. Isolation performance of double-layer spherical reticulated shell

For the common double-layer spherical reticulated shell structures in practical engineering, the isolation effect of the CC-FPB should be considered. In order to reasonably design the size of the member and avoid the problem of excessive slenderness ratio of the member, the structural member is designed with

multiple dimensions. The Truss element is selected as the bar element, and the rod connection method adopts hinge joint. The cross-sectional areas of the members are shown in Table 7. The non-isolated and the CC-FPB reticulated shell structure model are shown in Figure10.

Table 7. Cross-sectional area of the members.

Section type	Cross-sectional area (mm^2)				
	302	481	537	829	905

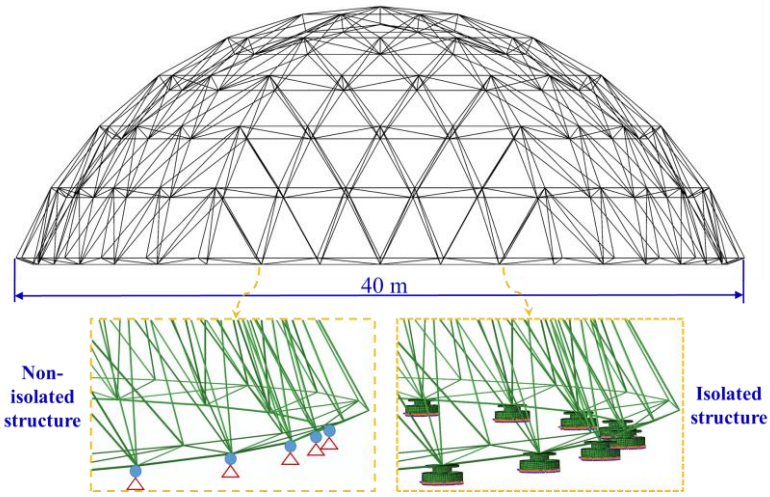

Figure 10. Numerical model boundary condition diagram.

The spectrum distributions of the non-isolated structure and the CC-FPB structure are shown in Figure 11. It is observed that CC-FPBs can also reduce the natural frequency of the double-layer spherical shell, and the natural frequency of the structure is reduced by 38 %, and the amplitude corresponding to the fundamental frequency is reduced by 93 %. At the same time, it is observed that the acceleration response and displacement response of the double-layer spherical reticulated shell structure with the CC-FPB isolation system are reduced by 27 % and 75 % respectively. The stress values of the structural members are significantly reduced, and the maximum stress values of the first layer members, second layer members, and connecting members of the double-layer spherical reticulated shell structure are reduced by 60%, 48%, and 55%, respectively.

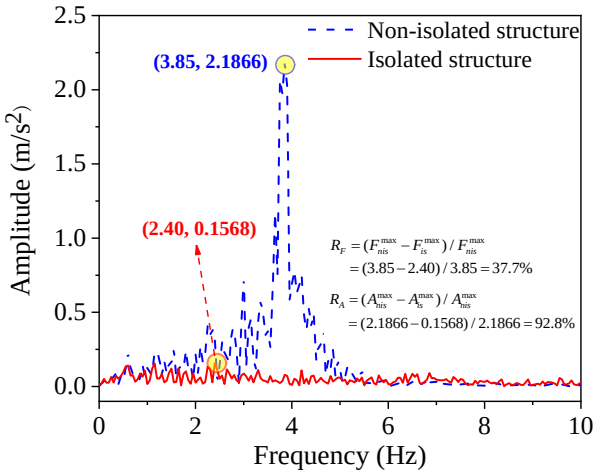

Figure 11. Spectrum distribution diagram.

6. Conclusion

In this study, a CC-FPB is proposed. Considering the bearing as the research object, a series of hysteresis tests and numerical simulations were carried out to obtain the isolation performance and energy dissipation capacity of the isolation system, and the variation of various mechanical performance indexes with external excitation. The seismic isolation effect of the isolation system was studied when applied to a double-layer spherical reticulated shell structure. The following conclusions can be drawn:

(1) The horizontal hysteresis curve of the CC-FPB was complete, and the CC-FPB exhibited high isolation performance and energy dissipation capacity. The isolation capacity of the CC-FPB decreases with an increase in vertical pressure. In an actual engineering isolation design, it is necessary to consider the number of isolation bearings in the isolation layer to ensure normal operation of the isolation system.

(2) The isolation performance of the CC-FPB has negligible effect on the loading frequency, whereas the energy dissipation capacity increased with the increase in loading frequency. When the higher frequency excitation was applied, the energy dissipation capacity due to the friction between the slider and the sliding surface of the chute improved.

(3) The isolation performance and energy dissipation capacity of the CC-FPB increased with the increase in loading displacement. Under the action of a large earthquake, the isolation layer produces a large relative displacement, which can isolate most of the earthquake transmission to the superstructure and increase the seismic energy consumed to overcome the friction.

(4) The refined simulation method of the bearing is proposed, and the bearing is applied to the double-layer spherical reticulated shell structure. the isolation effect of the double-layer spherical reticulated shell structure is better. The natural vibration period of the structure is effectively extended, and the fundamental frequency of the isolated structure is reduced by 93 %. At the same time, the dynamic response values of the structure are significantly reduced.

Abstract

Static elastic analysis procedures with seismic force reduction factor remain the cornerstone of seismic design practice even now because it is simple to use and does not require engineers to have an understanding of structural dynamics. However, particularly for metal spatial structures with complicated vibration characteristics, while code-based identical seismic force reduction factors (i.e. American R_μ or Japanese D_s) for specific seismic resisting systems are applied to the roof member design as it is in design practice, the actual (appropriate) force reduction factor has not been investigated yet in detail. Therefore, in this study, a series of nonlinear response history analyses (NLRHAs) for double-layered domes supported by single-story substructures were performed to investigate the effect of the roof span L of 60m to 150m, yielding story drift ratio θ_y, yielding base shear coefficient C_y of 0.3 to 0.6 and post-yielding stiffness ratio p of 0.01 to 0.5 on the seismic force reduction factor D_s and ductility ratio μ. According to the results, the D_s and μ mainly depend on the C_y and p, and are strongly affected by the resonance between the dome and substructure. Furthermore, a modified force reduction factor evaluation method considering the resonance was proposed and captured the NLRHA results more accurately compared with a conventional D_s evaluation method using an equivalent single-degree-of-freedom system.

Keywords: force reduction factor, seismic design, equivalent seismic load, dome, gridshell, buckling-restrained brace

1. Introduction

Static elastic analysis procedures with seismic force reduction factor [1], [2] remain the cornerstone of seismic design practice even now because it is simple to use and does not require engineers to have an understanding of structural dynamics. However, particularly for metal spatial structures with complicated vibration characteristics, while code-based identical seismic force reduction factors [3], [4] (i.e. American R_μ or Japanese D_s) for specific seismic resisting systems of multi-story buildings are applied to the roof member design as it is in design practice, the actual (appropriate) force reduction factor has not been investigated yet in detail. Therefore, in this study, a series of nonlinear response history analyses (NLRHAs) for double-layered domes supported by single-story substructures were performed to investigate the effect of the roof span L of 60m to 150m, yielding story drift ratio θ_y, yielding base shear coefficient C_y of 0.3 to 0.6, post-yielding stiffness ratio p of 0.01 to 0.5 on the seismic force reduction factor D_s and ductility ratio μ. Furthermore, a simple force reduction factor evaluation method considering the resonance between the dome and substructure was proposed. Finally, the static analyses with an equivalent seismic load[5] with the proposed D_s were compared to the NLRHA results.

2. Overview of the numerical analysis

2.1. Target structure and numerical modelling

An overview of the numerical analysis is shown in Fig. 1. The target structure is a double-layered dome supported by a single-story substructure, and is modelled as a 3D roof structure with a simple shear spring simulating the elasto-plastic behaviour of the substructure, as shown in Fig. 1(b). The double-layered roof members are modeled as an equivalent single-layered roof member for simplicity. The member specification of the roof structures is listed in Table 1. As shown in Fig. 1(d), the parameters in this study are the roof span L of 60m to 150m, yielding story drift ratio θ_y, yielding base shear coefficient C_y of 0.3 to 0.6, post-yielding stiffness ratio p of 0.01 to 0.5. As shown in Table 2 summarizes the relationships between the parameters and the target seismic resisting systems, an American buckling-restrained braced frame (BRBF, θ_y = 1/750 rad. and p = 0.01~0.05), Japanese special moment resisting frame with BRB (SMRF+BRB, θ_y = 1/750 rad. and p = 0.20~0.50), special moment resisting frame (SMRF, θ_y = 1/150~1/100 rad. and p = 0.01~0.05), and the dual system of SMRF+other devices (SMRF', θ_y = 1/150~1/100 rad. and p = 0.20~0.50) are adopted for the substructure, and the effect of the type of seismic resisting system on the seismic response is investigated in detail. In the non-linear response history analysis (NLRHA), the Newmark method (β = 1/4) was used to calculate the incremental displacement, and the large displacement response (i.e., geometric nonlinearity) of the roof structures was considered. The Rayleigh-type proportional damping matrix calculated from the initial stiffness and mass matrix was adopted for NLRHA, and the first and second modal damping ratios were set to 2.0%. The predominant modes of the double-layered domes and response spectra of input ground motions are shown in Fig. 2. In the double-layered dome, an antisymmetric 1 wave mode O1 is the fundamental mode, and the fundamental period ratio R_T of the substructure to the roof was used in the later discussion. As shown in Fig. 2(b), three Japanese spectrally matched seismic waves are assigned. The design spectrum is adopted from the Japanese design base earthquake level where the peak base shear factor is 1.0.

2.2. Conventional force reduction factor evaluation using equivalent SDOF system

Force reduction factor D_s can be theoretically evaluated by the structural dynamics of an equivalent single-degree-of-freedom (SDOF) system [6]. The schematic image of the evaluation procedure is shown in Fig. 3. Firstly, as shown in Figs. 2(a) and 2(b), a target structure is converted to an initial elasto-plastic SDOF system composed of the whole mass M_{eq}, the substructure's height H_s, and the substructure's stiffness K_s which is equal to $(M_{eq}C_y\mathrm{g})/(H_s\theta_y)$. The fundamental period T_0 is calculated by Eq. (1). As shown in Figs. 3(c) and 3(d), this elasto-plastic SDOF system is iteratively translated to the corresponding equivalent elastic SDOF system composed of the equivalent period T_{eq} and equivalent damping ratio ξ_{eq}, by Eq. (2) to Eq. (4). After the convergence, the force reduction factor D_s and ductility ratio μ are finally evaluated by Eq. (4) and Eq. (5). In Section 3, the theoretical D_s and μ are compared with the NLRHAs. Please note that D_s is equal to $1/R_\mu$ as shown in Eq. (5).

$$T_0 = \sqrt{\frac{\theta_y H_s}{C_y g}} \tag{1}$$

$$T_{eq} = \sqrt{\frac{\mu}{1-p+p\mu}}T_0 \tag{2}$$

$$\xi_{eq} = \xi_0 + \frac{2}{\pi\mu p}\ln\frac{1+p(\mu-1)}{\mu^p} \tag{3}$$

$$\mu = \left(\frac{S_A}{H_s\theta_y}\right)\left(\frac{T_0}{2\pi}\right)^2\sqrt{\frac{1+25\xi_0}{1+25\xi_{eq}}}\times\begin{cases}\dfrac{T_0}{T_{eq}}\dfrac{T_0+T_{eq}}{2T_{eq}T_0} & (T_{eq}<0.64)\\ \dfrac{T_0}{T_{eq}}\left\{\dfrac{T_0}{T_c}-\dfrac{(T_0/0.64-1)^2}{2(T_{eq}/0.64-1)}\right\} & (T_{eq}\geq 0.64, T_0<0.64)\\ \dfrac{T_0}{T_{eq}} & (T_0\geq 0.64)\end{cases} \tag{4}$$

$$D_s = \frac{1}{R_\mu} = \sqrt{\frac{1+25\xi_0}{1+25\xi_{eq}}}\times\begin{cases}\dfrac{T_{eq}}{T_0}\dfrac{T_0+T_{eq}}{2T_{eq}T_0} & (T_{eq}<0.64)\\ \dfrac{T_{eq}}{T_0}\left\{\dfrac{T_0}{0.64}-\dfrac{(T_0/0.64-1)^2}{2(T_{eq}/0.64-1)}\right\} & (T_{eq}\geq 0.64, T_0<0.64)\\ \dfrac{T_{eq}}{T_0} & (T_0\geq 0.64)\end{cases} \tag{5}$$

3. Numerical analysis results

Numerical analysis results of the force reduction factor D_s and ductility ratio μ are shown in Fig. 4. The results are organized by the post-yielding stiffness ratio p, the yielding base shear ratio C_y, the roof span L and the types of seismic resisting systems which yields in the combination of yielding story drift ratio θ_y and p. The average values of NLRHA to three input ground motions are plotted as the marker ○, □, and △. The variation of NLRHA to three input ground motions is plotted as the error bars. Furthermore, the theoretical D_s and μ are also written as "SDOF." In general, the D_s and μ mainly depend on the C_y and p, and have a trade-off relationship where lower C_y and p result in better D_s for the dome design but worse μ for the substructure response, and higher C_y and p result in better μ for the substructure response but worse D_s for the dome design. A higher post-yielding stiffness ratio (p = 0.20~ 0.50) has a greater effect on the average D_s and μ. Furthermore, the type of seismic resisting system has a remarkable effect on the average and variation of D_s and μ. As shown in Fig. 4(a), American BRBF with lower C_y is the best choice for mitigating the seismic input to the roof structure although the story drift response of the substructure is non-negligible. As shown in Fig. 4(c), the D_s of SMRF well agreed with the C_y, and can be controlled by the selection of C_y. However, the story drift response is generally greater than that of BRBF. In contrast to American BRBF and SMRF, as shown in Fig. 4(b), Japanese SMRF+BRB with lower C_y and p contributes to reducing both the seismic input to the roof structure and the substructure's response. On the other hand, while the code specified single force reduction factor (e.g. the D_s of 0.25 for BRBF, SMRF, and SMRF+BRB in Japan) is used in design practice, but generally underestimates the actual value as shown in Figs. 4(a), 4(b) and 4(c). The simple D_s sheet is summarized in Table 3 based on the NLRHA results and can be used as the alternative force reduction factor for regular double-layered dome structures.

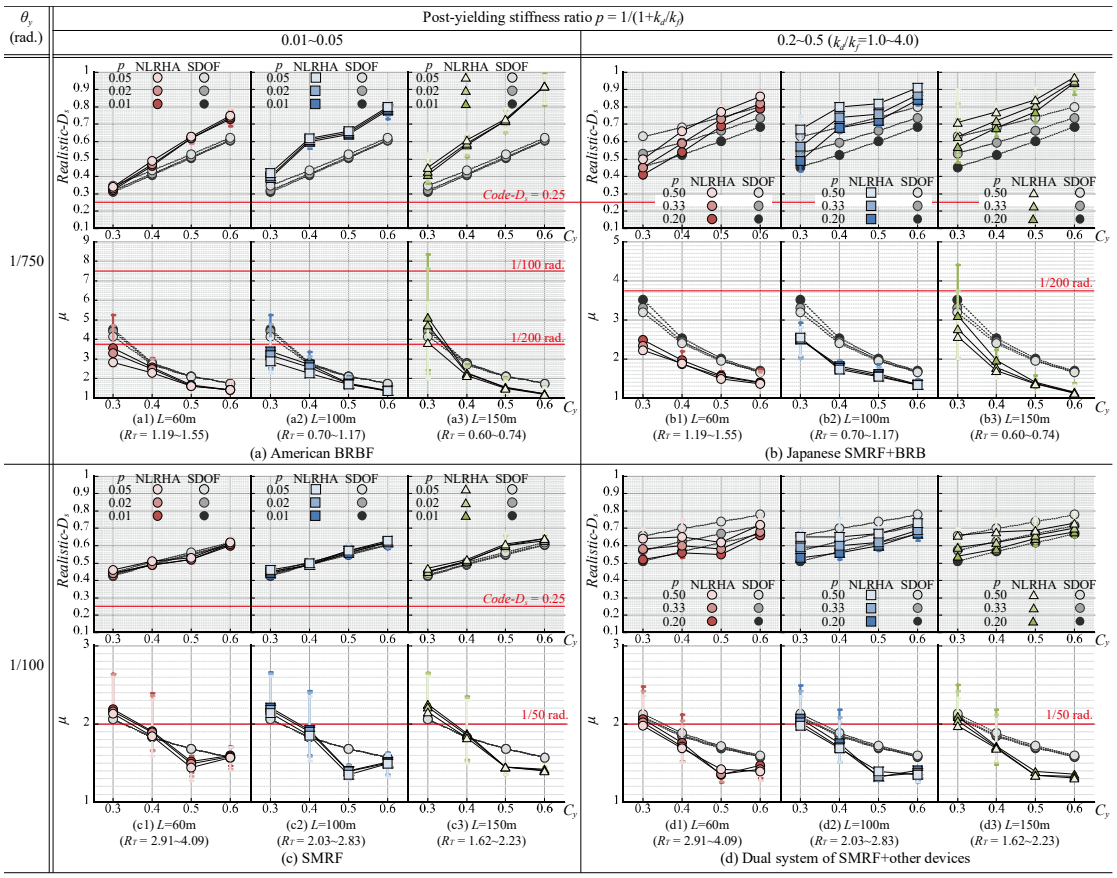

Figure 4. Numerical analysis results of the force reduction factor D_s and ductility ratio μ.

Table 3. Simple D_s sheet for the regular double-layer domes based on the numerical analysis results.

D_s (=1/R_u)		Post-yielding stiffness ratio p = 1/(1+k_d/k_f)					
θ_y	C_y	0.01	0.02	0.05	0.20 (k_d/k_f=4.0)	0.33 (k_d/k_f=2.0)	0.50 (k_d/k_f=1.0)

	0.5	0.55	0.55	0.55	0.60	0.60	0.65
	0.6	0.60	0.60	0.60	0.65	0.70	0.70

The response reduction effects on the roof acceleration and roof member's force are shown in Figs. 5 and 6, respectively. These results are the average values of NLRHA to three input ground motions. As shown in Fig. 5, while the horizontal response acceleration decreases in proportion to the yielding base shear factor C_y, the vertical response slightly increases by about 1.5 m/s^2 in some cases of SMRF with longer fundamental substructure's period T_0. As shown in Fig. 6, the axial forces and bending moment of roof members generally decrease in proportion to the C_y. Remarkably, the post-yielding stiffness ratio p has less effect on the response reduction. As shown in Figs. 5(c1) and 6(c1), the slight increment of the vertical acceleration response does not affect the member forces.

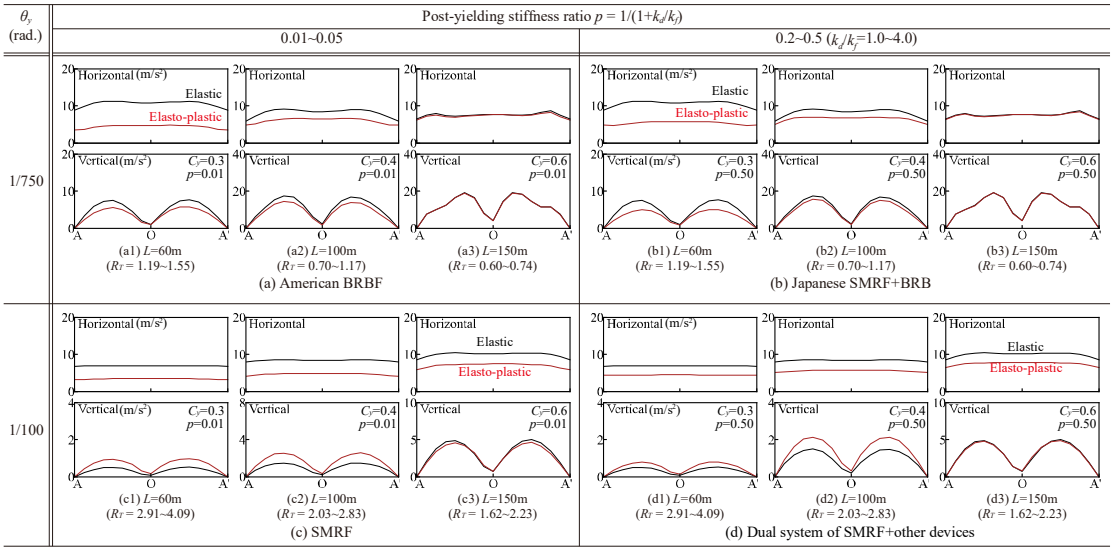

Figure 5. Response reduction effect on the roof acceleration.

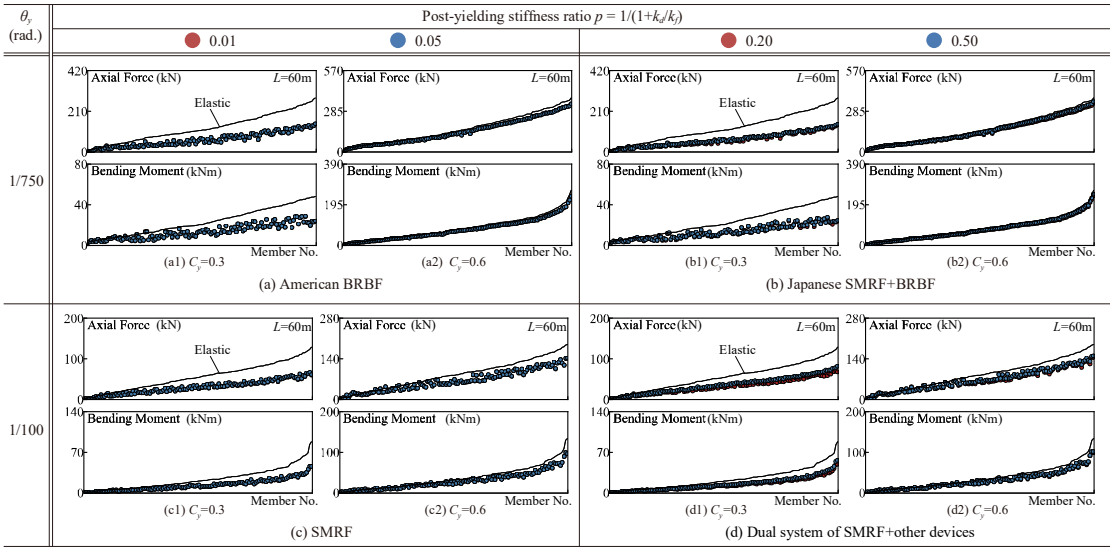

Figure 6. Response reduction effect on the member force of the dome structures.

4. Proposal of a simple force reduction factor evaluation method

As shown in Fig. 4, the equivalent linearization theory [6] of elasto-plastic SDOF systems qualitatively captures the NLRHA results of the partial 3D models. In other words, as shown in Eq. (1) to Eq. (5), the D_s and μ mainly depend on the θ_y, C_y, and p. However, as shown in Fig. 4, the theory significantly underestimated the D_s, particularly for American BRBF and Japanese SMRF + BRB. The relationships between the evaluation error and the fundamental period ratio R_T. are shown in Fig. 7. The relationships between the participation vector value β and the fundamental period ratio R_T. are shown in Fig. 8. As shown in Fig. 7(a), the evaluation error of D_s significantly increases as R_T is closed to 1.0 where the roof response is amplified by the resonance between the roof and substructures. As shown in Fig. 8, the substructure's participation vector value β_s similarly decreases, and have a large gap from the β_s of 1.0 assumed in the conventional theory, that is, the evaluation error of D_s is due to the non-consideration of the resonance effect.

The modified evaluation method was proposed. The schematic of the modified procedure is shown in Fig. 9. As shown in Fig. 9(b), a target building is firstly converted to a two-degree-of-freedom system considering the period ratio R_T between the roof O1 mode and substructure's fundamental mode and the effective mass ratio R_M. The substructure's participation vector value β_s is subsequently calculated by Eq. (6) and Eq. (7). While these equations are according to the theoretical eigenvalue analysis, the lower limit of 0.6 is defined in Eq. (6) based on the numerical results as shown in Fig. 8. In the modified procedure, the D_s and μ are evaluated by an elasto-plastic SDOF system where the acceleration spectrum value S_A is replaced with the $\beta_s S_A$. As shown in Fig. 10(a), the modified method accurately evaluates the D_s of NLRHAs. However, the evaluation error of μ has less improvement because of the large variation due to the input ground motions.

$$\beta_s = \max\left\{\frac{(1-C)+(1-C)^2 R_M}{1+(1-C)^2 R_M}, 0.6\right\} \tag{6}$$

$$C = \frac{\left\{\left(1+R_T^2\right)-\sqrt{\left(1+R_T^2\right)-4R_T^2\left(1+R_M^{-1}\right)}\right\}\left(1+R_M^{-1}\right)}{2R_T^2} \tag{7}$$

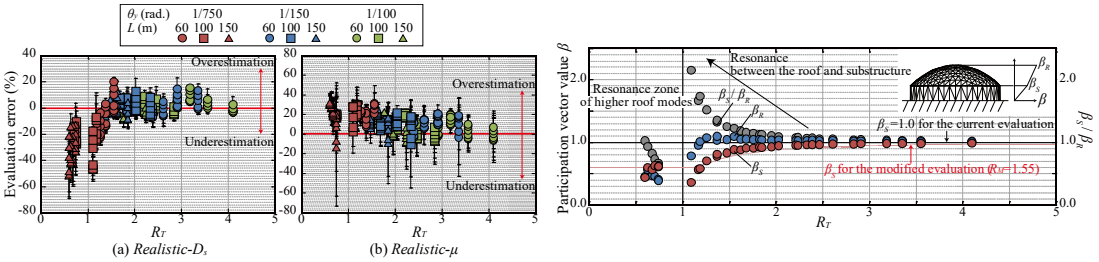

Figure 7. Evaluation error of the conventional method. Figure 8. Participation vector value – R_T relationships.

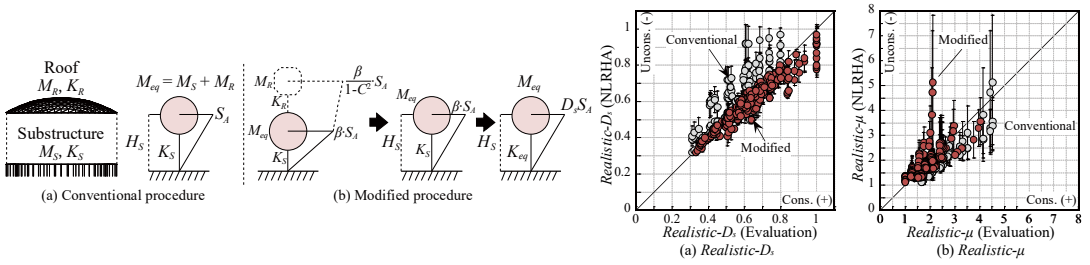

Figure 9. Modified evaluation procedure. Figure 10. Comparison between the evaluation and NLRHAs.

5. Static elastic analysis under the equivalent static seismic load with the proposed D_s

The seismic response computed by static elastic analysis under the equivalent static seismic load [5] with the proposed D_s was compared with that computed by NLRHA. The equivalent static seismic load is calculated by the product of the nodal mass and the distribution formula of roof acceleration. The horizontal and vertical distribution of roof acceleration is calculated by Eq. (8) and Eq. (9). This formula is based on the participation vector of the roof O1 mode shown in Fig. 2(a). The response amplification by the resonance between the roof and substructure is calculated by Eq. (10) to Eq. (13). The force reduction effect is considered by multiplying the D_s with S_A. The comparison of roof acceleration is shown in Fig. 11. The equivalent static seismic loads with the proposed D_s and the simple D_s listed in Table 3 are denoted as "Modified" and "D_s-table", respectively. The equivalent static seismic load captures the NLRHA results except for the cases where the vertical acceleration increases regardless of the D_s. The comparison of seismic response is shown in Fig. 12. The static elastic analysis with the proposed D_s has the same accuracy as the existing static elastic analysis for elastic substructures.

$$A_H(x,y) = D_s S_A \left\{ 1 + (F_H - 1)\cos\left(\pi \frac{\sqrt{x^2+y^2}}{L} \right) \right\} \tag{8}$$

$$A_V(x,y) = D_s S_A F_V \left(\frac{x}{\sqrt{x^2+y^2}} \right) \sin\left(2\pi \frac{\sqrt{x^2+y^2}}{L} \right) \tag{9}$$

$$F_H = \begin{cases} 1.5 & (0 < R_T \le 5/36) \\ \sqrt{5/(4R_T)} & (5/36 < R_T \le 5/4) \\ 1 & (5/4 < R_T) \end{cases} \tag{10}$$

$$F_V = \begin{cases} 3C_V\theta & (0 < R_T \le 5/16) \\ \sqrt{5/R_T - 1}\,C_V\theta & (5/16 < R_T \le 5) \\ 0 & (5 < R_T) \end{cases} \tag{11}$$

$$F_H' = \sqrt{F_H^2 + \left\{ (1-R_T^2)^2 + R_M^{-\theta} \right\}^{-1}} \tag{12}$$

$$F_V' = \sqrt{F_V^2 + \left\{ (1-R_T^2)^2 + R_M^{-1} \right\}^{-1}} \tag{13}$$

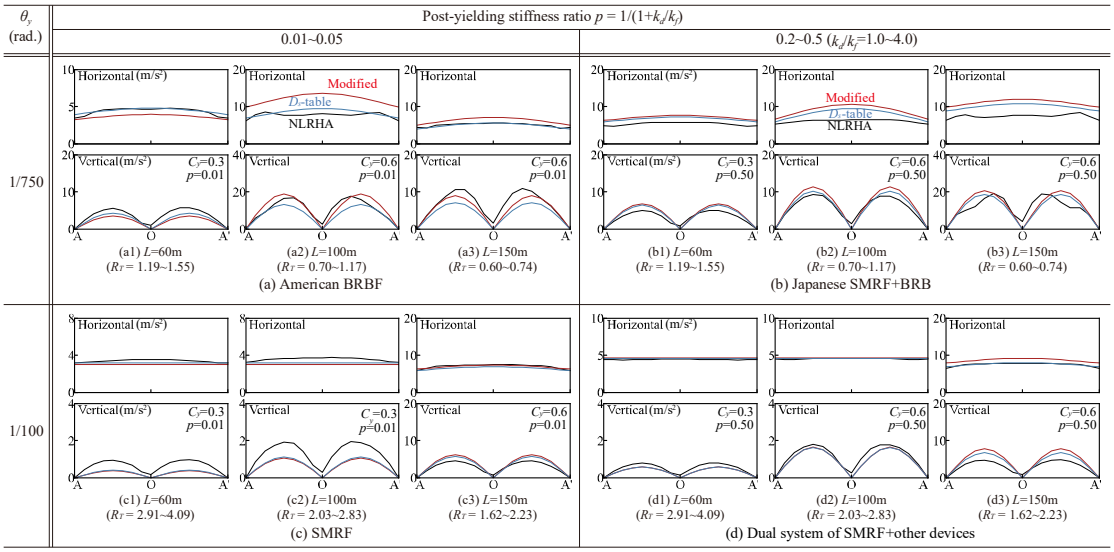

Figure 11. Comparison of roof acceleration between the equivalent static seismic load with Ds and the NLRHAs.

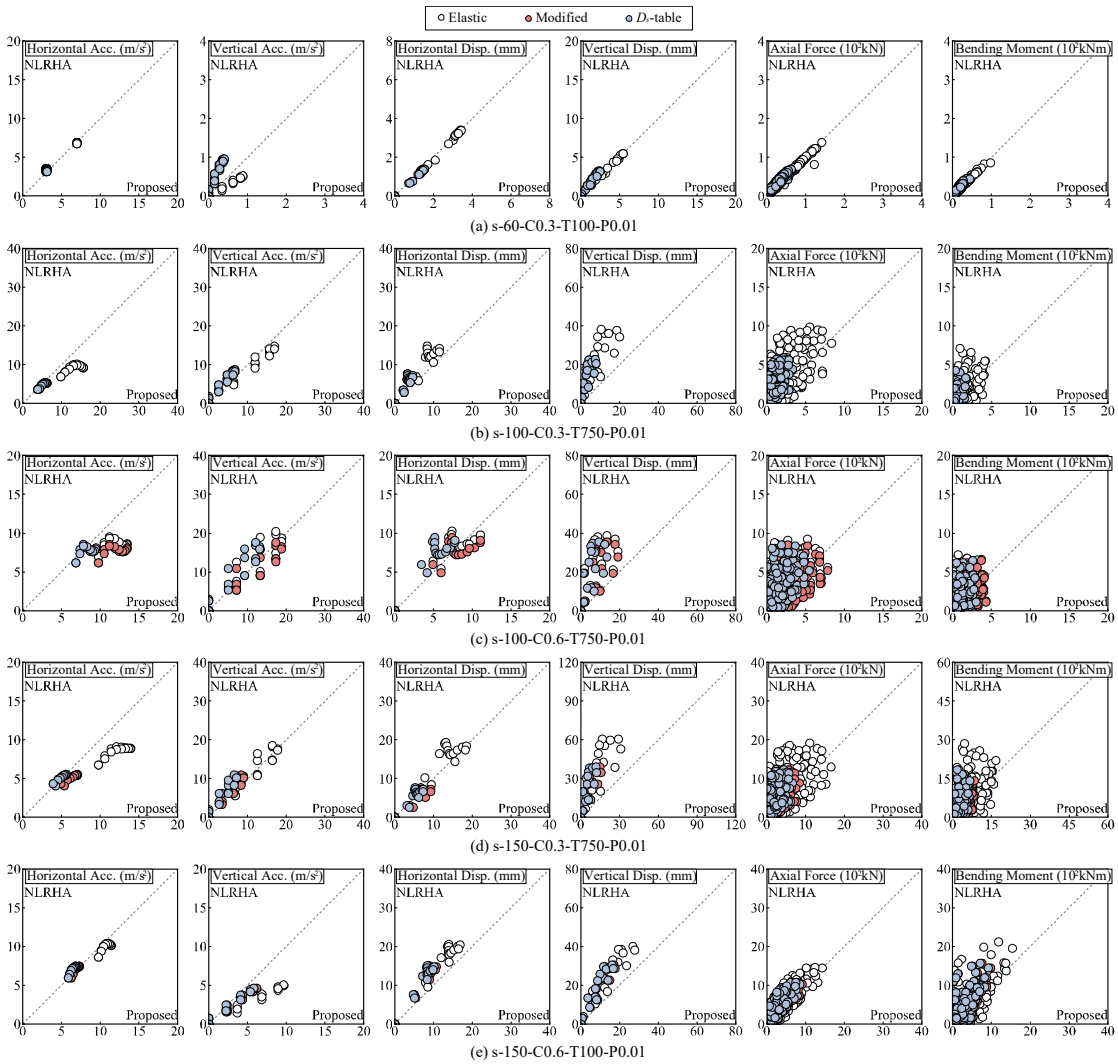

Figure 12. Comparison of seismic response between the static elastic analyses and the NLRHAs.

6. Conclusion

The following conclusions were obtained:

1) The force reduction factor D_s for the dome and ductility ratio μ mainly depends on the yielding base shear factor C_y and the post-yielding stiffness ratio p, and have a trade-off relation where lower C_y and p result in better D_s for the dome design but worse μ for the substructure response and higher C_y and p result in better μ for the substructure response but worse D_s for the dome design. Furthermore, the type of seismic resisting system has a remarkable effect on the D_s and μ. American BRBF with lower C_y is the best choice for mitigating the seismic input to the roof structure although the story drift response of the substructure is non-negligible. Japanese SMRF+BRB with lower C_y and p contributes to reducing both the seismic input to the roof structure and the substructure's response. The code-specified single force reduction factor (e.g. the D_s of 0.25 for BRBF, SMRF, and SMRF+BRB in Japan) is used in design practice, but generally underestimates the actual value.

2) The equivalent linearization theory [6] of elasto-plastic SDOF systems qualitatively captures the NLRHA results of the partial 3D models. However, the evaluation error of D_s significantly increases as the fundamental period ratio R_T is close to 1.0 where the roof response is amplified by the resonance between the roof and substructures. The substructure's participation vector value β_s similarly decreases, and have a large gap from the β_s of 1.0 assumed in the conventional theory, that is, the evaluation error of D_s is due to the non-consideration of the resonance effect.

3) The modified evaluation method of the D_s and μ was proposed, and accurately evaluates the D_s of NLRHAs. However, the evaluation error of μ has less improvement because of the large variation due to the input ground motions.

4) The static elastic analysis with the proposed D_s has the same accuracy as the NLRHA as the existing static elastic analysis for elastic substructures.

Abstract

The aim of this paper is to investigate the seismic behavior of space structures and extract the seismic response modification factors to answer the challenges faced by structural engineers to determine the effective seismic parameters of these types of structures. For this purpose, three types of space structures, including the single-layer diamatic dome (SLDD), double-layer diamatic dome (DLDD), and double-layer barrel vault (DLBV) with different span lengths, rise-to-span ratios, and length-to-span ratios are studied. The absence of a general criterion for determining the control point, target displacement, and logical load pattern in the pushover analysis of space structures is one of the important tips studied in this research. In all analyses, material and geometric nonlinearities were applied. First, these models were designed under the applied loads, based on valid regulations. Then, the nonlinear time history analyses were done by using three translational components of earthquake accelerograms to obtain the target displacement at the control node in both horizontal and vertical directions. Finally, by carrying out pushover analyses, the seismic response modification factors, including the behavior factor and the displacement amplification factor, for space structures in both horizontal and vertical directions were obtained.

Keywords: latticed space structures, seismic behavior of space structures, nonlinear analyses, seismic response modification factors

1. Introduction

Behavior factor of a structure includes the nonlinear performance and the hidden strength of the structure in the nonlinear phase. Thus, the required strength for the design is reduced. To obtain the behavior factor, the ductility factor, over-strength factor, and ductility reduction factor should be calculated. A small value of the behavior factor leads to the non-economic design, and its large values represent the acceptance of higher levels of nonlinear deformations in the structure. Therefore, determining this factor is of special importance [1]. Many investigations have been carried out on the seismic behavior of space structures. The 1995 Kobe and 2016 Kumamoto earthquakes showed that although these structures are safer than conventional structures, they cannot be considered safe. Moghaddam studied the seismic behavior of space structures and concluded that the seismic forces resulting from the dynamic analysis of space structures in the nonlinear region is much higher than conventional buildings. He recommended that the behavior factor, *R*, should be assumed as equal to 1.0 for determining the seismic forces in supports and nodal connections [2]. Takeuchi et al. reported buckling of the upper chord and diagonal members and fracture of the bolts of the longitudinal members connected to the bearing by the out-of-plan response of RC supporting frame which led to the falling of the members in space frame gymnasiums during the Kumamoto earthquake [3]. Khalili et al. studied the seismic response modification factors of single-layer barrel vaults and evaluated the effects of the rise-to-span ratio and the length of the structure on the seismic response modification factors. Also, they proposed equations to calculate the period, behavior factor, and displacement amplification factor of these structures [4]. It

should be noted that there is no comprehensive research on space structures, and no general criterion has been given to determine the control point, target displacement, and logical load pattern in the pushover analysis for the calculation of the seismic response modification factors of this kind of space structures. On the other hand, no specific behavior factor has been proposed in the codes for the design of these structures, and this issue is a main challenge for designers. Therefore, the present study aims to comprehensively investigate the seismic behavior of space structures and extract their seismic response modification factors.

2. Definition of the seismic response modification factors

In this paper, the Uang's method has been used to obtain the seismic coefficients. The overall ductility factor of the structure is defined as the maximum lateral displacement (Δ_{max}) to the yield lateral displacement (Δ_y) [1]. To obtain the ductility reduction factor in terms of ductility factor, the equation presented by Newmark-Hall has been used [5], as shown in Table 1.

Table 1. Ductility reduction factor according to the Newmark-Hall method [5].

Ductility reduction factor (R_μ)	Period of Structure (T)
$R_\mu = 1$	$T < 0.05\ sec$
$R_\mu = \sqrt{2\mu - 1}$	$0.12\ sec < T < 0.5\ sec$
$R_\mu = \mu$	$T \geq 1\ sec$

The over-strength factor is defined as the ratio of the load corresponding to the ultimate yield strength of the structure during the formation of the failure mechanism (C_y), to the load corresponding to the formation of the first plastic hinge in the structure (C_s); but to take into account some factors such as the effect of non-structural elements and the difference between the nominal and actual yield stress of the material, the over-strength factor is multiplied by 1.155 [6]. The behavior factor of the structure is obtained by multiplying the ductility reduction factor in the over-strength factor. The displacement amplification factor is obtained by multiplying the ductility factor in the over-strength factor [1].

3. Configuration and property of the models

In this study, three types of space structures including the single-layer diamatic dome (SLDD) (Figure 1: a), double-layer diamatic dome (DLDD) (Figure 1: b), and double-layer barrel vault (DLBV) (Figure 1: c) with different span lengths, rise-to-span ratios, and length-to-span ratios are considered as the structural models. The configuration of all the models is done by the Formian software.

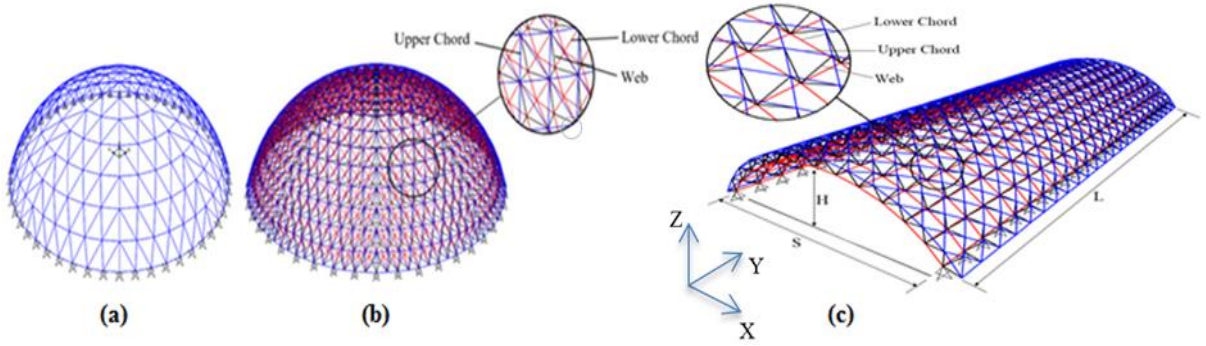

Figure 1. Configuration of the models studied in this research: SLDD (a), DLDD (b), DLBV (c).

3.1. Single-layer diamatic lattice domes

Single-layer Diamatic dome is one of the most widely used types of domes. Its feature betrays high stiffness and avoidance of accumulation of members in the crown of the dome. The length of the members is close to each other which results in a uniform structure and, as a result, a uniform stress distribution among the members. This type of domes includes a small number of members and nodes, which has a positive effect on reducing costs. In these models, pinned supports were used in the last ring. In this research, 12 models with span lengths of 30, 40, and 50 m and rise-to-span ratios of 1/7, 1/5, 1/3, and 1/2, which have different numbers of members, were used.

3.2. Double-layer diamatic lattice domes

In this research, double-layer diamatic domes have been studied with the rise-to-span ratios of 1/7, 1/5, 1/3, 1/2 and span lengths of 50, 65 and 80 meters which were formed based on Buckminster Fuller's icosahedron. An imprtant characteristic of double-layer diamatic domes is that they don't have element irregularity and cluttering problems in the crown of domes and are suitable for large spans due to their high rigidity. For models with span lengths of 50, 65, and 80 meters, the depth of the domes is equal to 1.25, 1.5, and 2 meters, and the frequency or in other words, the number of rings, is equal to 8, 10, and 12, respectively. The Nodal connections of members and support boundary conditions are pinned.

3.3. Double-layer lattice barrel vaults

Twelve models of double-layer barrel vaults are assumed. The span of the models is 50 meters in X direction, and the lengths are 50, 100 and 150 meters in Y direction with different rise-to-span ratios of 0.1, 0.2, 0.3, and 0.5. Due to better distribution of gravity forces on the supports, a square configuration for the bottom layer of the double-layer barrel vaults is considered. Also, the diagonal lattice is used for the top layer to increase the rigidity of the structures in the longitudinal direction.

4. Design of the models

The section of the members is tubular, and the steel grade used in the design of the structures is St-37 with mechanical properties given in Table 2.

Table 2. Mechanical properties of the material.

Density	Modulus of elasticity	Yield stress	Ultimate stress	Poisson's ratio
7850 kg/m^3	210 GN/m^2	240 MN/m^2	370 MN/m^2	0.3

Design loads including the dead, symmetric and asymmetric snow, wind, temperature, and earthquake loads were applied to all of the models according to the Iranian national building code (sixth volume) [7], the Iranian code of Practice for the skeletal steel space structures (Standard No. 400) [8], and the Iranian code of practice for the seismic resistant design of buildings (Standard No.2800, 4th edition) [9]. The SAP2000 software and AISC 360-16 code are used in the design process [10]. The spectral dynamic analysis was used for the design of structural models. In addition, site class *C* for DLDDs, *D* for SLDDs, and *E* for DLBVs were assumed [11]. It was assumed that the structures are located in a zone with a very high level of relative seismic hazard. Furthermore, the seismic effective mass is equal to dead load plus 20% of the snow load according to the Iranian seismic design code. Since the design spectrum is defined for a damping ratio of 5% according to the Iranian seismic design code, and the damping ratio of space structures is in the range of 1.5% to 2.5%, the design spectrum was multiplied by the damping modification factor (DMF) according to Eurocode 8 [12] as follows:

$$DMF = \sqrt{\frac{10}{5+\zeta}} = \sqrt{\frac{10}{5+2}} = 1.195 \quad (1)$$

5. Finite element modeling

In this study, the numerical analysis of space structures is investigated by using the ABAQUS finite element software. After the determination of loads and design of the structures by using the SAP2000 software, the models are transferred to the finite element software, to perform the nonlinear time history and pushover analyses. The geometrical and material nonlinearities are considered in these analyses. The elastoplastic and post-buckling behaviors are considered for tension and compression members respectively. In double-layer space structures, the initial imperfection is considered to be $0.001L$ in the middle of compression members. In the double-layer space structures, the member joints are considered pinned and the T3D2 truss element is used. In the single-layer domes, all connections are assumed to be rigid and the Timoshenko beam element (B31), which is in the form of two nodes, is used. In all analyses, the geometric and material nonlinearities are applied. The von-Mises yield level and Rayleigh damping are used as well. A sensitivity analysis for determining the number of elements is also performed to obtain the appropriate number of elements in the analyses. Given that the greater the number of elements, the more accurate the results obtained from the analyses; but the analyses will be time consuming. In this research, the number of elements selected for the finite element modeling of single-layer domes is equal to 5.

6. Verification of numerical modeling and time history analysis

To verify the accuracy of the finite element modeling in the current research, two studies were considered as follows:

6.1. Verification of modeling and buckling behavior of members

In this research, Parke's experimental model was investigated. This model is a double-layer flat grid with a square plan, 1800 mm length in the lower layer and 1400 mm in the upper layer and a height of 254.56 mm. In this model, three types of members are used, and the external load is applied in the vertical direction on the central node of the upper layer. The specifications of the members' materials in tension and compression are presented in Table 3.

Table 3. Characteristics and tensile and compressive behavior of the members [13].

Profile		T1		T5		T6	
Shape		Tubular		Tubular		Solid Circular	
Diameter (mm)		4.76		9.52		10	
Thickness (mm)		0.91		0.91		-

Compression Material Behaviour	Flexural Buckling Stress (MPa)	-		319		313	

Figures 3 and 4 showing the numerical results of the buckling behaviour of two compression members, T5 and T6 as well as the response of the structure in this research, respectively, indicate that they are close to the experimental results [13].

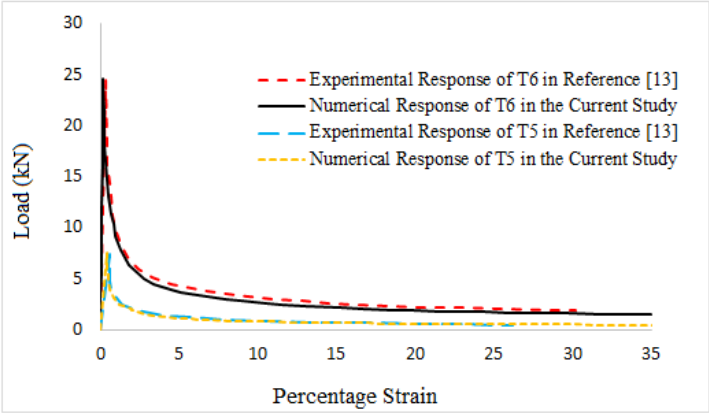

Figure 3. Buckling behaviour of two compression members T5 and T6 in the Parke's experimental response [13] and the current study.

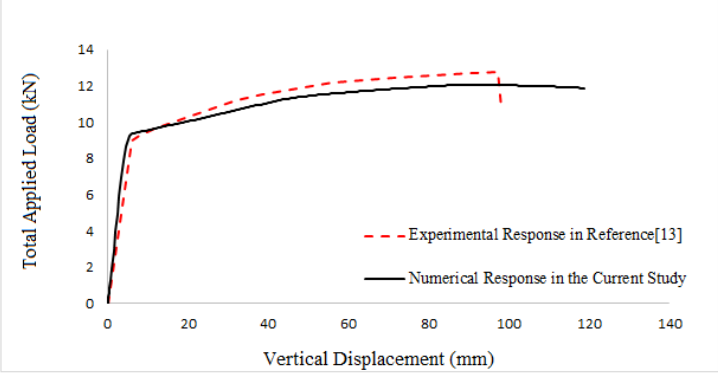

Figure 4. Load-displacement diagram of the experimental model [13] and the current study.

6.2. Verification of time history analysis

The second verification is related to the time history analysis of a single-layer diamatic dome under the El Centro ground motion. An experimental model with a span length of 23.4 m and a rise-to-span ratio of 0.5 was selected for this verification which has 1261 nodes and 3660 members. The mechanical characteristics of the materials are given in Table 4. Figure 5 shows the plan and the support conditions of the experimental model [14].

Table 4. Mechanical characteristics of the materials [14].

Cross-sectional type	Elastic modulus/GPa	Yield strength/MPa	Ultimate strength/MPa	Extensibility rate/%
Φ18 × 1	194.0	197.7	347.6	37.1
Φ23 × 1	189.2	200.5	408.1	37.3

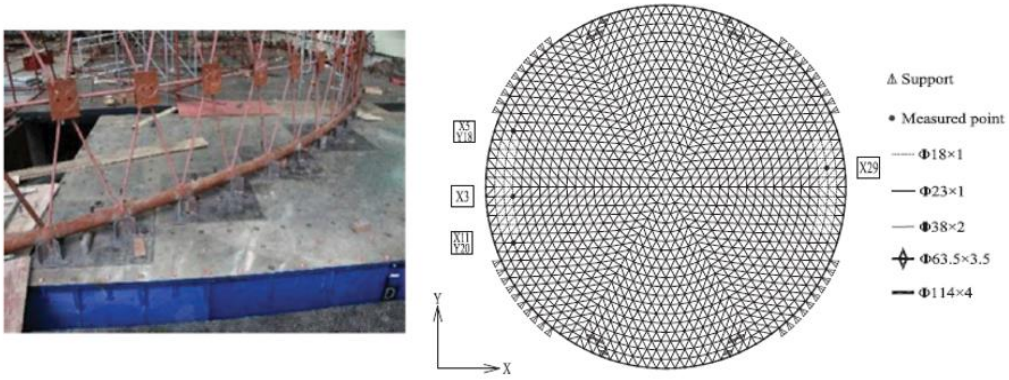

Figure 5. Plan and support conditions of the single-layer diamatic dome in Reference [14].

As shown in Figure 6, the displacement history obtained in the current study is in good agreement with that of the experimental study. Therefore, it was found that the finite element modeling is sufficiently reliable to be used in the current investigation.

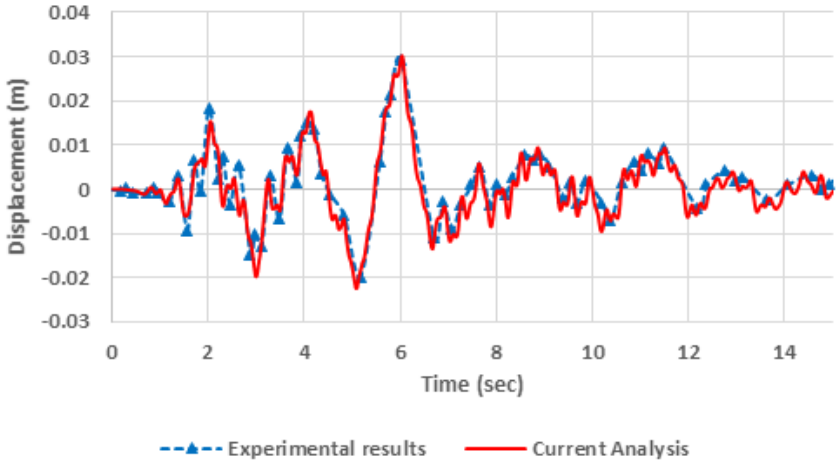

Figure 6. Displacement history of the single-layer diamatic dome obtained in the current study and Reference [14].

7. Nonlinear time history analysis

Time history analysis is the most accurate and reliable method of determining the forces and deformations of structures. In this study, a three-dimensional time history analysis is performed to determine the control point and the target displacement in the pushover analysis.

7.1. Selection and scaling the records

In the first step, 12 far-fault strong ground motions with a distance of more than 60 km and a magnitude upper than 6 are used to perform three-dimensional nonlinear dynamic time history analyses. The earthquake records were extracted from the PEER Ground Motion Database. The specification of the records for the three types of space structures are presented in Table 5. Scaling the horizontal components of ground motions is done using the FEMA P-750-2009 [15]. Also, according to a report presented by NEHRP and ATC for Engineering of Laboratory of National Institute of Standards and Technology (NIST GCR 11-917-15), the vertical component of ground motions is scaled by the same scaling factor used for the pair of horizontal components [16].

Table 5. The ground motion records used for the time-history analysis.

7.2. Determining the control point and target displacement

To determine the control point and target displacement, the history of displacements in the nodes under the effect of the relevant earthquake records is extracted; then, the absolute magnitude of all displacements is obtained, and their maximum amount is determined. Finally, the average of the absolute magnitude of the maximum displacements obtained under the earthquake records is calculated. The node that has the maximum displacement is selected as the control point, and the target displacement for the pushover analysis is considered to be equal to the maximum displacement obtained from the nonlinear time history analyses.

8. Pushover analysis

Due to the complexity and time-consuming nature of the time history analyses, a simpler and more practical method called the pushover analysis is used to determine the capacity of the structures and their seismic performance during an earthquake. This method is based on the static analysis so that the nonlinear behavior of materials is considered, and the structure is subjected to increasing static loads. In the second step, the pushover analysis is performed considering geometric and materials nonlinearities to obtain the force-displacement curve of the structures. According to FEMA-P695 [17], the pushover analysis is conducted under the gravity load combination of 1.05D+0.25L and static lateral forces. The lateral load applied to the structures is computed using the ASCE/SEI 41-06 [18] regulations that is equal to mΦ, where *m i*s the mass matrix, and Φ is the mode shape of the structure. It should be noted that the first mode of vibration of the structure in the horizontal direction was used to perform the pushover analysis in this direction. Also, to perform the pushover analysis in the vertical direction, the dominant mode, which has the largest effective modal participation mass ratio in the vertical direction, was used. For simplification, the capacity curve of the structure is approximated by a bilinear curve according to FEMA-356 [19].

9. Discussion of the results

The results of the nonlinear time history and pushover analyses in both horizontal and vertical directions are presented below.

9.1. Period of the models

The period of the dominant mode in the horizontal and vertical directions of the SLDDs, DLDDs, and DLBVs are shown in Figures 7, 8, and 9, respectively.

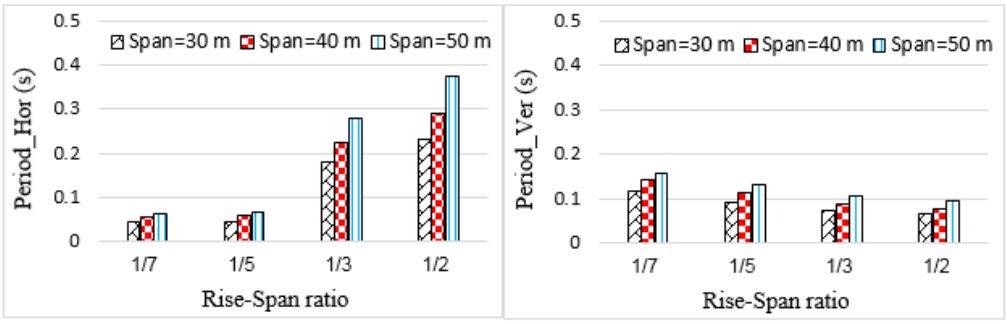

Figure 7. The period of the dominant mode in the horizontal and vertical directions of the SLDDs.

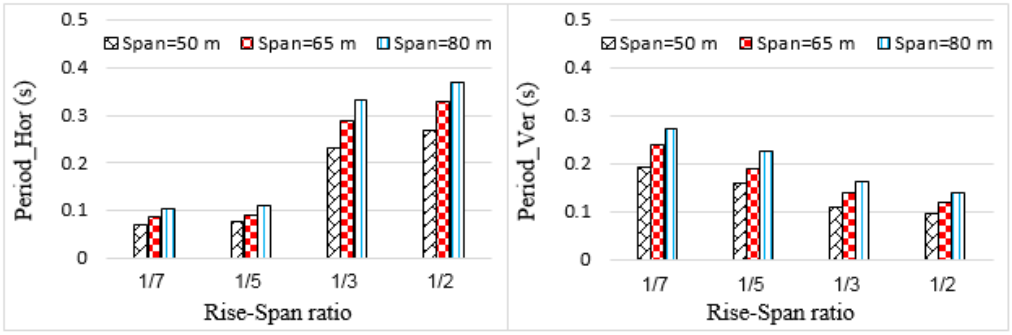

Figure 8. The period of the dominant mode in the horizontal and vertical directions of the DLDDs.

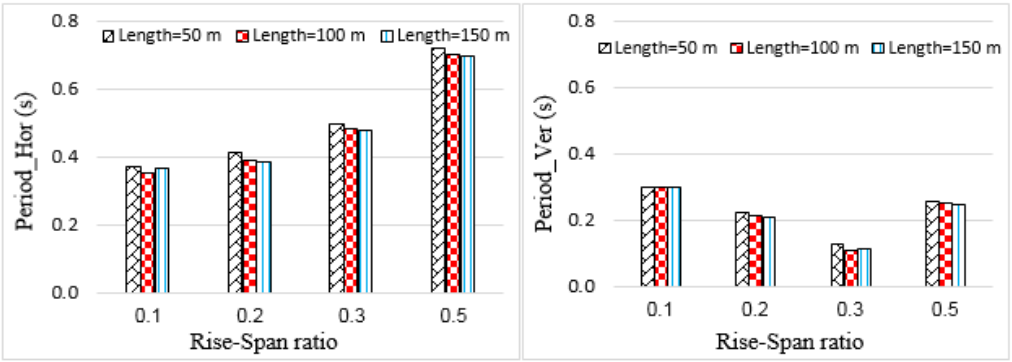

Figure 9. The period of the dominant mode in the horizontal, X, and vertical directions of the DLBVs.

9.2. Target displacement of the models

The target displacement in the horizontal and vertical directions of the SLDDs, DLDDs, and DLBVs are shown in Figures 10, 11, and 12, respectively. As shown in Figure 11, with the increase in the span length of the DLDDs, the target displacement increases in both horizontal and vertical directions. Also, with the growth of the rise-to-span ratio, the target displacement has an upward trend in the horizontal direction. Contrary to the expectation, due to the reduction of vertical stiffness of dome structures with a rise-to-span ratio of 1/5 compared to domes with a rise-to-span ratio of 1/7, the vertical displacement of these structures is less. The reason is that, in the design of the structures, the snow load pattern dominates, and the domes with the rise-to-span ratio of 1/7 are closer to the flat state than the domes with the rise-to-span ratio of 1/5. Therefore, the value of the slope coefficient, Cs, in the calculation of the snow load for the dome 1/7 is larger than the dome 1/5 at the height level of the control point. Consequently, during the time history analysis under earthquake records, the target displacement in the vertical direction of the dome 1/7 is less than that of the dome 1/5. The plastic hinges are first formed

in the members of a ring where the control point is determined in that ring. Also, the maximum horizontal displacement occurs near the center of mass of the domes.

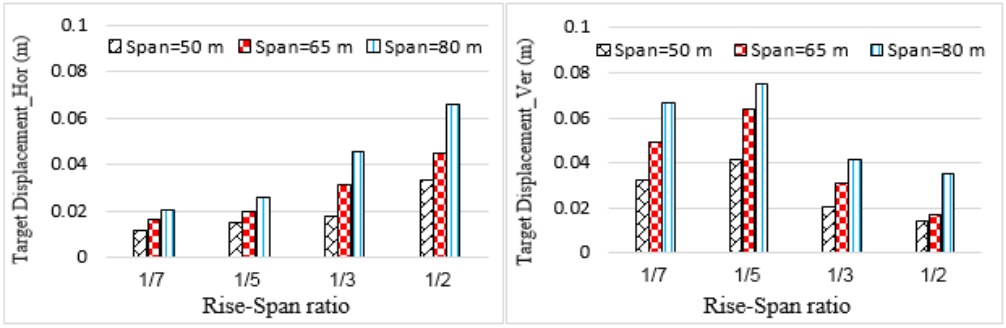

Figure 11. The target displacement in the horizontal and vertical directions of the DLDDs.

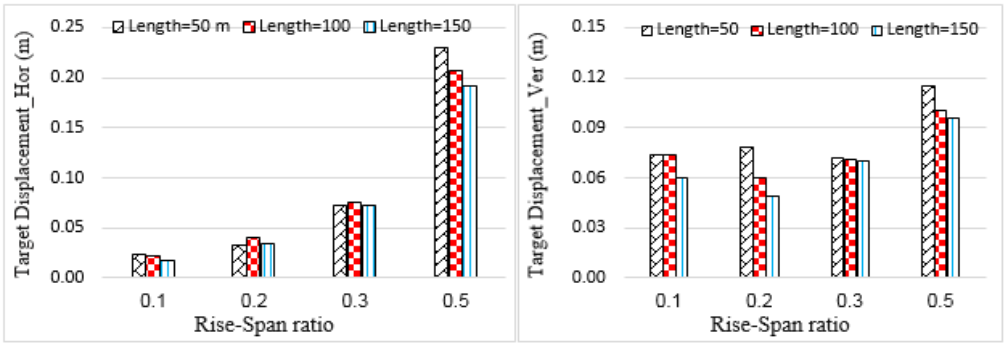

Figure 12. The target displacement in the horizontal, X, and vertical directions of the DLBVs.

9.3. Effective seismic parameters

The seismic response modification factors, obtained from the pushover analyses in the horizontal and vertical directions of the SLDDs, DLDDs, and DLBVs, are shown in Tables 6, 7, and 8, respectively. As seen in Table 6, the results illustrate that the behavior factor of SLDDs in the horizontal and vertical directions is in the range of 1.15-2.26 and 1.15-2.74, respectively. The behavior factor in the horizontal direction of the SLDDs with rise-to-span ratios of 1/7 to 1/3 for all the span lengths is equal to 1.15. Because these models remained in the elastic range in the horizontal direction, they should be designed considering a linear elastic behavior in this direction. For the models with a rise-to-span ratio greater than 1/3, if the span length is kept unchanged and the rise-to-span ratio increases, or if the rise-to-span ratio is kept constant and the span length increases, both the over-strength factor and the ductility reduction factor increase in the horizontal direction; thus, the behavior factor increases in the horizontal direction. If the span length is kept unchanged and the rise-to-span ratio increases, both the over-strength

factor and the ductility reduction factor decrease in the vertical direction; therefore, the behavior factor decreases in this direction. Also, the displacement amplification factor of SLDDs in the horizontal and vertical directions is in the range of 1.15-2.48 and 1.15-2.93, respectively.

Table 6. The seismic response modification factors in the horizontal and vertical directions of the SLDDs.

Models	Span length	30 m				40 m				50 m

	Displacement amplification factor	1.73	1.22	1.15	1.15	2.14	1.62	1.23	1.15	2.93	1.96	1.85	1.47

Table 7. The seismic response modification factors in the horizontal and vertical directions of the DLDDs.

Models	Span length	50 m				65 m				80 m			
	Rise-to-span ratio	1/7	1/5	1/3	1/2	1/7	1/5	1/3	1/2	1/7	1/5	1/3	1/2
Horizontal Direction	μ	1	1	1.18	1.19	1	1	1.15	1.23	1	1	1.23	1.44
	$R\mu$	1	1	1.16	1.17	1	1	1.14	1.21	1	1	1.20	1.37
	Ω	1.15	1.15	1.28	1.34	1.15	1.15	1.29	1.34	1.15	1.15	1.27	1.31
	Behavior factor	1.15	1.15	1.49	1.57	1.15	1.15	1.47	1.62	1.15	1.15	1.53	1.79
	Displacement amplification factor	1.15	1.15	1.51	1.59	1.15	1.15	1.48	1.65	1.15	1.15	1.56	1.88
Vertical Direction	μ	1.67	2.30	1.89	1.24	1.39	2	2	1.29	1.44	1.90	1.66	1.68
	$R\mu$	1.53	1.90	1.60	1.14	1.34	1.73	1.74	1.26	1.37	1.67	1.53	1.54
	Ω	1.44	1.49	1.16	1.26	1.53	1.74	1.18	1.34	1.64	1.82	1.35	1.23
	Behavior factor	2.21	2.82	1.86	1.44	2.10	3	2	1.69	2.25	3.05	2.06	1.89
	Displacement amplification factor	2.41	3.42	2.20	1.56	2.14	3.49	2.37	1.74	2.36	3.46	2.25	2.07

Table 7 demonstrates that the value of ductility factor (μ), ductility reduction factor ($R\mu$) and overstrength factor (Ω) in the horizontal direction for structures with the rise-to-span ratio of 1/7, 1/5 and the entire span lengths of the domes are equal to unity and the structures are in the elastic range. Then, an upward trend is observed with the growth of the rise-to-span ratio. The value of the overstrength factor is almost constant with the growth of the span length of the domes. In other words, the rate of changes of the yield load level to the load level corresponding to the formation of the first plastic hinge is almost constant. In the vertical direction, the aforementioned coefficients increase for the rise-to-span ratio of 1.7 to 1.5, then decrease with the growth of the rise-to-span ratio which is affected by the target displacement. The behaviour factor increases with the growth of the rise-to-span ratio and the span length of the domes in the horizontal direction. In structures with the rise-to-span ratio of 1/7 and 1/5 and for the entire span lengths, based on the dominant period of these structures, which are near the acceleration-sensitive region, the value of the behaviour factor is equal to 1.15. This implies that these structures should designed in the elastic state. In the vertical direction, the maximum value of the behaviour factor belongs to the domes with the rise-to-span ratio of 1/5. In the structure with the rise-to-span ratio of 1/2 and the span length of 80 meters, the maximum value of displacement amplification factor reaches 1.88 in the horizontal direction. In the vertical direction, the value of this coefficient increases with the increase in the rise-to-span ratio until it reaches 1/5, and then it has a downward trend.

Table 8. The seismic response modification factors in the horizontal and vertical directions of the DLBVs.

Models	Length	50 m				100 m				150 m			
	Rise-to-span ratio	0.1	0.2	0.3	0.5	0.1	0.2	0.3	0.5	0.1	0.2	0.3	0.5
Horizontal Direction	μ	1	1	1	1.11	1	1	1	1.07	1	1	1	1
	$R\mu$	1	1	1	1.11	1	1	1	1.07	1	1	1	1
	Ω	1.15	1.15	1.15	1.18	1.15	1.15	1.15	1.16	1.15	1.15	1.15	1.15
	Behavior factor	1.15	1.15	1.15	1.32	1.15	1.15	1.15	1.24	1.15	1.15	1.15	1.15
	Displacement amplification factor	1.15	1.15	1.15	1.32	1.15	1.15	1.15	1.24	1.15	1.15	1.15	1.15
Vertical Direction	μ	1	1.25	1.87	2.68	1	1.03	1.93	2.75	1	1.04	1.82	2.25
	$R\mu$	1	1.22	1.54	2.09	1	1.03	1.43	2.12	1	1.04	1.53	1.87
	Ω	1.15	1.22	1.26	1.48	1.15	1.15	1.18	1.35	1.15	1.15	1.17	1.23
	Behavior factor	1.15	1.49	1.95	3.1	1.15	1.19	1.69	2.86	1.15	1.2	1.79	2.3
	Displacement amplification factor	1.15	1.52	2.37	3.99	1.15	1.19	2.28	3.7	1.15	1.2	2.14	2.78

According to Table 8, the behavior factor of the DLBVs in the horizontal and vertical directions is in the range of 1.15-1.32 and 1.15-3.1, respectively. In the horizontal direction, the behavior factor of the DLBVs with rise-to-span ratios of 0.1 to 0.3 for all the barrel vault lengths is equal to 1.155. So, these models remained in the elastic range, and they should be designed considering a linear elastic behavior in this direction. For the models with a rise-to-span ratio greater than 1/3, if the barrel vault length is kept unchanged and the rise-to-span ratio increases, or if the rise-to-span ratio is kept constant and the barrel vault length decreases, both the over-strength factor and the ductility reduction factor increase in the horizontal direction. So, the behavior factor increases in the horizontal direction. If the barrel vault length is kept unchanged and the rise-to-span ratio increases, both the over-strength factor and the ductility reduction factor increase in the vertical direction; therefore, the behavior factor increases in this direction. Also, the displacement amplification factor of the DLBVs in the horizontal and vertical directions is in the range of 1.15-1.32 and 1.15-3.99, respectively.

10. Conclusions

The present paper investigates the seismic behavior of three types of space structures called SLDDs, DLDDs, and DLBVs and extracts the seismic response modification factors. After the design of the structural models and performing the nonlinear time history and pushover analyses, the target displacement and the idealized force-displacement curve are extracted. Then, the behavior factor and displacement amplification factor are evaluated. The results illustrate that the models with a low rise-to-span ratio have elastic behavior in the horizontal direction, and by increasing the rise-to-span ratio, the ductility and behavior factor increase in the horizontal direction. The behavior factor in the vertical direction for the dome models decreases by increasing the rise-to-span ratio, but increases in the barrel vault models.

Abstract

Suspended-dome structures are widely used as a typical representative of spatial structures with large spans. While there have been many studies on the seismic performance of traditional spatial grid structures, such as reticulated shells, trusses, and arches, there are relatively few studies on the seismic performance of suspended-dome structures under strong seismic. This paper aims to investigate the mechanical response and failure mechanism of suspended-dome structures under strong seismic considering different bearing conditions. The results indicate that the displacement under the action of three-way hinged constraints is smaller than that of the radial release structure, and the failure mode of the suspended-dome structure under different support conditions during strong seismic is steel tie rod failure.

Keywords: suspended-dome structure, strong seismic action, seismic response, numerical simulation

1.Introdution

With the development of social economy and technology and the improvement of people 's living standards, people 's demand for large-span buildings is increasing, such as large stadiums, exhibition centers, station terminals, hangars, etc. The grid structure suitable for the construction of large space has become the preferred structural system. The research on the seismic performance of large-span spatial structure is an important basis for the progress of engineering disaster prevention and mitigation technology [1-2]. The suspended-dome structure has high mechanical performance and broad application prospects. Scholars at home and abroad have carried out a lot of research on reticulated shell structure and achieved rich results. However, there is no in-depth study on the strong seismic of suspended-dome structure, and its seismic performance needs further study.

In terms of reticulated shell structures, a large number of theoretical, experimental and large-scale numerical analysis studies have been carried out on the failure mechanism of steel reticulated shells under strong seismics at home and abroad. Shen et al [3] proposed a criterion for dynamic instability and strength failure of reticulated shell structures under strong seismics. Zhou et al [4] proposed the progressive collapse mode of ' double inclined rod fracture zone ' under the condition of strong seismic of cylindrical reticulated shell with longitudinal support. Li et al [4] analyzed the dynamic stability of-Kiewitt-8 single-layer spherical reticulated shell structure under seismic. Ma et al [5] studied the dynamic behavior and seismic design method of single-layer reticulated shells with semi-rigid connections. In the aspect of seismic performance of suspended-dome, domestic scholars mainly carried out relevant research on structural dynamic characteristics, dynamic stability and dynamic response time history analysis in combination with practical projects. Ding et al [6] analyzed the dynamic characteristics of the latticed shell string structure of the gymnasium roof of Anhui University. Cai et al [7] compared and analyzed the natural frequency and basic characteristics of suspended-dome with

different prestress levels and different upper single-layer reticulated shell sections. Wei et al [8] analyzed the dynamic characteristics and seismic response of the elliptical suspended-dome roof structure. Liu et al [9] summarized the effects of structural parameters, uniform load and the introduction of cables on the dynamic stability of suspended-dome structures under seismic loads. Gui et al [10] analyzed the dynamic stability of long-span suspended-dome structure. Li et al [11] studied the dynamic response of Kiewitt suspended-dome with large span and small rise-span ratio. Zhang et al [12] used bilinear constitutive model and strain-damage coupling constitutive model to analyze the whole process dynamic time history of an 8-point supported suspended-dome structure under different seismic accelerations. Based on 18 examples, Wang et al [13] studied the elastic-plastic response characteristics of suspended-dome under rare seismics. In the study of suspended-dome structures, Lu [14-16] conducted dynamic scale model tests to obtain the natural frequency and damping measurements of the structure. Zhao [17] investigated the seismic performance of suspended-dome structures with different lower supports using dynamic scale model tests and finite element numerical analysis. Wang [18] created a 1:20 scale model of the roof structure of Lanzhou Olympic Stadium to investigate the prestressed distribution characteristics and static characteristics of the ribbed small-rise-span ratio cantilever dome structure.

However, these studies have mainly focused on conventional seismic action and have not explored the effects of strong seismic action on the structure. The destructive impact of strong seismics, as demonstrated by the recent seismic in Turkey, highlights the importance of studying the behavior of structures under such conditions. Therefore, this paper aims to analyze the time-history response differences and failure modes of the suspended-dome structure under strong seismic action, taking into account various bearing conditions.

2. Engineering background and overview

The structure of Lanzhou Olympic Sports Center Gymnasium adopts a rib-ring and union-square combined single-layer reticulated shell for the roof, as shown in Figure 1. The chord-supported dome roof structure has the characteristics of large span, dense nodes, and complex seismic performance. Based on this, this paper chooses the chord-supported dome roof structure of Lanzhou Olympic Sports Center Gymnasium as the research object for dynamic characteristics, which is more representative and typical.

The structural parameters of Lanzhou Olympic Sports Center Gymnasium's chord-supported dome roof structure are a span of 94 meters and a rise of 8 meters. The seismic fortification intensity is 8 degrees, the design seismic basic acceleration is 0.2g, and the design seismic grouping is the third group. The site category is category II. The structure consists of an upper single-layer reticulated shell and a lower Levy-type cable support system, as shown in Figure 2. The permanent load value is 1.2 kN/m^2, and the live load value is 0.5 kN/m2. The upper reticulated shell is composed of 528 rods and 253 nodes. There are 12 central nodes where the 12 shell diameter rods intersect, forming a circular shape in plan view. The roof has a total of 7 rings of ring rods, and the outermost ring is divided into 48 equal parts by the diameter rods. The outer 4 rings have diagonal support rods to increase the overall stability of the structure. There are 24 evenly distributed supports along the outermost ring of the roof. The lower part is a Levy-type cable support system consisting of 5 rings of circular cables, 186 radial steel tension rods, and 90 vertical bracing rods. The prestressed value of the cable support system from the outer to the inner ring is 2800, 1300, 700, 350, 300 kN, respectively. Both the radial and ring rods are of box section while the diagonal support rods are of circular pipe section, all made of Q355B material. The cables are high-vanadium-plated tension cables, the radial steel tension rods are solid round rods of Q690D, and the vertical bracing rods are circular steel pipes of Q355B.

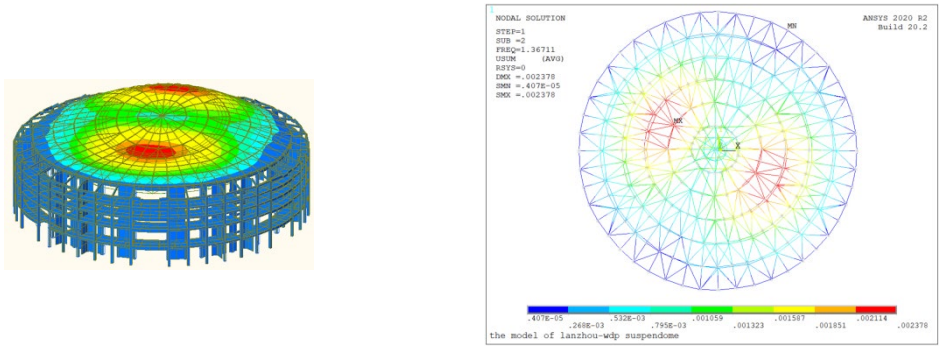
3.1. Model verification



A finite element model was established using the large finite element software ANSYS. Firstly, the finite element model of the prototype structure was compared and analyzed with the modal analysis results of the design institute model to verify the correctness of the finite element model. As shown in Figure 3 and Table 1, the natural frequencies of the modal analysis can be well matched, proving that the built model can meet the actual requirements well. Then, time-history analysis under strong seismic action was carried out, and three-directional inputs were selected for analysis, with horizontal X and Y directions and vertical Z direction. The proportional selection of three-directional inputs was 1:0.85:0.65. The structure is located in Lanzhou, a rare seismic zone with a design intensity of 8 degrees. Considering two types of supports: three-way hinged constraints and radial release, seismic response analysis was performed under extremely rare seismics. The trend of member internal force and displacement changes of the structure under the extreme rare seismic action was obtained, and the time-history response variation law of the structure under different seismic waves such as TAFT wave, EL-Centro wave, and Beijing wave was obtained through time-history analysis. Combining the model with the on-site experimental situation and according to the symmetry of the structure, specific members were selected for analysis at appropriate positions in the finite element analysis model, as shown in Figure 4. The specific member selection situation was given in the form of "xa-b" with "x" as the test content code, "a" as the radial number (there are 48 radial member numbers in total as shown in Figure 4(a)), and "b" as the circumferential number (from inner to outer, there are 1-7 circles, and the vertex number of the net shell is 1-0).

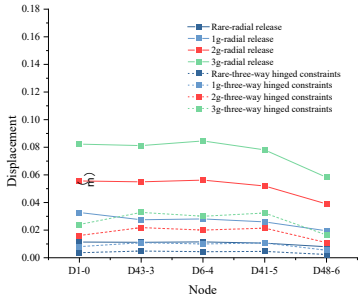
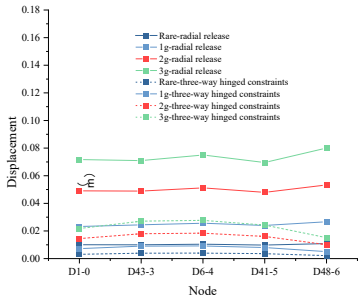
3.2. Seismic response analysis of structure under different bearing conditions



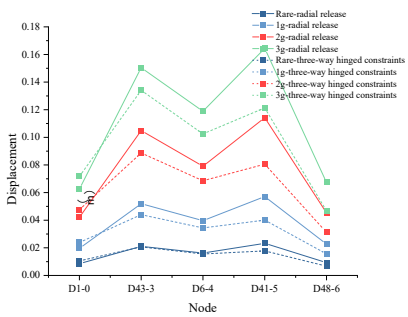
To investigate the effect of boundary support conditions on the seismic performance of suspended-dome structure, simplified models with boundary conditions of radial release and three-way hinged constraints were established using the numerical modeling method described in the previous section. A comparative analysis of the strong seismic mechanical performance of the suspended-dome structure under different support conditions was conducted.

3.2.1. Extremely rare seismics



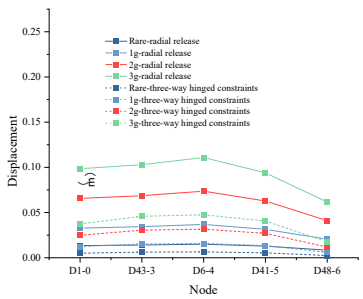
(1) Displacement

Fig. 5 to 7 show the peak horizontal and vertical displacements under different seismic waves and amplitudes. By comparing the displacements at different locations of the models with radial release and tri-axial hinge constraints, it is found that as the seismic waves and amplitudes increase, the vertical displacement of the suspended-dome structure with tri-axial constraints decreases significantly compared to that of the radial release.

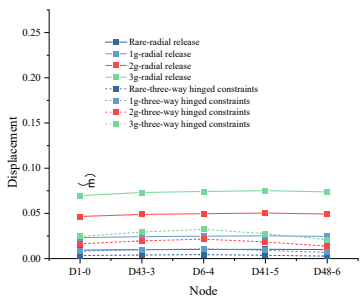


Under extremely rare seismic conditions, as the seismic waves increase, the displacement gradually increases, and the trend is consistent with that under rare seismic conditions, with a larger increase in the Z-direction displacement than in the horizontal displacement. As the seismic waves increase, the displacement at the middle position of the suspended-dome structure with tri-axial hinge constraints gradually increases, but it is still smaller than that of the radial release structure. The main reason for this is that the structure support cannot deform, and the seismic forces are mainly counteracted by the central structural members, resulting in smaller displacement.

(a) X-direction displacement



(b) Y-direction displacement



(c) Z-direction displacement

Figure 7. Peak displacement response of Beijing wave

(2) Internal force of structural members

Based on the analysis above, the structure is more sensitive to EL-Centro wave, so EL-Centro wave was selected for member force analysis. The variation of maximum member forces of the model under rare seismic and extremely rare seismic effects under different support conditions is shown in Figure 8. As shown in Figure 8, for different support conditions, the internal forces of the ring rod members C29-7 and C22-6 near the support in the three-axis constrained support structure are smaller than those of the middle circumferential members, which is significantly different from the variation trend of the radial release support structure. The main reason for this is that the deformation is restricted at the support, and the members at the support cannot generate large deformation, resulting in a decrease in internal forces. However, the seismic action is mainly offset by the members in the middle structure, resulting in internal forces larger than those of the middle members in the radial release structure. In addition, as the amplitude of the seismic wave increases, the internal forces of the ring rod members increase slower than those of the radial members. For cable members, under the three-way hinged constraints condition, the minimum cable force on the outer ring is significantly reduced compared with that of the radial release support, but slack is still observed in the inner ring cable.

Through Figure 8, it can be observed that the support has a significant influence on the internal forces of the members near the support position. The internal forces at the support will decrease, but there will be an increase in internal forces for the middle members of the structure. The internal forces of the structure will have significant differences under different support conditions, and the influence of support conditions on the structure should be considered in structural design.

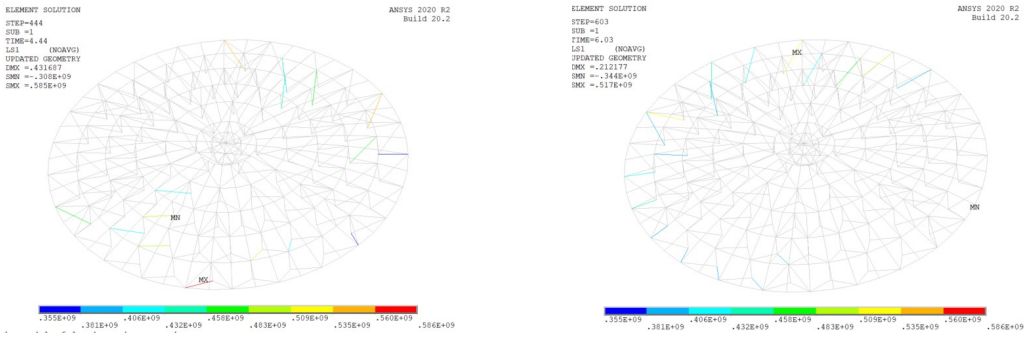
3.3. Failure analysis of suspended-dome structure under strong seismic



3.3.1. Radial release constraint support

The failure mode analysis of the suspended-dome structure under strong seismic action is studied in this section, as shown in Figures 9 to 12. Under seismic waves of 3g and above, the upper shell structure and cable of the structure did not enter the plastic state, but some of the steel tie rods entered plastic state under seismic action, and even some tie rods reached the ultimate load, so the suspended-dome structure is selected for failure analysis in this section. According to the existing Q355B material, its ultimate strength is 470MPa. Under the 3g seismic wave action, when the structure has the maximum downward displacement, the maximum stress of the steel tie rod component near the support reaches 490MPa, which reaches the ultimate load. When the structure has the maximum upward displacement, the steel tie rod near the support enters plastic state without reaching the ultimate load. With further increase in seismic action, the upper shell structure and cable of the structure still did not enter plastic state. When the structure had the peak displacement in the downward direction, the steel tie rod gradually developed plasticity from the outside to the inside, and when the peak displacement was in the upward direction, the trend was consistent with the downward direction and developed from the outside to the inside, but did not reach the ultimate load. For the suspended-dome structure, when the stiffness of the upper shell structure is large, the steel tie rod strength failure will occur in the structure, and attention should be paid to the design of the steel tie rod in the design process.

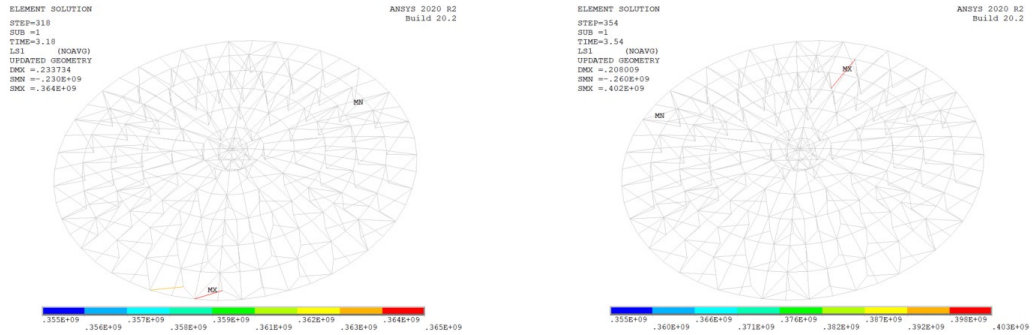
Figure 12. 6g seismic wave plastic rod distribution

3.3.2. Three-way hinged constraints



The failure mode analysis of the suspended-dome structure with three-way hinged constraints under strong seismic action was studied, as shown in Figure 13. Under seismic waves with an acceleration of 3g or more, the upper mesh shell structure and cables of the structure did not enter plastic deformation. However, some steel rods entered plastic deformation under seismic action, and compared with the radial release support, no rods in the structure reached the ultimate bearing capacity. According to the existing Q355B material, its ultimate strength is 470MPa. Under the downward maximum peak displacement of the structure under 3g seismic waves, the maximum stress of the steel rod component near the support reached 356MPa, and the rod entered plastic deformation. When the structure reached the upward maximum peak displacement, the steel rod near the support entered plastic deformation, but no rods reached the ultimate bearing capacity. When the seismic action was further increased, as shown

in Figures 14 to 16, the upper mesh shell structure and cables of the structure still did not enter plastic deformation. When the structure reached the downward peak displacement, the steel rods gradually developed plastic deformation from the outside to the inside, and when the structure reached the upward peak displacement, the trend was consistent with that when it reached the downward peak displacement, developing from the outside to the inside. When the acceleration reached 6g, the internal force of the rod reached the ultimate bearing capacity when the structure reached the upward peak displacement. For the suspended-dome structure with different supports, there are significant differences in its seismic performance and internal forces of the rods, but steel rod design should be carefully considered during the design process, as the steel rods of the suspended-dome structure will experience strength failure.

4.Conclusion

This article conducts a finite element numerical simulation analysis of the suspended-dome structure of the Lanzhou Olympic Sports Center under strong seismic conditions. The dynamic method is used to obtain the natural vibration characteristics of the structure, and then the time-domain response of the suspended-dome structure is obtained to analyze the impact of support conditions on the structure. Finally, an extremely rare seismic analysis is conducted to obtain the failure mode of the suspended-dome structure. The main conclusions are as follows:

(1) Under strong seismic conditions, there are significant differences in the internal force changes of the structure under three-way hinged constraints and radial release restrained supports. The internal forces of the members near the support under the t three-way hinged constraints are smaller than those under the radial release restrained support condition, but the internal forces of the members in the middle of the structure under the three-way hinged constraints are larger than those under the radial release restrained support condition. Additionally, the internal forces of the circumferential cable members near the support decrease significantly under seismic action.

(2) Under strong seismic conditions, the failure mode of the suspended-dome structure is strength failure. When the stiffness of the upper shell is high, the shell will not experience plastic deformation, but the lower steel cables will undergo plastic deformation, mainly in the steel cable members near the support. Therefore, the design should focus on the steel cable design.

Abstract

Mode is the most basic and important dynamic characteristic of a structure. Modal analysis is mainly used for dynamic property evaluation, vibration fault diagnosis, structural health monitoring, etc. For conventional rigid structures, modal testing and prediction methodology are well established and mature enough. However, for flexible inflatable membrane structures, the modal state is significantly influenced by the internal pressure and surrounding air, which makes the modal identifications more difficult. In this paper, a scaling stratospheric airship with a length of 2.48 m was used to study the dynamic mechanical properties of the airship envelope under different pressure. To obtain the overall vibration modes of the inflatable airship, the 3D laser vibrometers were arranged at four positions under each pressure condition, and the results were combined to obtain the global vibration mode diagram. It was found that the vibration mode distribution of the envelope was mainly breathing, and the frequency values of the first four modes indicated that the larger the internal pressure of the airship envelope, the greater the stiffness. This study realized the full-field modal testing and analysis of the flexible airship envelope. The measured data was reliable, which can provide experimental system support and test program reference for the dynamic characteristics of stratospheric airships as well as other inflatable membrane structures.

Keywords: stratospheric airship; inflatable membrane structures; dynamic analysis; modal identifications; full-field measurement

1. Introduction

As one of the most crucial and seminal dynamic characteristics for structural systems, modal analysis has been widely adopted across a broad spectrum of industries including aerospace, machinery, civil engineering, and the like. Essentially, modal analysis is to transform complex physical coordinates in vibration differential equations into uncoupled modal coordinates [1]. It is primarily used to investigate the natural frequencies and modal shapes of structures, thus providing support for vibration fault diagnosis, structural dynamic modifications, design optimization, and other related aspects in engineering. The modal identification of conventional rigid structures such as reinforced concrete and vehicles is a well-established and streamlined process, which is little affected by environmental factors. However, the modal characteristics of flexible membrane structures such as airships are substantially influenced by the ambient air and pressure [2]. The discrepancy between pure solid simulation results and experimental frequencies can reach up to 50% [3]. While the simulation of fluid fields and geometric nonlinearity is complex and demands considerable computational resources. To solve for the vibration properties of membrane structures in still air, various numerical simulation and experimental methods have been developed.

The representative numerical methods mainly include the added-mass method [4], acoustic-structure interaction (ASI) [5], and fluid-structure interaction (FSI) [6]. The added-mass method is a widely employed approach for analyzing the dynamics of flexible membranes or plates in fluid flow, which

Copyright © 2023 by Longlong CHEN and Wujun CHEN Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

equivalently relates the kinetic energy of the fluid to added mass [7]. Chen et al. [8] derived the added mass of one-way tensioned membrane vibrating in the fluid domain. The results demonstrated that the added mass was related to the modal order. The ASI method considers the fluid domain as an acoustic medium, and the vibration energy is transferred through acoustic pressure [9]. Srivastava et al. [10] investigated the effect of internal gas filling on the dynamic response of inflatable torus using the ASI approach. The results showed that the air significantly altered the eigenfrequency value and vibration modes. The FSI method is a combination of computational fluid dynamics (CFD) and computational solid mechanics (CSM). It can solve the coupled modes of complex membrane structures with irregular shapes and accurately reflect the interaction between fluid motion and structural deformation [11]. Based on the FSI theory and potential fluid theory, Qiu et al. [12] established a theoretical model on the membrane structure and the air field interaction.

In addition to numerical simulation, experimental methods play an important role in modal analysis. Hu et al. [2] tested the modal behaviors of an inflated tube cantilever, and the targets were arranged on the front side of the tube. Zhang et al. [13] developed a method for simultaneously calculating the top and bottom Z-displacement of the hexagon air cushion. However, the research mentioned above mainly focused on flat films or part region of airships. To the best of the authors' knowledge, there have been no reports on three-dimensional full-field modal testing of inflatable membrane structures. Therefore, this paper aims at the full-field modal testing and analysis of a scaling airship envelope. The PSV-500-3D scanning vibrometer was employed to identify the airship modes under five loading cases. The modal testing principle and main process are clarified. And the experimental results of different pressure are thoroughly analyzed and compared.

2. Modal testing principle and process

2.1. Experimental principle

The vibration testing was conducted using the PSV-500-3D full-field scanning laser vibrometer from the German company Polytech, while the modal extraction was performed using the LMS modal analysis software from Siemens. To ensure the rationality and accuracy of the experiments, the elaboration on the measurement and modal identification principle is necessary.

2.1.1. vibration measurement principle

Polytec laser vibrometer utilizes laser Doppler interferometry technology, which is widely used in the fields of national defense and basic research. It mainly utilizes the optical Doppler principle [14] to measure the vibration magnitude of objects. Laser measurement has the advantages of non-contact, high measurement accuracy, large measurement dynamic range, and high spatial resolution. The laser emitted by the laser generator is divided into two beams of light through a lens. Beam 1 is the reference beam and beam 2 is reflected by the surface of the moving object. The Doppler signal proportional to the velocity of the moving object is generated by interference, and the time history signal of the velocity and displacement of the moving object can be obtained by frequency and phase demodulation.

2.1.2. Modal identification principle

Since the PSV-500-3D three-dimensional full-field scanning laser vibrometer is only a modal testing software and cannot directly perform post-processing analysis on each order mode. In order to calculate the modal assurance criterion (MAC) of each order vibration mode, the test results need to be imported into professional modal analysis software LMS. Fast Fourier Transform (FFT) is one of the most commonly used signal decomposition methods in LMS. The classical Fourier principle shows that any continuous measured time sequence or signal can be represented as an infinite superposition of sine wave signals with different frequencies. For computers, only discrete and finite-length data can be processed. Hence, the Discrete Fourier Transform (DFT) is more suitable for discrete signal transformation. And FFT is one fast algorithm of DFT to reduce computational complexity.

The MAC is used to measure the similarity between two modal vibration modes, which can be expressed as follows:

$$MAC_{ij} = \frac{\left|\varphi_i^T \varphi_j\right|^2}{(\varphi_i^T \varphi_i)(\varphi_j^T \varphi_j)} \tag{1}$$

where φ_i is the *i*th order vibration mode of one model, φ_j is the *j*th order vibration mode of another model, and *T* represents the conjugate transpose of the matrix.

2.2. Experimental process

2.2.1. The experimental airship layout

The illustration and experimental layout of the airship can be seen in Figure 1. The full length of the model is 2.48 m, and the maximum diameter is 0.548m. The airship membrane is URETEK-3216LV laminated fabric material, which is interwoven by warp and weft yarns.

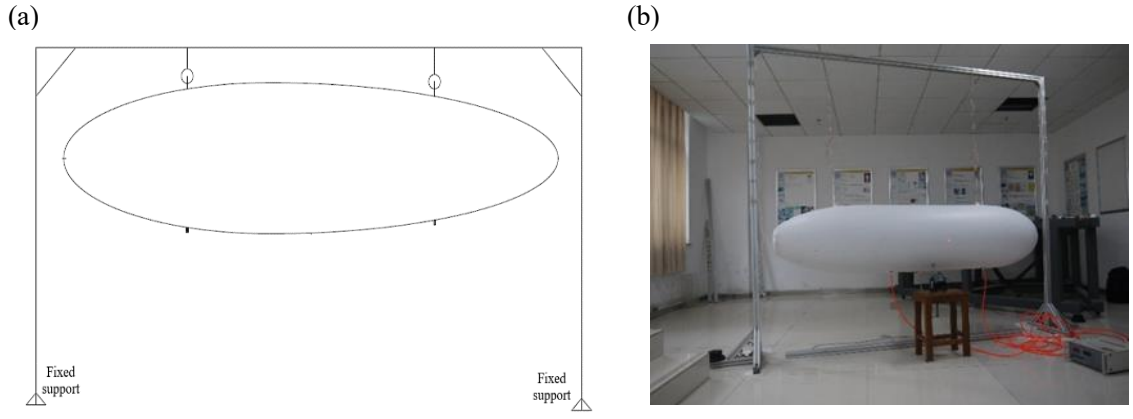

Figure 1. Layout of the airship envelope, (a) Illustration, (b) Experiment.

2.2.2. Testing system

The experimental system and equipment are shown in Figure 2, including a fixed frame, suspension connector, inflation and pressure control system, three-dimensional photogrammetry system and data acquisition system. The fixed support is an aluminium alloy profile with a height of 2.3 m and a width of 2.8 m. The inflation and pressure control system is independently developed by our laboratory. The measurement system uses the German PSV-500-3D Scanning Vibrometer full-field laser vibrometer, which includes a three-dimensional laser emitter, controller and test integration system, and the measurement error is less than 0.1%. All measurement data are digital signals stored in the host data management system, and the data acquisition is controlled by the PSV-500-3D software.

2.2.3. Experimental implementation

Five loading cases (2 kPa, 4 kPa, 6 kPa, 8 kPa and 10 kPa) were set to investigate the effect of pressure difference on the dynamic characteristics. For each case, the air pressure state, vibration mode and frequency, and modal assurance criterion of the airship were monitored or calculated. Measurement points (as shown in Figure 3) were firstly arranged and the modal shaker sweeping excitation was activated. Then the PSV-500-3D full-field scanning laser vibrometer was applied to measure the vibration modes and frequencies. To obtain the global vibration mode of the inflatable envelope, the laser vibrometer was arranged at four positions under each air pressure condition, and the four results were combined together to obtain the overall vibration mode contour.

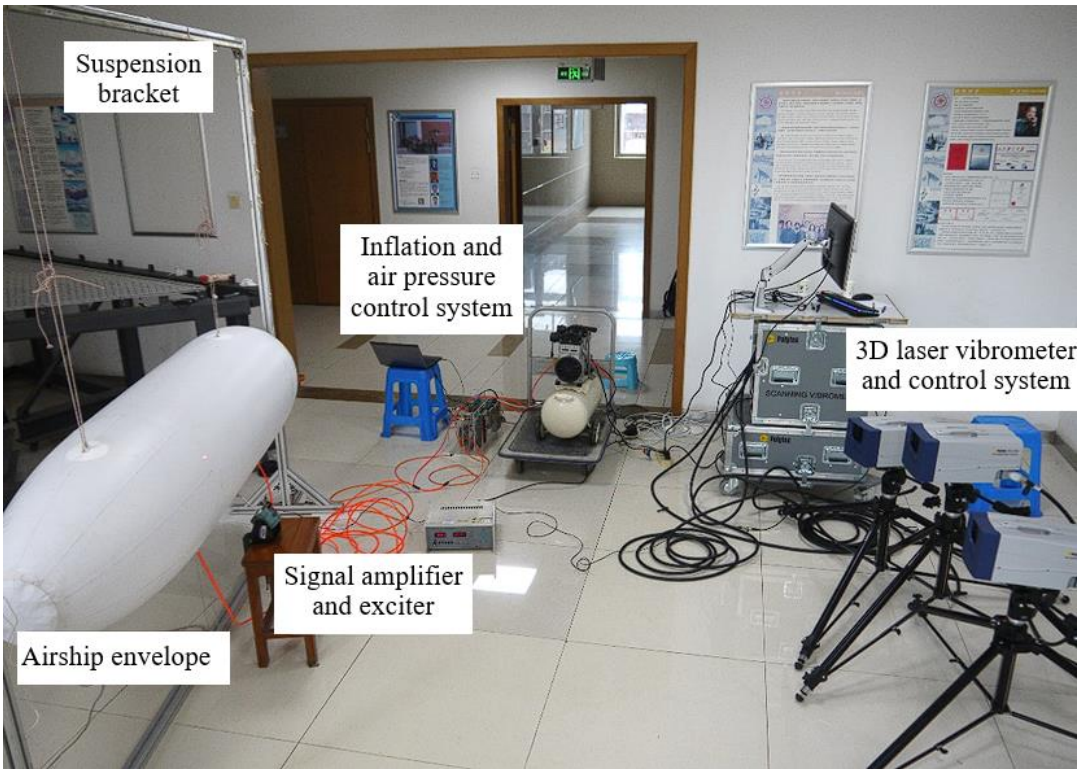

Figure 2. Modal testing system of the airship envelope.

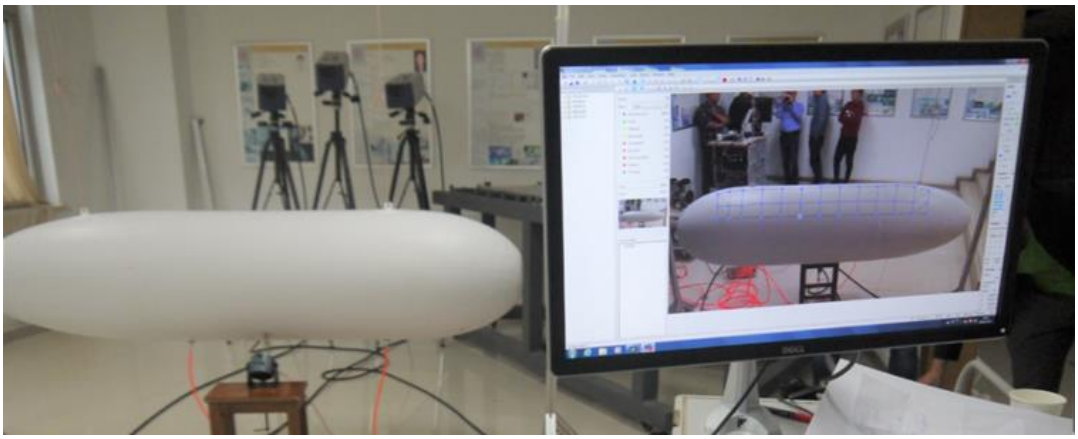

Figure 3. Measurement points arrangement of the envelope.

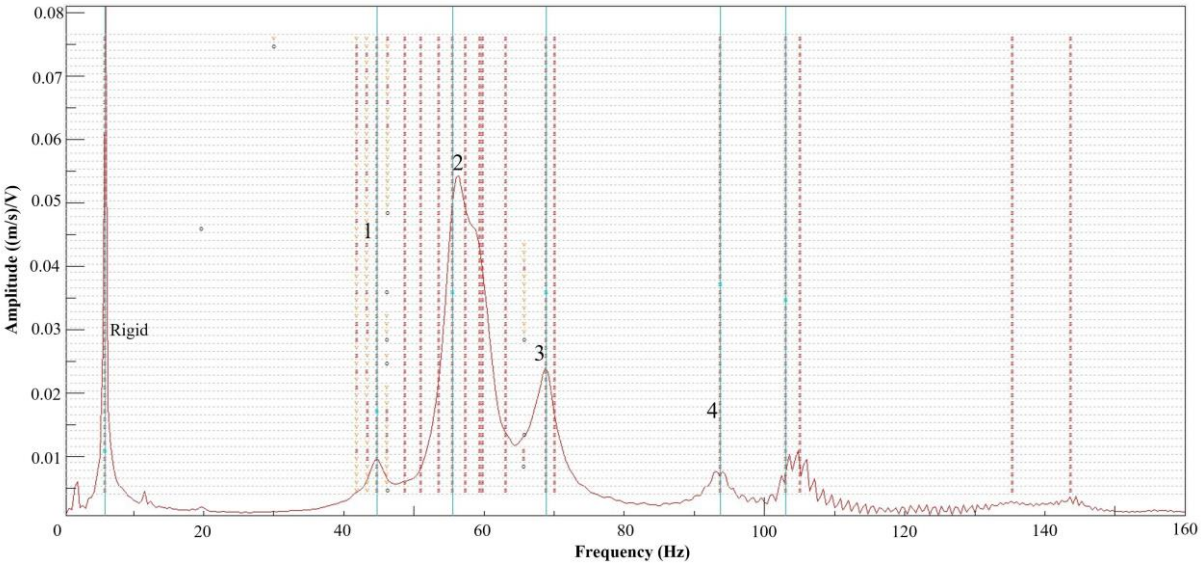
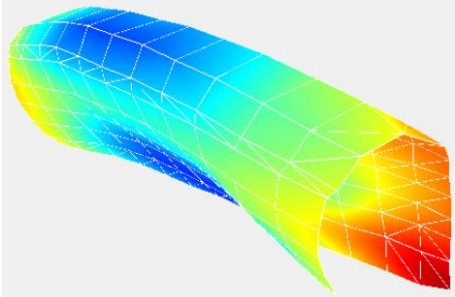
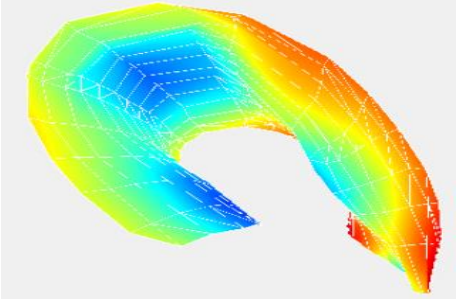
3. Results and comparisons

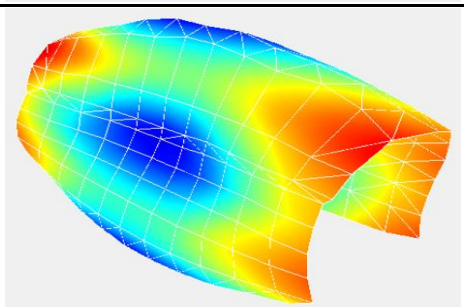
3.1. Results of 6 kPa pressure

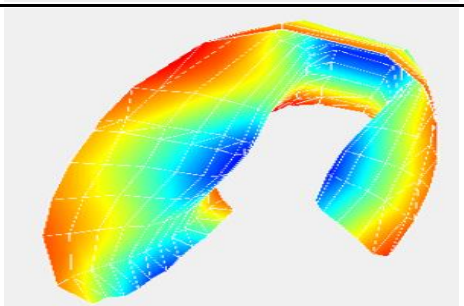
The testing results of the airship envelope under the 6 kPa air pressure condition were chosen as representative for analysis. The full-field amplitude-frequency curve is shown in Figure 4. To measure the first four modes of the airship envelope, the frequency domain range was selected as 0~160Hz. Based on the figure, the rigid body modes of the airship envelope are concentrated in the range of 0~15 Hz, and the first main mode is about 50Hz, which meets the requirement that the rigid body vibration mode is less than one-third of the main mode frequency. Typical modes identified by LMS analysis software are shown in Table 1. The modal contours of the flexible airship under various pressure showed that the vibration modes are mainly breathing modes.

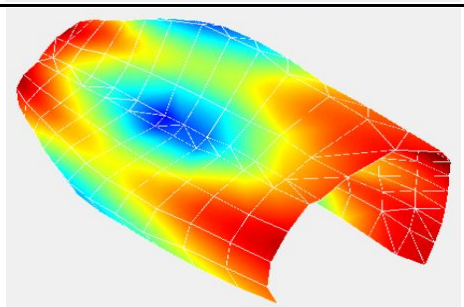


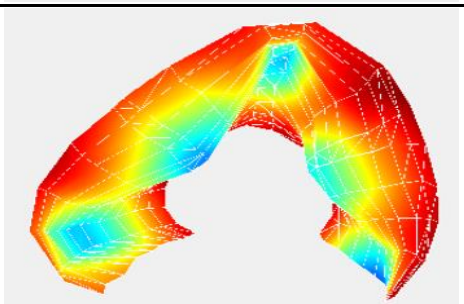


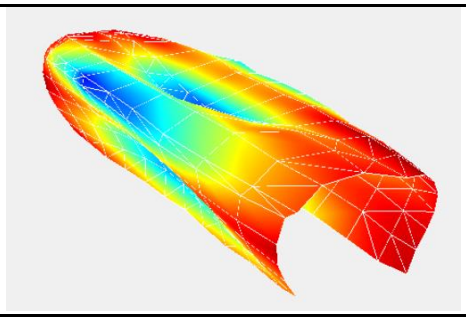












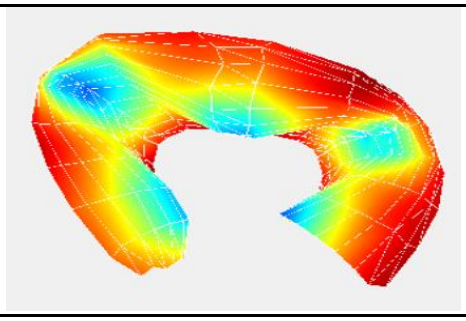


Figure 4. The amplitude-frequency curve identified by LMS.

Table 1. The vibration modes under 6 kPa pressure.

Modes /Hz	Side view	Perspective view
1st Mode /44.8		
2nd Mode /56.4		
3rd Mode /68.8		

4th Mode /93.2		

The modal assurance criterion under 6 kPa pressure are listed in Table 2. The coefficients on the main diagonal are all 100%, while the average value of the off-diagonal coefficients is 19.4%, indicating a high level of stability and reliability for the vibrating modes.

Table 2. The modal assurance criterion under 6 kPa pressure.

Modes	MAC values / %				
Rigid mode	100	17.279	0.083	0.39	1.392
Mode1	17.279	100	28.346	58.495	10.559
Mode2	0.083	28.346	100	36.004	26.468
Mode3	0.39	58.495	36.004	100	14.986
Mode4	1.392	10.559	26.468	14.986	100

3.2. Comparisons of different loading cases

The experimental results under different pressure conditions are graphed in Figure 5. It is evident that with the increase of internal pressure, the frequency values of the first four modes of the airship exhibit a rising trend. Moreover, this trend becomes more pronounced at higher internal pressure. The results demonstrated that the greater the internal pressure of the airship, the greater its stiffness.

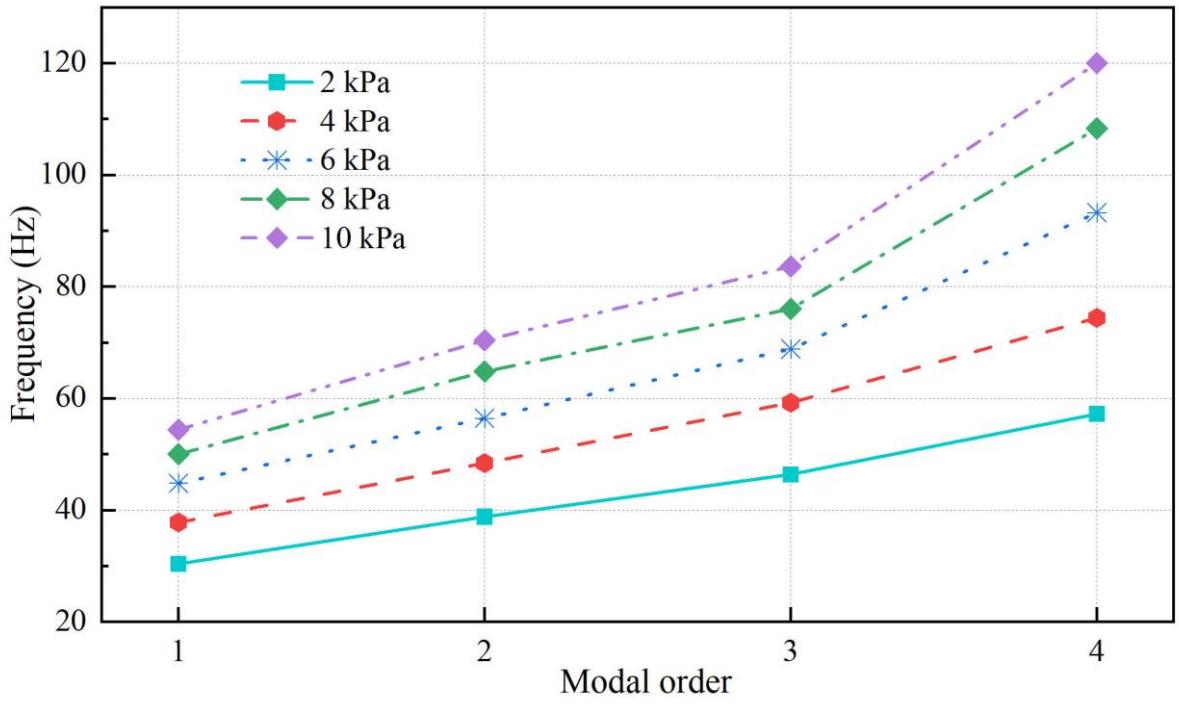

Figure 5. The frequencies of the airship under different pressure.

4. Conclusions

This paper presents a full-field vibration test and analysis system based on the PSV-500-3D Scanning Vibrometer, and the vibration characteristics of a scaling airship envelope under different pressure are investigated using the system. Specifically, the frequencies, vibration patterns and MAC values of the first four modes of the main envelope were analyzed under five pressure cases. The main conclusions can be drawn as follows:

(1) The rigid body vibration mode was less than 1/3 of the main modal frequency under each internal pressure condition, which indicated that the experimental results were credible. Besides, it showed that the boundary and excitation equipment were properly arranged and achieved the expected experimental objectives.

(2) The vibration mode distribution was primarily breathing, and the first four vibration modes were all breathing modes under five different pressure conditions.

(3) By comparing the frequencies under different pressure, it can be observed that as the internal pressure increases, the frequency values of the first four modes of the airship show an increasing trend. This indicates that the stiffness of the airship is positively correlated with the internal pressure.

This experimental research has established a good experimental foundation for testing and analyzing the modal behaviors of the flexible airship. The measured data is reliable, providing experimental support for the study of the dynamic properties of airships and other inflatable membrane structures.

Abstract

The paper explores a new type of programmable structural system that uses chain mail-like structures made of interlocking identical skeletal cubes. The programmable aspect of the system is defined as the ability of the initially planar modular assemblies to be reversibly constructed as distinctive self-supporting curved structures. The study focuses on an initially planar identical chain mail structure that was used to construct various curved structures by placing it in different placement orientations and erecting it in several steps of the same actuation procedure. The study found that various shapes of curved formations can be developed reversibly from the same planar structure. It also found the range of dimensional variations can be significantly increased by modifying the input of the orientation and actuation sequence parameters. Furthermore, it also found that by applying a local transformation only on a single row of interlocking modules at one end of the strip-like structure, an average of two-thirds of the modules in the configuration can be actuated to create a curved structure. Overall, this study provides a systematic investigation of the impact of applying a simple transformation mechanism on the overall behavior of the chain mail structure. The findings demonstrate the preliminary potential of chain mail structures as a new model of programmable modular structures, which could be useful in a variety of applications where flexibility, adaptability, and ease of construction are essential.

Keywords: programmable structure, interlocking assembly, adaptive structure, chain mail structure, form-finding

1. Introduction

1.1. Research interest surrounding chain mail structure

In simple terms, chain mail can be defined as an armour or protective garment formed of interlinked metal rings. In general, it is mostly known as a type of armour that was widely used by soldiers from the Middle to the early Renaissance era [1]. However, outside of the field of ballistic study, designers' and researchers' interest in chain mail-like material systems has developed quite rapidly in the last two decades [2]. This phenomenon is driven by the development of 3D printer fabrication technology and its increasingly widespread, easy and inexpensive use, which has triggered the emergence of a wealth of new design variations for chain mail-like material systems that were previously challenging to fabricate. As a result, the range of potential functionality of chain mail has been significantly expanded from wearable electronic devices [3], wearable medical support [4-6], and soft robotic components [7] to lunar mobility structures [8].

1.2. Chain mail material system for architectural application

Specifically in the architectural field, in the last ten years, there have been several publications that point out the potential implementation of a chain mail material system for an architectural application, for example, as an adaptive building skin [9, 10] and as transportable reconfigurable structures [4]. In both studies, as well as in some other studies which are not directly touching on the architectural field, the

concept of 'programmability' emerges through the abstraction of programmable-related design goals (such as being adaptive, customisable, and tunable products) [4, 6, 7, 9].

However, although chain mail adaption for an architectural scale holds exciting prospects, judging by the number of sources and depth of information published, there has been little progress in advancing this concept. Although several chain mail applications can indeed be found on built projects, for example, as an internal screen or an external building façade, in terms of design-led innovation, this is still relatively behind compared to other fields of science.

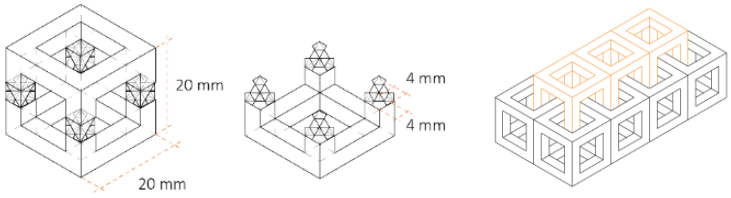
1.3. Identified problem

One recent study mentioned that despite the vast design space for a chain mail-like structures (geometrical interlocking assemblies), there is a lack of formalised design process to work with them, and the existing product development is largely dependent on intuition [11]. The importance of design method in architecture cannot be understated, especially when working with a new system [12]. However, there is currently a lack of explanation for the absence of research progress on chain mail-like structures for an intended application in an architectural context. Therefore, we consider the knowledge gap around chain mail material system adoption for architectural application to be due to the lack of a systematic design method.

2. Methodology

2.1. Research objective and scope

Aimed to advance the development of a chain mail material system for an architectural application, with emphasis on its potential programmability, we develop a body of research focusing on systematically exploring various design parameters and constraints tied to the development of a chain mail material system for architectural application. The objective of the programmability here is the ability of the initially planar modular assemblies to be reversibly constructed as distinctive self-supporting curved structures. The relevance of this system comes from the continuous need to improve efficiency in the construction of free-form architecture, which is strongly associated with highly-customized irregular curved geometries. Thus, it follows that the design of our chain mail module is limited to something that is made of simple and rigid identical modules in the form of a skeletal cube.



Based on a literature study and a series of pilot projects, we have discovered that one of the significant parameters in the design system is the transformation mechanism. In this context, the transformation mechanism defined as a series of conditions and processes that must be executed to 'actuate' certain sets of the desired physical behaviour of the chain mail structure (geometries) in accordance with a pre-arranged design program. Specifically, in this study, the scope of the transformation mechanism would be limited to examining the impact of two construction process-related parameters. These are the impact of structure orientation and structure actuation sequence on the chain mail structure's flexible shape-forming capacity and self-supporting capacity.

2.2. Prototype design

This specific study utilises only physical simulation on a small-scale physical model to identify the potential and limitations of programming the structure's physical behaviour through controlling the structure's boundary condition (specifically its pre-actuated placement orientation) and actuation sequence. The chain mail model was produced using a rapid prototyping method in the form of Fused Deposition Modelled (FDM) 3D prints using Polylactic Acid filament.

The chain mail physical model is in the form of a slender, strip-like assembly made of 3 rows of interlocked cubes sized 20 x 20 x 20 mm each, with a total length of 15 modules and a width of 2 modules in its basic, contracted state. Each chain mail module has two parts of an element with a 4 x 4 mm dimension of rectangular cross-section, as seen in Figure 1. Each of the elements is connected using

a 'kawai-tsugite' joint typically applied in timber constructions. These choices of dimension-to-thickness ratio and joint type are the result of another focused study on the same parent topic that is yet to be published.

(a) (b)

Figure 1. (a) Cube module dimension and (b) module assembly pattern used in this study.

The decision to use a small-scale, 3D printed prototype derives from the importance of this particular research in the larger systematic design study is to examine the relationship between placement orientation, actuation sequence, and flexible shape-forming capacity, which hypothetically is scale invariant. Additionally, self-supporting capacity is considered the most basic structural function that the structure should perform. Therefore, self-supporting capacity comes as a consequential significant parameter that can be observable regardless of the prototype scale and choice of material. It should be noted the design considerations for production and assembly of our chain mail structure are not within the scope of this paper.

2.3. Simulation procedure

2.3.1. Placement orientation

The first step of the simulation procedure begins with placing the structure in certain placement orientations. Here, there are six placement orientations that were applied, which were derived from two conditions, which are the structure's face placement and the structure's twisting.

As can be seen in Figure 1, the three rows of interlocking chain mail modules composing the test prototype form two levels of module stack. This stack can be placed with either the central row of modules (drawn in orange line in Figure 1b) facing up or facing down. Then, for any of the face placements, the structure can also be placed flat on the ground or the test base or can also be twisted to a certain degree of twisting, called by the term 'twist cycle' here. According to the number of faces in the cubic module, at least four stages of twist can be applied within one axis of rotation, as illustrated in Figure 2. Then, following the slender, strip-like proportion of the structure, intuitively, each twist can be initiated from either one or both ends of the structure.

(a) (b) (c) (d) (e)

Figure 2. End view representations of four types of that twisting cycles that can be applied sequentially to the structure: (a) no twisting, (b)1/4 cycle, (c) 1/2 cycle, (d) 3/4 cycle and (e) 1 full cycle.

Among the many combinations of placement orientation that can be generated, we applied six different types of input for the "structure orientation" parameter in this study, which are flat-up, flat-down, 1/2 cycle-up, 1/2 cycle-down, one cycle-up and one cycle-down orientation. The detailed definition and visualisation of each orientation type (illustrated with photos of the chain mail structure taken from above), are provided in Table 1.

Table 1. Six types of initial structure placement which act as the inputs for placement orientation parameter illustrated with photos of the chain mail structure taken from above.

No	Name	Definition	Visual information (top view)
1	Flat-up orientation	The central chain mail row is facing up without any twisting applies at both ends of the structure	
2	Flat-down orientation	The central chain mail row is facing down without any twisting applies at both ends of the structure	
3	1/2 cycle-up orientation	The central chain mail row is facing up with 1/2 cycle twisting applies at one end of the structure	
4	1/2 cycle-down orientation	The central chain mail row is facing down with 1/2 cycle twisting applies at one end of the structure	
5	One cycle-up orientation	The central chain mail row is facing up with 1 cycle twisting applies at one end of the structure	
6	One cycle-down orientation	The central chain mail row is facing down with 1 cycle twisting applies at one end of the structure	

2.3.1. Actuation method

Following the structure placement, the next step of the simulation procedure is to actuate the structure to transform it from a planar modular assembly into a reversibly constructed distinctive self-supporting curved structure. The actuation method that was used here is a mechanical actuation method that follows the general principle of installing designed instabilities that would create either temporary or permanent deformations in the structure [13]. The actuation method used in this study is made of only two simple step-procedure, such as rotating the last rows of the modules and then securing them to the base. The rotation is done in a 1/4 cycle intensity along the axis parallel to the structure's long side and in the opposite direction to where the structure span will be constructed, as seen in the illustration provided in Table 2.

While the actuation method is kept simple and identical in every simulation iteration, the actuation sequence can be customised as part of the programmable system's transformation mechanism. As with the structure's twisting, the structure's actuation process can also be initiated from either one or both ends of the structure. To examine the impact of actuation sequence in the curved structure's physical behaviour, four different types of actuation sequences were applied in each of the six simulation iterations (based on the number of different placement orientation types tested).

Technically, the four different sequences are part of a four step-procedure that is performed sequentially. However, for analysis purposes, according to the research objective, each step of the procedure will be analysed independently as a different type of actuation sequence. The detailed definition and visualisation of each actuation sequence type are provided in Table 2.

Table 2. Four types of structure actuation actions which act as the inputs for actuation sequence parameter illustrated with photos of the chain mail structure taken from the side.

No	Name	Definition	Visual information (side view)

1	First stage single end-actuation	The chain mail unit at the first end of the structure is rotated and secured. One curvature is formed.	
2	First stage double end-actuation	The first end of the structure is kept actuated, while the chain mail unit at the second end of the structure is rotated and secured. Two curvatures are formed.	
3	Second stage single end-actuation	The first end of the structure is deactuated (unsecured to let loose), while the second end of the structure is kept actuated. One curvature is formed.	
4	Second stage double end-actuation	The first end of the structure is re-actuated (re-rotated and re-secured), while the second end of the structure is kept actuated. Two curvatures are formed.	

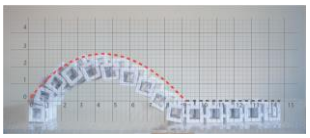
2.4. Data capturing

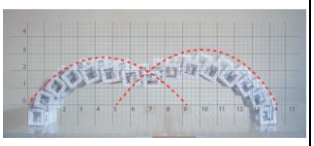
Considering the initial stage of the study and its objective (to effectively explore and identify the potential and limitations of programming the structure's physical behaviour through a particular transformation mechanism for providing immediate feedback into the larger systematic method study under construction), a simple data capturing method via sequential photography is used. Two cameras were set at two different points to capture the simulation process simultaneously. One camera captured the simulation from the side view along the long axis of the structure and another camera captured it from the top view.

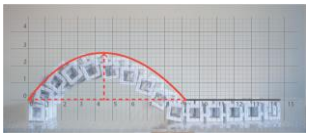
2.5. Data extraction, accuracy, and unit of measurement

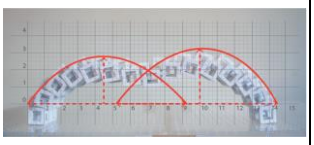
This research employs a quantitative approach. Therefore, a form of quantifiable measurement is required from each set of data generated out of the simulation. At the same time, a photograph would always naturally create a perspective image which may contain a certain degree of distortion depending on the photo's field of view. Thus, to emphasize the concept of scale invariance and avoid misinterpretation related to the level of accuracy of dimensional measurement that can be extracted from a photograph, the dimension of one module itself will be used as the unit of measurement in this study.

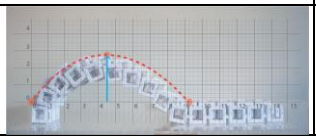
Then, to improve the accuracy level in the data reading, a smaller grid of measurement is provided by dividing one module size by a factor of four. In the data analysis process, the measurement grid was overlaid on top of every photo. The point of origin is started above the upper line of the structure in its initial planar position to ensure that any measurable dimension from the photo is only the one created after the actuation action has been implemented.

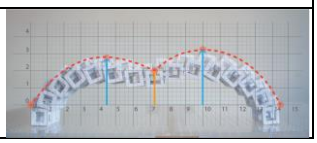




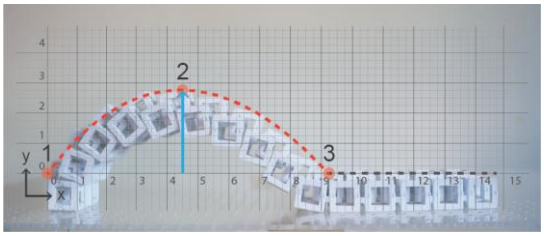






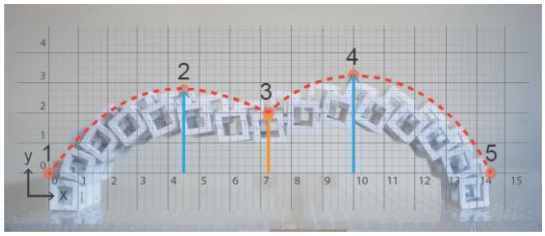


3. Data and discussion



3.1. Evaluation points

In total, there were twenty-four unique sets of visual data that can be observed in this study. They are generated from simulations of chain mail structure placed in six different types of orientation and then actuated with four types of actuation sequence. Based on their striking physical characteristics, the curved structures resulting from the simulation can be categorised into two groups. The first group consists of simulations involving actuation sequences 1 and 3, where there is a single curvature identified within the curved structure, while the second group consists of simulations involving actuation sequences 2 and 4, where two curvatures are identified in each curved structure.



To enable a quantitative data analysis process, there must be quantifiable evaluation parameters that can be extracted from each group. To do this, a set of evaluation points is mapped throughout the structure's outer form, following the location of unique sections along the curvatures. Borrowing the concept of wave evaluation, some of the essential points of evaluation which can be identified in those structures are the curved lines' boundary (that are the start and end points), the crest or peak points, and the interference or intersection point. The procedure to identify the location of the mentioned Evaluation Points (EPs), the definition of each point, and visual information on their location in each simulation group are provided in Table 3, Table 4, and Figure 3.

Table 3. Three steps-procedure to identify the structure's evaluation points in each simulation

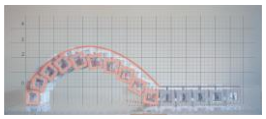
No	Definition	Visualization	
		Group 1: single end-actuated structure	Group 2: double end-actuated structure
1	Trace the outer form of the structure, differentiating parts that are impacted by the actuation process to form the curvature (marked by the red line), and parts that are not impacted (marked by the grey line).		
2	Focusing on the traced red line, use the line as a guideline to approximate the general shape of the curves and then check if the structures have been categorised within the correct group (based on the number of curvatures).		
3	Use the traced line as a guideline to approximate the location of several evaluation points and then extract their coordinates within the grid system.		

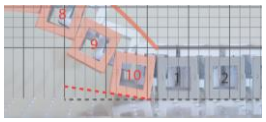
(a)

(b)

Figure 3. Different number and distribution of evaluation points for each of the simulation group: (a) Group 1 for curved structure with a single curvature and (b) Group 2 for curved structure with two intersecting curvatures

Table 4. Defintions for each evaluation point





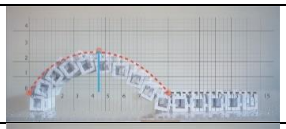
No	Name	Definition	Evaluation point (EP)	
			Group 1	Group 2
1	Start point	The position where the identified curved portion of the structure is started	1	1
2	Peak point	The highest point in the curved portion of the structure	2	2 and 4
3	Intersection point	The location where the two curvatures meet (happened only in the second group of simulation)	-	3

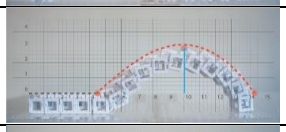
4	End point	The position where the identified curved portion of the structure is ended	3	5

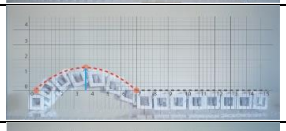
3.2. Evaluation parameters

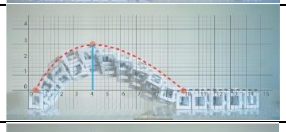
Based on the evaluation points mapped on each simulation data, at least three quantifiable sets of parameters can be evaluated to examine the shape-forming and self-supporting capacity of the structures. The definition, extraction method, result indication, and limitation of each evaluation parameter are described in Table 5.

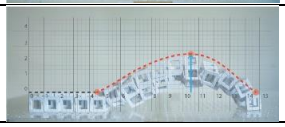
Table 5. The definition, extraction method, result indication, and limitation of the three evaluation parameters











No and name	**1. Actuation reach**	**2. Curved structure's span and rise**	**3. Curved structure's regularity index**
Definition	Actuation reach is the count on the number of modules that can be actuated from one point of actuation, indicated by a rise on the module's base from the test platform/ground.	Span is the distance between the two endpoints of the curved structure, while rise is the height of the peak point of the curvature.	The regularity index is a value to indicate the profile of the curved structure, whether it is closer to a regular, half-circle-like curve with high vertical symmetry or if it is closer to an irregular, floppy curve.
Data extraction method	The regularity of the structure's design enables the count of actuated modules to be taken from only one of three rows of interlocking modules (the front row with the most visibility from the side photograph).  	The span can be measured by calculating the distance between the first and last EPs along the x-axis. **<u>Group 1:</u>** The rise is the distance between EP 2 and the origin axis along the y-axis. **<u>Group 2</u>**: For simplification, the rise is determined by averaging the distance between EP 2, 3, and 4 from the origin axis along the y-axis.	**<u>Group 1:</u>** **Span-to-rise ratio:** measured by dividing half of the span with the rise. *Result:* <1 = the sharper the curve is likely to be; 1 = the more likely the structure to have a more regular, half-circle-like profile; >1 = the flatter the curve is likely to be. **Peak point position:** subtracting half of the span with the distance of EP 2 to EP 1/EP 3. *Result:* in its absolute value form, the smaller the subtraction result is, the more likely the structure to have vertical line symmetry. **<u>Group 2:</u>** **Peak point similarity:** subtracting the height of EP 2 and EP 4 along the y-axis. **Peak point position:** subtracting half of the span with the distance of EP 3 to EP 1/EP 5. *Result:* for both factors, in their absolute value forms, the smaller the subtraction results, the more likely the structures will have vertical line symmetry.
Result indication	The larger amount of modules actuated, the more effective the structure's actuation mechanism, and the more significant the structure's flexible	The larger the curvature span and rise, the more effective the structure's actuation mechanism is and the larger the structure's flexible	Overall, the higher the structure's regularity, the greater the structure's self-supporting ability, as it does have many floppy proportions of its curved structure.

	shape-forming and self-supporting ability.	shape-forming and self-supporting ability.	
Current limitation	Although it is visually clear that each module is actuated with different intensities (indicated by its rotational angles), this parameter is not measured yet due to the potentially low precision measurement for small details caused by perspective distortion inherent in a photograph.	The current method of approximating the curvature's dimension is greatly simplified. Although together, span and height can generally indicate the overall dimension of the structure, it does not confirm the actual profile of the curve itself.	The current method of approximating the curved structure profile is greatly simplified, especially because they left out some sections between the evaluation points.

3.3. Simulation data

Table 6 and Table 7 below are the simulation data for Group 1 and Group 2, respectively, along with the measurement of all the identifiable evaluation parameters.

3.4. Discussion

Referring back to the focus of the study, to examine the impact of two construction process-related parameters, such as "structure orientation" and "structure actuation sequence", on the chain mail structure's flexible shape-forming and self-supporting capacity, there are two findings that can be observed out of the data presented in Table 6 and Table 7.

Firstly, various shapes of curved formations can be developed reversibly from the same planar structure. This claim is evidenced by the presence of at least two categories of structures (Group 1 for structures with a single curvature and Group 2 for structures with double curvatures) that can be actuated from the same test prototype, even when the structure is put in the same pre-actuated orientation.

Furthermore, there were more variations that were generated within each group of structures parallel with the increasing number of orientation variations applied for each actuation sequence in this study. These variations can be quantified by the different ranges of structure span and rise. For the span, the range of structure span in Group 1 is significantly larger than that of Group 2, with the longest span up to 100% and only approximately 31% greater than the shortest span in the first and second groups of data, respectively. As for the rise, the range is relatively close between the two groups, with the highest rise being around 3,16 and 3,5 times greater than the shortest rise in the first and second groups of data, respectively.

Moreover, an additional sub-finding observable from this exercise that supports the main argument is that the actuation sequence plays a significant role in determining the final shape of the structure. This claim is evidenced by the different readings of evaluation parameter results, for example, in the curved structure's rise and span between structures generated with actuation type 1 and 3, and type 2 and 4, albeit the structures being made of the same test prototype which was also positioned in identical orientations. These findings confirm the importance of considering not only geometrical-related factors

(such as the structure design) but also the construction process-related factor (such as the actuation sequence) in the systematic method of designing chain mail as a programmable structure.

Secondly, aside from the shape-forming capacity, there is another important finding related to the self-supporting ability of the structure. The result of the simulations has shown that the self-supporting formations can be erected effectively by applying local transformation on only a small area of the structure. This is evidenced by, for example, the number of modules impacted for each actuation sequence. The most apparent evidence is illustrated within the first group of structures, where the actuation sequence is only initiated from one end of the strip-like prototype. For each of the simulations within this group, the number of modules that are impacted by the action and thus raised to the curved structure is predominantly more than 50% of the total number of the modules. The smallest number in the actuation range is 47%, with some simulations managed to transform up to 100% modules in the configuration with just a single actuation action.

4. Conclusion and future study

4.1. Conclusion

Concluding, this paper has presented a systematic study examining the impact of two construction process-related parameters, such as structure orientation and structure actuation sequence, on a chain mail structure's flexible shape-forming capacity and self-supporting capacity. In relation to the first dependent variable, the result of the study has shown that by applying only a simple transformation mechanism a single planar chain mail structure can be programmed to create a self-supporting curved structure with a relatively large range of span and height. Furthermore, by modifying the input of the orientation and actuation sequence parameters, the range of the dimensional variation of the structures can be enlarged significantly. Then, regarding the second dependent variable, the study has demonstrated the effectiveness of the designed actuation sequence in constructing the curved structure as a local transformation applied in a single row of modules which can impact an average of 76% of the modules in the configuration. These findings have demonstrated the preliminary potential of chain mail structure to be developed as a new model of programmable modular structure for constructing irregular, curved, free-form structures effectively.

4.2. Future study

Developed as a part of a body of research on the systematic design of programmable chain mail structure, the results from this study have been fed back into the project to aid with the next stage of research development. Some of the topics for the subsequent studies that will be developed out of this research include a study on the integrity of the curved structure when subjected to local transformation post-actuation and also a study on the scaling up of the test prototype to examine the scale invariant-ability of the research subject and method.

Abstract

The current climate changes call for sustainable development in many sectors, and the temporary structures sector is on this list. Temporary structures primarily define spaces and regulate the voids between permanent constructions, but they can be designed for disassembly as a way to reuse the same materials in different applications. This could further expand the flexibility of the systems to be rapidly assembled and disassembled, rebuilt in different configurations, and to be easily transported from one place to another. While deployable systems that deal with plate components like folded plates or curved surfaces face many challenges and complexity in articulating viable structural solutions, the paper focuses on designing double-curved plate modular components to fit together within a transformable system. The plates component are to be adjustable into different spacial configurations. The paper presents two main case studies that investigated double-curved plate components in a framework of developing the project ReciPlyDome [1]. The first case study used adjustable plate slits, in which the plate curvature can be controlled through adjustable slit surface connections. The second case study used double-layered bending-active plates, in which the components consist of two connected bending-active plates. In Addition, the paper discusses possible configurations of those two modules in structural sets based on polyhedral geometries or different surface tesselations. The resulting temporary systems can be reconfigured in different shapes and sizes using the same components, and are demountable systems with reversible dry connections. The paper also explores transformable kit-of-parts systems through digital and physical models and undergoes design and structural analysis using visual coding software.

Keywords: transformability, modularity, prefabrication, configurable, plates, temporary structures

1. Introduction

Over the last few years, the effects of climate change on the environment have become increasingly clear to people. There is an urgent need for more to be done to address this issue, leading to action being taken in a variety of fields to move towards a more sustainable future. Despite this, there is still much to be done. In the construction and building sector, there is a focus on creating sustainable strategies for permanent architecture, but less attention is given to the in-between, temporary structures that are found in all outdoor spaces. When walking around European cities, these temporary structures can be seen everywhere, ranging from street markets to festivals and parades. Even though the function of those temporary systems is only short-term, the use of materials and the reuse of the whole systems are permanent.

Temporary structures are those which are built to serve a specific purpose for a limited amount of time and then be taken apart. Some of these structures are designed to be used only once and their materials are either recycled or discarded. Examples of these could include event stages, exhibition pavilions, and decorative installations. On the other hand, this research approaches temporary structures as systems that are designed for disassembly with reversible connections and can be taken apart, relocated, and reassembled. Demountable structures provide great potential for creating a reconfigurable system that can be modified by rearranging its components.

Architectural engineering from VUB has been striving to create reversible systems. This effort was furthered when the ReciPlyDome [1], created in collaboration with the Royal Danish Academy of Fine Arts (KADK) in Copenhagen, demonstrated the potential of combining active bending double-layered reciprocal beams into a demountable structure. Although the ReciPlyDome has enabled the possibility of creating a demountable structure where every element is self-stabilized and works within the system, further development of the skeleton result is needed in order to provide a cover and a more enclosed space. To that end, two Master's theses were developed to investigate the potential of utilizing double-curved plate components to allow more covering areas in the system. These two research are represented as two case studies in this paper. The first case study simplified the double-layered beam system into single beams within reciprocal perpendicular cross-sections, then coupled the system with double-curved configurable plates for cladding. The second case study investigates plate bending-active elements instead of beams which reveals the potential of constructing a multifunctional system that offers coverage while preserving its structural qualities. "Figure 1" shows the different approaches of the case studies to tackle the cladding feature in the system.

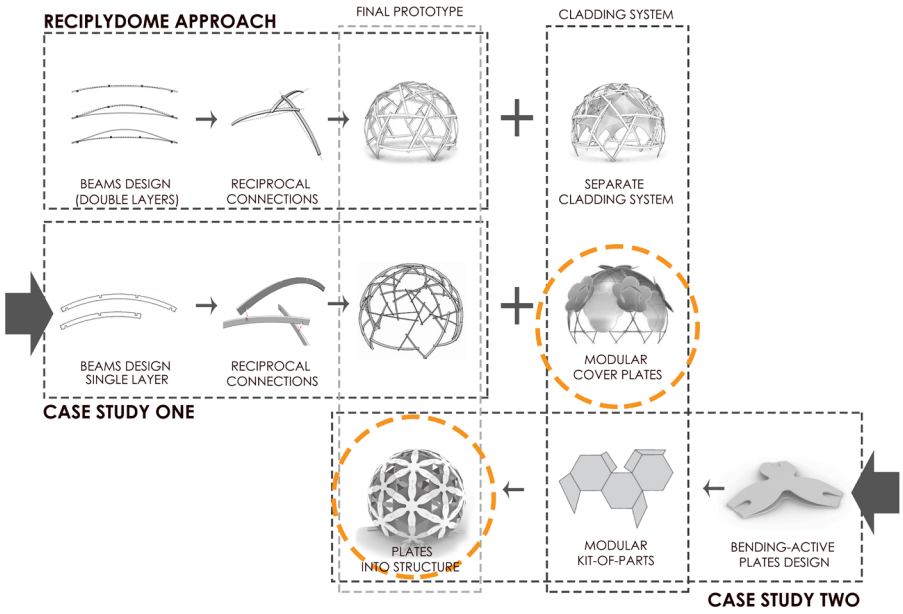

Figure 1. Different approaches of the case studies

2. Case study one

2.1. Design

After studying and reflecting on the ReciPlyDome, this research investigates the cover for a developed version of the dome. By replacing the double-layered beam system with single beams, It merges the knowledge of double-curved plates with the insights acquired during the testing and development of the skeleton system of the new modular beams.

The double-curved plates were simply created through slits designed into a flat plate surface, by creating a slit in the radius of a circular form, two overlapping ends can be used to form a conical shape "Figure 2". This action will cause the radius of the circle to decrease while creating a new double-curved cone with increased height. The same methodology was tested with different shapes and configurations and resulted in a library of shapes that can correlate with the regular polygons on 3D polyhedral geometries.

By selecting the appropriate module types from those variables, a fully enclosed lid for the dome can be made efficiently. During the design of these modules, the attachment to the dome and the joints between the modules were examined. In addition, the ideal materials for these modules were explored since the previously tested wooden modules did not seem to be suitable.

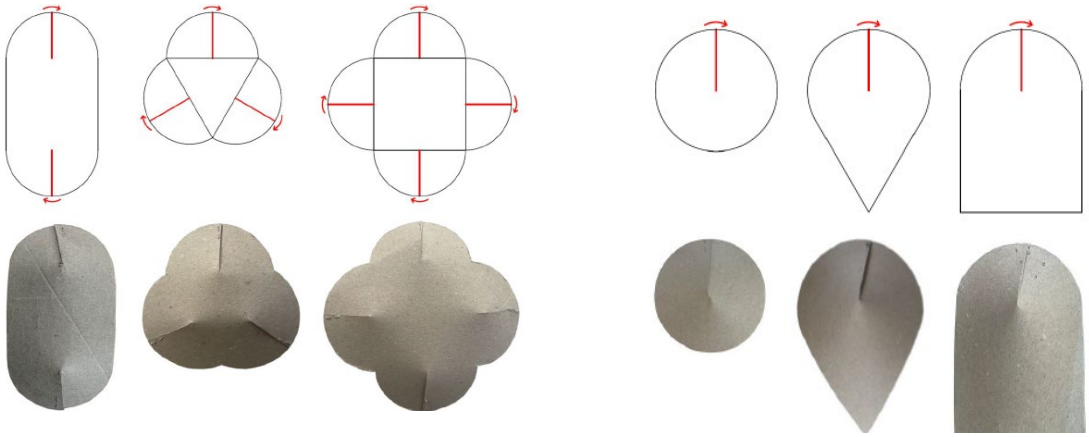

Figure 2. Different alterations of modular double-curved units

In order to create a covering for the ReciPlyDome, the double curved plates are placed on top of the grid of beams in different configurations. The dome consists of multiple equilateral triangles and pentagons which can be used as a central part around which semi-circles are placed to form optimized modules respectively. "Figure 3" shows the cover configuration on a scaled model using two types of double-curved units. The units were used to provide a semi to full covering state for the dome.

Figure 3. Scaled model of the ReciPlyDome after the addition of different levels of coverage.

The modular system allows the creation of two options for covering the dome: the first, which provides shading with a semi-enclosed surface, connects the corners of the central piece and the triangles and pentagons in the dome "Figure 4". The second creates an overlap between the triangle and pentagon surfaces to provide a fully covered option. Alternating the panels can create a more dynamic and open outlook "Figure 5", The cutting pattern can also be optimized in terms of material. By making the cutting boundaries straighter, less material is wasted and an even better cover is achieved.

Additionally, The panels of both the triangular and pentagonal plates have incisions that allow them to overlap and create the desired curvature. The incision is finished with a circular cutout, which not only makes it easier to overlap with thicker materials but also serves as an ideal connection point.

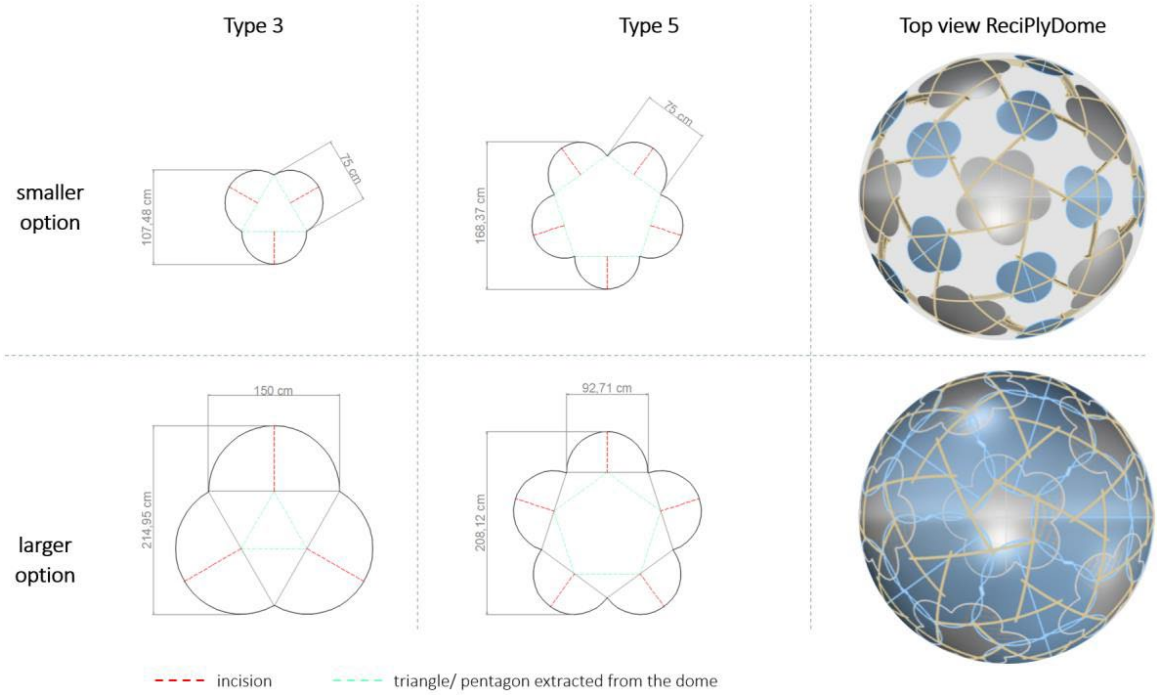

Figure 4. Cover for the ReciPlyDome, obtained by combining different modules and creating variations of the shading percentage within the space.

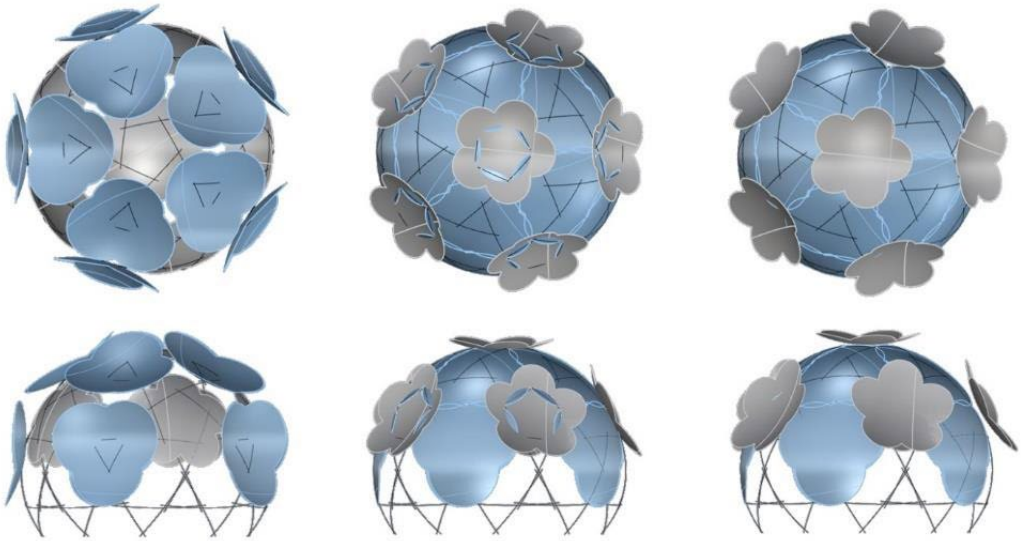

Figure 5. Alternating the panels by flipping part/all of them result in a different shape and shade configurations

2.2. Materiality

In order to choose the best material, some comparative analysis was conducted on the petal-shaped modules, Several materials were tested using physical models to define the future possibilities of scaling up the cover modules. Polypropylene, Polycarbonate, and Aluminium were chosen for their elastic flexibility to strength properties "Figure 6".

Figure 6. Models of one panel of Type 5 in polycarbonate, polypropylene and aluminium on scale 1:4.

Table 1. Summary of the results of the material study on scale 1:4 for the materials polycarbonate, polypropylene and aluminium.

	POLYCARBONATE	**POLYPROPYLENE**	**ALUMINIUM**
TRANSMITTANCE	transparent	translucent	opaque
THICKNESS	1mm	1mm	0.5mm
FLEXIBILITY	Stiff	Flexible	Very stiff
MAINTENANCE	Dirt is easily visible	Low	Can corrode
WEIGHT RATIO	1	1	2

This analysis suggests that either the polypropylene foil or the aluminium module may be the best material for the dome's coverage. The polypropylene foil will provide a peek into the interior when a light is illuminated from within, while the aluminium can create an attractive reflection of the environment. Additionally, a variety of colors can be chosen for the polypropylene to suit the occasion. When considering the outdoor elements, polypropylene is a more flexible material that can withstand heavy wind loads, while the aluminium panel is 1.6 times heavier than the polypropylene panel, meaning that a heavier primary structure may need to be installed to support it. Ultimately, the best material will depend on the desired outcome and environmental conditions.

3. Second Case Study:

3.1. Design

Despite the large amount of research that has been conducted on active-bending structures over the years, the advent of digital tools has opened up new opportunities to explore further the potential of these structures. However, few projects have merged the concepts of bending-active and demountable transformable systems together. This case study examines the potential for combining these two concepts and the flexibility and adaptiveness that such a combination could generate. It intertwin the double-layering of **bending-active plates** within a reconfigurable kit-of-parts system based on polyhedral geometries.

The plates based their shape on regular polygons to allow connectivity within uniform grids. The grid system determines the location of the joints and thus the connection points of the component. As depicted in "Figure 7", the joint connections (blue dots) serve as the basis of the component when applied to a regular n-sided polygon (e.g. triangle, square, pentagon, hexagon, heptagon). The number of supports will be equal to the number of sides of the polygon. In addition, the load distribution of the component plate is defined by the apothem line (from the center of the polygon to the midpoint of sides). Consequently, Using "form conversion" design process [2], the form-finding of the unit is constrained by the different constraints, the position of the support points, the load distribution along the apothem line in addition to the material properties (especially plastic deformation), and local stresses.

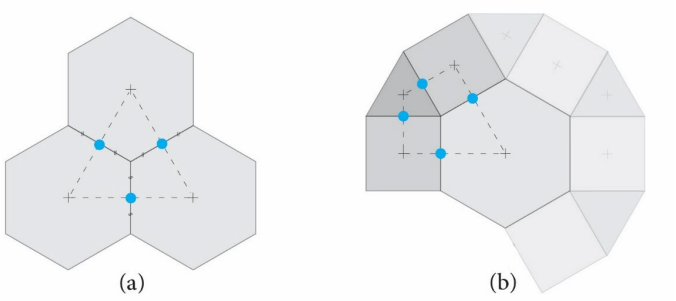

Figure 7. Application of joint positioning method with (a) Similar geometries (b) different sets of geometries in a tessellation.

The plates are then theoretically bent to create a convex multi-curved surface with maintaining the support points intact. A conversation between the form and the material's characteristics, with the boundaries determined by the material's behavior under tension. The surface being bent causes different stresses in material fibers. Removing the stress area of the material from the surface releases the rest of the surface fibers from the encompassing stress, resulting in spaces between the material's strips on the surface, and into the "star" shape with n-Fins.

The same methods were used to build the modular unit of the project based on n-gons. By fixing the location of the supports and the boundaries of the component, the desired shape was specified. After considering the minimum shape requirements and the elastic deformation of the material, the final form of the top layer was determined. Removing the areas of stress between the fins during bending "Figure 8", enabled the fins to bend independently in different directions.

The shape of the various versions of the components was parametrically designed, evaluated, and adjusted in response to the simulated stress. Plywood materials were assumed as the primary calculated properties in this paper. A slight alteration in the material used should lead to a modified shape. Different bases for the components (other regular polygon-based) will result in different variations of the unit.

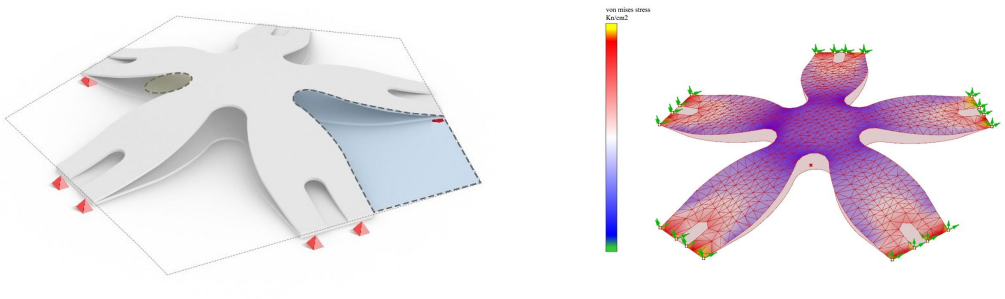

Figure 8. Simulated von mises stress, Pentagon-based component. The areas with dotted boundaries show the Simulated stress, Pentagon-based component.

(a) (b)

Figure 9. ReciPlyDome three main beam component [1] (b) Concept development, Double layering in plates within Regular triangle based component design.

The fundamental principles of the ReciPlyDome served as the basis for the design of the proposed modular unit. This technique is characterized by the use of two layers of components of different lengths that are pre-curved and connected to create self-restraint and structural rigidity. The ICD/ITKE 2010 research pavilion [3] applied a similar technique that utilized two layers of adjoining strips. In addition, Lienhard [3] conducted structural studies concerning the double layering of active-bending components. This research builds upon this concept by applying it to a transformable system. A comparison of ReciPlyDome's "beam" component design and the new "plate" component design can be seen in “Figure 9”. The form was parametrically simulated with Grasshopper scripting to allow for expanded exploration possibilities “Figure 11”. This algorithmic process creates components with adjustable proportions, determined by parameters such as the curvature, width, thickness of the stripe, size of the component, and most importantly, the base shape of the unit.

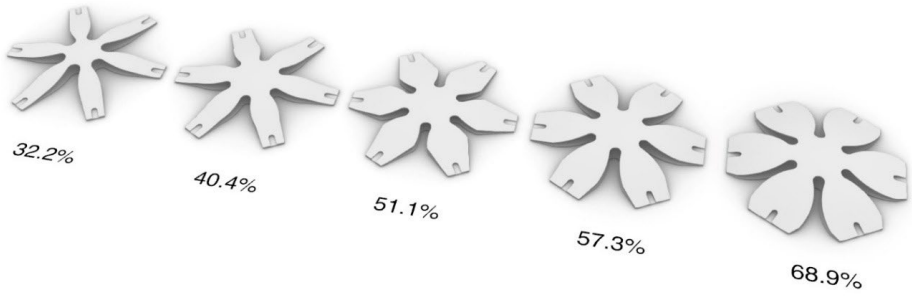

Figure 10. The percentage of solid area to the total area of the base hexagon outline.

In addition, Altering the proportions of the component within its structural limits can create a new ratio between the solid and voided areas. An example of this is illustrated in "Figure 10", which demonstrates the change in the solid area of a hexagon-based component from approximately 70% to 32% of the total area of the hexagon outline. This additional solid area will create a self-shading effect within the space.

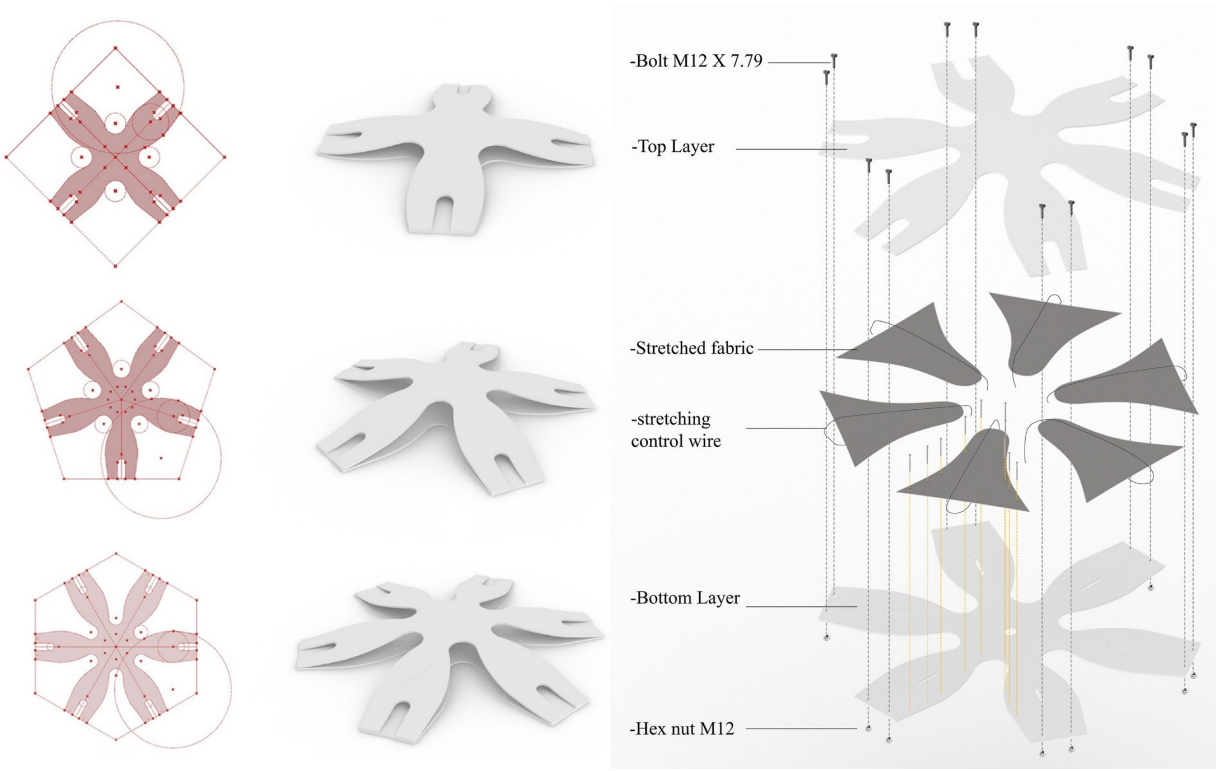

Figure 11. Different variations of the unit based on n-gons geometries, and exploded view of a hexagon-based component with the internal shading system.

The impeded shading system can be customized to accommodate various applications by extending the fabric between fins to cover the voids in the full geometry and attaching it with zippers "Figure 11&Figure 12". This creates a completely sealed system. However, the amount of fabric needed to cover the voids will vary depending on the application, Therefore, the impeded shading system can be effectively used in most applications but will need to be customized and tailored to provide a completely sealed shading system within each case.

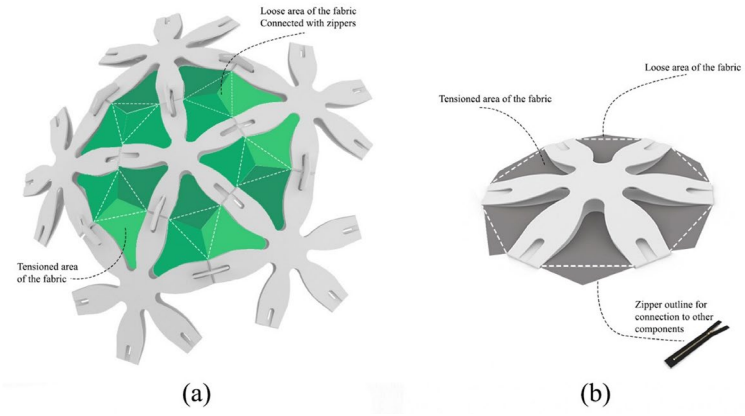

Figure 12. (a) Fully sealed solution for the impeded shading system, (b) Extended shading system of one component.

3.2. Joints:

The design of the joint component is a major challenge as it must be reversible and simple to assemble in order to provide the flexibility needed in a transformable system. Moreover, it is critical in forming the structural integrity of the overall system. In the proposed system, the most important responsibility of the joint is to set the dihedral angles between components in order to achieve the desired shape. For example, the dihedral angle between components in a cube is 90 degrees whereas in an icosahedron it is 138.18 degrees. This difference in shape requires different angles for the joint to create the desired shape. This necessitated the development of two types of joints: the Fixed Joint (FJ) and the Hinged Joint (HJ) in order to facilitate the reconfiguration of the system and maintain its transformability. This paper illustrates the Fixed joint that is used and tested during the fabrication process "Figure 13".

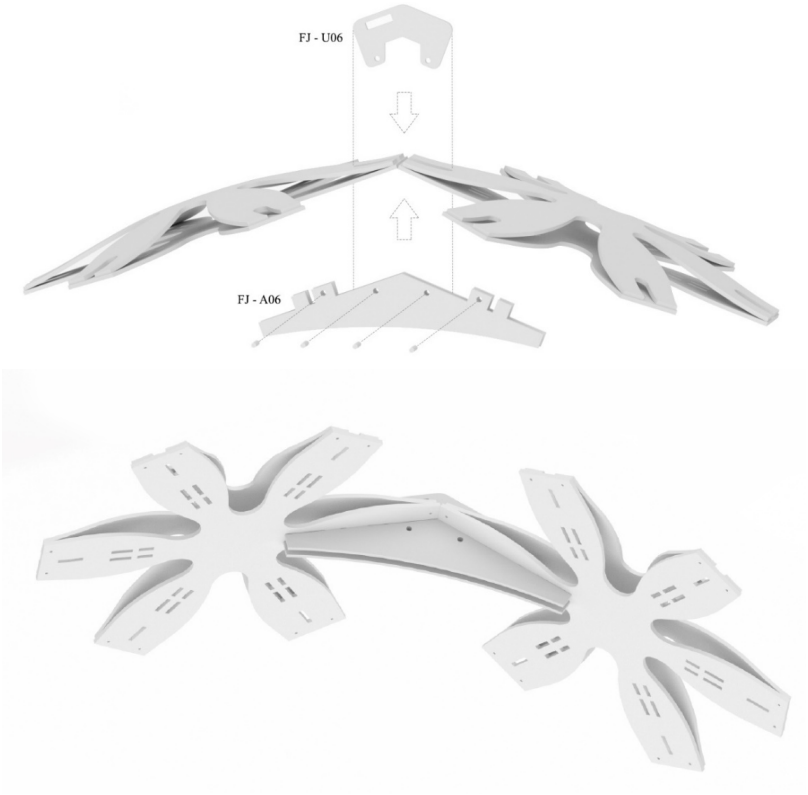

Figure 13 – Fixed joint with two Hexagon-based units

The angular unit of the (FJ) is composed of wooden plates connected with spacers in between to form a lintel. This unit is affixed to the main components with a reversible mortise and tenon connection. The second part of the joint (FJ-U) is then slotted inside the two layers of the lower unit (FJ-A) to provide more stability and a secure angle. Moreover, to reinforce the connection, four "wooden keys" are used to fasten the two components. This technique provides a viable, reversible locking mechanism.

3.3. Polyhedral geometric applications

The research explored the potential for application to various families of geometries. In order to apply the system to different applications, the main idea is to substitute each regular face with a modular component and link all the components with the joints on the right dihedral angle joints. As a result, equilateral shapes such as platonic and Archimedean solids are well-suited to be simple applications for the system due to their symmetrical nature within a complex appearance. "Figure 14" shows an exploration of the possible application based on Archimedean solids.

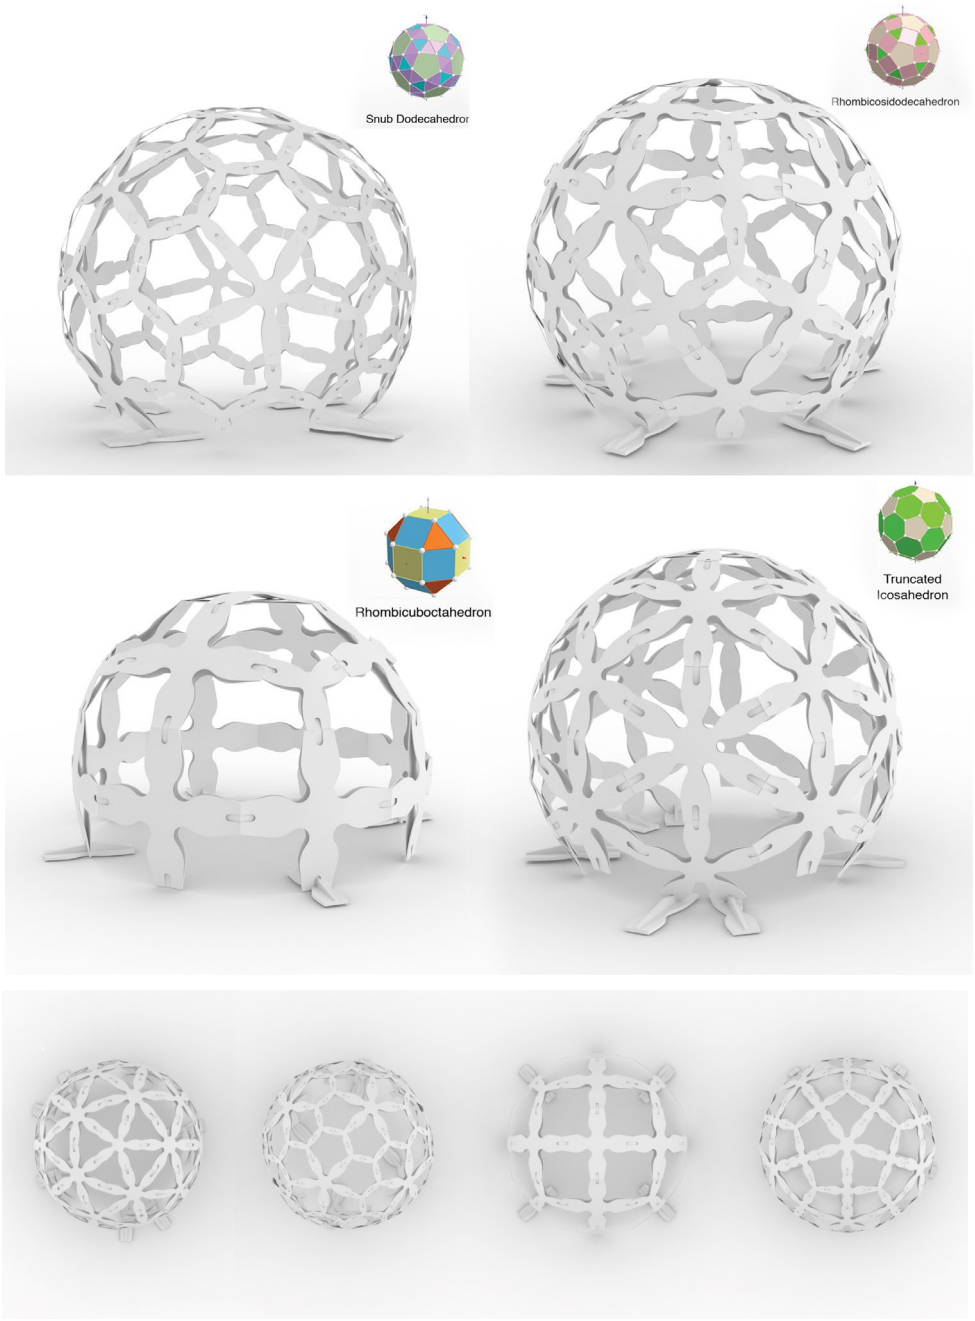

Figure 14 - 3D View of the application of the system on a Rhombicosidodecahedron, Rhombicuboctahedron, Truncated icosahedron and snub dodecahedron base form.

3.4. Truncated icosahedron prototyping

For proof of concept, a Truncated icosahedron-based physical prototype was fabricated for testing. The components were analyzed using different sizes and materials to investigate the response of the materials when subjected to external loads. “Figure 15” shows scaled 4mm MDf modular components of two laser cut layers. The components were put together based on the truncated icosahedron planes to create the full dome “Figure 16”.

Figure 15. MDF physical model, Hexagon-based component

The objective of the design is to enhance structural resilience against external loads through the use of bending-active double layering. To validate this concept, physical tests were conducted on different cases to conceptually (not numerically) test the behavior of materials under loads. “Figure 17” shows the increase of stiffness in comparison to the same load being applied to a flat plate of the same component. Further structural analysis should be done to map the exact structural effect.

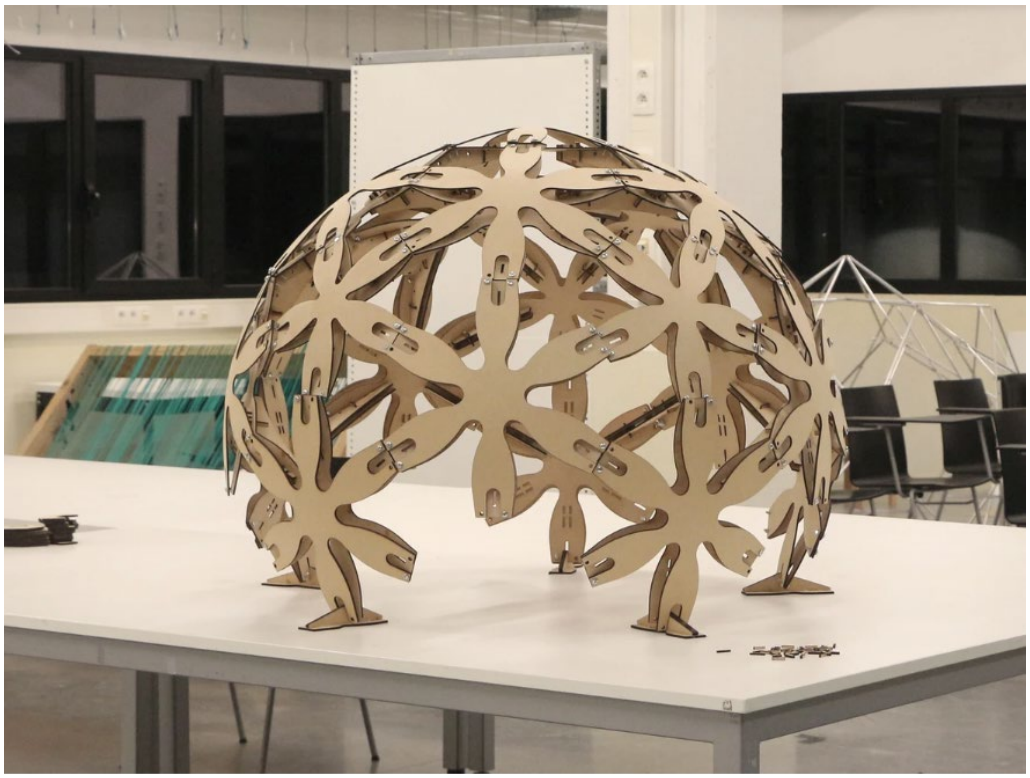

Figure 16. Application to truncated icosahedron base form- scale 1:4.

(a) (b)

Figure 17. (a) One layer of the component under stress, (b) Double-layer components in bending-active state.

4. Conclusion

This paper proposed two alternatives for a rapidly assembled temporary structure based on double curved plates. Both case studies created a systematic methodology that is developed to connect configurable components into different variations. The final structures allowed a responsive use for the user, giving the user the ability to alter the covering ratio and add the shading systems. These kit-of-parts methods encourage the efficient use of the materials for different applications and seasons. However, throughout the research, Two major conclusions were apparent; The complications of the plate-based systems mostly come down to the connection systems. While the double-curved plates generally have a lot of potential and areas for improvement and exploration for new systems. Demountable systems still need to focus on the innovation within the connection systems that can result in structural strength. Additionally, the research focused on analyzing and testing the detailing of a limited amount of possible variations. While those variations showed significant potential. more research could be done into testing and experimenting with different configurations within free-form-based shapes. It is important to point out the crucial impact of the scale size of the samples. Scaling up the samples will be limited by the thickness of the plates and the material properties of the units, potentially restricting the final geometric space of the structure. Further research may be required to gain a deeper understanding of how the units behave on a larger scale.

Abstract

Auxetic materials show unusual reaction behaviors under uni-axial compression or tension forces. For instance, they contract perpendicular to the load direction under an applied compressive force and expand under tension. Their unique behavior has been harnessed in the fields of sensors, medical instruments, sportswear, aerospace devices, etc. As a continuation of the previous research that proposes to use algebraic 2D graphic static for the design of 2D auxetic metamaterials, this paper presents a novel approach to designing 3D auxetic metamaterials using an algebraic formulation of polyhedral reciprocal diagrams (PGS), resulting in concave geometric configurations that are shared by many auxetic materials. The proposed method offers two approaches for generating these concave configurations: modifying a convex polyhedral framework using geometric transformations or constructing a concave polyhedral framework directly using the algebraic formulation of PGS. The validity of the proposed method is demonstrated by testing two models using the finite element method, which clearly shows a negative Poisson's ratio.

Keywords: auxetic materials, negative Poisson's ratio, three-dimensional graphic statics, algebraic graphic statics, reciprocal polyhedral diagrams

1. Introduction

Auxetic metamaterials show unusual reaction behaviors under uni-axial compression or tension forces. They contract perpendicular to the load direction under an applied compressive force and expand under tension. This unique behavior, namely negative Poisson's ratio, has found its way to be applied to various fields such as sensors, medical instruments, sportswear, aerospace devices, etc [1]. Reid et al. [2][3] stated that this behavior heavily depends on internal concave cellular geometries. Existing methods for designing auxetic materials are mostly empirical, meaning that people usually sculpt the configuration based on experiences as well as intuitions.

A previous research project aims to provide a more systematic approach to designing 2D auxetic materials using algebraic 2D graphic statics (A2DGS) [4]. Focusing on the geometric formulation, the algebraic method has shown its ability to create a variety of 2D auxetic patterns. This paper intends to extend this design method to three dimensions through the algebraic formulation of polyhedron-based 3D graphic statics (3DGS), also called polyhedral graphic statics (PGS) [5], hoping to provide a tool and help the science, design, and engineering communities investigate and develop new auxetic metamaterials with ease.

1.1. Related work

1.1.1. Current design approaches of auxetic materials

Auxetic behaviors exist in both natural and man-made materials. Within the scope of man-made materials, there are various types of geometrical configurations, including re-entrant models [6–10], rotating polygonal models [11–14], chiral models [15–19], crumpled sheets models [20, 21], perforated sheets models [22–24], random network models [2, 3], etc. Among those different geometrical configurations, some are periodic cellular, and others are irregular and disordered. The discoveries and reports of new auxetic models usually lack a general guideline. Reid et al. [2][3] observed that the concave geometric configuration is a common characteristic of the auxetic metamaterials, upon which a computational algorithm was developed to generate random network-based patterns with negative Poisson's ratio.

1.1.2. Algebraic formulation of graphic statics and its application in auxetic materials

Graphic statics is a geometric form-finding tool based on reciprocal form and force diagrams. Hablicsek and Akbarzadeh [4] found the algebraic formulation of 2DGS convenient in tuning the global configuration of form diagrams based on the geometric degrees of freedom (GDoF), which can be used to create 2D auxetic patterns. The polyhedral nature of PGS makes it a great tool for creating cellular geometries. The algebraic formulation for PGS has also been formulated by Hablicsek et al. [25], Akbarzadeh and Hablicsek [26, 27], and Lu et al. [28] proposed an improved formulation with comprehensive edge length and vertex location controls for the polyhedral reciprocal diagrams, providing a handy tool for generating 3D cellular geometries with concave configurations.

1.2. Problem statement and objectives

As stated above, the previous explorations and discoveries of auxetic metamaterials are case specific. Some explorations have provided a systematic approach in 2D. By extending the approach developed for 2D materials to 3D, this paper aims to propose a new design method that can create more complex and sophisticated geometries with concave configurations that exhibit negative Poisson's ratio. One of the major challenges in this approach is ensuring that the resulting configurations are truly concave without any entangling and self-intersecting, which is addressed by exploiting the power of the enhanced algebraic formulation of PGS.

2. Method

In the context of PGS, a form diagram is usually generated given an input force diagram. There are two existing implementations of PGS, an iterative approach based on nodal operations [29], and an algebraic approach based on the mathematical essence of the form and force reciprocity [25–28]. The iterative approach is limited solution space due to the geometrical restrictions introduced by the iterative algorithm, which makes it difficult to create concave cellular geometries. Focused on the more abstract mathematical relationships, the algebraic method has a greatly extended solution space that enables the flexible exploration of the GDoF, making it easier to generate geometries with concave cells. This section is based on the enhanced algebraic formulation with comprehensive edge length and vertex position control that has been extensively described by Lu et al. [28]. Since only the edge length control is used in this paper, this formulation can be simplified as a system of non-homogeneous constrained linear equilibrium equations written as follows:

$$\mathbf{Mq} = \mathbf{t}. \tag{1}$$

Here **q** is a vector that contains all edge lengths in the form diagram, and the matrix **M** is named the constrained equilibrium matrix, obtained by vertically stacking the equilibrium matrix **A** and the edge constraint matrix **B**:

$$\mathbf{M} = \begin{pmatrix} \mathbf{A} \\ \mathbf{B} \end{pmatrix}. \tag{2}$$

Matrix **A** contains the reciprocal constraints for the form and force diagram, and matrix **B** represents which edges are constrained. The column vector **t** is obtained by vertically stacking the zero vector and the vector **l**, which encodes the target lengths of the constrained edges. Each solution of **q** represents a set of edge lengths of the form diagram that satisfy all equilibrium requirements and constraints, and it can be used to construct the form diagram.

There are two ways that this algebraic formulation can be used to find a form with concave configurations. First, it can start from a convex configuration and modify the strut lengths based on the GDoF to turn certain cells into concave. Alternatively, the concave configuration can be generated directly from a force diagram with concave cells, which is not supported by the iterative approach as the form diagram can become entangled during the solving process and therefore cannot converge.

2.1. Concave configuration turned from convex configuration through GDoF

When a force diagram only contains convex cells, it usually leads to a form diagram with a convex configuration. However, not all form diagrams can be turned into concave without entangling and self-intersecting. For those that can be turned, there is a common characteristic that they all contain a group of edges with common directions. By assigning proper negative edge lengths to those edges, each cell can be turned concave without creating any self-intersection (Figure 1).

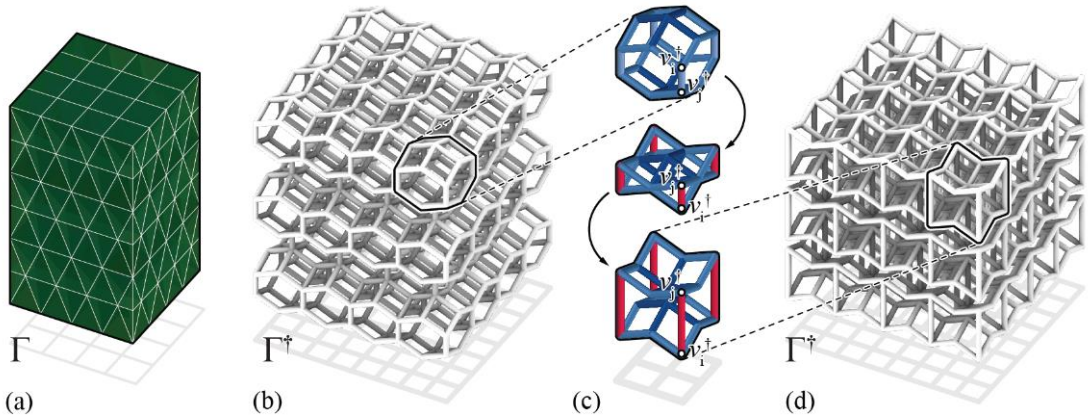

Figure 1. A simple example that shows a geometry with a convex configuration can be turned concave by assigning negative edge lengths to the parallel edges. (a) An input force diagram, (b) a form diagram with a convex configuration, (c) Negative edge lengths are assigned to the edges that share directions, and (d) the modified form with a concave configuration.

2.2. Concave configuration directly generated from negative force cells

Thanks to the flexibility of mathematical abstraction, all solutions that satisfy the reciprocal relationship can be freely accessed without being limited by geometrical restrictions. Therefore, a force diagram with concave cells can be accepted by the algebraic approach without any issue. The resulting form diagram will directly have a concave configuration (Figure 2). In this case, there is no need to go through the edge length modification process as described in Section 2.1.

3. Verification of the auxetic behavior

After having the geometries with concave configuration generated from Section 2, the finite element method (FEM) is used to verify their auxetic behavior. The specimens are modeled with a footprint of 50 mm by 50 mm, and all edges are materialized as 1.2 mm diameter struts using a linear elastic material. The bottom vertices are fixed in *z*-direction, and a total vertical force of 10 kN is distributed to

all top vertices. The simulation results are shown in Figure 3. The deformation clearly shows those two specimens manifest negative Poisson's ration under vertical loads.

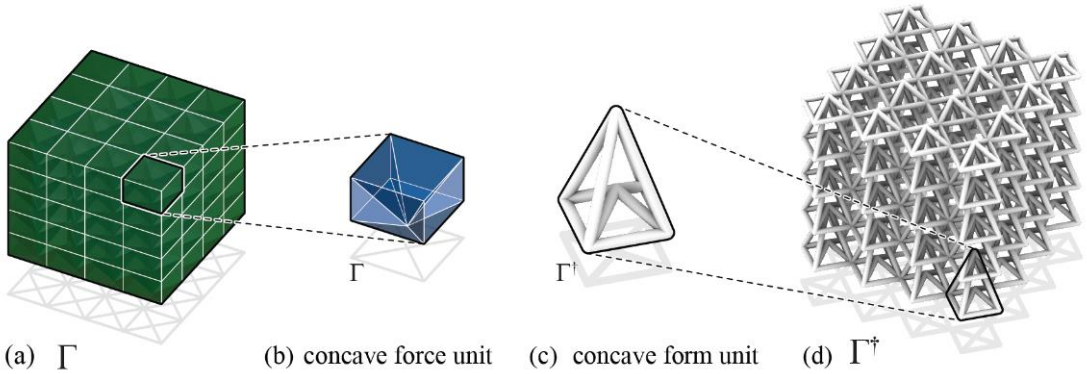

Figure 2. A form geometry with a concave configuration can be generated directly from a force diagram with concave cells. (a) The input force diagram that contains concave cells, (b) a highlighted concave unit of the force diagram, (c) a highlighted concave unit of the form, (d) The form geometry with a concave configuration

The Finite Element Method (FEM) used to simulate the mechanical behavior of materials is computationally intensive and can be time-consuming to set up and run. As an alternative, matrix kinematic analysis can be used to quickly assess the kinematic response to applied loads [30]. This analysis method treats the geometry as a pin-jointed, inextensible framework and ignores its material properties, focusing only on the kinematic behaviors. This lightweight analysis method allows for qualitative and rapid evaluations, making it suitable for fast design iterations and explorations.

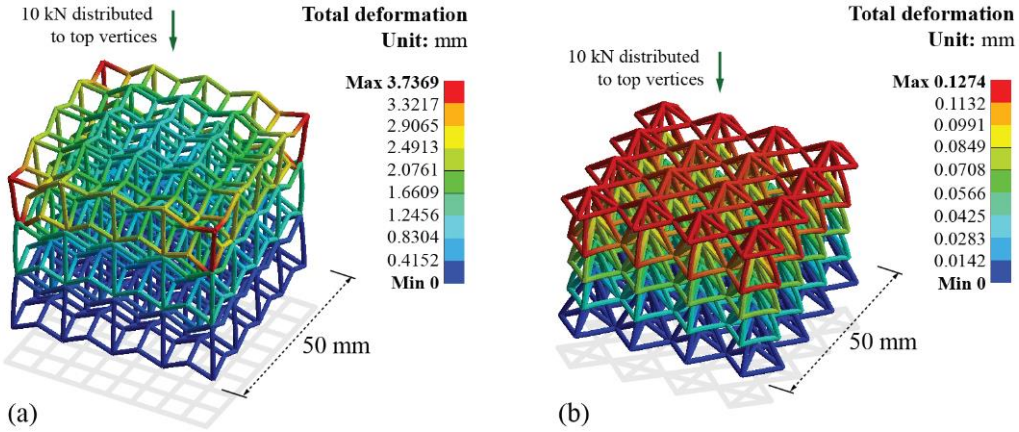

Figure 3. The auxetic behaviors of the two form geometries are verified using FEM. The displacements clearly show negative Poisson's ratios.

4. Conclusion

This paper presents a novel approach to designing 3D auxetic metamaterials using an algebraic formulation of PGS, resulting in concave geometric configurations that are shared by many auxetic materials. The proposed method offers two approaches for generating these concave configurations. The first approach involves starting with a convex polyhedral framework and modifying it using geometric transformations to create a concave configuration. The second approach involves constructing a concave polyhedral framework directly using the algebraic formulation of PGS. Two models are tested using the finite element method, and the results clearly show a negative Poisson's ratio, proving the validity of the proposed method.

By expanding the current design toolset with this novel systematic approach, this research has the potential to drive innovation in various industries. Moreover, this research opens new possibilities for creating materials with unique mechanical properties that can be tailored to specific applications. This has the potential to revolutionize various fields of engineering, from materials science to civil and mechanical engineering, by enabling the development of materials with unprecedented mechanical properties and performance.

The extended affine method for form finding of a spoke wheel system in light of graphic statics: part 2

Hiroki TAMAI[a,*]

[a,*] Nikken Sekkei
Chiyoda-ku Tokyo
tamai.hiroki@nikken.jp

Abstract

This paper provides an alternative proof for the proposition that the ring shapes of a spoke wheel system, having equal and uniform magnitude of forces in the compression and tension rings and equal forces in the radial cables, as well as minimizing the sum of the squared segment lengths, approach to a cycloid if the number of divisions increases infinitely. The proof is rendered in the dual space expressed by the Airy stress force polyhedra. The optimality condition about the minimum sum in terms of x and y coordinates in the form diagram can be translated in terms of only z* coordinates of the force polyhedra, and the recursive expression represents a polyline inscribing to the trajectory of a rotating regular n-polygon.

Keywords: graphic statics, spoke wheel structure, graphic form finding, dual Airy stress polyhedra, optimization, cycloid

1. Introduction

The form finding of a spoke wheel roof structure is a highly nonlinear problem as it requires simultaneously determining the geometry of tension ring and radial cables, flying struts, and compression ring as well as ensuring prestressed self-equilibrium such that there are only axial forces. While such difficulty lies in the general form of the problem, the affine method was developed for non-computational approaches and has been applied by Schlaich Bergermann und Partner since their early spoke wheel roof structures [1]. However, the original affine concept was, in fact, developed only on concentric arcs, patched smoothly, such as a three-centered arc (aka korbborgen). Therefore, applications were limited to symmetric circular or elliptic shapes.

The author extended the concept of the affine spoke wheel roof system for converting more arbitrary closed convex curves to self-stressed equilibrium geometry. Two graphical constructions were demonstrated to apply this concept. In the first construction method, by laying out identical isosceles, as many as the axis number, adjacent to each other along the legs, the geometry of radial cables is defined by the legs. Then by cutting them out with two polygons, all segments of which are set parallel to the bases of the isosceles, tension and compression rings are defined. (Figure 1 top). In the alternative construction method, an arbitrary closed convex curve can be directly converted to a segmented compression ring by translating the edges of a regular polygon to the points of tangency on the given curve. Then the tension ring is generated by offsetting the compression ring inward by an equal distance. The radial cables are defined by connecting the corresponding vertices of the polygonal rings. (Figure 1 bottom).

In both constructions, the polygons for the compression and tension rings are convex and the inner angles all become equal, but the side lengths may not be equal. The distances between the compression

Copyright © 2023 by Hiroki TAMAI. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

and tension polygons are set to be all equal. Note, however, that the two polygons are not similar to each other in general. Thus, the tension and compression rings cannot be scaled to one another.

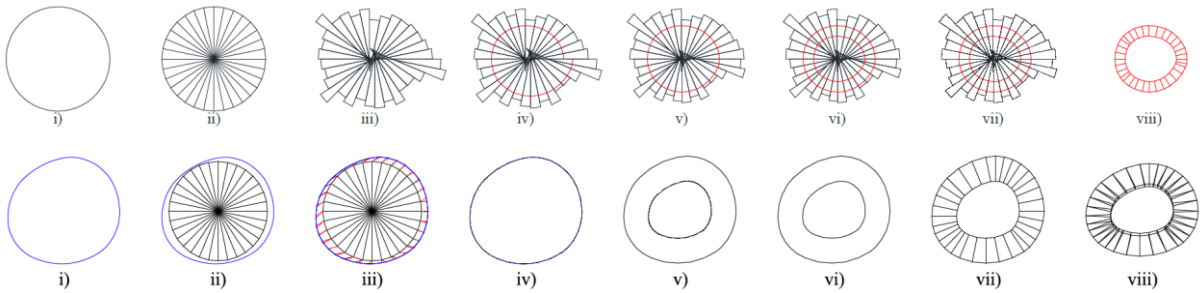

Figure 1. Graphical form finding of a spoke wheel roof system with an arbitrary shape [3]

The structural advantages of the spoke wheel structure generated by the extended affine concept are that the magnitude of the forces in the compression and tension rings can be made equal and uniform all around, and the forces in the radial cables are all equal [3]. Of course, this also means that the level of material utilization is well balanced over the structure, and more notably that the differential cable forces over clamping nodes are all zero in theory for the prestressed self-equilibrium state. Consequently, they are nearly zero under the dead load condition, so the size of the clamps can be made smaller than otherwise.

The author demonstrated determinate and indeterminate applications of the extended affine concept for non-circular shape constraints [3]. These include how to control the total length of the compression ring by minimizing the sum of the squared segmented lengths, as well as how to control the uniformity of the polygonal curve of the ring by minimizing the variance of the segmented lengths. The in-depth study revealed the unexpected relationship between the two sets of geometry; Any polygonal ring with the minimum variance of the segment lengths can be generated as an involute of the polygonal ring with the minimum sum of squared segment lengths with the same number of divisions (Figure 2). In other words, the polygonal ring with the minimum sum of squared segment lengths is the evolute of the other. The study also found that the limit curve of the evolute polygonal curve was a cycloid (Figure 3). Mathematical explanations on these propositions were given later by the author [4].

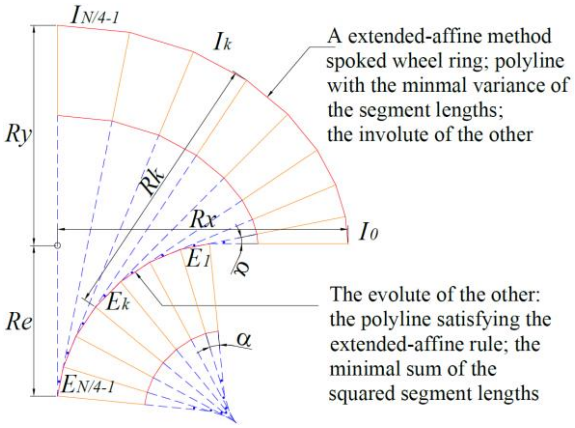

Figure 2. Involute and evolute polylines

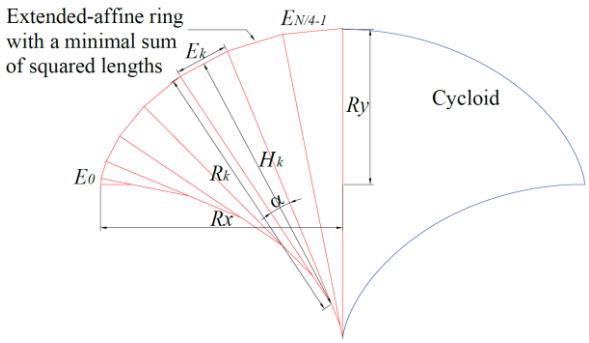

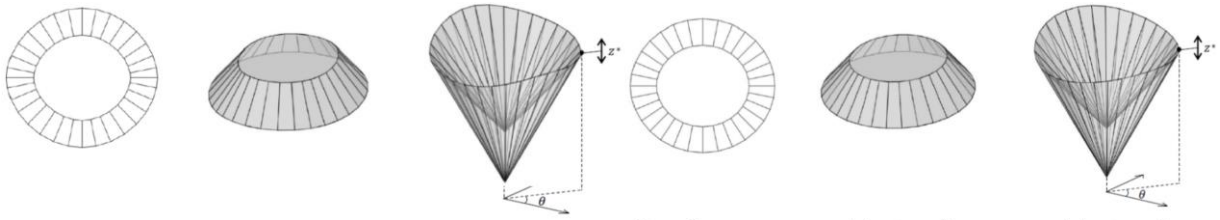

Figure 3. Extended-affine ring and cycloid

The previous paper re-examined the above-mentioned geometric findings in light of graphic statics [5]. The starting point of the study was the fact that the force diagram is unique, though scalable, for all spoke wheel geometry that can be generated by the extended affine concept within the same topology.

The dual discrete Airy stress polyhedra, defined by Cremona's mapping rule [6], of the two special groups of spoke wheel systems, one with the minimum sum of the squared lengths and the other with the minimum variance of the lengths, were investigated in order to find relevant connections between them as found in the forms. The z* coordinates of them are of great interest since only this distinguishes the forms from each other. The limit shapes of the two discrete Airy stress polyhedra were derived based on the knowledge that the limit polygonal curve of the evolute is a cycloid, and found in quite simple expressions of trigonometry.

a) minimum sum of squared ring segments (evolute) b) minimum variance of ring segments (involute)

Figure 4. Form diagram, Airy stress form polyhedron and Airy stress force polyhedron

However, despite the remarkable relation in the forms of evolute and involute found in their form diagrams, the equivalent relation has not been thoroughly revealed and therefore not visualized in the dual force polyhedra. The trigonometric function defining the parts of the Airy stress force polyhedron neither reversely led to any alternative derivation of a cycloid yet nor revealed the connection to the optimality conditions of the form diagrams.

As a part of reflection on the questions above, this paper attempts to provide an alternative proof for the proposition that the limit curve of extended affine spoke wheel ring geometry with the minimum sum of squared segment lengths approaches a cycloid.

2. Notes on terms

This section adds a few notes on the specific terms used in this paper since they may sometimes lack mathematical correctness for the sake of readability.

spoke wheel system (or structure): Although the study concerns roof structures with a spoke wheel system that usually has two layers of radial cables stretched by flying struts, in this paper the word *spoke wheel system* is in most cases used to refer to the 2-dimensional projection of the system or simply a planer spoke wheel structure. The validity of the following discussion is not affected as far as it concerns the in-plane self-equilibrium state by prestressing.

Affine method, affine concept or affine spoke wheel: The word affine is not used with the exact mathematical definition in this paper. Rather it only refers to the method reported by Bergermann [1]. In his paper, the term was used to describe the non-computational form finding method of spoke wheel systems by setting equal angles for the inner tension and outer compression rings in relation to each radial cable in the form of a circular and a three-centered-arc also known as korbbogen.

Involute polyline (polygonal curve, or polygon): An involute polyline is defined as a polygonal curve inscribed in the involute curve of a polyline (evolute) at the points where the rotational radius of the involute changes corresponding to passing the vertices of the polyline (evolute).

Evolute polyline (polygonal curve, or polygon): An evolute polyline appears as a special case of evolute where the centers of the curvature of the involute jumps, corresponding to the step change of the rotational radius. The polyline connecting the discrete locus is referred to as an *evolute polyline* in general, or an *evolute polygon* if it is closed.

3. Proposition

From the two propositions on equilibrium geometry of spoke wheel structures, addressed by the author [4], the one relevant to this paper is rewritten as below.

Proposition on the limit curve of ring geometry of extended affine spoke wheel system with minimum squared lengths:

Let a polyline be a part of the ring geometry of a spoke wheel system determined by the extended affine rules. Suppose it is symmetric and the set of segments is selected to minimize the sum of the squared segment lengths, then a series of polylines can be defined in terms of the number of segments. The limit curve of the series with an infinitely large number of segments is a cycloid. (Figure 3)

4. Proof by dual polyhedra

The dual force polyhedron is used for an alternative proof for the proposition that the limit curve of extended affine spoke wheel ring geometry with a minimum sum of squared segment lengths approaches a cycloid. The outline of the proof is as follows;

1. Express the optimality condition for the minimum sum of squared lengths in terms of z* coordinates of the force polyhedra.

2. Identify the geometry that satisfies the condition.

3. Unroll the geometry to the rotating regular polygon along a line

4. Increase the edge number of the polygon infinitely, and let a circle represent the limit geometry of the n-polygon.

4.1. Calculation of the ring form diagram in dual problem using Airy stress force polyhedron

The difficulty to obtain the form diagram (x, y) lies in the fact that it is defined implicitly by the optimal condition of the minimum sum squared length in the form of a Lagrangian function that includes the geometric boundary condition as follows.

$$L_{\substack{(x_k, y_k, \lambda_i) \\ k=1\ldots n/2, i=1\ldots 4,}} = \sum_{k=1}^{n/2}\{(x_k - x_{k-1})^2 + (y_k - y_{k-1})^2\} + \lambda_1(x_0 - 1) + \lambda_2(y_0 - 0) + \lambda_3\big(x_k - (-1)\big) + \lambda_4(y_k - 0) \quad (1)$$

Eq.(1) does not include any of the constraints between nodes imposed by the extended affine rules. It should be noted that the variables of the equation use nodal coordinates rather than the lengths unlike the equations presented in the author's other paper, which is integrated by the extended affine rule's constraints [4].

Let us think of solving this minimization problem in Cremona's dual space (x^*, y^*, z^*) rather than the primal space of (x, y, z) because we know about the force diagram better than the form diagram. That is, at this point we do not know x_k and y_k but we do know x^*_k and y^*_k due to the common nature of the extended affine spoke wheel system that the two-dimensional force diagram is always a regular n-polygon.

In Cremona's dual Airy stress polyhedra for the force diagram, the adjacent two vertices (x^*_k, y^*_k, z^*_k) and (x^*_{k+1}, y^*_{k+1}, z^*_{k+1}) and the corresponding apex (x^*_O, y^*_O, z^*_O) of the polyhedra are on the same plane defined by $z^* = y_k\, x^* - x_k\, y^* + z_k$; in other words, the plane's normal vector is (y_k, $-x_k$, -1) and the z*-intercept is z_k.

$$\begin{Bmatrix} x^*_O & y^*_O & 1 \\ x^*_k & y^*_k & 1 \\ x^*_{k+1} & y^*_{k+1} & 1 \end{Bmatrix} \begin{pmatrix} y_k \\ -x_k \\ z_k \end{pmatrix} = \begin{pmatrix} z^*_O \\ z^*_k \\ z^*_{k+1} \end{pmatrix} \quad (2)$$

where (x^*_O, y^*_O, z^*_O) is selected as the origin (0, 0, 0). Now recall that the force diagram is a regular n-polygon and it is rotated clockwise by 90 degrees plus π/n by Cremona's mapping rule. The radius of the vertices can be assumed to be unity without losing the generality. Thus, the force diagram is expressed as below.

$$\begin{aligned}(x^*_k, y^*_k) &= \left(cos\left(\frac{2\pi}{n}k - \frac{\pi}{2} - \frac{\pi}{n}\right), sin\left(\frac{2\pi}{n}k - \frac{\pi}{2} - \frac{\pi}{n}\right)\right) \\ &= \left(sin\frac{(2k-1)\pi}{n}, -cos\frac{(2k-1)\pi}{n}\right)\end{aligned} \tag{3}$$

Plug Eq. 3 into Eq. 2 and solve for x_k and y_k. Then x_k and y_k for k = 1 to n/2 can be expressed only with z^*_k as independent variables as below.

$$\begin{aligned}x_k &= \csc\left(\frac{2\pi}{n}\right)\left(\ sin\left(\frac{(1+2k)\pi}{n}\right)z^*_k + sin\left(\frac{(1-2k)\pi}{n}\right)z^*_{k+1}\right) \\ y_k &= \csc\left(\frac{2\pi}{n}\right)\left(-cos\left(\frac{(1+2k)\pi}{n}\right)z^*_k + cos\left(\frac{(1-2k)\pi}{n}\right)z^*_{k+1}\right)\end{aligned} \tag{4}$$

Substituting Eq.(4) to Eq.(1), the Lagrangian is rewritten in terms of z^*_k instead of (x_k, y_k) as Eq. (5). It is interesting to see how the expression of the squared lengths is simplified by z^*_k.

$$\begin{aligned}L_{k=1\ldots n/2, i=1\ldots 4,}(z^*_k, \lambda_i) &= \csc\left(\frac{2\pi}{n}\right)^2 \sum_{k=1}^{n/2}\left(z^*_{k-1} - 2cos\left(\frac{2\pi}{n}\right)z^*_k + z^*_{k+1}\right)^2 \\ &+ \frac{1}{2}\lambda_1\left(-2 + \sec\left(\frac{\pi}{n}\right)(z^*_0 + z^*_1)\right) + \frac{1}{2}\lambda_2\left(2 - \sec\left(\frac{\pi}{n}\right)\left(z^*_{n/2} + z^*_{n/2+1}\right)\right) \\ &+ \frac{1}{2}\lambda_3\csc\left(\frac{\pi}{n}\right)(-z^*_0 + z^*_1) + \frac{1}{2}\lambda_4\csc\left(\frac{\pi}{n}\right)\left(z^*_{n/2} - z^*_{n/2+1}\right)\end{aligned} \tag{5}$$

Now the minimization problem is defined as

$$arg\min_{z^*_k, \lambda_i \in R} L_{k=1\ldots n/2, i=1\ldots 4}(z^*_k, \lambda_i) \tag{6}$$

by the Lagrangian of the objective function and the boundary conditions. The necessary conditions for optimality are

$$\frac{\partial L(z^*_k, \lambda_i)}{\partial z^*_j} = 0 \quad \text{for } j = 0\ldots\frac{n}{2} + 1 \tag{7}$$

$$\frac{\partial L(z^*_k, \lambda_i)}{\partial \lambda_j} = 0 \quad \text{for } j = 1\ldots 4. \tag{8}$$

Note that the total number of variables is n/2+5 since the indexed variables are from z^*_0 to $z^*_{n/2+1}$, and there are four Lagrange multipliers. The four variables, z^*_0, z^*_1, $z^*_{n/2}$ and $z^*_{n/2+1}$, can be solvable from the four equations in Eq (8), while other variables including λ_i for i = 1~4 are dependent sequentially.

Among them, let us take a general part that does not include λ_i, which is expressed as below.

$$\frac{\partial L(z^*_k, \lambda_i)}{\partial z^*_j} = 2\left(l_{j-1} - 2cos\left(\frac{2\pi}{n}\right)l_j + l_{j+1}\right) = 0 \quad \text{for } j = 2\ldots\frac{n}{2} - 1, \tag{9}$$

where l_k is defined, referring to Eq. (5), as

$$l_k = z^*_{k-1} - 2cos\left(\frac{2\pi}{n}\right)z^*_k + z^*_{k+1} \tag{10}$$

and it is the length of the k-th segment in the form diagram scaled by $\sin\left(\frac{2\pi}{n}\right)^2$. It is interesting to see that the optimal condition in terms of the segment lengths in the form diagram and the segment length in terms of z* have the same expression.

The optimality conditions can be rewritten in a recurrence sequence as

$$l_{j+1} = 2cos\left(\frac{2\pi}{n}\right) l_j - l_{j-1} \quad \text{for } j = 2\ldots\frac{n}{2} - 1, \tag{11}$$

or by De Moivre's formula,

$$l_k = sin\left(\frac{2\pi}{n}k + \frac{\pi}{n}\right)\frac{l_0}{sin\frac{\pi}{n}} \quad \text{for } k = 0\ldots\frac{n}{2} - 1. \tag{12}$$

These two expressions identify the geometry in different manners.

4.2. The geometry satisfying the optimality condition

Lemma: Suppose the two identical regular polygons with m (=n/2 for the sake of convenience) vertexes connected to each other at the corresponding vertexes, translate one of them by the edge length parallel to a major diagonal passing the centroid, and rotate by 2 π /m radian. Then the lengths of the skewed edges connecting the vertexes satisfy the condition described by Eq.(11) or Eq.(12). See edges in Figure 5, lengths of which are denoted by l_0, l_1 (*or* l_{k-1}), l_k, l_{k+1}, and so on.

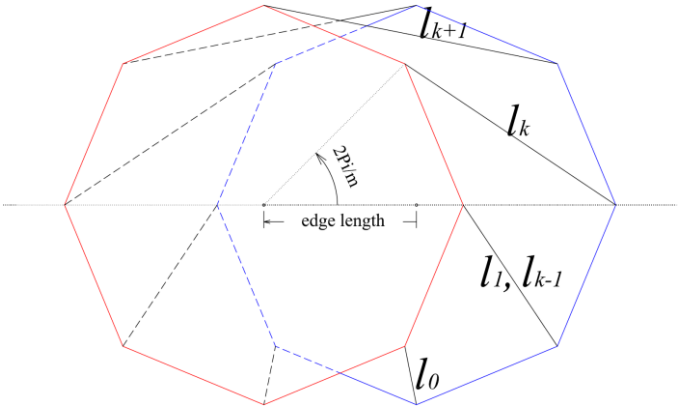

Figure 5. Series of segments satisfying the optimality condition

4.2.1. Proof for Eq.(11)

Point A in a) and point A' in b) of Figure 6 are both defined by the above-mentioned translated polygons in green and blue, relative to the ones in red, and the parallelograms sharing the edges with the polygons. Although they are determined differently, it is evident that they are in the same position within the base (red) polygon. Find the identical parallelograms in a) and b), two edges of which are shared with red polygons. Since points A and A' are found to be identical, the edges AV and A'V' are both equal to l_k from the other parallelograms composed with AV or A'V'. In c) of Figure 6, a) and b) are laid over with the common red polygon. The isosceles A (=A')VV' with the base angle a equal to 2 π /n (= π /m) self-evidently illustrates the recurrence relation in Eq.(11).

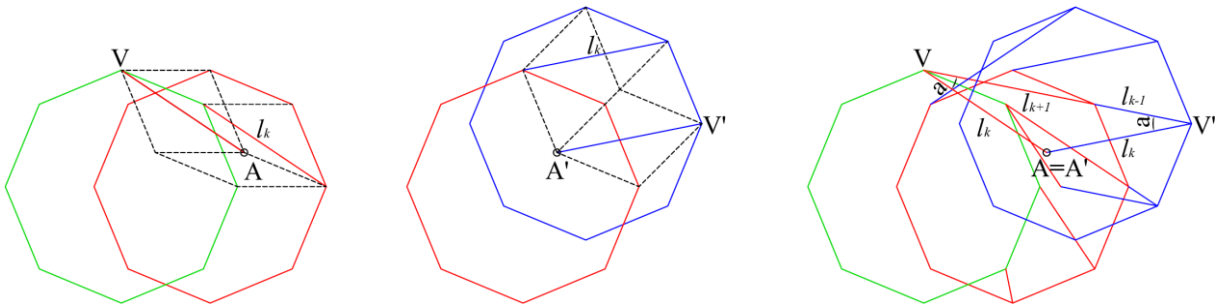

Figure 6. Series of segment lengths expressed by the recursive relation of adjacent segments

4.2.1. Proof for Eq.(12)

By using the angle $a_0 = 2\pi/n$ (for an octagon, $a_0 = 2\pi/(2m) = \pi/8$) and $a_k = 2\pi/n + 2\pi k/m$ in Figure 7, Eq.(12) can be rewritten as

$$l_k = \sin\left(\frac{a_k}{2}\right)\frac{l_0}{\sin\frac{a_0}{2}} = 2l_e\sin\left(\frac{a_k}{2}\right) \quad \text{for } k = 0\ldots\frac{n}{2}-1 \tag{13}$$

where l_e denotes the edge length of the regular polygon. Figure 7 evidently illustrates that Eq.(13), thus Eq.(12) is met.

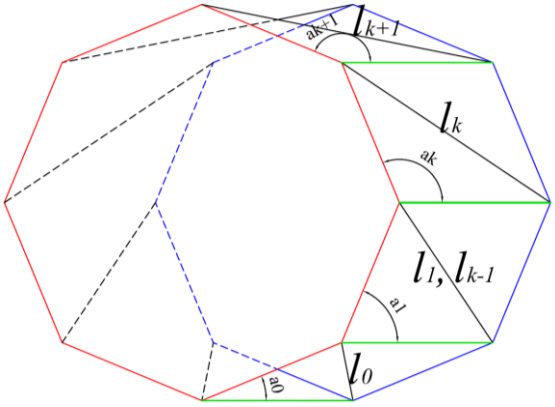

Figure 7. Series of segment length expressed by an arithmetic sequence of angles

4.3. Unroll the geometry to the rotating regular polygon along a line

Now unroll the m-sided polygon along a line, such that m+1 identical m-sided polygons are positioned with equal spacing, that is equal to the edge length, and connect vertexes in the same manner as constructed in Figure 5, but between the adjacent polygons in one stroke. As shown in Figure 8, this results in an extended affine polyline inscribing the trajectory of a vertex of the rotating regular polygon with m (=n/2) sides. (These results can be confirmed by numerical calculations from various approaches.)

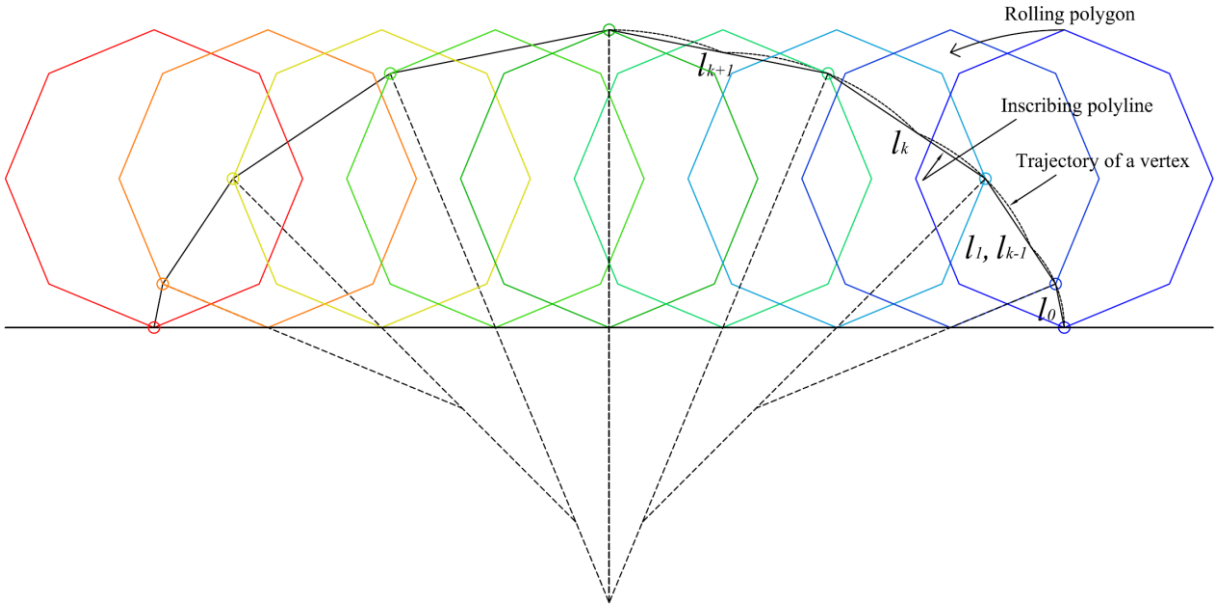

Figure 8. Extended affine spoke wheel ring with minimum squared lengths shown as polyline inscribing the trajectory of a rotating regular polygon

4.4. The limit curve

Noticing that a circle is the limit curve of regular polygons with the side numbers infinitely increased, the trajectory and the inscribing polyline, which minimizes the sum of squared lengths, should approach a cycloid. This completes the proof.

5. Concluding remarks

An alternative proof based on dual polyhedra is provided to the proposition that the limit curve of extended affine spoke wheel ring geometry with a minimum sum of squared segment lengths approaches a cycloid. The proof neither requires any sophisticated trigonometric identities, nor solution of linear algebra including the boundary conditions. Therefore, it is more directly associated with the optimality condition and yields a more illustrative understanding. Since the proof provided in this paper retains the representation of the length in the form diagram, it is also possible that the proof steps 4.3 and 4.4 can be integrated with the other formulation with lengths as unknown variables [4].

Applying the dual polyhedron shows advantages in reducing the number of variables while satisfying the geometric constraints by the extended affine rules implicitly but very easily. However, the meanings of z* coordinates are neither clarified nor play a significant role in the proof steps. The geometric lengths of the segments remain relevant although the dual space used in the proof is a force polyhedron. It should be addressed with further study whether or not the problem can be converted to a purely dual problem including conversion of the minimization to possibly maximization.

Although the proposition concerned in this paper is a very special case of choosing a ring shape under the extended affine concept, it is of great interest from the aspect of graphic statics, or in other words from mechanical and mathematical aspects, because it relates a type of force diagram that makes great sense in structural performance to a form diagram (or part of it) that is well known in mathematics and physics, through a filter of optimization. The first question is if this is purely a coincidence or more than that. If not more, in fact, the intriguing relation has been proved more directly and graphically by applying graphic statics, particularly Airy stress polyhedra of both diagrams, than by the geometric approach alone. It may not be always the case that the dual problem or mixed problem like this case makes the problem simpler or more understandable. Nonetheless, the study has indicated that the duality leads to a new solution approach to form and force problems, i.e. form finding, of spoke wheel systems. Suppose there are some geometric constraints to satisfy for an extended affine spoke wheel system; rewrite them only with z^* coordinates of the vertexes of the undulated regular polygon. Then form finding is reduced to solve for z^*s instead of nodal coordinates xs and ys.

The other questions raised in the introduction, such as the translation of the evolute-involute relation of two form diagrams into force diagrams or the meaning of the trigonometric curve of the z* beyond just the conversion by Cremona's duality mapping rule, have not been successfully answered or thoroughly investigated yet. Again, it is not necessarily certain if these questions are even meaningful, but yet they remain fascinating for some as there seem to be hints to develop new aspects of form finding of spoke wheel structures.

Abstract

Recent developments in applied algebraic topology can simplify and extend results in graphic statics – the analysis of equilibrium forces, dual diagrams, and more. The techniques introduced here are inspired by recent developments in cellular cosheaves and their homology. While the general theory has a few technical prerequisites (including homology and exact sequences), an elementary introduction based on little more than linear algebra is possible. A few classical results, such as Maxwell's Rule and 2D graphic statics duality, are quickly derived from core ideas in algebraic topology. Contributions include: (1) a reformulation of statics and planar graphic statics in terms of cosheaves and their homology; (2) a new proof of Maxwell's Rule in arbitrary dimensions using Euler characteristic; and (3) derivation of a novel relationship between mechanisms of the form diagram and obstructions to the generation of force diagrams. This last contribution presages deeper results beyond planar graphic statics.

Keywords: graphic statics, graphical methods, Maxwell's rule, sheaf theory, cosheaves, cellular sheaves, algebraic topology, homology, Euler characteristic

1. Introduction

Applied topology is a branch of contemporary applied mathematics that uses algebraic topology as a toolset in applications [1]. Some prominent examples from the past two decades include the use of topological tools in data analysis [2], neuroscience [3], sensor networks [4], and signal processing [5].

One of the more recent and exciting developments in applied topology is the establishment and implementation of *cellular sheaf theory*. Building on the classical and powerful sheaf theory of the 1950s-60s [6], cellular sheaves (and dual *cosheaves*) provide a locally finite and inherently computation-friendly toolset which matured in the thesis of Curry [7]. These tools have been used in network coding [8], pursuit and evasion games [9], distributed optimization [10], opinion dynamics [11], scene analysis [12], and extending spectral graph theory [13].

In this introduction we use cellular cosheaves to characterize the static behavior of trusses. Following a classical history [14], [15], advances in the late 20th century [16]–[18] laid foundations for homological methods in static analysis. Algebraic foundations for the mechanical properties of two dimensional graphic statics has been further developed since [19]–[21]. Additional great strides have been made in algebraic descriptions of 3D polyhedral graphic statics [22]–[24]. Our contributions via cellular cosheaves extend these threads.

2. Cellular cosheaves

In the simplest possible setting, cosheaves are algebraic structures attached to a *network* (or graph of vertices and edges) and comprised of *vector spaces* and *linear transformations*.

2.1. A general construction

Let $X = (V, E)$ denote a graph with vertex set V and (undirected) edge set E, with each edge connecting distinct vertices. A *cosheaf* $\mathcal{F}$ on X associates to each vertex $v \in V$ and each edge $e \in E$ a finite dimensional vector space $\mathcal{F}_v$ ($\mathcal{F}_e$ respectively). These vector spaces – called *stalks* – can be thought of as *local data*, and they can vary from vertex to vertex and edge to edge. The cosheaf consists not only of the underlying graph along with the stalks, but also linear transformations connecting the stalks where edges and vertices meet. For each incident edge-vertex pair $e \trianglerighteq v$, the cosheaf contains a linear transformation $\mathcal{F}_{e \trianglerighteq v}: \mathcal{F}_e \to \mathcal{F}_v$ from data over e to data over v. In all examples in this introduction, the vector spaces have explicit bases, and the maps $\mathcal{F}_{e \trianglerighteq v}$ are matrices. One thinks of these *cosheaf matrices* as being programmable: they define the constraints of the cosheaf stalk data.

Example 1: For any graph X, the unit *constant cosheaf* $\mathcal{I}_X$ has a 1-dimensional vector space as every stalk with all cosheaf matrices the identity. For a fixed (not necessarily 1-dimensional) vector space V, the V-constant cosheaf V_X has a copy of V on each vertex and edge, connected by identity matrices.

Example 2: Consider single-variable *polynomial splines* over a graph. These splines over edges are degree $\leq m$ polynomials in a single variable, meeting at vertices with global smoothness class C^r (r times continuously differentiable). Consider the cosheaf $\mathcal{K}$ with edge stalks consisting of P_m, the vector space of degree $\leq m$ polynomials. The vertex stalks are quotient vector spaces P_m/I^{r+1}, where I^{r+1} is the subspace of polynomials which vanish at the vertex with complementary degree at least $r + 1$. The matrices $\mathcal{K}_{e \trianglerighteq v}$ are quotient projections $P_m \to P_m/I^{r+1}$. Further exposition may be found in [25].

Our definitions have focused on the case where the base space is an undirected network. Extension to (regular) higher dimensional cell complexes is straightforward [7], with stalks attached to higher dimensional cells and corresponding cosheaf matrices.

2.2 The force cosheaf

Our central object of study is the *force cosheaf* – a means of tracking force vectors across a truss. Fix a graph $X = (V, E)$ modelling a mechanical truss built from axial geometric members E pinned at their ends with free-rotational joints V. Assume that X is realized in Euclidean space $\mathbb{R}^n$ (with $n = 2,3$ being typical) by an assignment $p: V \to \mathbb{R}^n$ (that embeds edges linearly). The force cosheaf $\mathcal{F} = \mathcal{F}(X, p)$ for this realization of X has vertex stalks $\mathcal{F}_v$ all equal to $\mathbb{R}^n$, encoding the static loads at the joints. The edge stalks $\mathcal{F}_e \cong \mathbb{R}$ encode a stress along the member: positive or negative for tension or compression respectively. For each edge e connecting joints u and v, the matrices $\mathcal{F}_{e \trianglerighteq u}: \mathcal{F}_e \to \mathcal{F}_u$ and $\mathcal{F}_{e \trianglerighteq v}: \mathcal{F}_e \to \mathcal{F}_v$ send the basis vector of $\mathcal{F}_e$ to the vectors $p(u) - p(v) \in \mathcal{F}_u$ and $p(v) - p(u) \in \mathcal{F}_v$ respectively. A sketch of the force cosheaf is pictured on the right in Figure 1.

The force cosheaf contains within it all the data from which statics and graphic statics unfolds. What reveals degrees of freedom and equilibrium is the classical algebraic-topological tool called *homology*.

3. Homology

Given a graph, one often considers its global topological properties such as the number of its connected components or independent cycles. These intuitive properties generalize greatly to homology – the algebraic study of *"holes."* Cosheaves, as introduced above, appear as mere containers of data; deeper meaning follows from considering their homology.

3.1 Classical cellular homology

We begin by describing a simple, classical instance of homology. In the case of $X = (V, E)$ a graph, one defines the vector spaces $C_0 = C_0X$ and $C_1 = C_1X$ with basis the formal set of vertices and edges respectively. Counting the number of edges and vertices we have $\dim C_0 = |V|$ and $\dim C_1 = |E|$. One may then define the *oriented incidence matrix* $\partial: C_1 \to C_0$ with respect to an arbitrary orientation given to edges. This matrix sends a basis edge e to the linear combination of vertices $\partial e = u - v$, respecting

this orientation. The null space, or *kernel* of this matrix $H_1X = \ker \partial$ has basis of oriented cycles in X, where multiplication by -1 changes the orientation of the cycle. The quotient vector space $H_0X = C_0/\operatorname{im}\partial$ of C_0 by the image of the oriented incidence matrix is known as the *cokernel* (isomorphic to the left null space of ∂); it has basis of connected components of X.

This graph construction generalizes to X a higher dimensional cell complex with more specialized language. The vector space $C_k = C_kX$ is known as the space of *k-chains*, linear combinations of formal k-cells (with arbitrary orientation). These vector spaces assemble into a sequence called a *chain complex* by means of *boundary matrices* $\partial\colon C_k \to C_{k-1}$ which send a basis k-cell σ to the linear combination of boundary $(k-1)$-cells $\partial\sigma = \sum \pm\tau$, where the sign comes from compatibility of orientation [26]. Composed boundary matrices are the zero matrix, with $\partial_k \circ \partial_{k+1} = 0$.

The crucial definition is this. The (cellular) *homology* of X, HX, is a collection of vector spaces $H_k = H_kX$. This k^{th} homology of X is defined to be the quotient vector space $H_kX = \ker \partial_k \,/\, \operatorname{im}\partial_{k+1}$: kernels mod images, or equivalence classes of collections of k-cells with vanishing boundary, modulo distributions that are the boundary of a higher dimensional chain. The dimensions of the homologies, $\beta_k = \dim H_kX$, are known as the *Betti numbers* of X. In general, β_0 gives the number of connected components of X, and higher Betti numbers count the number of different dimensional holes within X (in a graph, cycles are 1-dimensional holes). Homology is invariant with respect to the arbitrary orientation of cells and any homotopy (think: controlled deformation) of the space X.

3.2 Cosheaf homology

Homology extends to cosheaves. Let $\mathcal{F}$ be a cosheaf over a graph $X = (V, E)$. The space of cosheaf *0-chains* $C_0 = C_0\mathcal{F} = \bigoplus_v \mathcal{F}_v$ is the product vector space bundling data over all vertices, and the space of *1-chains* $C_1 = C_1\mathcal{F} = \bigoplus_e \mathcal{F}_e$ is the corresponding amalgamation of vector data over all edges. A vector in C_0 (or C_1) is interpreted as a distribution of data over vertices (or edges). The *cosheaf boundary matrix* $\partial\colon C_1 \to C_0$ acts on a 1-chain $\xi = (\xi_e)$ yielding a 0-chain $\partial\xi$ whose value on a vertex v is given by

$$(\partial\xi)_v = \sum_{e_i \triangleright v} \pm\mathcal{F}_{e_i \triangleright v}\left(\xi_{e_i}\right) \tag{1}$$

where the sign is informed by an arbitrary choice of orientation and the sum is over all edges incident to v. Summations of the form (1) occur over all vertices, utilizing cosheaf matrices $\mathcal{F}_{e_i \triangleright v_j}$ to transform a distribution of data over edges to data over vertices. One imagines the vertices communicating and pulling data from their neighbor edges. For a cosheaf over a n-dimensional cell complex, the boundary matrix extends to a sequence of linear transformations $\partial_k\colon C_k \to C_{k-1}$, the entire sequence being collected into a chain complex $C\mathcal{F} = (C_k, \partial_k)$, with $\partial_k = 0$ when $k \leq 0$ or $k > n$.

The *homology* of the cosheaf, $H\mathcal{F}$, is the collection of vector spaces $H_k = H_k\mathcal{F}$, where $H_k\mathcal{F} = \ker \partial_k \,/\, \operatorname{im}\partial_{k+1}$. This is kernels mod images, just as in (classical) cellular homology. The difference between cellular homology and cosheaf homology is in the difference of data of the chain complex CX or $C\mathcal{F}$ - the process of taking homology is afterwards identical.

Examples: Recall the examples in Section 2.1.

1. The cellular homology of a network X is the same as the homology of the unit constant cosheaf $\mathcal{I}_X$ over it. Here, $H\mathcal{I}_X \cong HX$ and so the homology is the same as the cellular case. The Betti numbers of $\mathcal{I}_X$ count connected components and independent cycles of X. For a general constant cosheaf V_X, this has homology isomorphic to m copies of HX, where $m = \dim V$.
2. The space of splines over a polygonal cycle is isomorphic to $H_1\mathcal{K}$, the 1st homology of the spline cosheaf of Example 2. This is a simple example of more general results on splines [25].

These examples hint at the role that homology plays in classifying solutions of constrained systems.

3.3 Force cosheaf homology

What does the homology of the force cosheaf entail? At the physical level, each truss joint combines the axial forces along incident members. In the mathematical model, this is precisely what the force cosheaf boundary matrix describes. Given a 1-chain – a choice of axial force along all members – the boundary matrix $\partial: C_1\mathcal{F} \to C_0\mathcal{F}$, otherwise known as the *equilibrium matrix* [27], evaluates a distribution of net forces at all joints. This is significant: *the homology of the force cosheaf, $H\mathcal{F}$, characterizes equilibrium-stresses and configurations of the mechanism.* The details are worth emphasizing:

1. The 1-dimensional homology $H_1\mathcal{F} = \ker \partial$ consists of all stress distributions that keep the structure in static equilibrium (zero net force at each joint). The dimension of this null space (the 1st Betti number $\beta_1 = \dim H_1\mathcal{F}$) records the number of dimensions of *self-stress*.
2. The 0-dimensional homology, $H_0\mathcal{F} = C_0\mathcal{F}/\text{im } \partial$, records distributions of forces at joints which cannot impart forces to edges. This space of un-resistible forces is interpretable as the space of constrained *degrees of freedom* of vertices of X, including global translations, rotations, and mechanisms [19]. Under these infinitesimal motions, edge lengths would remain constant.

A sample graph X with non-zero self-stress is provided in Figure 1. As is common in a well-constructed cosheaf, homology characterizes/classifies properties of the global system. With these tools, nontrivial inferences can be made in a unified fashion.

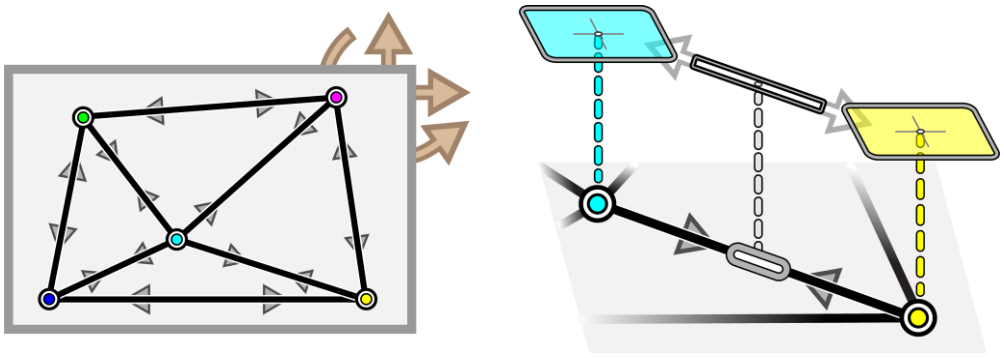

Figure 1. The force cosheaf $\mathcal{F}$ over the graph (left) has cosheaf boundary matrix of size 10 by 8 with nullity 1. The homology of $\mathcal{F}$ characterizes the self-stress over edges and three degrees of freedom (two translational and one rotational of the entire structure). A local view of $\mathcal{F}$ is highlighted (right), with the cosheaf matrices mapping edge stalks to vertex stalks "above" the graph.

4. Euler, Maxwell, & Betti

Maxwell's Rule [14] is the classic condition for a frame structure to be isostatic. The modern form for 3D trusses is given in [27]:

$$3|V| - |E| = 6 + |M| - |S|, \tag{2}$$

where $|M|$ is the number of linkage mechanisms, $|S|$ is the number of self-stresses, $|V|$ is the number of vertices of the truss, and $|E|$ is the number of its edges. The prevalence of differences (especially in the number of vertices and edges) is a clue that this is related to *Euler characteristic*.

Recall that elementary topological fact that for a finite polyhedral *spherical* surface X with $|V|$ vertices, $|E|$ edges, and $|F|$ faces, the Euler characteristic $\chi(X) = |V| - |E| + |F|$ equals $+2$, independent of how the spherical surface is discretized. The reason for this is an elementary but fundamental result. For a finite collection of finite-dimensional vector spaces $C = \{C_k\}$, its Euler characteristic

$$\chi(C) = \sum_k (-1)^k \dim C_k \tag{3}$$

is likewise finite and agrees with the classical formula that counts vertices, edges, and faces. This is formulated as an alternating sum of Betti numbers by the following classical result:

Lemma 1: [26] *The Euler characteristic of a chain complex $C = (C_k)$ and its homology H agree:*

$$\chi(C) = \chi(H) = \sum_k (-1)^k \beta_k \,, \tag{4}$$

This is why for a triangulated spherical surface $\chi = 2$, since its homology satisfies $\beta_0 = \beta_2 = 1$ and $\beta_1 = 0$. The proof of Lemma 1 is neither more nor less than the rank-nullity theorem from linear algebra, suitably generalized. Indeed, a single linear transformation $A: U \to V$ *is* an elementary chain complex where $C_1 = U$ and $C_0 = V$. Taking homology, one recovers the rank-nullity theorem as a special case.

We reinterpret Maxwell's Rule as coming from a chain complex and its homology: in this case, the force cosheaf $\mathcal{F}$. For a structure in n-D, its Euclidean group of translations and rotations in n-D has dimension $\binom{n+1}{2} = \frac{1}{2}n(n+1)$. With this, Lemma 1 applied to the force cosheaf $\mathcal{F}$ in n-D yields

$$n|V| - |E| = \dim C_0 - \dim C_1 = \dim H_0 - \dim H_1 = \binom{n+1}{2} + |M| - |S|. \tag{5}$$

This is the Maxwell Rule in dimension n, giving equation (2) when $n = 3$.

5. Boundary conditions

Trusses are outfitted with external loadings and reaction forces in practice. The statics of these trusses are characterized by *relative homology*, meaning homology relative to an external structure. This requires some additional theoretical tools.

5.1 Cosheaf maps and quotients

For two cosheaves $\mathcal{F}$ and $\mathcal{G}$ over a graph $X = (V, E)$, a *cosheaf map* $\phi: \mathcal{F} \to \mathcal{G}$ is comprised of stalk-wise linear maps $\phi_x: \mathcal{F}_x \to \mathcal{G}_x$ for x ranging over every cell of X. In addition, the cosheaf map must respect the cosheaf matrices of $\mathcal{F}$ and $\mathcal{G}$: the equations $\phi_v \circ \mathcal{F}_{e \triangleright v} = \mathcal{G}_{e \triangleright v} \circ \phi_e$ must hold.

It may be the case that the data of cosheaf $\mathcal{F}$ can be considered as a subset of the data of $\mathcal{G}$. In this special case, $\phi: \mathcal{F} \hookrightarrow \mathcal{G}$ is an *inclusion* of the stalks of $\mathcal{F}$ into the stalks of $\mathcal{G}$, and one can think of $\mathcal{F}$ as lying "inside" $\mathcal{G}$. To model the data in $\mathcal{G}$ not captured by $\mathcal{F}$, one builds the *quotient cosheaf* $\mathcal{G}/\mathcal{F}$ with stalks of quotient vector spaces $(\mathcal{G}/\mathcal{F})_x = \mathcal{G}_x/\mathcal{F}_x$, with x ranging over all cells. One can think of the cosheaf $\mathcal{G}/\mathcal{F}$ as encoding the *orthogonal compliment* to $\mathcal{F}$ inside of $\mathcal{G}$, satisfying the isomorphism of cosheaves $\mathcal{F} \oplus \mathcal{G}/\mathcal{F} \cong \mathcal{G}$ (comprised of vector space isomorphisms between stalks). Here, the data of $\mathcal{G}$ is subdivided into its constituent components parallel and orthogonal to $\mathcal{F}$. This construction will help with modelling external forces on a truss.

5.2 External loadings

We model external forces on a truss somewhat differently from other authors [19], [21], [27], considering boundary conditions as residing on an exterior truss abstracting the origin of the boundary loads. This exterior truss loosely set to be a loop around the structure: the intention of this is to model the loaded truss of interest as a sub-truss of a larger structure. The benefits of this approach are a clear differentiation between loaded vertices and unloaded vertices, as well as a homological formulation of equilibrium stresses. This is specifically important in simple 2D graphic statics, where loads are only applied on the exterior of a loaded truss.

Suppose that $Y = (V_Y, E_Y)$ (the exterior truss loop) is a closed subgraph of $X = (V, E)$ (the extended original truss with *boundary conditions*) as in Figure 2. For the force cosheaf $\mathcal{F} = \mathcal{F}_X$ with domain over X, the cosheaf $\mathcal{F}_Y$ has stalks identical to those of $\mathcal{F}_X$ for vertices and edges in Y and zero stalks

elsewhere. It is straightforward to define the inclusion cosheaf map $\iota: \mathcal{F}_Y \hookrightarrow \mathcal{F}_X$, with stalk-wise linear maps the identity matrix over cells of Y and the zero matrix over $X - Y$. The ensuing quotient cosheaf $\mathcal{F}_{X-Y} \coloneqq \mathcal{F}_X/\mathcal{F}_Y$ has support strictly on the set $X - Y$ (which is topologically an open disk). Some edges $\{e_l, e_r\}$ of $X - Y$ have an open end in Y - these are *loaded edges* and *reaction edges* of $X - Y$. These edges represent lines of action of forces transferred between Y and $X - Y$.

The quotient cosheaf $\mathcal{F}_{X-Y}$ models the static behavior of the original truss $X - Y$ with respect to the space of peripheral boundary conditions Y. The *relative homology* $H_1\mathcal{F}_{X-Y}$ of this cosheaf characterizes the full space of *equilibrium stresses*, including internal self-stresses as well as external equilibrium loadings from edges $\{e_l, e_r\}$ (ignorant of whether Y could deliver these forces or not). Here, the truss $X - Y$ is blind to the statics of Y and liberally permits any possible loading through edges $\{e_l, e_r\}$. Our next goal is to relate the homologies of the force cosheaves $\mathcal{F}_X, \mathcal{F}_Y$, and $\mathcal{F}_{X-Y}$ with varying domains.

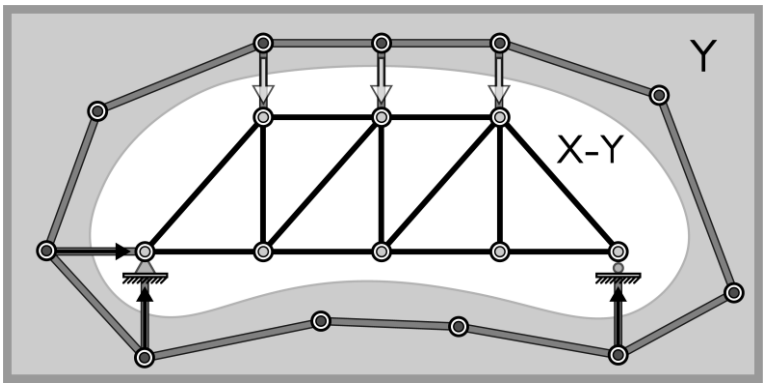

Figure 2. Boundary conditions in the form of loading and reaction forces are modeled as edges connecting the truss to an external loop Y.

5.3 Exact sequences

Exactness is a criterion of sequences of vector spaces and linear transformations that compactly characterizes a myriad of relationships between. Such a sequence of vector spaces

$$\ldots \to V_3 \to V_2 \to V_1 \to V_0 \to V_{-1} \ldots \tag{6}$$

is said to be *exact* if the image of every incoming transformation is equal to the kernel of the outgoing transformation at every vector space. That is, the homology of the sequence (6) completely vanishes. In the special case that (6) is non-zero only at the central three terms, there is an isomorphism of vector spaces $V_1 \cong V_0 \oplus V_2$ where $V_0 \cong V_1/V_2$; this can be worked out using properties of exactness [26].

It is a fact that any triple of cosheaves of the form $\mathcal{F} \hookrightarrow \mathcal{G} \to \mathcal{G}/\mathcal{F}$, where the first cosheaf map is an inclusion and the second is a quotient projection, induces a *long exact sequence* in homology

$$\ldots \to H_{k+1}\mathcal{G}/\mathcal{F} \to H_k\mathcal{F} \to H_k\mathcal{G} \to H_k\mathcal{G}/\mathcal{F} \to H_{k-1}\mathcal{F} \to \cdots, \tag{7}$$

derived from the corresponding exact sequence of cosheaf chain complexes [7]. True to its name, sequence (7) is an exact sequence of vector spaces and is a core feature of *homological algebra*.

Applying this to the externally loaded force cosheaf $\mathcal{F}_Y \hookrightarrow \mathcal{F}_X \to \mathcal{F}_{X-Y}$, where $\mathcal{F}_{X-Y} = \mathcal{F}_X/\mathcal{F}_Y$, one has

$$0 \to H_1\mathcal{F}_X \to H_1\mathcal{F}_{X-Y} \to H_0\mathcal{F}_Y \to H_0\mathcal{F}_X \to H_0\mathcal{F}_{X-Y} \to 0 \tag{8}$$

where $H_1\mathcal{F}_Y = 0$ (because Y is assumed to be a loop with no self-stress) and all higher-homology terms vanish. This sequence collates the following elements:

1. The 1st homology $H_1\mathcal{F}_X$ is the vector space of *internal self*-stresses of X.

2. The relative 1st homology $H_1\mathcal{F}_{X-Y}$ is the total space of equilibrium stresses including those from boundary conditions.
3. The 0th homology $H_0\mathcal{F}_Y$ is the space of degrees of freedom of the frontier Y.
4. The 0th homology $H_0\mathcal{F}_X$ captures degrees of freedom of X (potentially including those of Y).
5. The 0th homology $H_0\mathcal{F}_{X-Y}$ is the space of *constrained degrees of freedom* of $X - Y$ with respect to the various loadings and reactions restricting said freedom.

Exactness of (8) means that there are constraints tying together sequential terms. For example, the statement that *"every self-stress is an equilibrium stress with zero loading"* is equivalent to exactness of (8) at $H_1\mathcal{F}_X$ (the transformation $H_1\mathcal{F}_X \to H_1\mathcal{F}_{X-Y}$ is injective). Exactness at $H_1\mathcal{F}_{X-Y}$ has the interpretation: *"every equilibrium stress of a loaded structure is a sum of internal self-stresses and those resulting from outside forces"*. These outside forces are generated by instabilities in Y that, in the larger structure X, "push" and "pull" on $X - Y$. Similar statements may be made about the remaining terms.

6. Planar graphic statics

Maxwell's seminal paper [14] made the astute observation that force vectors within members of a static truss combine to form a *reciprocal diagram* topologically dual to the primal (see Figure 3 for examples). Various aspects of 2D duality have been studied, such as the planarity condition [21] or kinematic properties [19], [20]. Here we develop the root of the duality in its substantial form and extend to new territory.

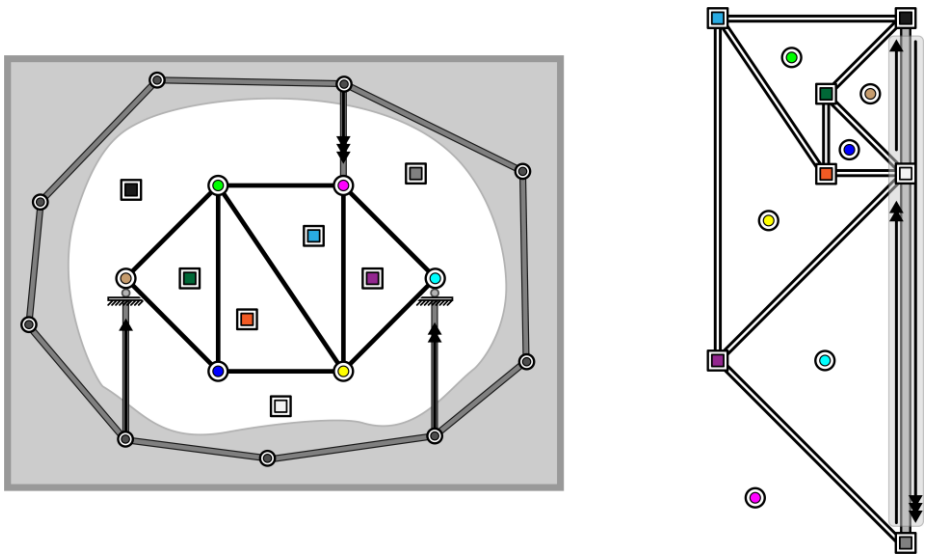

Figure 3. An example of graphic statics with boundary conditions is pictured. A form diagram is subject to external loads (left), with a single degree of equilibrium. A representative force diagram (a combined free body diagram) is drawn (right), with edge lengths equal to the load over the primal edge. Equilibrium of forces on the left is equivalent to dual face cells on the right being closed. The grey exterior (*cf.* Figure 2) on the left is dualized to the interior of the vertical degenerate triangle on the far right.

We focus on finite *planar graphs* with straight, non-overlapping edges. For a particular realization of a planar graph in the plane, the polyhedral regions interior to minimal cycles are *face cells*. Introducing these face cells extends a planar graph to a two-dimensional *cell complex*. Including the exterior which extends to infinity as one additional face yields a cell complex with the topology of the sphere $\mathbb{S}^2$. We remind the reader that although this cell complex $X = (V, E, F)$ has spherical topology, it remains realized in the flat plane by an assignment $p: V \to \mathbb{R}^2$. This is called a *form diagram*.

It is natural to extend our definitions of cosheaves over the plane as a 2D cell complex. The force cosheaf $\mathcal{F}$ over this spherical cell complex $X = (V, E, F)$ is an extension of that over its graph (V, E): the stalks over all face cells are set to zero (0-dimensional vector spaces) with zero-matrices from face stalks to incident edge stalks. There is more to the story, based on how this force cosheaf is situated in the plane.

6.1 The position cosheaf

While the force cosheaf $\mathcal{F}$ describes the compatibility of forces over the truss, it is a natural question what the complementary data to forces are in the plane. Namely, since edge stalks $\mathcal{F}_e$ contain force information *parallel* to edges, what data structure describes information *perpendicular* to edges? This question naturally leads to its *complimentary cosheaf*, the quotient of the constant cosheaf $\mathbb{R}^2_X$ by $\mathcal{F}$. The reason for considering the constant cosheaf here is that it encompasses the *ambient space* of the plane. Stalks of $\mathbb{R}^2_X$ are akin to the tangent space: copies of $\mathbb{R}^2$ allocated to each location in the plane, stitched together by identity matrices.

There is an inclusion map $\phi\colon \mathcal{F} \hookrightarrow \mathbb{R}^2_X$ of cosheaves which we now describe. The force cosheaf has no edge stalks so ϕ_f is the zero matrix over faces. By ϕ_e over edges, the vector $\mathcal{F}_e \cong \mathbb{R}$ is sent to the vector $p(u) - p(v)$, the position of the edge endpoints. Over vertices, stalks of $\mathcal{F}$ and $\mathbb{R}^2_X$ are both copies of $\mathbb{R}^2$, so it is valid to let ϕ_v be the identity linear transformation. It is straightforward to check that ϕ is a valid cosheaf map by this construction.

The quotient cosheaf $\mathcal{G} \coloneqq \mathbb{R}^2_X/\mathcal{F}$, called the *position cosheaf*, is the complementary data structure we desire. Over faces, this cosheaf has face stalks $\mathcal{G}_f \cong \mathbb{R}^2$ encoding *positions* (to be detailed momentarily). There is trivial data over vertices, with $\mathcal{G}_v = 0$. The edge stalks $\mathcal{G}_e = \mathbb{R}^2/\mathcal{F}_e$ represent the linear subspace perpendicular to the thrust of e in the plane. The non-trivial cosheaf matrices $\mathcal{G}_{f \rhd e}$ are projection matrices $P_{e^\perp}$, projecting from the face stalk $\mathcal{G}_f$ onto the perpendicular space $\mathcal{G}_e$.

Recall the *Poincaré dual* cell complex to $X = (V, E, F)$ is the cell complex $\tilde{X} = (\tilde{F}, \tilde{E}, \tilde{V})$ where faces are converted to dual vertices, edges to dual edges, and vertices to dual faces [26]. In this way, the cell structure is dualized to an alternative cell structure on the sphere $\mathbb{S}^2$. We note that $\tilde{X}$ is merely the topological dual to X as of now; the geometric bearing of cells of $\tilde{X}$ is informed by homology classes of the position cosheaf.

Face stalks of $\mathcal{G}$ encode the positions of the *dual vertices* of $\tilde{X}$ in $\tilde{F}$. Namely, $\mathcal{G}_f \cong \mathbb{R}^2$ may be considered as the space of possible positions for the dual vertex $\tilde{f}$ in the plane. With this identification, the homology space $H_2\mathcal{G}$ consists of these realizations of dual vertices subject to constraints along edges. For every edge bounded by faces $e \lhd f_1, f_2$, there is the corresponding dual incidence $\tilde{e} \rhd \widetilde{f_1}, \widetilde{f_2}$ and dual restraint. For ξ to be a homology element of $H_2\mathcal{G}$ it must be the case that

$$\mathcal{G}_{f_1 \rhd e}(\xi_{f_1}) = \mathcal{G}_{f_2 \rhd e}(\xi_{f_2}) \tag{9}$$

or equivalently that

$$P_{e^\perp}\left(\xi_{f_1} - \xi_{f_2}\right) = 0. \tag{10}$$

In other words, the difference between ξ_{f_1} and ξ_{f_2} along the perpendicular direction to e is zero – and so *any difference between these two positions lies along the linear subspace to edge* e. This means that the difference in positions of dual vertices $\widetilde{f_1}, \widetilde{f_2}$ is parallel to edge e as determined by ξ. Moreover, every parallel dual realization $\xi\colon \tilde{F} \to \mathbb{R}^2$ is a homology class of $H_2\mathcal{G}$ as this condition is descriptive. A parallel dual graph to that of Figure 1 is pictured in Figure 4.

In conclusion, the vector space $H_2\mathcal{G}$ of the position cosheaf encodes *all possible parallel realizations* of the dual cell complex $\tilde{X}$ in the plane. These realizations of $\tilde{X}$ are called *force diagrams*.

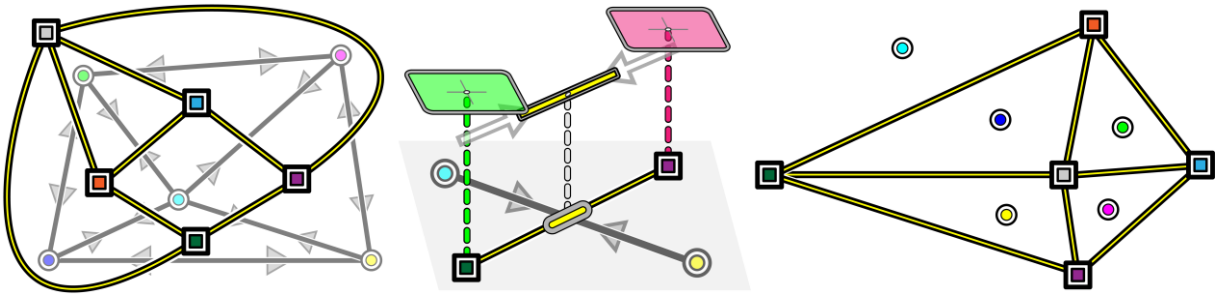

Figure 4. The topological dual to the form diagram of Figure 1 is pictured (left), with its geometry realized (right). A local view of the position cosheaf $\mathcal{G}$ is highlighted (center), with cosheaf matrices mapping face stalks to edge stalks. A generator of $H_2\mathcal{G}$ provides the geometric coordinates to dual vertices on the right, characterizing a force diagram. This parallel dual realization may be derived from the self-stress of the form diagram via the graphic statics of Theorem 1.

6.2 Dual trusses

We arrive at the heart of 2D graphic statics. While the classical history of form and force diagram duality reaches back over a century and a half [14], cosheaves permit an efficient modern reformulation. The cosheaf triple $\mathcal{F} \hookrightarrow \mathbb{R}^2_X \to \mathcal{G}$ leads to a long exact sequence as per sequence (7):

$$... \to H_2\mathcal{F} \to H_2\mathbb{R}^2_X \to H_2\mathcal{G} \to H_1\mathcal{F} \to H_1\mathbb{R}^2_X \to H_1\mathcal{G} \to H_0\mathcal{F} \to H_0\mathbb{R}^2_X \to H_0\mathcal{G} \to 0 \tag{11}$$

The force cosheaf has zero-stalks over faces, so $H_2\mathcal{F} \cong 0$. The constant cosheaf has homology $H_2\mathbb{R}^2_X \cong \mathbb{R}^2$, $H_1\mathbb{R}^2_X \cong 0$, and $H_0\mathbb{R}^2_X \cong \mathbb{R}^2$, matching Betti numbers of the underlying sphere (multiplied by two, see example 1, Section 3.2). These computations simplify and split the exact sequence (11) into two:

$$0 \to \mathbb{R}^2 \to H_2\mathcal{G} \to H_1\mathcal{F} \to 0 \tag{12}$$

$$0 \to H_1\mathcal{G} \to H_0\mathcal{F} \to \mathbb{R}^2 \to 0 \tag{13}$$

The first exact sequence (18) *is* the establishment of 2D graphic statics. The space $\mathbb{R}^2$ corresponds to *global translations* of dual realizations of $\tilde{X}$ in $H_2\mathcal{G}$: these are global shifts of all dual vertices by the same translation vector. The linear transformation $H_2\mathcal{G} \to H_1\mathcal{F}$ takes the pointwise difference between dual coordinates and converts them to force values within a self-stress.

Theorem 1: [14], [17] *Over a truss X realized in $\mathbb{R}^2$, there is a bijective correspondence between self-stresses of X and parallel dual realizations of $\tilde{X}$ in $\mathbb{R}^2$ up to global translation.*

This is the isomorphism of vector spaces

$$H_1\mathcal{F} \cong H_2\mathcal{G}/\mathbb{R}^2 \tag{14}$$

following exact sequence (12). The ease of writing this equation conceals the underlying linear relationships at play. The force within each edge of a self-stress is equivalent to the distance between dual nodes in the corresponding force diagram. A benefit of the abstraction presented here is the readily generalization of isolated graphic statics to graphic statics with boundary conditions – the isomorphism of vector spaces

$$H_1\mathcal{F}_{X-Y} \cong H_2\mathcal{G}_{X-Y}/\mathbb{R}^2. \tag{15}$$

As $X - Y$ (Figure 2) has the topology of an open disk, its dual counterpart $\tilde{X} - \tilde{Y}$ has the topology of a closed disk. Equation (15) then is the statement that equilibrium stresses over a structure with boundary forces are equivalent to parallel realizations of the dual disk $\tilde{X} - \tilde{Y}$, up to global translation. An example is pictured in Figure 3.

Isomorphism (15) relies on $X - Y$ having $\beta_1 = 0$ so the constant cosheaf homology $H_1\mathbb{R}^2_X$ vanishes. If this requirement is exempted it is still possible to formulate graphic statics, such as the case of *internally applied loadings* where loads are applied within the structure (and holes inserted into $X - Y$). In this case, exact sequence (11) does not split into the two sequences (12) and (13) so more care is required.

There are numerous applications and extensions of the abstract formulation here. With care, the boundary loop Y can generalized to empower *relative graphic statics*. One can consider *partial* form diagrams $X - Y$ of a larger truss and rigorously compute consequent *partial* force diagrams $\tilde{X} - \tilde{Y}$. The relations to the whole are given by sequences analogous to (8).

6.3 Impossible rotations of the dual

The second exact sequence (13) also has meaning, although the homology $H_1\mathcal{G}$ is difficult to interpret. This space consists of *impossible dual edge rotations* in the sense that edges of any parallel dual realization of $\tilde{X}$ cannot possibly rotate in the specified manner (even if edges are permitted to freely extend or contract axially). These edge rotations *obstruct* dual realizations. Just as mechanisms of a truss are not resistible by truss members, these rotations are *not realizable* by nodal positions. In fact, rotations of truss members under mechanism or global rotation *are* impossible edge rotations on dual force diagrams. Only the space $\mathbb{R}^2$ of global translations of X does not rotate edges; the isomorphism

$$\mathbb{R}^2 \cong H_0\mathcal{F}/H_1\mathcal{G} \tag{16}$$

of vector spaces following exact sequence (13) certifies this. This relationship is novel.

Theorem 2: *The system of edge rotations from any mechanism or global rotation of a truss X in $\mathbb{R}^2$ are impossible to satisfy on any force diagram $\tilde{X}$ in $\mathbb{R}^2$, even permitting dual edges in $\tilde{X}$ to freely extend axially.*

Note that dual edges have their rotations flipped when realized in tension versus compression (see Figure 5). The symmetry of sequences (12) and (13) suggests this theorem is as fundamental as Theorem 1. Indeed, if rotation values are converted to stress values along edges (with clockwise rotation converted to compression, and counterclockwise to tension for instance), they form a self-stress of the dual $\tilde{X}$. This is *graph reciprocity*, the mirroring of the force and form diagrams [19], [20].

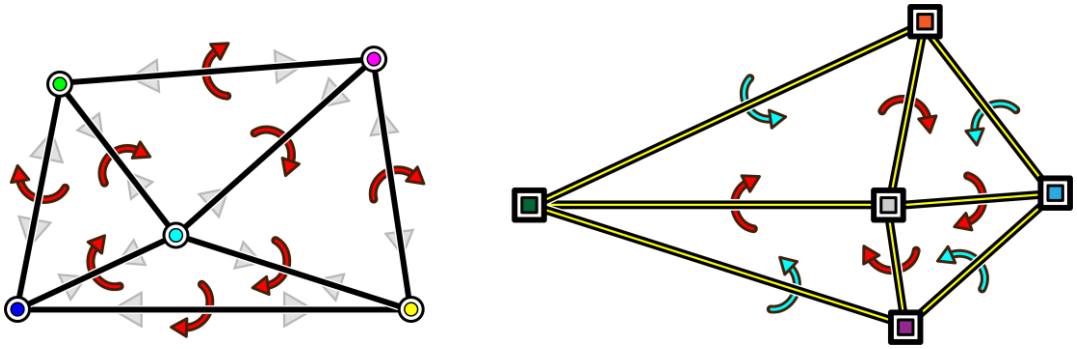

Figure 5. The form diagram of Figure 1 is globally rotated clockwise (left), inducing edge rotations. In a force diagram (right), dual edges have their rotations flipped when the primal edge is in tension. Even allowing dual edges to extend or contract, it is impossible to simultaneously rotate the internal four dual edges clockwise and rotate the external four dual edges counterclockwise. This illustrates Theorem 2; the single dimension of global rotation of the form diagram corresponds to the dimension of impossible dual edge rotations of force diagrams.

If the nodes of a truss are fixed connections instead of pinned, free-rotational connections, then impossible edge rotations are equivalent to states of *self-shear* of the structure. In this setting,

perpendicular shear forces are applied along each member instead of parallel axial forces. These self-shear forces are in equilibrium, with zero net force at nodes.

One central application of graphic statics is in *form finding*, where a force diagram is manipulated to find efficient geometry for the primal truss. In this context, a repositioning of dual nodes of a force diagram $\tilde{X}$ (not necessarily parallel) may be considered as an element of $C_2\mathcal{G}$. Its boundary $\partial\xi$ is a possible system of rotations of dual edges, and therefore, it is in the zero class of $H_1\mathcal{G}$. By sequence (13), this system of rotations (with rotations flipped over edges in tension) lies in the zero class of $H_0\mathcal{F}$. This force assignment to vertices of X is free of any translational, rotational, or mechanical components. Consequently, any preimage in $C_1\mathcal{F}$ of such an element of $C_0\mathcal{F}$ is a (not necessarily conservative) edge force assignment of X. This outlines a method of translating between *general* dual coordinates and *general* force assignments of force and form diagrams.

7. Beyond the plane

There are numerous potential extensions of the cosheaf-based graphic statics presented here.

One clear path is the extension of the well-known 3D polyhedral theory by Maxwell [14], [15] and Cremona [28], among others. Self-stresses of a cell complex X in the plane are in bijective correspondence to a family of three-dimensional *lifted polyhedra* that project vertically onto X. As 2D reciprocal graphic statics is very much linked to plane liftings of the truss [17] with a correspondence that is homological in nature [18], one can build a cosheaf adaptation.

Recalling Example 2 on polynomial splines, there is potential to integrate splines with *linear shape functions* utilized in structural engineering. For a beam in bending, the deflection, moment, and shear quantities all may be approximated by polynomials. At ends, beams are connected and restrained by C^r differentiability conditions - equivalent to compatibility conditions of spline cosheaves. More generally, the *finite element method* deconstructs complex shapes into simplified constituent components. It may be fruitful to investigate the homological properties of equilibrium equations in these models.

Finally, as presented in Sections 2 and 3, the force cosheaf $\mathcal{F}$ makes sense in dimension 3 and above. Indeed, the derivation of the Maxwell Rule (2) here given is no more difficult in n-D than in 2-D. To what extent, then, can the framework of cosheaves be integrated with recent breakthroughs in 3D polyhedral graphic statics [22]–[24]?

With 3-dimensional cells, the complexity between relationships of equilibrium spaces increases dramatically. While a single cosheaf map initiated 2D graphic statics in Section 6, higher dimensional graphic statics requires *filtrations* (or increasing sequences) of cosheaves, the analysis of which prompts the use of *spectral sequences*, a far-reaching generalization of the cosheaf long exact sequence (7).

Abstract

In the event sector, where there is a search for architectural constructions with an innovative morphology, reuse is key to strive towards more sustainable events. Designing modular structures and detailing them for easy disassembly and re-assembly is an ideal way to encourage and facilitate reuse. This way a longer lifespan is assured for the used components. However, temporary (event) structures are often hard to assemble, which can compromise their reusability. The difficulties of assembly are usually induced by the morphology of the modules or by using certain types of connections. Therefore these structures require optimization in terms of assembly while remaining resource efficient. The main objective of this research is to reimagine a developed structure, the ReciPlyDome, and optimize it in terms of assembly. The ReciPlyDome is a reciprocal dome structure based on a rhombic triacontahedron, whereby all elements are identical (except for the five elements that touch the ground). During the assembly phase of the first version of the ReciPlyDome, torsion in the components appeared to hinder efficient construction. To eliminate this, the dome was reviewed, which led to the development of a new connection system and an improved shape for the beams. A new full-scale version of the dome has been built, showing the positive effect of the improved connection system and the optimised beam position. In-situ measurements were made after construction, illustrating good correspondence between the digital and built model. Further research will focus on the covering of this modular reciprocal dome for outdoor use.

1. Introduction

As events only last for a couple of days or maybe a few months, their structures are usually designed for short-term use. Afterwards, they are thrown away and generate about 20.4 kg/m² waste per year [1]. For events in France, except for travel and accommodation, the carbon emissions related to space design and production are the largest, reaching up to about 55% of all emissions for the average events [2]. To resolve this, reuse is key. A study of Catalan covered trade fairs has proven that when 75% of stands are reusable, the waste generation is 3.5 times lower than when none of the structures are reusable. In these cases, gluing all parts of the structure together was the main factor making them non-reusable. Since the useful life of the stands are on average 4.3 days, changing the connection systems to make the overall structure reusable could already significantly prolong the life of these stands [1]. Thus, in these type of structures reuse can mainly be obtained through providing an easy assembly and disassembly phase. Additionally, designing the structures to be easily compacted allows for a smoother transportation.

Modularity can play an important role to provide this easy assembly and disassembly. Because of the standardization of the used elements, modularity often helps to simplify the process. This standardization often even makes place for flexibility to create several designs with the same 'module', as in the case of the ReciPlyDome.

The ReciPlyDome, a reciprocal plywood dome, is a structure designed and prototyped by VUB researchers Stijn Brancart, Lars De Laet and Niels De Temmerman and by Olga Popovic Larsen of the Royal Danish Academy of Fine Arts, School of Architecture, Design and Conservation. Its identical elements are composed of two beams, with different lengths, connected at the ends. This not only allows pre-tensioning of each module but also increases the cross-sectional thickness, both elements that lead to a higher overall stiffness [3]. Only at the bases , the elements have a shorter length to provide a stable connection to the ground. In total four type of beams were designed which allow to create six different structures. Although its modularity already increases the easy for assembly, the torsion that occurred during this phase makes it still challenging. Therefore, some optimizations are needed.

Figure 1. The assembled ReciPlyDome, version 1.

2. Rethinking the structure

To eliminate the torsion occurring during the assembly phase, a stress-free alternative was required. This is obtained through rotating the beams by 90 degrees.

However, when rotating these beams, the current connection method would result in eccentricities (Figure 3 (a)). Therefore, incisions were provided on the places of the eccentricities, which also helped fixing the beams (Figure 3 (b)). Another result of the rotation is that the beams needed to be cut out in a curved shape to obtain the same curvature in a stress-free manner (Figure 3 (b)). The curvature of these beams was optimized to obtain a material efficient cutting pattern. Additionally, the elements were reduced to a single layer beam.

This version of the dome was tested with a model, obtained through laser cutting the required beams (Figure 2). The incisions were made slightly bigger to allow for some movement during the assembly of the model. However, this resulted in the structure falling apart halfway through the assembly. Therefore some locking around the connection points was needed to secure the structure. Furthermore, using these incisions would also create weak spots in the elements, causing them to rupture over time.

A solution to these weak points could be to increase the beam height, however it was opted not to do so as this would not be material efficient. Therefore it was decided to eliminate the incisions and create a connection system. (Figure 3 (c)).

3. Connection system

3.1. Model scale

To connect the unstrained curved beams with each other, without creating cut-outs, a connection system was designed. With this system the beams were able to lean on each other in a reciprocal manner (Figure 5). It also allowed for sidewards movements to facilitate the assembly.

In total, three different type of connectors were designed, two for connecting the beams to each other and a third to connect them to the ground. Within the first-mentioned, a distinction was made based on the geometries that can be found in the dome. When looking closely, it can be seen that the dome consists of rhombuses and equilateral triangles and pentagons. The connection system was thus based on the corners of these equilateral triangles and pentagons, resulting in respectively a 'Type 60°' connector and a 'Type 108°' connector.

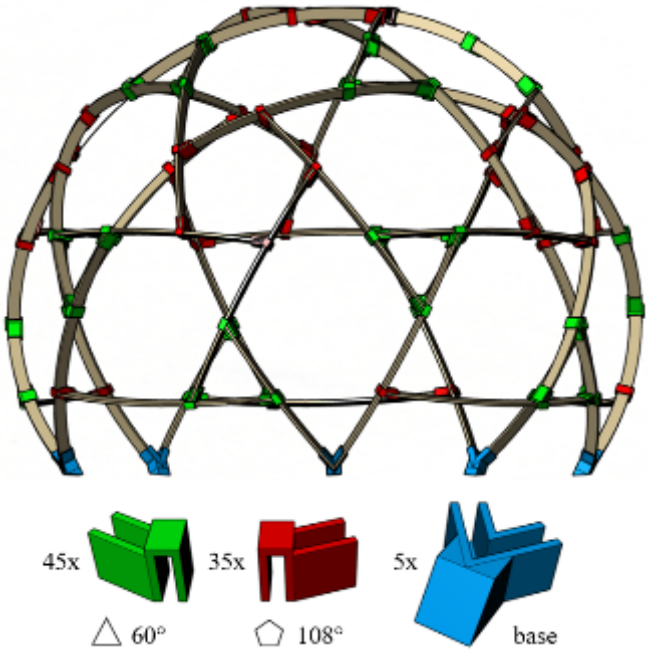

Figure 5. Connection system for the unstrained version of the ReciPlyDome with curved beams, consisting of three types: Type 60° for the triangles, Type 108° for the pentagons and Type base for a connection to the ground.

To test this connection system, 3D models were made and 3D printed. The design allowed for the Type 60° end Type 108° to be easily slid over the beams, while the adjacent beam can lean on the side of the connector (Figure 6).

To connect the dome to the ground, a base type was designed where two beams come together under an angle of 60°. By incorporating this angle in the connection piece, the base was able to touch the ground on a stable flat side (Figure 7).

Figure 6. The (a) Type 60° and (b) Type108° connection system, which can be respectively used to create (a) triangles and (b) pentagons.

Figure 7. The Type Base connection system, to provide a stable connection between the lower beams and the ground.

3.2. Prototype scale

To translate this connection system to the prototype scale, some alterations had to be made. First, to make the system more efficient in terms of material use and fabrication, the design was simplified. The first result of this was a connection system consisting of a pre-drilled 2 mm U-shaped steel plate welded onto a another pre-drilled 2 mm steel plate. However, since it still included a lot of operations, cutting out the right shape, drilling, folding and welding, it was simplified even more.

The next version consisted of two 2 mm L-shaped stainless steel plates of 60° and 120° for the Type 60° connector and 108° and 72° of the Type 108° connector (Figure 10). However, although equilateral triangles and pentagons are used in the dome, there corners turned out to be slightly different. Due to the three dimensional spherical shape of the structure, the connection angles

Figure 8. First version of the connection system Type 60° on prototype scale.

are turned inwards as can be seen in Figure 9. Therefore more correct angles would be 60.77° and 119.23° for the Type 60° connectors and 70.18° and 109.85° for the Type 108° connectors.

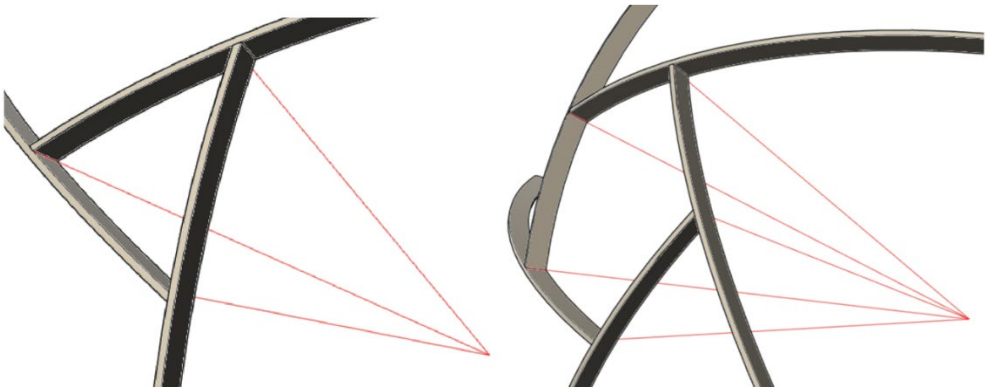

Figure 9. Inclined connection angles due to the sperical shape of the structure.

Another change was elongating the holes in the steel plates on the side that would be connected at one third of the beam length (Figure 10). This allows for some flexibility during assembly, but still sufficient stiffness once fully assembled. Lastly, some smaller holes were added onto the plates to allow a future cladding system.

(a) (b)

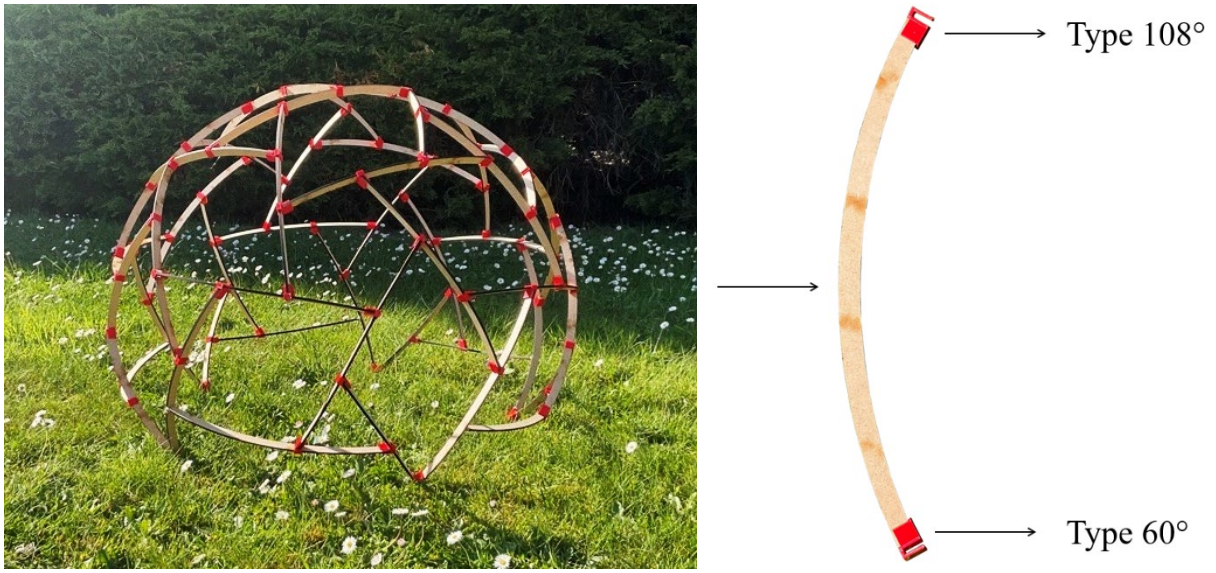
Figure 10. Second version of the connection system (a) Type 60° and (b) Type 108° on prototype scale.

4. Assembly

4.1. Assembly of the model

For a smooth assembly of the scale model, the laser-cut beams were prepared by attaching the 3D printed connection pieces to the end of each beam. As can be seen in Figure 11, each beam contains a Type 60° connector on one side and a Type 108° connector on the other side. Only for the five beams at the base the Type 108° connector was exchanged for a Base connector. By subsequently attaching the connectors at one third of the beam length, triangles can be created from the Type 60° connectors and pentagons from the Type 108° connectors (Figure 12).

Compared to the earlier model with incisions, this version allowed an easier assembly thanks to the connection system. Additionally, the structure was more secure, whereas the previous version started to fall apart halfway through the assembly. Therefore the connection system allowed for an overall stiffer structure.



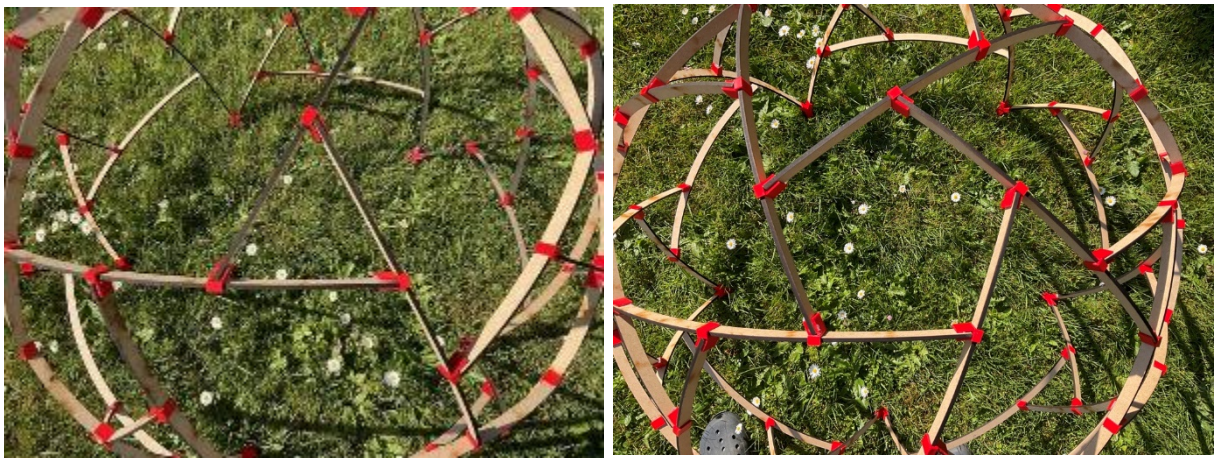


Figure 12. Assembly of the scale model of the rethought ReciPlyDome with modular beams and connection pieces of Type 60°, Type 108° and Base.

(a) (b)

Figure 11. (a) Triangles and (b) pentagons formed by respectively the Type 60° and Type 108° connectors.

4.2. Assembly of the first prototype

The first connectors made for the prototype were obtained through drilling holes through 2mm steel plates, folding the steel plates and finally welding the required edges together. Afterwards a coating was applied to achieve a homogeneous look and protect the connectors from corrosion. The final result were three Type 60° connectors.

Figure 13. First prototype for the Type 60° connection system.

The plywood beams for the prototype were manufactured with the aid of a jigsaw. However, due to the curved shape of the beams, a lot of plate material was wasted. Therefore options to repurpose the leftover materials should be explored.

For the assembly, the beams were prepared in a similar manner as the scale model. At the end of each beam a Type 60° connector was attached. Next, the beams were connected to each other by attaching the connector at one third of the beam. This connection system allowed for a torsion- and stress-free assembly of a triangular fragment of the dome.

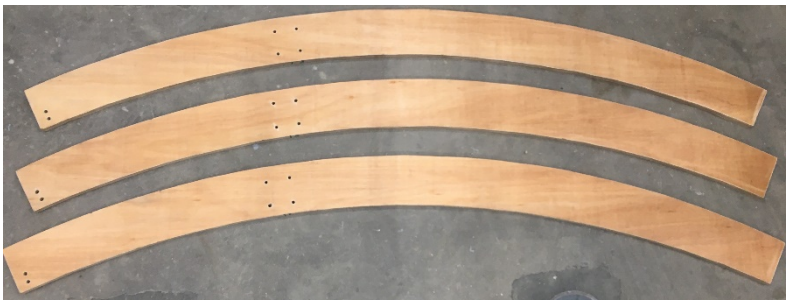

Figure 14. First prototype for the single-layer curved beams.

Figure 15. The prototype of the Type 60° connection system connected to the beams.

Figure 16. Assembly of a triangular fragment of the dome with the first prototypes of the Type 60° connection system and single-layer curved beams.

4.3. Assembly of the second prototype

To make the connection system more material efficient and easier to fabricate, a second version was developed. The beams were already prepared by connecting the adapted Type 60° and Type 108° connection system, now consisting of L-shaped plates, respectively to each side of the beam. Thereafter six pentagons were made by connecting each time five beams with each other through the Type 108° connectors. The central pentagon was then attached to a lift, whereafter the other pentagons could be attached to this central pentagon by raising and lowering the lift. Lastly the remaining beams were attached from top to bottom.

The two beams forming a base of the structure are connected with the L-shaped plate bended over 70.18°, which is part of the Type 108° connection system. To fix it to the ground a U-shaped anchor was used. During future research a better connection to the floor will be developed.

From this assembly it was concluded that the torsion present in the ReciPlyDome with the double-layered beams was eliminated. However the assembly process might still be optimized in the future by working out a smoother plan such as a beam per beam top to bottom assembly starting from the central pentagon, as during the tested assembly process the attachment of the pentagons to each other was still challenging due to their size.

Figure 17. Assembly of the full scale prototype of the second version of the ReciPlyDome.

Figure 18. The assembled ReciPlyDome, version 2

5. Conclusion

While working towards reusable temporary structures, the ReciPlyDome was reviewed to obtain a smoother assembly and disassembly process. To achieve this goal, the torsion present in the assembly process needed to be eliminated. This was mainly achieved by rotating the beams by 90° degrees and reducing them to a single-layered module. However, to obtain the same curvature the beams are cut out in a curved manner, which results in some material losses.

Next to the rotation of the beams, a new connection system was developed that also contributes in the elimination of torsion and a smooth assembly due to the margins provided by the slotted holes. A connection system to fix the dome to the ground still needs to be developed. In future research it will be reviewed if these excess pieces of wood created by the curved shape of the beams can be used in the design for the base connection pieces of the dome.

The hands-on approach during this research allowed for accurate insights in the performance of the developed concepts. Additionally, the prefabrication of the beams and the connection system contributed to an overall smoother assembly. However, for future use a more fluent assembly plan will be designed.

The next step in this research is to conduct both a physical as a digital structural analysis to asses the optimisations. Additionally, a cladding system will be designed to provide more comfort in outdoor usage of the structure.

Alex.edwards@arup.com

Abstract

The original Sydney Football Stadium (SFS), completed in 1988, was demolished to make way for a new stadium that opened in 2022. This paper outlines the early stages of the engineering design work for the roof structure. The roof of the stadium is a PTFE fabric covered form-found grid shell structure that is light and elegant. Arup developed a reference design for the project, supported the winning architect in the design competition and worked with that architect to develop the project though an early contractor involvement phase. Following a design and construct tender process, the contract was awarded to a different contractor and the design was then completed by the new contractor's (John Holland) team. Arup were engaged by the Client to continue our involvement and peer review the contractor's design finalisation.

1. **Introduction**

The original Sydney Football Stadium (SFS) [1], completed in 1988, was demolished to make way for a new stadium that opened in 2022. The roof of the new stadium is twice as efficient as its predecessor, and twice the size. Structurally, it is an evolution of AAMI Park in Melbourne and Adelaide Oval with a dash of Suncorp from Brisbane.

A great many recent stadium roofs have used some variant of opposing cable nets using one or two perimeter compression rings and one or two inner tension ring(s). All owe their pedigree to Schlaich Bergermann Partner's original at Stuttgart in 1993. While using high strength tensile steel cables is very efficient, could a well-proportioned single layer tension/compression structure be similarly efficient?

The height constraints for the new SFS hinted that a single layer shell configuration of some sort might be an attractive proposition. The new stadium had to remain low around the eaves, especially along the northern side adjacent to housing in Paddington, and there was an overall height limit for the entire development (similar to the original) which was too low to accommodate a Pantheon style "dome with a hole". So the design team decided to trade the upper seating in the corners for the ability to more directly support the roof from the stand itself (as Suncorp) [2].

Borrowing Antoni Gaudi's hanging chain approach, albeit in a digital form, we inverted the roof and form-found the funicular grid shell shape hanging from the perimeter and the corners of the lower stand. The diagrid roof uses deeper members in the arching radial direction to facilitate erection on a bay-by-bay basis.

The Arup team developed the roof, through design development, including the fabric, steelwork connections and indicative construction sequencing, which was then finalised, documented and constructed by the John Holland design and construct team.

The finest contemporary stadiums integrate into the fabric of the communities they serve, taking on the dual roles of both entertainment destination and iconic city landmarks. This innovative, sophisticated, multi-purpose building is aesthetically pleasing, environmentally sensitive, and maintains a high degree of future flexibility.

2. Site history

The original Sydney football stadium was opened in 1988 and served as the major stadium for rectangular pitch events in NSW. The design was innovative, however the stadium only offered weather protection to 25,000 of the possible 40,000 spectators and was lacking in modern spectator amenities. Arup were involved in numerous investigations in the 2000's to extend the existing roof, increase seating capacity, add a full retractable roof, or to create a larger stadium on an adjacent site [3].

In 2017 the NSW government committed to demolishing the existing stadium and replacing it with a contemporary facility on roughly the same site that addressed the shortcomings of the existing stadium and provide a new world class stadium for sporting fans to enjoy.

3. Reference design

In early 2018 Arup were engaged to provide technical input into the brief for a new stadium to be built on the site of the existing stadium. It was intended that the new stadium be at least 45,000 seats over 3 tiers and provide a modern, iconic world class rectangular pitch facility that could be utilized both for sporting and entertainment events. The stadium was to be integrated with the Moore Park precinct, and in particular, with the Sydney Cricket Ground (SCG) to the south, allowing ease of concurrent events and sharing of facilities to optimize operation, performance, spectator enjoyment, and player satisfaction.

The technical brief required the stadium to be best in class internationally and required as a minimum full compliance with international design criteria as set by FIFA and World Rugby. It was intended that

the roof covers a minimum of 100% of the seating, on the basis of a vertical drip line, and provide adequate rigging provision for all modern sporting activities and entertainment events as could be reasonably expected to be held at the venue.

As part of that work Arup developed a range of structural options for the roof form including tension rings, truss arrangements, cantilevers and shell options.

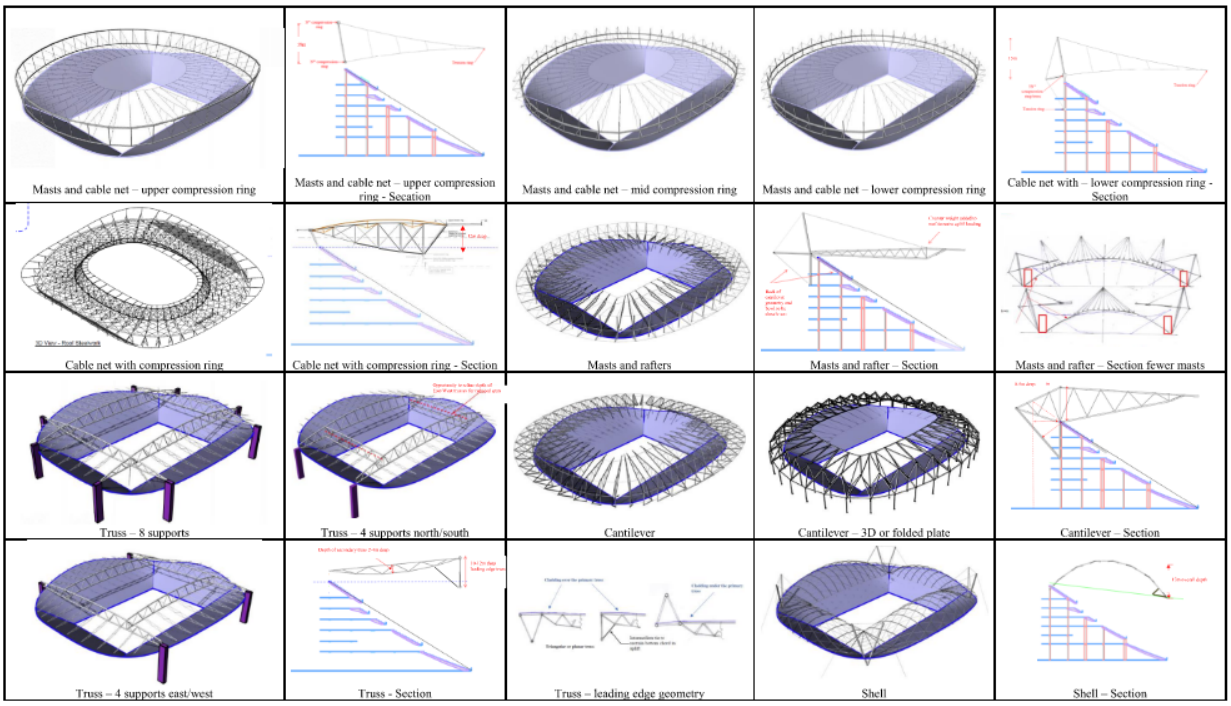

Figure 2. A subset of the stadium geometry forms developed for the reference design. The shell option ultimately used is a development of the lower right.

4. Design competition

In late 2018 an architectural design competition was held for the roof, façade and public realm. Arup supported COX architecture through the design competition. The design was geometrically constrained by:

- a height plane that limited the overall height of the roof to similar to the existing stadium;
- a requirement that every seat have visibility of the scoreboard; &
- that all the seats have roof coverage, vertically.

The design also needed to be low in scale at the north so as not to dominate the adjacent residential areas. The design developed utilized the corners of the seating bowl for the primary support of the roof while maximizing the clear span to provide uninterrupted views for the spectators from every seat.

The resulting roof form was a grid shell supported by a tension ring that is propped off the rear of the seating bowl. The inner edge of the shell is supported by 4 arches, roughly following the geometry of the pitch. The shell and the arch have been digitally form-found. This has the following consequences:

- The arches are not planar but are 3-dimensional space curves that respond to the applied loads from the shell onto to the arch. This means that though the steelwork looks like a truss the axial force is concentrated into only one of the chord members;

- The arches can be adjusted in height by adjusting the tension used in the form finding, such that the resultant lateral thrusts from the two (2) arches into the derrick (refer Figure 3) structure remain aligned with the derrick plan geometry;
- The lateral thrusts of the arches combined with the vertical loads of the roof mean that the line of action extends through the concrete abutment structure continuously to foundation level, eliminating vertical eccentricity in the abutment and alleviating the need for tension piles.

The design competition proposed two material choices for the roof, the first being a timber hybrid roof where the diagonal "radial" members of the shell were 600 deep glulam timber elements and the shell circumferential hoops being steel. An all-steel option was also presented.

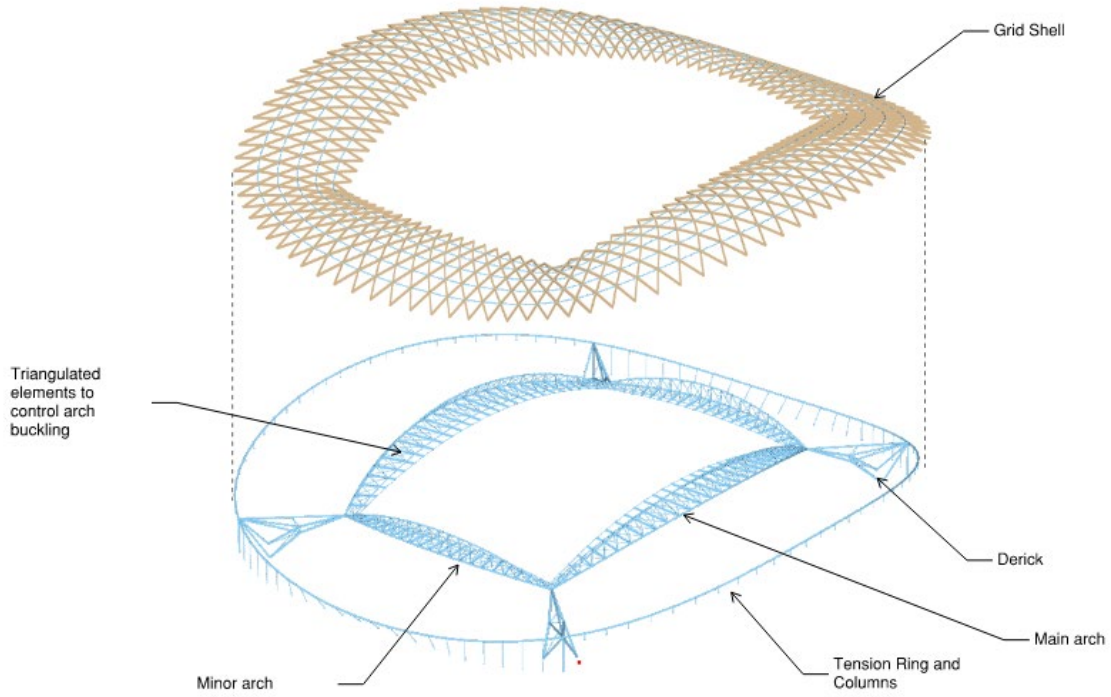

Figure 3. Key components of the roof structure.

5. Design development

Following the design competition a period of design development was undertaken with the involvement of a contractor to develop pricing and design options on an Early Contractor Involvement (ECI) basis. Arup were engaged to develop the design of the roof through this period as subconsultant to the architects. Early on in this process it became apparent that while the design principles were set, there was still considerable need to explore bowl geometries, sightlines and roof curvatures while remaining within the limiting height plane.

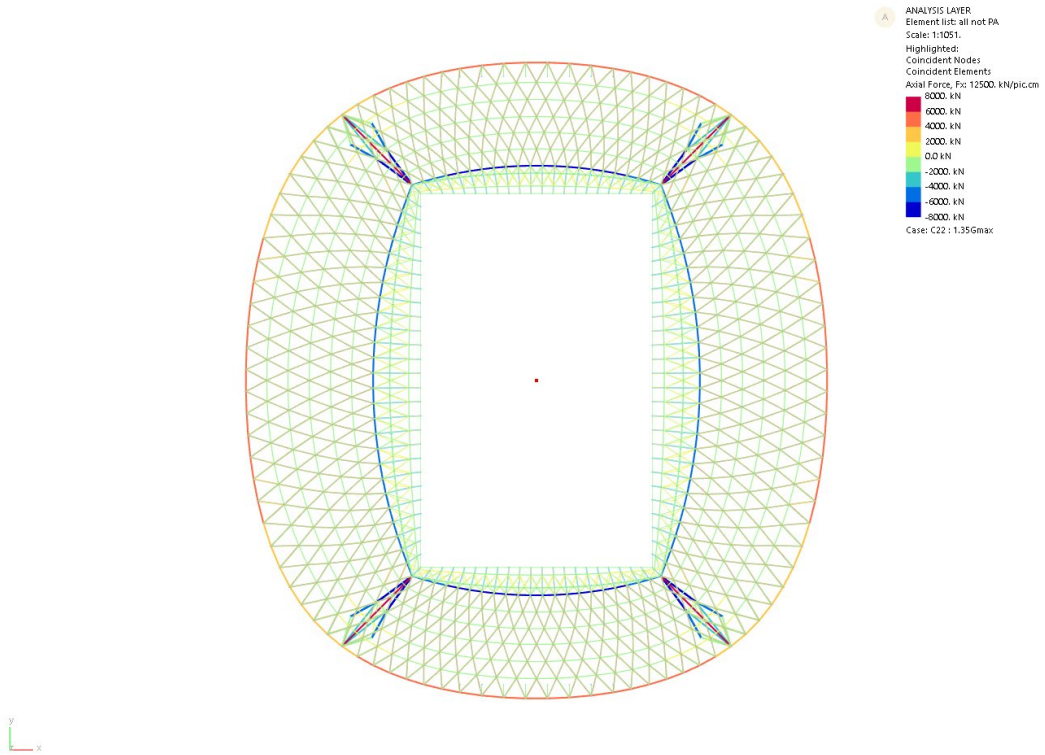

Figure 4. Axial Force in the roof members under gravity loads. Note the compression in the single arching member showing that this portion of the roof is acting as an arch rather than as a truss.

A fully automated digital workflow was developed in conjunction with the architects to allow for the rapid investigation of geometries. The workflow used Grasshopper and Rhino for the geometry, Oasys GSA for the structural analysis, and utilized GHData files for the transfer of information between the architects and engineers. The general process was:

- The architects provided the geometry of the rear line of the bowl, the front rows of seats, bowl structural grid, the arch/derick intersection height - a key driver of the sightlines, and the maximum allowed height plane for the roof;
- Arup developed an initial roof geometry form those generating constraints that represented an approximate starting point for the form finding;
- GeometryGym was used to export the initial structural geometry to GSA where a form-finding analysis was run to determine the shape of the shell and arches. The Grasshopper script could take parameters for how much curvature was allowed in the shell part of the roof and how much in the arches. Greater curvatures generally mean better structural performance but at the expense of an overall height of the roof, thus one of the key decisions was how the curvature should be distributed rather than the absolute amount. The relative curvatures of the major and minor arches was tuned so that the reaction into the corner supports was aligned at a 45-degree angle (this angle was set by planning and sightlines, recognising that this is not the most efficient resultant thrust angle for the rectangular roof footprint);
- This form-found geometry was taken back into grasshopper and the full model of the roof developed - including the front eyebrow steelwork and the bracing members to provide stability for the arch;
- This full model geometry was exported again to GSA via geometry gym and an iterative member sizing routine used to determine optimum member sizes; &

- A GHdata file was sent back to the architects that included key splines and locations for them to automatically position sports lighting, scoreboards and access walkways.

This process allowed for the rapid investigation of alternative bowl geometries and roof sizes through this stage of the project.

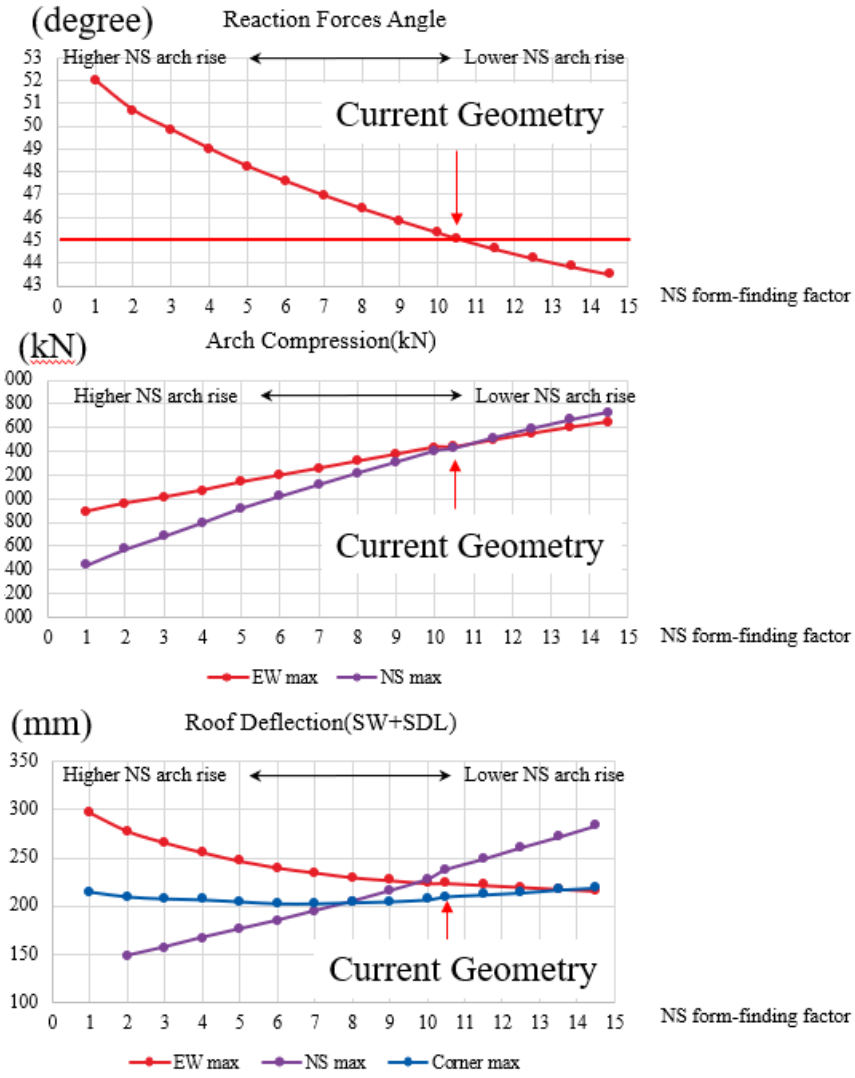

Figure 5. Graphs showing the geometry investigations. These graphs show how balancing the height of the north, south-and east west arches of the roof affect the angle of the reaction force into the derrick, the arch compression, and the roof deflections.

The two options for member material were progressed in parallel during this stage of the project. One of the key risks identified by the ECI contractor was the timber connections. Arup addressed this in two ways, initially by providing three options for each type of connection based on the 75th, 95th and 100th percentile design forces. Quite often designers, especially when time is limited, will only document the worst case and this causes concern to contractors and clients. By having automated model results we were able to produce three designs relatively quickly demonstrating that whilst there were some members with high forces, the vast majority of the of the connections were relatively easy to construct.

The other method was to concentrate the complexity into only part of the system, while making the rest of the system less complex. Glulam is most cost effective when the members are straight. The shell geometry requires a curved member to follow the overall shape as well as a twist to follow the local surface normal. The solution developed was to utilize straight timber elements orientated to normal to the shell at the member mid-point, with a steel node where the twist and the facet could be taken by profile cutting a single plate. To connect the timber to the steel onsite, a connection type similar to that used for furniture was proposed. Steel bars were threaded into a solid steel cross rods in holes in the timber. This portion is similar to that used with great success by the designers of the Nelson Airport terminal [5], and Arup previously at the Royal Agricultural Society at Homebush.

The ECI contractor had a strong preference to remove risk form the project and considered the timber likely to have substantial program and cost uncertainty. With the project timeframe being tight and the budget stretched, the decision was made to focus attention on the full steel option and not progress the timber design any further. The steel option was further developed as described in the sections below.

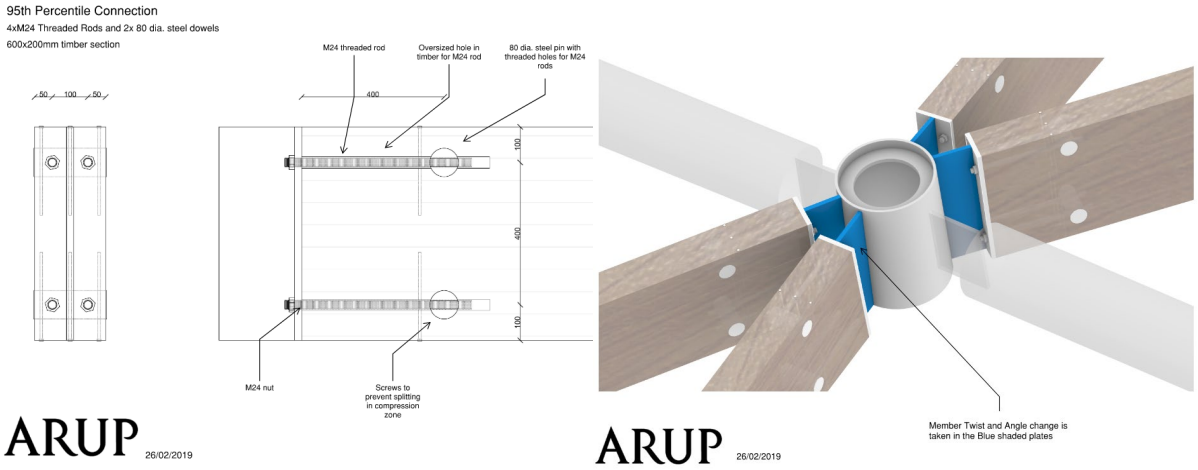

Figure 6. Timber connection design option. The highlighted blue plate was cut in a trapezoidal shape with 1 curved edge to accommodate required twist and facet angle particular to this location. The circular node is made from a section of 457 dia CHS with 2 internal stiffeners.

6. Wind tunnel analysis

A 1:300 scale model of the Stadium was tested in the CPP boundary layer wind tunnel in Sydney. The top and bottom surfaces of the stadium roof were instrumented with a total of 310 pressure taps and the time-history pressures recorded for 36 cardinal directions. The 310 pressure tap results were mapped to 64 load patches for application onto the structural analysis model.

The full time-history data from the wind tunnel was processed to determine the critical load cases for consideration in the structural design. A unit load was applied in the structural analysis model to each of 64 load patches in turn. The design action at a point of interest was extracted for each of the patch loads and multiplied component wise by the pressure from the wind tunnel time-history and summed - thus a time history of the design action of interest could be created. The time-histories for each direction were broken into wind-storm events of approximately 10 minutes at full scale and the worst design action for each wind-storm event calculated. The median of the worst 5 design wind-storms was extracted as a load pattern and used in the structural analysis. This process was automated using scripts for convenience as the total number of time steps exceeded two million.

The choice of which design action to maximize or minimize was made using an understanding of the behavior of the structure. Finding the extremes of axial force in the arching members was an obvious

area of interest, however shell and arch structures are susceptible to out-of-balance loads and lateral deflection was used as a proxy to find the cases that caused the worst pattern load in the structure. These load distributions used for the structural analysis for member sizing. A selection of images showing the various design actions and the resulting wind load patterns are shown below in Figure 7.

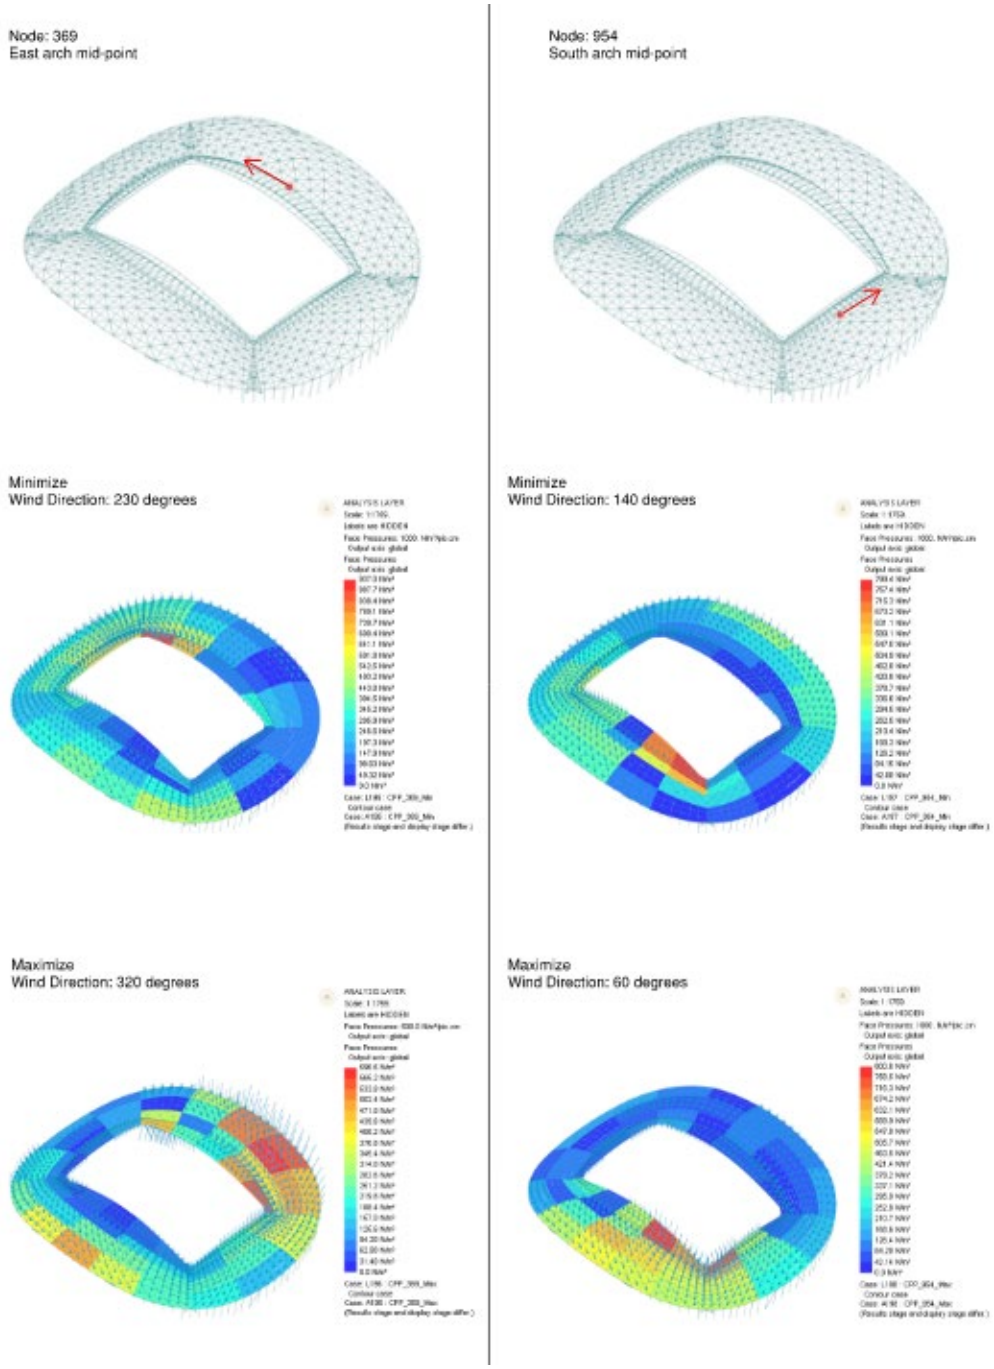

Figure 7. Extracted patterns of wind load from the wind tunnel time-history. These cases represent cases that generate the maximum lateral displacement on the major and minor arches and were used to determine the most adverse out-of-balance load for the strength design of the arches. Colours show pressure magnitude and arrows show the direction.

Figure 8. Stadium model in the wind tunnel showing modelling of surrounding buildings.

7. Construction sequence analysis

Construction of the roof was given careful consideration both in conceiving the roof concept and developing the design. This allowed us to demonstrate a functional construction sequence, and to quantify the effects of construction sequence on the material quantities. The original competition entry envisioned the arches being constructed on towers at six (6) locations with sections of the shell being lifted into place between the tension ring and the arches. This construction methodology meant that the only temporary support that the roof needed during construction was very close to the pitch, having minimal impact on the construction and fit-out of the stadium bowl below.

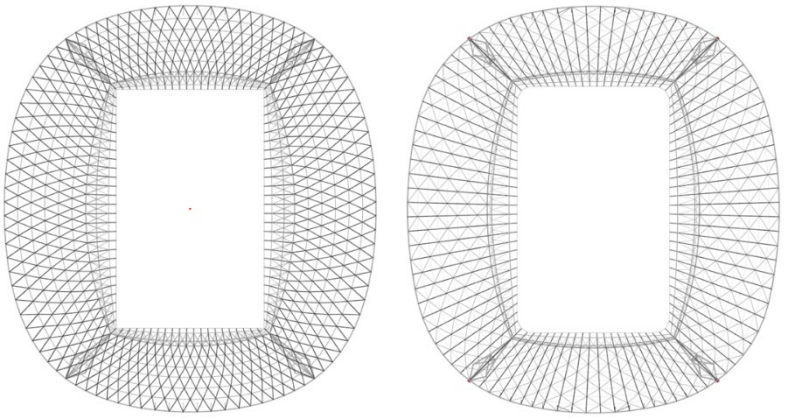

Figure 9. The competition geometry left, compared with the developed geometry right. The change allows pairs of shell members to be lifted into place as a unit and then infill lacing between units installed.

The spiral nature of the shell geometry meant that ideal size of element to be lifted was relatively large, with approximately six lifts on each of the long sides of the stadium. By rotating the grid of the shell by 30 degrees compared to the competition scheme and using a temporary tension tie, sections of the shell roof consisting of only two ribs and one bay of lacing were stable and could be lifted into place.

Construction of the roof could proceed in two directions to speed installation with the weight of the roof supported by the towers. The base case envisioned that the roof would remain on the towers until the structure was complete, though options were investigated to allow early de-propping of the roof, this case needing some temporary ties in the arches and more careful management of tolerance and deflections. Ultimately the construction sequence developed by the contractor and their team followed that developed during this stage.

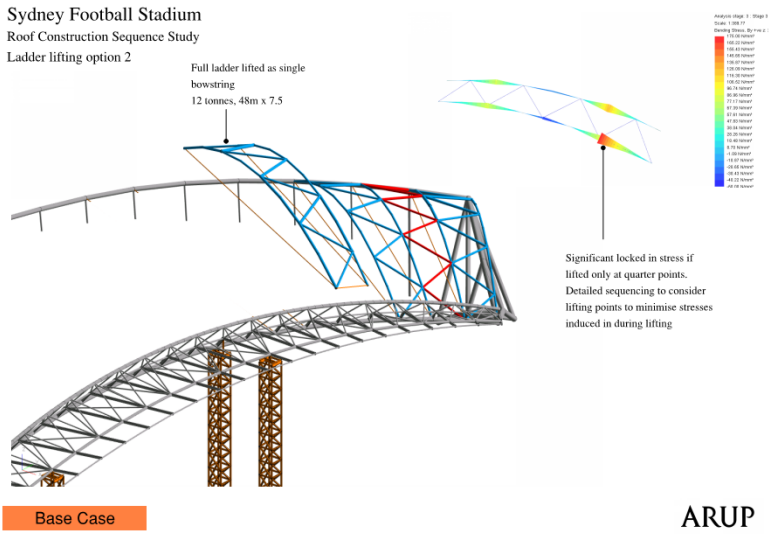

Figure 10. Extracts from the construction sequence sketch pack showing lifting and erection of the shell elements.

Figure 11. Construction stage image showing support of towers at discrete locations and the installation of temporary ties to the shell members.

8. Designing for robustness

The client brief had a specific robustness requirement - the removal of any one element was not to lead to disproportionate collapse of the roof. This procedure is documented in BV2 of the Australian National Construction Code.

Initial investigations of the analysis model indicated that it was difficult to determine which elements to remove and investigate further and so the process was automated and all elements were considered. One structural element was removed at a time and the impact on maximum member stresses in the remaining members and resulting change in loading at support points considered. In all approximately 5000 analysis models were generated. To minimize the run-time several techniques were used including running the models on several computers in parallel, as individual analyses were independent, and initially using elastic material properties for faster analysis time to find cases where the structure remained elastic following element removal. Once removal of a particular element was identified as needing further investigation the analysis was re-run with material non-linearity to allow redistribution of the load into surrounding areas.

The analysis indicated that there were a few elements where increasing the size was needed to meet the elements removal requirement, but overall, this increase in tonnage was only about 48t or 4% or the total roof weight.

9. Fabric design

Preliminary analysis of the fabric membrane was undertaken to confirm the structural performance of the membrane, as well as to inform the structural design of the roof. One of the key issues was the spacing of the supporting rafters in the primary structure. A larger primary rib spacing leads to fewer steel connections and so increasing the spacing as much as possible lead to a more economic outcome. The automated workflow used for the primary structure design was extended to form-find and analyse the fabric so that multiple options could be considered. Clashing of the fabric with the primary structure of the roof under wind loading cases was also considered.

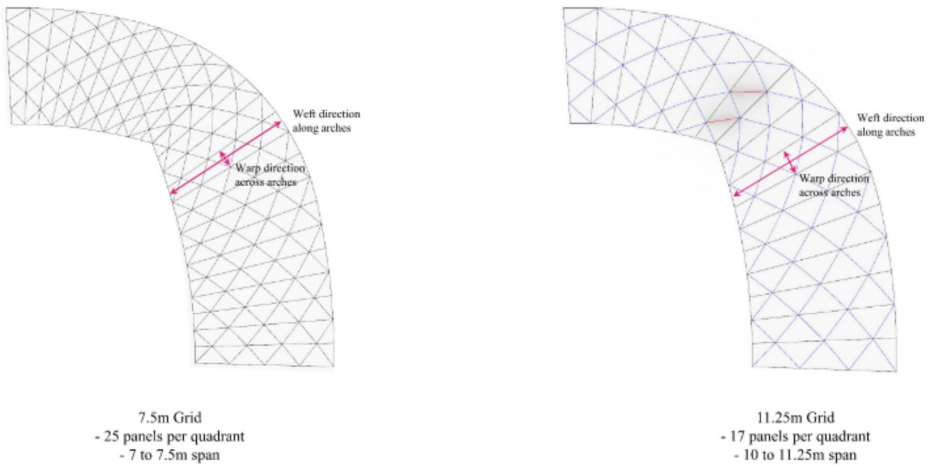

Figure 12. Images of the fabric analysis models showing 2 grid options under consideration.

Also of interest was ponding of water on the fabric membrane. Areas of possible ponding were identified by looking at the vertical height contours of the fabric surface and identifying areas where they formed closed loops. The geometry was checked for both the at-rest condition and extremes of primary structure and fabric deflection to ensure adequate drainage under all conditions.

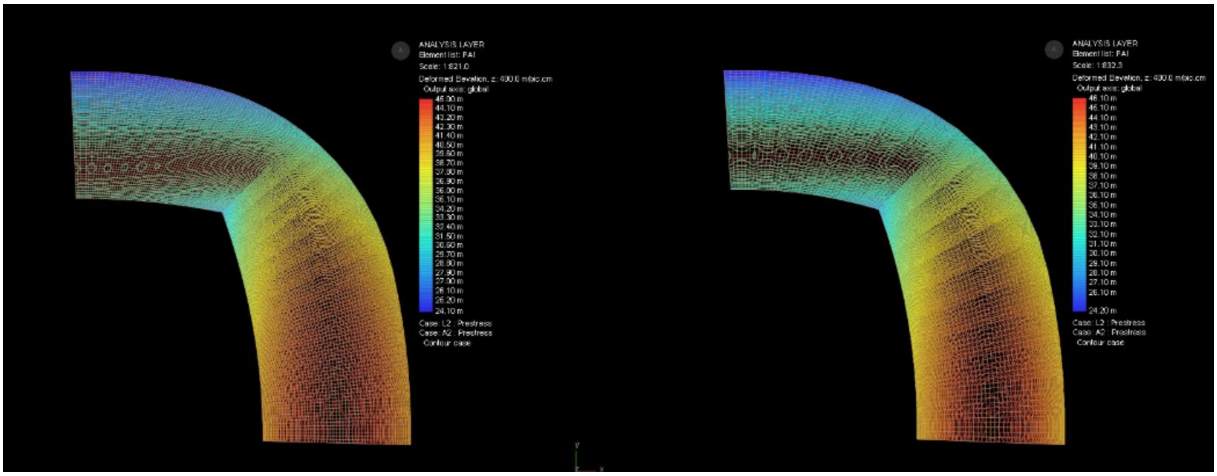

Figure 13. Vertical height contours of the form-found fabric membrane used to detect possible areas of ponding.

10. Post tender

In late 2019 the NSW government awarded the design and construction contract to John Holland group to complete the design and construction of the stadium. Arup were retained by the client to peer review the design as it progressed while the contractor engaged a team of Engineers including Aurecon and Schlaich Bergermann und Partner to continue working with COX and carry out the detailed design and documentation of the roof. That almost all the design principles mentioned in this paper have survived the design and construction process is a testament to the whole team's skill and dedication. The end result is a structurally generated stadium roof that is elegant, efficient and wonderful.

Abstract

FreeGrid is meant to offer a common benchmark to test and compare different approaches to the design and optimization of steel gridshells, from man-based heuristic design to AI-based one. FreeGrid sets three design baseline problems: a barrel vault, a paraboloidal dome, and a hyperbolic paraboloid, having their spring line partially not constrained (free-edge) and subjected to symmetric and asymmetric load conditions. Participants are called to modify the baseline gridshell(s) in order to improve their structural performances, buildability, and sustainability, all three of them weighted in a single, bulk quantitative performance metric. Participants shall comply with a limited number of design constraints, while any other design solution is allowed. Baseline setups, performance metrics and design constraints will be fully detailed in technical specifications made publicly available. The full data of the baseline structures will be offered to participants according to an Open Data policy, together with postprocessing utilities intended to align the procedure to obtain the performance metrics. The FreeGrid benchmark will be launched within the IASS Symposium 2023 in Melbourne.

Keywords: freeGrid, benchmark, steel gridshell, free-edge, conceptual design, optimisation

1. Introduction

FreeGrid is a benchmark on design and optimization of gridshells (Fig. 1) conceived by the Authors of the present paper as members of its Steering Committee, advised by an international Scientific Committee. FreeGrid moves from seven general problem statements, and towards the related goals, as briefly listed in the following.

i. The activity in Structural Engineering in general, and about gridshell as well, is increasingly polarized between mechanical modelling and analysis versus design practice and applications [1]. FreeGrid is intended to bridge these two approaches. It proposes a genuine design problem, and targets the rigorous quantitative comparison of the solutions and their performances.

ii. The design and optimization of gridshells as form-resistant discrete structures is intrinsically a multidisciplinary activity jointly carried out by experts in mathematics, computer graphics, mechanics,

structural engineering, architecture, designers and builders. FreeGrid aims at gathering competences and input from all the above fields around a common design problem.

iii. Artificial Intelligence (AI) is among the most recent generalized trends in contemporary science, and in structural engineering as well [2]. FreeGrid is meant to offer a common benchmark to comparatively test the readiness of different approaches to the conceptual design of form-resistant structures, from the classical man-based heuristic design, to the optimization approach in its different forms (e.g. gradient-based, topological, genetic-algorithm-based), to the AI-assisted design methods (e.g. artificial neural networks, machine learning).

iv. Horizontal spring line and/or perfect infinitely rigid constraints only seldom occur in built gridshells. Usually and more and more frequently, gridshells include edges free of constraints eventually bounded by stiffening members [3]. Conversely, the structural performances of free-edge gridshells and their design proposals are scarcely treated in scientific systematic studies. FreeGrid aims at filling the gap between the design practice and the scientific literature in this field by adopting free-edge gridshells as case studies.

v. Design is a holistic activity accounting for multiple goals [4]. FreeGrid calls for the holistic improvement of structural, buildability, and sustainability performances. Multiple, even if not necessarily exhaustive, design goals and related performance metrics are defined.

vi. Benchmarking best practices require that *studies and related results are reproducible* [5]. FreeGrid sets mandatory requirements to participants intended to secure the full description of (a) the geometrical and mechanical features of the design solutions, (b) the methods adopted for design/optimization/assessment, (c) the obtained results. FreeGrid adopts an Open Data policy applied to preprocessing and postprocessing files offered by the organizers and/or required to participants.

vii. The *fair comparative evaluation* of contributions in benchmarks on structural design and optimization is recognised as a challenging issue [5]. FreeGrid precisely and analytically adopts objective, purely quantitative performance metrics that do not need a posteriori assessment.

Figure 1. Logo of the FreeGrid benchmark

The present paper articulately describes in what follows the way in which FreeGrid plans to achieve the above goals. For a better understanding, the terminology used in the present paper and in the benchmark is summarized in Table 1.

Table 1. Main terminology adopted in the paper

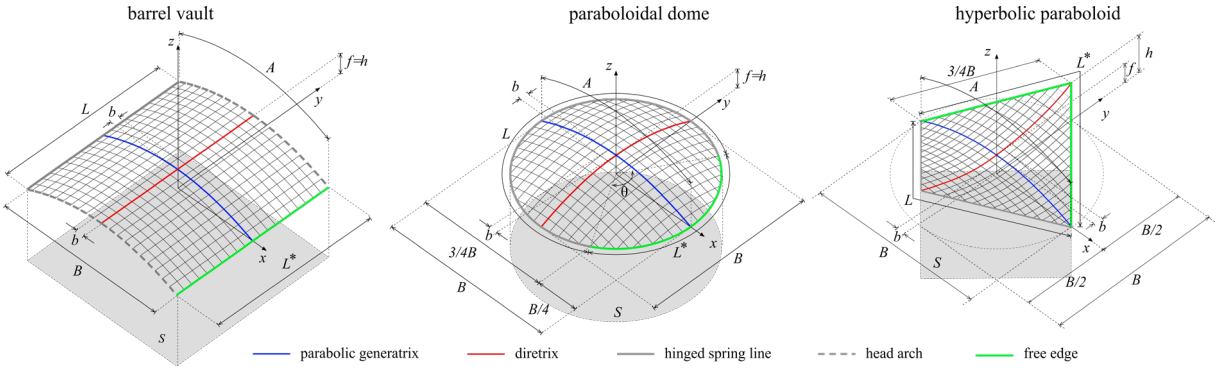
entity	**geometry**	**Structure / construction**	**mathematical model**	**Subscript, total number**
0D	vertex	joint	node	*j, N*
1D	edge / line / arc	member	element	*i, M*
2D single entity	face	panel	---	*f, F*
2D overall entity	mesh	grid	discretization	

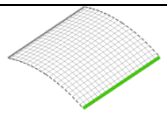
2. Baseline gridshells

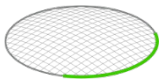
FreeGrid considers three types of gridshells (Fig. 2): a barrel vault, a paraboloidal dome, and a hyperbolic paraboloid, with simple, double gaussian positive, and double gaussian negative curvature, respectively. By 'Background Gridshells' we refer to gridshells fully hinged along their boundaries, while by 'Design Baseline Gridshells' (DBGs) we refer to gridshells having their spring line partially not constrained along what is called a 'free-edge' [3]. Although imperfections play a role in gridshell design and optimization [6], for the sake of clarity DBGs are free from any kind of imperfections induced by constraints, load conditions, mechanical properties, or geometrical features.

2.1. Geometrical setups

The main geometrical features of the DBGs are shown in Figure 2.







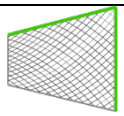


Figure 2. FreeGrid DBGs: barrel vault, paraboloidal dome, hyperbolic paraboloid

All the DBGs share the same parabolic generatrix, whose equation is included in Table 2.

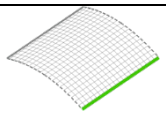
Table 2. Geometrical features of the DBGs

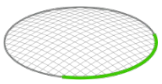
			
Generatrix equation	$z = -\frac{x^2}{2B} + f, \quad D = \left\{-\frac{B}{2} \le x \le \frac{B}{2}\right\}$ $A = \frac{B}{4}\sqrt{5} + B \cdot ln\left(\frac{1+\sqrt{5}}{2}\right)$		
Directrix equation	$z = f,$ $D = \left\{-\frac{B}{2} \le y \le \frac{B}{2}, x = 0\right\}$	$z = -\frac{y^2}{2B} + f,$ $D = \left\{-\frac{B}{2} \le y \le \frac{B}{2}, x = 0\right\}$	$z = \frac{y^2}{2B} + f,$ $D = \left\{-\frac{B}{2} \le y \le \frac{B}{2}, x = 0\right\}$
f	$B/8$		
h	$B/8$	$B/8$	$B/4$
L	A	$\frac{2}{3}\pi B$	$3/2B$
L^*	L	$L/2$	L
S	BL	$\pi B^2/4$	$\pi B^2/2$
b	$A/20$		

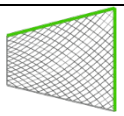
The generatrix span B =30 m is adopted as reference length, and $f = B/8$ is its rise. The horizontal plane $z = 0$ is referenced in the following as 'horizontal reference plane'. The generatrix arc length A accommodates 20 edges with constant length b. The directrix is split with the same step b. Therefore, all DBGs are discrete translational surfaces, whose resulting mesh is homogeneous, and made by planar square faces, except for boundary ones that are obtained by intersection with the horizontal reference plane. The other main geometrical features of the DBGs are: $\boldsymbol{h}$ is the maximum height above the horizontal reference plane; the lengths $\boldsymbol{L}$ and $\boldsymbol{L}^*$ of the spring line and free-edge respectively refer to their continuous counterpart; the surface extent $\boldsymbol{S}$ corresponds to the area encircled by the projection of the continuous spring line, free-edge and head arches, if any, on the horizontal reference plane.

2.2. Structural setups

2.2.1. Structural members







All the structural members of the DBGs are made of steel with a bilinear elastic-perfect plastic constitutive law. Table 3 summarizes the adopted material properties.

Table 3. Material properties of the structural members in the DBGs

Steel grade	density	Young's modulus	Poisson's ratio	yield strength
S355	ρ = 7850 kg/m^3	E = 2.1e+5 MPa	v = 0.3	f_y = 355 MPa

Structural members have circular hollow cross-section and are not subjected to initial prestressing in all the DBGs. The structural members of a single DBG have the same cross section. The cross-section dimensions differ among the DBGs (Table 4), in order to ensure their homogeneous mechanical performances.

Table 4. Cross-section dimensions of the structural members in the DBGs

			
Section type (type, diameter, thickness [mm])	O/139.7/14.2	O/101.6/10	O/101.6/10
Area [mm^2]	5596	2876	2876
Inertia [mm^4]	11157936	3052611	3052611

2.2.2. Structural constraints

External constraints at the structural joints along the spring lines L are perfect hinges, except for the head arches of the barrel vault, along which only z- and x-wise joint displacements are constrained in order to avoid non-linear stiffening induced by the y-wise members. All the internal structural joints are rigid. The structural joints along the free-edge length L^* are not constrained.

2.2.3. Load Conditions

The design solutions shall be evaluated with reference to two Load Conditions (LC$_k$, k =1:2). Both LCs are simplified and exploratory, intended to assess structural performances under ideal and controlled working conditions. Nevertheless, their moduli have the same order of magnitude of standardized design loads on gridshells. They are sketched in Figure 3 in terms of piecewise uniform loads for the sake of clarity.

The first Load Condition (LC_1) cumulates the distributed self-weight of the structural members and the point loads $Q_{1,j} = (q_1 + q_2)s_j$ applied to all the structural joints, where s_j is the projection on the horizontal plane of the tributary area of the j-th structural joint, q_1 is the uniform distributed load that mimics the permanent weight-like load of a glass cladding, and q_2 is the uniform distributed load that mimics the live snow-like load.

The second Load Condition (LC_2) mimics not only the effects of non-uniform vertical loads, but also the ones of wind-induced loads or other horizontal loads. LC_2 cumulates the distributed self-weight of the structural members, the point loads $Q_{2,1,j} = q_1 s_j$, where q_1 is the uniform distributed load as described above, and the point loads $Q_{2,2,j} = q_2 s_j$, where q_2 is the piecewise uniform distributed load as described above, and it is applied on the surface with $x \geq 0$ (barrel vault and parabolic dome) and $y \geq 0$ (hyperbolic paraboloid).

Structural performances at Ultimate Limit States (ULS) are evaluated by setting $q_1 = 600\ \mathrm{N/m^2}$ and $q_2 = 1200\ \mathrm{N/m^2}$, while the ones at Serviceability Limit States (SLS) are assessed under $q_1 = 400\ \mathrm{N/m^2}$ and $q_2 = 800\ \mathrm{N/m^2}$.

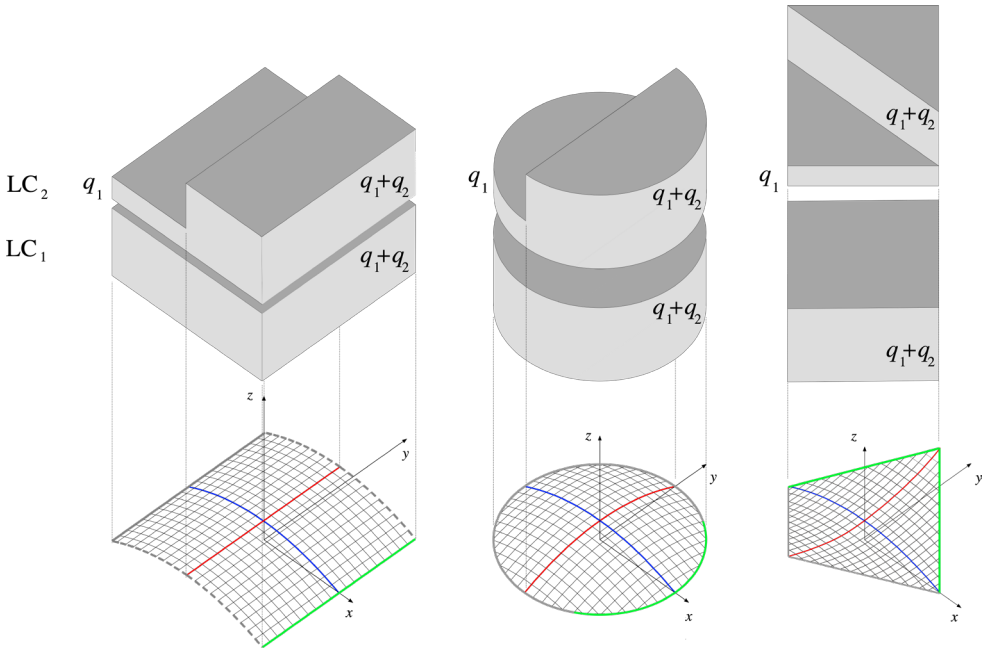


Figure 3. FreeGrid Load Conditions

3. Design goals and performance metrics

Participants to the benchmark are called to modify the above DBG(s), and conceive the Design Solution Gridshell(s) (DSG) in order to achieve seven selected Design Goals (DGs) in a genuine holistic perspective.

The whole performance assessment of each DSG develops in three conceptual steps (Fig. 4). First, each DG is expressed through a quantitative metric to be increased (↑) or decreased (↓), and made dimensionless with respect to the corresponding metric of the DBG (subscript 0). Second, DGs are grouped into three performance categories, covering the structural response (subscript *s*), the buildability (subscript *b*) and the sustainability (subscript *su*) of the DSG(s). Correspondingly, the single DG metrics are clustered into partial performance metrics P_k ($k = s, b, su$). Finally, a bulk performance metric P is obtained as linear combination of the above partial ones.

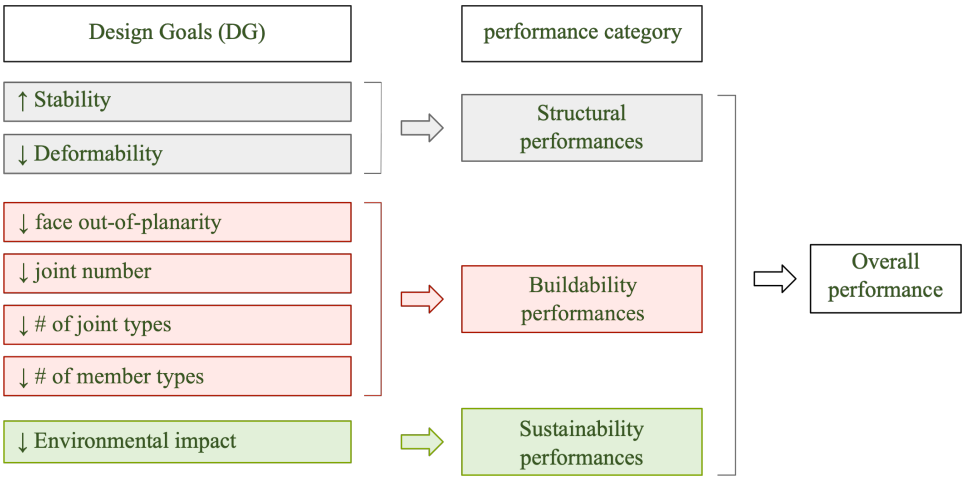

Figure 4. Performance assessment framework

3.1. Structural goals and metrics

Gridshells are form-resistant structures, and the design and optimization of their shape traditionally mainly focus on their mechanical performances, e.g. [7][8][9]. As a result, they are as efficient as exposed to instability and deformability issues [10] at ULS and SLS, respectively.

Stability (ULS). The adopted DG quantitative metric to be increased is the critical Load Factor $\widehat{LF}$, with reference to both LC_1 and LC_2 defined in subsect. 2.2.3. $\widehat{LF}$ accounts for global, local and member instability, and/or member plasticization [11][12][13]. The adopted lower limit value is $\widehat{LF}_l = 1$.

Deformability (SLS). The adopted DG quantitative metric to be decreased is the modulus of the maximum joint vertical displacement $|\hat{\delta}_z|$ over the whole gridshell, under LC_1 and LC_2 load conditions. The adopted upper limit value is $\hat{\delta}_{z,l} = B/200$.

The structural performance metric is averaged over the Load Conditions LC_k (k =1:2) and is defined as

$$P_s = \frac{\sum_{k=1}^{2} \frac{\widehat{LF}_k}{\widehat{LF}_{k,0}} \Big/ \frac{|\hat{\delta}_{z,k}|}{|\hat{\delta}_{z,k,0}|}}{2}. \quad (1)$$

Under the setup conditions specified in Sect. 2, the background gridshells fulfil the selected structural requirements at both ULS and SLS, while the DBGs do not.

3.2. Buildability goals and metrics

To the authors' best knowledge, buildability performances (also known as 'fabrication-aware design') are not thoroughly and unanimously defined in literature, in spite of their paramount design role and recent excellent proposals [14][15][16]. As such, the selected DGs, the related metrics and the resulting partial metric are intended to be an intentionally not all-encompassing, although rigorous, buildability performance model. In particular, the selected buildability DGs only refer to the geometry of 2D gridshell panels coincident with the face, 1D line-like structural members coincident with edges, and 0D joints at vertices. Hence, in a truly conceptual design perspective, the adopted DGs do not include issues related to the panel-face offset and to the joint 3D manufacturing (e.g. kinks at joints, edge offset [15]).

Face out-of-planarity. Face planarity is the most widespread and traditionally considered construction constraint for double curvature gridshells (e.g. [17][18]). Indeed, planar faces accommodate cheaper flat panels that are significantly less expensive than moulded or cold bent doubly curved panels. The adopted

DG quantitative metric $\overline{\Delta}$ to be decreased is the average, computed over the whole gridshell, of the modulus of the mean distances of the face vertices from the best fitting plane divided by the face semiperimeter [19][20].

Joint number. The number of structural joints largely affects the overall cost and buildability [21]. The adopted DG quantitative metric to be decreased is the cardinality of the structural joints $\#(N)$.

Uniformity of structural joints. The DG is aimed at shortening the joints chart, but also affecting the gridshell aesthetics. In what follows the joint type results from its valence v and the relative angles θ between converging members [22]. The adopted DG quantitative metric to be decreased is the cardinality of the joint type $\#(J)$.

Uniformity of structural members. The DG is aimed at shortening the members chart, but also affecting the gridshell aesthetics. In what follows the member type results from its length and cross section. The corresponding DG quantitative metrics to be decreased are the standard deviation of members length $\tilde{l}$ [14][23] and the cardinality of the members cross-sections $\#(C)$.

The buildability performance metric results from the average of the DG metrics as

$$P_b = \frac{1}{\frac{1}{5}\left[\frac{1+\bar{\Delta}}{1+\bar{\Delta}_0} + \frac{\#(N)}{\#(N_0)} + \frac{\#(J)}{\#(J_0)} + \frac{1+\tilde{l}}{1+\tilde{l}_0} + \frac{\#(C)}{\#(C_0)}\right]}. \quad (2)$$

3.3. Sustainability goals and metrics

Weight reduction is the traditional, widespread and largely emphasized design objective for structures in general, and for lightweight ones in particular, gridshells included, e.g. [24]. In a Life Cycle Assessment perspective, steel weight reduction is rephrased in the reduction of the gridshell embodied carbon that depends on the steel weight and grade, and on the type of sections of the structural members [25][26]. The adopted corresponding DG quantitative metric to be decreased is $W = \sum_{i=1}^{M} g_i \cdot l_i \cdot \alpha_i$, where the summation over the *M* structural members includes the weight per unit length g, the length l of the *i*-th member, and a correction coefficient α that depends on the steel grade and the type of member cross section, and that is normalized with respect to hollow sections made of S235.

The sustainability performance metric reads as

$$P_{su} = \frac{1}{\frac{W}{W_0}}. \quad (3)$$

3.4. Bulk performance metric

A bulk performance metric *P* results from the three partial performance metrics above

$$P = \gamma_s \cdot P_s + \gamma_b \cdot P_b + \gamma_{su} \cdot P_{su} \quad (4)$$

where $\gamma_s, \gamma_b, \gamma_{su}$ are partial weighting factors constrained by $\gamma_s + \gamma_b + \gamma_{su} = 1$, so that $P_0 = 1$. In the FreeGrid benchmark, the partial weighting factors are uniformly set equal to $\gamma_s = \gamma_b = \gamma_{su} = 1/3$ in order to offer to the participants a common term of reference. In a broader perspective, designers are in charge to discuss the overall performance of DSG(s) by setting other values of the partial weighting factors.

Being *P* a sortable performance metric, the ranking of the DSG issued from the benchmark for each DBG does not depend to a subjective and *a posteriori* assessment.

4. Design constraints

DSGs shall fulfil the following Geometrical (GC) and Mechanical (MC) Constraints. They are listed in the following by making general reference to a design solution with generic shape and structural features:

GC.1. the single-layer gridshell structural type cannot be changed, i.e. the mesh is 2-manifold, that is non-manifold vertices and edges are not permitted [27];
GC.2. the position, shape and length of the continuous spring line and of the head arches (for barrel vault only) cannot be modified;
GC.3. the gridshell spans along the x and y directions B_x and B_y, respectively, shall not be shorter than 30 m, being B_x and B_y generally defined as the maximum span free of external constraints;
GC.4. the extent of the projection of the overall gridshell surface on the horizontal reference plane shall be no smaller than $S - 0.05S$;
GC.5. the rise shall be kept equal to f=B/8, being f generally defined as the distance between the horizontal reference plane and the horizontal tangent plane to the shell surface having the minimum height;
GC.6. the height h shall be not longer than B /4, being h generally defined as the distance between the horizontal reference plane and the horizontal plane passing through the shell vertex having the maximum height;
GC.7. geometrical vertices and structural joints cannot lie below the horizontal reference plane;
MC.1. along the spring line L, x-, y- and z-displacements of all the structural joints resulting from mesh generation shall be externally constrained (perfect hinges);
MC.2. along the head arches (barrel vault), x- and z-displacements of all the structural joints resulting from mesh generation shall be externally constrained;
MC.3. additional structural external constraints are not allowed anywhere;
MC.4. the structural members shall have commercial cross sections;
MC.5. the structural material shall be steel.

Whichever design parameter can be varied if not explicitly excluded above, for instance geometry (e.g. overall shape of the gridshell, node position, grid density and topology), number and properties of the structural members (cross section, length), number and type of the structural joints, steel grade, prestressing magnitude, et cetera.

5. Design approaches and performance assessment methods

Whatever approach to design and optimization is welcome, for instance man-based heuristic design, AI-based design (e.g. neural networks, machine learning), gradient-based or topological optimization, physical scale model-based, models based on continuous analogy, et cetera.

Any kind of structural models can be used by the participants during the design/optimization (e.g. Reduced Order Models, surrogate models, simplified models such as linear static or buckling analysis).

Final structural performance assessment of the retained DSG(s) shall be carried out by a Geometrically and Materially Nonlinear Analysis (GMNA).

6. Requirements for participants

The method adopted for the performance assessment of the retained DSG(s) shall be well documented in order to guarantee the *reproducibility* of the results, and the *comparability* among them.

In order to reduce the model uncertainties, the following specifications about the Finite Element Model and the numerical solver used in GMNA are given:

- Finite Elements shall be 3D beam elements based on Timoshenko model, with cubic shape function;
- The Distributed Plasticity (DP) approach [28] shall be adopted, with nonlinear behaviour modelled along the element and over the element cross section;

- each structural member should be preferably discretised by 4 Finite Elements of equal length, in order to account for member buckling;
- the load control path-following procedure shall be applied within the analysis. The load step magnitude shall be set equal to 1/1000 the magnitude of the load condition LC_i;
- the iterative convergence shall be accomplished at each load step by means of the standard Newton-Raphson method, with a tolerance set equal to 5e-3 in terms of weighted residuals of the variables.

To pursue reproducibility and comparability, data about DSG, design approaches, performance assessment tools, and results shall be provided by the participants as Open Data. The complete set of requested data is detailed in the FreeGrid Technical Specifications.

In order to guarantee *comparability*, participants are strongly advised to precisely specify for each proposed design solution each single Design Goal metric, partial performance metrics, and bulk performance metric.

In order to allow *reproducibility*, participants are warmly encouraged to precisely specify for each proposed design solution: (i) *data on DSG*, i.e. geometrical and structural features; (ii) *data on models*, i.e. adopted design approach (e.g. heuristic approach, optimization algorithm(s), AI technique), name and version of the Finite Element code(s) and details about the Finite Element Model used for performance assessment; (iii) *main output* of the structural performance assessment.

Open Access automatic tools will be made available in order to assist participants in checking the fulfilment of the design constraints during the conceptual design, and in the calculation of buildability performance metrics during the final assessment.

The above information shall be delivered by participants in the form of data uploaded on the FreeGrid web site, technical report/white paper sent to the FreeGrid Steering Committee, or published scientific paper.

7. Outlook and conclusion

The FreeGrid benchmark is launched at the IASS 2023 Annual Symposium in Melbourne. The benchmark technical specifications are made available at the FreeGrid website (https://sites.google.com/view/freegrid). A position paper will discuss in deep the mechanical behaviour of the background and design baseline gridshells, in order to provide to participants stimuli for design solutions.

In itinere special sessions will be possibly organized in the following years at international conferences. The benchmark first milestone is tentatively set within the IASS Annual Symposium 2026, when the FreeGrid ArcelorMittal Steligence Awards will be remitted according to given specific regulation to the young author(s) of the most performing design solution for each type of DGS, together with an additional award remitted to the author(s) who will deal with all the three DGS and obtain the highest performances in average.

Acknowledgements

The Authors gratefully acknowledge the support of the Italian Council for Steel Structures (CTA, https://www.collegiotecniciacciaio.it), the umbrella of the International Association for Shell and Spatial Structures (IASS, https://iass-structures.org), and the partnership with ArcelorMittal Steligence (https://steligence.arcelormittal.com). The Authors thank Riccardo Zanon and Marina D'Antimo (ArcelorMittal Steligence) for the stimulating insight and fruitful discussion about steel gridshell sustainability. The Authors warmly thank Yi Min ‘Mike’ Xie and Jane Burry, Co-Chairs of the IASS

annual Symposium 2023, and its Organizing Committee for hosting the launch of the benchmark within the event.

Abstract

Our recent paper, "Interactive exploration of tension-compression mixed shells" [1], discusses the topic of the form-finding of shell structures in which both compression and tension are present and proposes a novel numerical approach that can iteratively refine the problem until a solution is found. This is achieved by regarding two surfaces—a shell and a stress function—as unknown functions, and then iterating until equilibrium is satisfied. This new approach allows us to explore a new frontier. In that paper, we propose that these shells can be used as an initial design step for discrete grid shells. This study takes up this task by using an equation presented in [1] to trace out a special set of curves on an equilibrium pair of continuum shell and stress function surfaces. This unique set of curves is both conjugate and funicular; that is, it is aligned with a grid on the shell that is locally flat-paneled, and it is in axial force equilibrium as a grid shell with no bending in the grid members under the applied load. In this paper, we propose an algorithm to trace these simultaneously stress- and flat-panel-aligned curves on equilibrium shell–stress function pairs. We test the method on several analytical examples, and then move to general form-found shells. The conditions of existence of the curve networks are not trivial, and we need to modify the method of [1] to add a constraint that guarantees that the curve networks exist on form-found shells. After modifying the method, we present several different complex examples of the resulting curve networks.

Keywords: airy stress functions, form-finding, tension-compression mixed shells, variable projection method, hyperbolic boundary problems, bilinear tensor least squares problems, conjugate curve networks, funicular grid shells

1. Introduction

In 2015, an Airy stress function-based form-finding method that does not rely on triangulated mesh surfaces but directly calculates smooth and continuous NURBS surfaces was presented [5]. The method requires the Airy stress function to be convex everywhere and can only compute a pure-compression shell. In 2022, we presented a novel computational approach that enables us to execute a form-finding analysis of shells that can balance with a mixed tension-compression stress state [1]. Although a similar method was previously proposed by Yu-Chou et al. [2], we pointed out that in tension-compression mixed cases, it is very likely that the equilibrium equation does not provide any solution in general. Our new method deals with this issue by refining the stress function as well as the shell, so that both the shell and stress function are iterated until the problem converges to an equilibrium solution. To solve the problem, Yu-Chou et al. [2] selected a simple alternating approach (ALT). However, a comparison presented by Elden et al. [4] reports that, while ALT is not guaranteed to converge or the rate of convergence is extremely low, the variable projection (called VP or VarPro; we call it VP in this paper)

Copyright © 2023 by Masaaki MIKI and Toby MITCHELL. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

can solve the problem with sufficient accuracy. Hence, we concluded that VP is more suitable to solve this problem. Although the computational cost of VP is extremely high, we successfully accelerated the computation using modern Nvidia GPUs and the Cuda toolkit library. With the successful solutions obtained by executing the proposed method, we concluded that the well-posed problems form a vast solution space that is comparatively far less well-studied than the case of all-compression or all-tension surface structures.

This new method has significant merits from both aesthetic and technical viewpoints. The shells, classically derived with pure compression, are now extended to include tension-compression mixed regions, and overhanging anticlastic surfaces are now possible. Furthermore, from a technical viewpoint, because the solutions are represented by NURBS surfaces, continuous curvature and stress tensors can be computed everywhere on the surface.

Helmut Pottmann's research group has published an extensive body of surface structure shape optimization techniques that rely on mesh surfaces. One study [3] presented a method to obtain a net that is simultaneously conjugate and funicular by tracing the eigenvectors of a generalized eigenvalue problem in terms of the Hessians of the shell and stress function. Thus, a net that can support load with no bending action and that also has all planar quad faces can be easily computed. Although Helmut Pottmann's research group applied this idea to discretized mesh surfaces, here, we directly compute the eigenvectors on the obtained NURBS surfaces and perform a curve tracing algorithm to obtain nets that provide simultaneously stress- and flat-panel-aligned curve networks.

2. A net that is simultaneously conjugate and funicular

In shell form-finding, the stress field is often described using an Airy stress function. In this study, we consider two functions $z(x, y)$ and $\phi(x, y)$ that represent the shape of the shell and the stress function, respectively. In the following, the shell has units of length, and the stress function has units of force times length. The equilibrium of the shell in the vertical direction is given by the Pucher equation

$$\frac{\partial^2\varphi}{\partial x^2}\frac{\partial^2 z}{\partial y^2} - 2\frac{\partial^2\varphi}{\partial x\,\partial y}\frac{\partial^2 z}{\partial x\,\partial y} + \frac{\partial^2 z}{\partial y^2}\frac{\partial^2\varphi}{\partial x^2} = p \tag{1}$$

For zero-shear stresses and flat panels (conjugate curves) to be aligned on a membrane shell, we must have

$$\begin{aligned}\frac{\partial^2 z}{\partial u\,\partial v} &= 0\\ \frac{\partial^2\varphi}{\partial u\,\partial v} &= 0\end{aligned} \tag{2}$$

where *u* and *v* are some sets of curvilinear coordinates on the projected *x*-*y* plane, which do not need to be orthogonal. The first condition gives panel flatness via vanishing of the off-diagonal curvature tensor entry, while the second condition yields zero shear in the *u* and *v* directions, which is required if bending is to be avoided along the *u* and *v* curves.

Given $z(x, y)$ and $\phi(x, y)$, we want to solve for the specific *u* and *v* that satisfy (2). It is easier to solve in terms of coordinates that we already know, for example, *x* and *y*. Using the chain rule, we can write

$$\frac{\partial^2 z}{\partial u\,\partial v} = \frac{\partial^2 z}{\partial x^2}\frac{\partial x}{\partial u}\frac{\partial x}{\partial v} + \frac{\partial^2 z}{\partial x\,\partial y}\frac{\partial x}{\partial v}\frac{\partial y}{\partial u} + \frac{\partial^2 z}{\partial x\,\partial y}\frac{\partial x}{\partial u}\frac{\partial y}{\partial v} + \frac{\partial^2 z}{\partial y^2}\frac{\partial y}{\partial u}\frac{\partial y}{\partial v}$$

$$= \begin{bmatrix}\frac{\partial x}{\partial u} & \frac{\partial y}{\partial u}\end{bmatrix}\begin{bmatrix}\frac{\partial^2 z}{\partial x^2} & \frac{\partial^2 z}{\partial x\,\partial y}\\ \frac{\partial^2 z}{\partial x\,\partial y} & \frac{\partial^2 z}{\partial y^2}\end{bmatrix}\begin{bmatrix}\frac{\partial x}{\partial v}\\ \frac{\partial y}{\partial v}\end{bmatrix} = 0 \tag{3}$$

Therefore, by treating the *u* and *v* derivatives of *x* and *y* as unknown vectors, the problem of finding the stress- and panel-aligned coordinate curves reduces to

$$\begin{aligned} v_1^T[\nabla^2 z]v_2 &= 0 \\ v_1^T[\nabla^2 \varphi]v_2 &= 0 \end{aligned} \tag{4}$$

where the bracketed terms are the Hessians of the shell and the stress function, that is,

$$[\nabla^2 z] = \begin{bmatrix} \frac{\partial^2 z}{\partial x^2} & \frac{\partial^2 z}{\partial x \partial y} \\ \frac{\partial^2 z}{\partial x \partial y} & \frac{\partial^2 z}{\partial y^2} \end{bmatrix}, [\nabla^2 \varphi] = \begin{bmatrix} \frac{\partial^2 \phi}{\partial x^2} & \frac{\partial^2 \phi}{\partial x \partial y} \\ \frac{\partial^2 \phi}{\partial x \partial y} & \frac{\partial^2 \phi}{\partial y^2} \end{bmatrix} \tag{5}$$

and where

$$v_1 = \begin{bmatrix} \frac{\partial x}{\partial u} \\ \frac{\partial y}{\partial u} \end{bmatrix}, v_2 = \begin{bmatrix} \frac{\partial x}{\partial v} \\ \frac{\partial y}{\partial v} \end{bmatrix} \tag{6}$$

are the tangent vectors of the *u* and *v* coordinate curves. Solving the two simultaneous Eqs. (4) is equivalent to solving the generalized eigenvalue problem

$$[\nabla^2 z]v = \lambda[\nabla^2 \varphi]v. \tag{7}$$

Eq. (7) was first presented in [3].

The eigenvalues of (6) are given by

$$\lambda^2 \left(\frac{\partial^2 \varphi}{\partial x^2} \times \frac{\partial^2 \varphi}{\partial y^2} - \left(\frac{\partial^2 \varphi}{\partial x \, \partial y} \right)^2 \right) - \lambda \left(\frac{\partial^2 \varphi}{\partial x^2} \times \frac{\partial^2 z}{\partial y^2} - 2 \times \frac{\partial^2 \varphi}{\partial x \, \partial y} \times \frac{\partial^2 z}{\partial x \, \partial y} + \frac{\partial^2 \varphi}{\partial y^2} \times \frac{\partial^2 z}{\partial x^2} \right) + \left(\frac{\partial^2 z}{\partial x^2} \frac{\partial^2 z}{\partial y^2} - \left(\frac{\partial^2 z}{\partial x \, \partial y} \right)^2 \right) = 0 \tag{8}$$

However, we can recognize the middle term as the left-hand side of Eq. (1), and the other terms as determinants of the Hessians, so that Eq. (8) becomes

$$\lambda^2 \det(\nabla^2 \varphi) - \lambda p + \det(\nabla^2 z) = 0. \tag{9}$$

Note that the determinants of the Hessians (called the "isotropic Gaussian curvatures" in [3]) are related to the (ordinary Euclidean) Gaussian curvatures of the shell and stress function. In particular, the sign of the determinants is the same as the sign of the Gaussian curvatures.

It follows that

$$\lambda = \frac{p \pm \sqrt{p^2 - 4\det(\nabla^2 \varphi)\det(\nabla^2 z)}}{2\det(\nabla^2 \varphi)}. \tag{10}$$

From elementary linear algebra, we know that Eq. (7) has real eigenvalues if $\det(\nabla^2 \varphi) > 0$ and $\det(\nabla^2 z) > 0$, since both matrices are then symmetric positive definite. Also, the cases in which $\det(\nabla^2 \varphi) > 0$ and $\det(\nabla^2 z) < 0$ or $\det(\nabla^2 \varphi) < 0$ and $\det(\nabla^2 z) > 0$ clearly have a real discriminant. The only case in which we must pay special attention is when both determinants are negative. In those cases, the solution discriminant must be checked, that is,

$$p^2 \geq 4\det(\nabla^2 \varphi)\det(\nabla^2 z) \tag{11}$$

must be examined to determine whether the inequality is satisfied.

An interesting special case is the "self-Airy" case [8], where $z(x,y)=\phi(x,y)$. In this case,

$$p^2=\left(2\frac{\partial^2 z}{\partial x^2}\times\frac{\partial^2 z}{\partial y^2}-2\times\left(\frac{\partial^2 z}{\partial x\,\partial y}\right)^2\right)^2=4\left(\frac{\partial^2 z}{\partial x^2}\frac{\partial^2 z}{\partial y^2}-\left(\frac{\partial^2 z}{\partial x\,\partial y}\right)^2\right)^2=4\det(\nabla^2 z)\det(\nabla^2 z), \tag{12}$$

that is, the self-Airy case corresponds to the equality case of (11). In this case, the eigenvalues of (7) are not distinct, so the eigenvectors of (7) can be chosen in any conjugate directions, with stress-alignment guaranteed for any choice.

3. Curve tracing algorithm

The procedure to trace the stress- and flat-panel-aligned curves given by (7) is as follows.

When a NURBS surface is represented by three functions $x(u^1,u^2), y(u^1,u^2)$, and $z(u^1,u^2)$, where (u^1,u^2) are the isocurve parameters of the NURBS surface, we compute

$$\bar{g}_1=\begin{bmatrix}\frac{\partial x}{\partial u^1} & \frac{\partial y}{\partial u^1}\end{bmatrix}^T, \bar{g}_2=\begin{bmatrix}\frac{\partial x}{\partial u^2} & \frac{\partial y}{\partial u^2}\end{bmatrix}^T, \tag{13}$$

which are the basis vectors projected onto the *x*-*y* plane. We also compute the second derivatives as

$$\bar{h}_{11}=\begin{bmatrix}\frac{\partial^2 x}{\partial (u^1)^2} & \frac{\partial^2 y}{\partial (u^1)^2}\end{bmatrix}^T, \bar{h}_{12}=\begin{bmatrix}\frac{\partial^2 x}{\partial u^1\,\partial u^2} & \frac{\partial^2 y}{\partial u^1\,\partial u^2}\end{bmatrix}^T, \bar{h}_{22}=\begin{bmatrix}\frac{\partial^2 x}{\partial (u^2)^2} & \frac{\partial^2 y}{\partial (u^2)^2}\end{bmatrix}^T, \tag{14}$$

which are also projected onto the *x*-*y* plane. Using these, we compute the first fundamental form by $\bar{g}_{ij}=\bar{g}_i\cdot\bar{g}_j$ and $\bar{g}^{ij}=\left(\bar{g}_{ij}\right)^{-1}$. The dual basis vectors can then be computed as $\bar{g}^i=\bar{g}^{ij}\bar{g}_j$. With these, Christoffel's symbols of the second kind are computed by $\overline{\Gamma}^k_{ij}=\bar{h}_{ij}\cdot\bar{g}^k$, and we finally compute the Hessian on the curvilinear coordinates in terms of the second covariant derivative as

$$\nabla^2 z=z|_{ij}=\frac{\partial^2 z}{\partial u^i\,\partial u^j}-\overline{\Gamma}^k_{ij}\frac{\partial z}{\partial u^k}. \tag{15}$$

Although it is possible to solve the generalized eigenvalue problem in curvilinear coordinates directly using the laws of raising and lowering indices, we extract its components in the *x*-*y* coordinates via

$$z|_{\alpha\beta}=z|_{ij}\left(e_\alpha\cdot\bar{g}^i\right)\left(e_\beta\cdot\bar{g}^j\right), \tag{16}$$

where $e_1=[1,0]^T$ and $e_2=[0,1]^T$.

Following this procedure, for a set of two surfaces: the Airy function $[x(u^1,u^2), y(u^1,u^2), \phi(u^1,u^2)]^T$ and the shell $[x(u^1,u^2), y(u^1,u^2), z(u^1,u^2)]^T$, with $x(u^1,u^2)$ and $y(u^1,u^2)$ in common between them, we obtain two Hessians $\nabla^2\phi$ and $\nabla^2 z$. By setting those two matrices to the first and second matrices in the generalized eigenvalue problem defined in Eq. (7), we obtain two normalized directions v_1 and v_2, that is, we obtain the eigenvectors (6). To trace the stress-aligned conjugate curve network in the initial step, given an initial point p_0, we select the initial velocity vector from $v_1,-v_1,v_2,-v_2$ and set it to the velocity vector v_0. Except in the initial step, the angles between the previous v_0 and $v_1,-v_1,v_2,-v_2$ are checked, and the one that gives the smallest angle is chosen as the new velocity v_0. With a sufficiently small step size dt, we then generate a point series by repeating:

$$p_{t+1}=p_t+v_0\mathrm{dt}. \tag{17}$$

Given that the level of approximation is not very high, termination of the point generation is recommended when even the smallest angle exceeds a predefined threshold (e.g., we used 0.6 in radians as the threshold in our code).

4. Simple cases in which analytical solutions can be hand-calculated

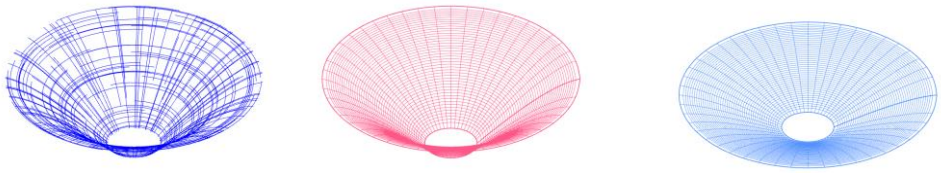
There are relatively simple tension-compression mixed cases in which analytical solutions can be derived by hand. We use these solutions to demonstrate the results of tracing the stress-aligned conjugate curve network.

4.1. Equilibrium equation in curvilinear coordinates

In curvilinear coordinates described with $\{r, \theta\}$ (not limited to polar coordinates for the time being), Eq. (1) becomes:

$$\left(\frac{\partial^2 z}{\partial r \partial r} - \Gamma^r_{rr}\frac{\partial z}{\partial r} - \Gamma^\theta_{rr}\frac{\partial z}{\partial \theta}\right)\left(\frac{\partial^2 \phi}{\partial \theta \partial \theta} - \Gamma^r_{\theta\theta}\frac{\partial \phi}{\partial r} - \Gamma^\theta_{\theta\theta}\frac{\partial \phi}{\partial \theta}\right) - 2\left(\frac{\partial^2 z}{\partial r \partial \theta} - \Gamma^r_{r\theta}\frac{\partial z}{\partial r} - \Gamma^\theta_{r\theta}\frac{\partial z}{\partial \theta}\right)\left(\frac{\partial^2 \phi}{\partial r \partial \theta} - \Gamma^r_{r\theta}\frac{\partial \phi}{\partial r} - \Gamma^\theta_{r\theta}\frac{\partial \phi}{\partial \theta}\right) + \left(\frac{\partial^2 z}{\partial \theta \partial \theta} - \Gamma^r_{\theta\theta}\frac{\partial z}{\partial r} - \Gamma^\theta_{\theta\theta}\frac{\partial z}{\partial \theta}\right)\left(\frac{\partial^2 \phi}{\partial r \partial r} - \Gamma^r_{rr}\frac{\partial \phi}{\partial r} - \Gamma^\theta_{rr}\frac{\partial \phi}{\partial \theta}\right) = \det g\, p, \quad (18)$$

where Γ^k_{ij} is the Christoffel's symbols of the second kind. In polar coordinates, it is known that $\Gamma^r_{\theta\theta} = -r$, $\Gamma^\theta_{r\theta} = \Gamma^\theta_{\theta r} = \frac{1}{r}$, $\det g = r^2$, and all others are zero. Hence, in polar coordinates, we obtain:



$$\left(\frac{\partial^2 z}{\partial r \partial r}\right)\left(\frac{\partial^2 \phi}{\partial \theta \partial \theta} + r\frac{\partial \phi}{\partial r}\right) - 2\left(\frac{\partial^2 z}{\partial r \partial \theta} - \frac{1}{r}\frac{\partial z}{\partial \theta}\right)\left(\frac{\partial^2 \phi}{\partial r \partial \theta} - \frac{1}{r}\frac{\partial \phi}{\partial \theta}\right) + \left(\frac{\partial^2 z}{\partial \theta \partial \theta} + r\frac{\partial z}{\partial r}\right)\left(\frac{\partial^2 \phi}{\partial r \partial r}\right) = r^2 p. \quad (19)$$

4.2. A simple self-Airy example

If the stress surface and the shell are given by the same functions, there is no need to solve the generalized eigenvalue problem, because any conjugate directions are already stress-aligned (since the eigenvalues of (7) are not distinct). An analytical solution can be obtained by introducing an assumption that the shell and the stress are the same except for the scaling factor and that they are both surfaces of revolution, that is, $z = f(r), \phi = Af(r)$. In this case, an analytical solution can be obtained [6] as

$$z(r) = \frac{1}{2\sqrt{2A}}\left(r\sqrt{B^2 - r^2} + \arcsin(r)\right), \quad (20)$$

where A and B are the integration coefficients. Figure 1 shows the solutions and the traced curvature lines when $A = 0.5, B = 1,$ and $0.2 < r < 1$.

(a) (b) (c)

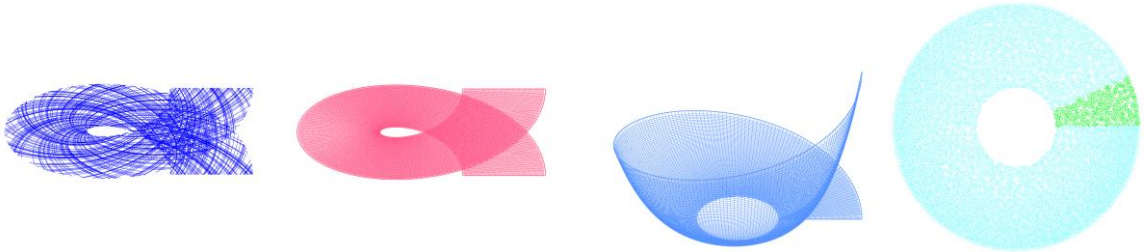
Figure 1. (a) Curvature lines traced using the algorithm described above, (b) shell surface, and (c) stress surface.

4.3. Monkey saddle ($z = r\cos 3\theta$)

An example of a shell-stress function pair that does *not* admit real eigenvalues of (7) anywhere on the surface was discussed in [8] as

$$z = r\cos 3\theta\,, \phi = r\sin 3\theta. \quad (21)$$

This is a self-stressed surface, with no external loads applied (roughly similar to a cable net or tensile fabric membrane, but with tension and compression both present). Both determinants are negative (and in fact identical, since ϕ is just a rotated copy of z). The lack of any real eigenvalues of (7) then follows from the fact that p is zero in (11). This solution shows that it is possible for large areas of a shell to have *no* solutions to the eigenvalue problem (7).



Note that it is not generally true that self-stressed surfaces do not have real eigenvalues in (7). This example is unusual in that it has tension and compression both present in the self-stress state. For a pure compression or pure tension self-stress state, the shell will be negatively curved while the stress function will be positively curved, so that the product of determinants in (11) is positive and therefore the surface will have real eigenvalues even with no applied load present.

4.4. Helicoid

A pair of helicoidal shell and stress surfaces that partially yields negative Gaussian curvatures was derived in [7] as

$$z = \frac{h}{2\pi}\theta, \phi = -p\frac{\pi r^4 \theta}{3h} \tag{22}$$

where h is the total height of a full $2 * \pi$ turn. This is an interesting example because there is a region where both surfaces give negative Gaussian curvatures (in the range $\theta < \sqrt{3}/4$), and yet a stress-aligned conjugate net exists in that region, because Eq. (11) is satisfied everywhere. Figure 2 shows the surfaces, the stress-aligned conjugate net obtained by using the algorithm described above, and the region where the two surfaces give negative Gaussian curvature.

(a) (b) (c) (d)

Figure 2. (a) A stress-aligned conjugate net, (b) shell surface, and (c) stress surface. (d) The region where both surfaces give negative Gaussian curvatures (green).

This example shows that real eigenvalues can indeed be found for fairly general shell-stress function pairs with negative-negative regions: this class of solutions is *not* restricted to a trivially small set. Between this example and the previous example, we can see that the condition for stress- and flat-panel-aligned curves to exist is neither trivially satisfied nor trivially restrictive. It is not necessarily possible to find sets of curves that are simultaneously stress- and flat-panel-aligned on any given surface, but the class of such solutions is still rich enough to be worth exploring. This exploration can be done by using shell form-finding, and in fact, we can impose the constraint (7) on shell form-finding results to ensure that solutions exist.

5. Mixed tension-compression shell form-finding

In this section, we briefly summarize the novel tension-compression mixed-shell form-finding method that we have proposed. Readers interested in the full technical details can navigate to [1].

If ϕ is given in equation (1), then the equation becomes

$$A\frac{\partial^2 z}{\partial x \partial x} - B\frac{\partial^2 z}{\partial x \partial y} + C\frac{\partial^2 z}{\partial y \partial y} = p, \tag{23}$$

where the terms A, B, and C are given functions of x and y over the surface.

In a tension-compression mixed case, this second-order partial differential equation becomes hyperbolic, or hyperbolic-elliptic mixed, and it is known that a compatible set of boundary conditions must be sought first before solving the problem; otherwise, the problem becomes ill-posed. In general, finding a compatible set of boundary conditions is a challenge, and thus, this type of problem is considered

notoriously difficult to solve. This is very different from pure-compression cases, which make the problem elliptic and thus provide solutions regardless of what kind of boundary conditions are given.

Although the problem is very likely ill-posed when the coefficients are chosen freely, a preliminary study conducted by the authors and C. J. K. Williams's research group from Chalmers University of Technology [6] strongly suggests that combinations of the coefficients that make the hyperbolic problem provide a solution do exist. The basic idea of our method is that instead of attempting to solve a problem that can easily become ill-posed, we solve a parameter identification problem to find a set of coefficients that makes the equilibrium equation well-posed. To this end, we simply regard both z and ϕ as unknown functions. If we do so, the problem is described with two unknown functions versus one condition, which expands a unique solution that may not exist to a vast solution space.

By defining the residual of Eq. (1) by

$$r(\phi, z) = \frac{\partial^2 \varphi}{\partial x^2}\frac{\partial^2 z}{\partial y^2} - 2\frac{\partial^2 \varphi}{\partial x\,\partial y}\frac{\partial^2 z}{\partial x\,\partial y} + \frac{\partial^2 z}{\partial y^2}\frac{\partial^2 \varphi}{\partial x^2} - p, \tag{24}$$

the problem can be approximately solved by solving a least squares problem defined by

$$\int r(\phi, z)^2 \ \mathrm{d}\bar{a} + \int b_\phi(\phi)^2 \mathrm{d}\bar{l} + \int b_z(z)^2 \mathrm{d}\bar{l} \to \min,$$

where b_ϕ and b_z are additional residual functions of the stress function and shell boundary conditions respectively, evaluated and integrated on the projected boundary curves $\bar{l}$. Note that the projected boundary curves are the same between the shell and stress function, so it is not necessary to distinguish the domain over which these terms are integrated. When ϕ and z are represented with NURBS basis functions, this least squares minimization problem results in a bilinear tensor least squares (BTLS) problem [4]. Considering either the shell or the stress function to be given (called "pinning" in [1]), we obtain two partial linear least squares problems, defined as:

$$\int r(\phi, \bar{z})^2 \ \mathrm{d}\bar{a} + \int b_\phi(\phi)^2 \mathrm{d}\bar{l} \to \min, \tag{25}$$

$$\int r(\bar{\phi}, z)^2 \ \mathrm{d}\bar{a} + \int b_z(z)^2 \mathrm{d}\bar{l} \to \min, \tag{26}$$

where $\bar{\cdot}$ was put above ϕ or z when it is "pinned". Hence, the basic strategy for solving this type of problem is to find a solution that simultaneously satisfies both partial problems. The ALT method is a simple approach that alternately solves two problems. As mentioned earlier, we reported that VP works better than ALT. The computational results presented in [1] are showcased in Figure 3. Figure 4 also shows the 3D prints of an obtained pair.

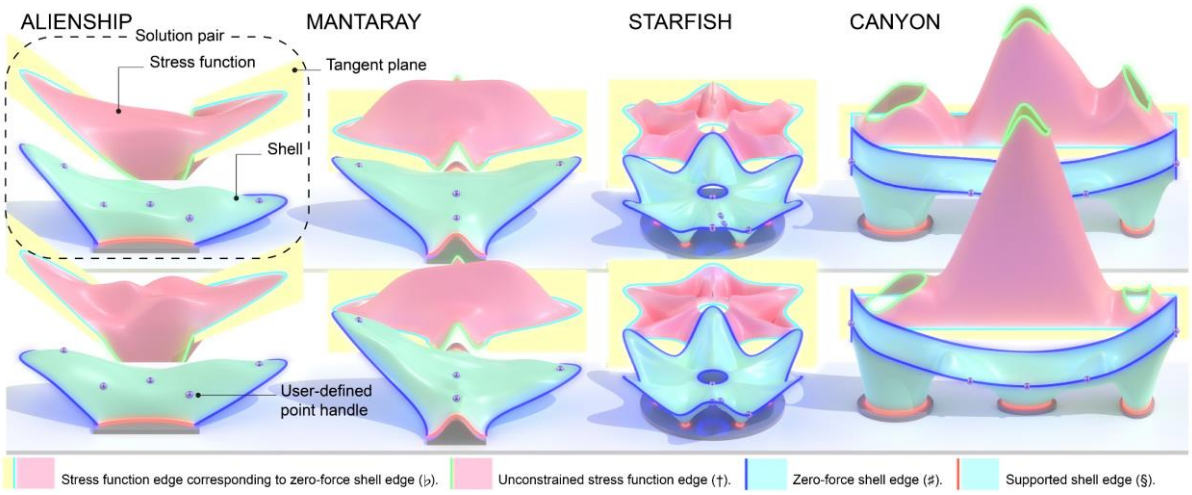


Figure. 3. Pairs of stress functions and shells obtained using the proposed method.

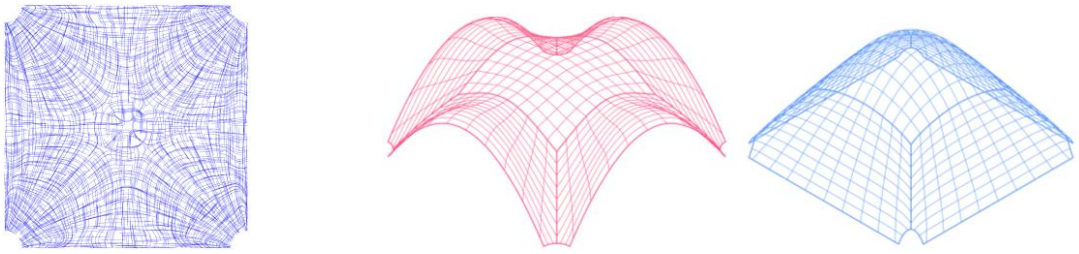
Figure 4. Above: A tension-compression mixed shell whose shape was computed using the proposed method. Below: An Airy stress function was used to compute the shell floating above, which was also an optimization result obtained by the proposed method.

5.1. Inequality constraints for existence of stress- and flat-panel-aligned curve networks

Examining curve-traced results on several general mixed tension-compression shells made it clear that regions where (11) is *not* satisfied will often be present on form-found shells. Even though equilibrium holds everywhere on the shells, regions where no real eigenvalues exist are often found, sometimes extending over large regions of the surface. Therefore, for the method of [1] to be suitable for stress- and flat-panel-aligned curve tracing, it is necessary to modify it by *imposing* equation (11) as an inequality constraint on the form-finding algorithm.

To incorporate Eq. (11) into our computational framework, we extended the original method in a way that it can also solve inequality constraints. We do this via a penalty method approach. We add a least squares term defined as $w * (f)^2$ to the method, where w is a penalty coefficient, and where $f = p^2 - 4\det(\nabla^2\varphi)\det(\nabla^2 z)$ is the inequality constraint term. In each step, the inequality constraints are checked to determine if $f \geq 0$, and the penalty coefficient is set to a constant non-zero number if the condition is violated and to 0 when it is satisfied.

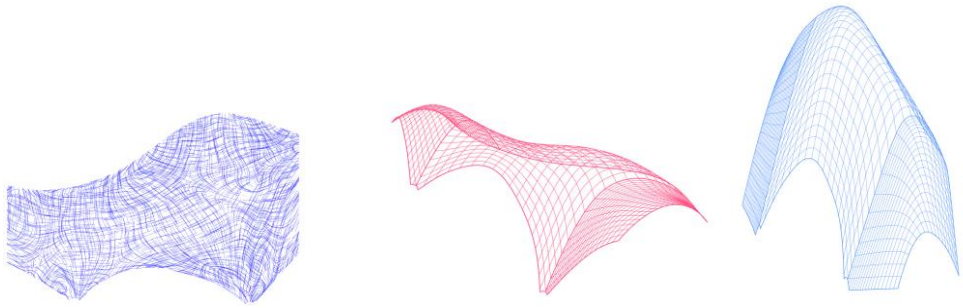
This activate-deactivate process makes the computation far less efficient than with no inequality constraints and thus longer computation times were needed. However, we were able to obtain interesting and useful results. As a byproduct, this extension enabled us to limit the Gaussian curvatures of the two surfaces to certain ranges.



As is typical for penalty methods in general, the choice of the penalty coefficient w affects the accuracy of the results. A penalty coefficient that is too low leads to violation of the constraint, that is, the surface will still have imaginary eigenvalues. Conversely, a penalty coefficient that is too high can result in an ill-conditioned problem. Our penalty values were chosen by trial and error, and tended to result in sufficient constraint enforcement at the cost of less accurate iteration convergence (around 1e-4 in the L2 norm of the residual vector when the inequality constraint is active versus 1e-6 or less for the original, unconstrained method).

6. Curve tracing on NURBS surfaces

Now that it is possible to incorporate inequality constraints into our method, we show several examples of our curve-tracing method, in order of increasing difficulty of solution.

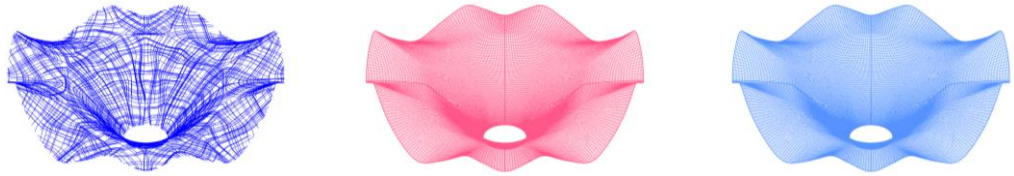


6.1. All-compression examples

Figures 5–6 (b) and (c) show the successful form-finding results of pure compression cases, and Figures 5–6 (a) show stress-aligned conjugate curve networks obtained by the curve tracing algorithm. In pure compression cases, the generalized eigenvalue problem always gives solutions; thus, there is no need to ensure that Eq. (11) is satisfied.

(a) (b) (c)

Figure 5. (a) A stress-aligned conjugate net obtained by our algorithm, (b) a shell obtained by limiting the Gaussian curvature to greater than -2, and (c) a stress function obtained by limiting the Gaussian curvature to greater than 0.



(a) (b) (c)

Figure 6. (a) A stress-aligned conjugate net obtained by our algorithm, (b) a shell obtained by limiting the Gaussian curvature to greater than -1, and (c) a stress function obtained by limiting the Gaussian curvature to greater than 0.

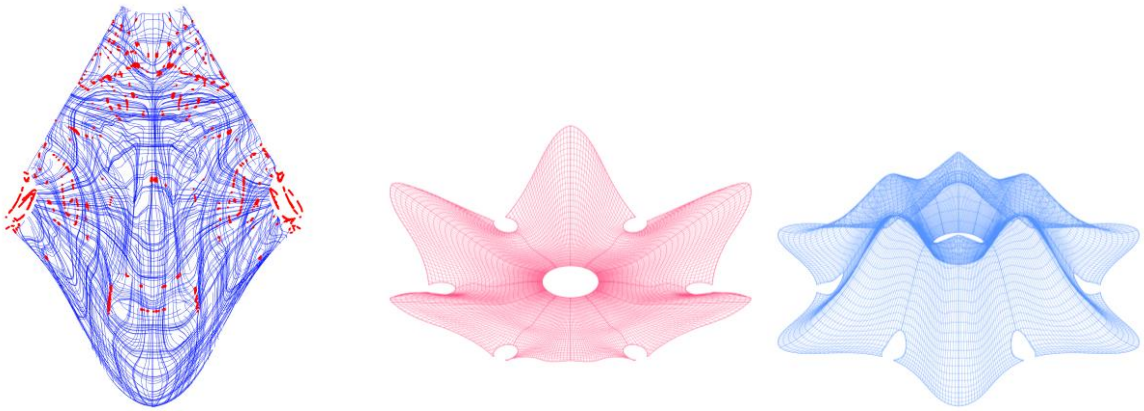
6.2. Non-trivial self airy example

Using the proposed method, by setting $\phi = z$, a non-trivial self-Airy case can be computed. Figure 7 shows the two surfaces obtained by the proposed method. Similar to example 4.2, the conjugate curves are chosen to be the lines of curvature for this example; since Eq. (7) does not give distinct eigenvalues in the case of self-Airy shells, we can select a preferred conjugate network at will.

(a) (b) (c)

Figure 7. (a) Curvature lines of the two surfaces, (b) shell surface, and (c) stress surface.

6.3. General mixed tension-compression examples



Two typical tension-compression mixed examples, obtained using the approach explained in Section 5 were also studied. The results are shown in Figures 8 and 9. Unlike the previous examples, Eq. (11) must be ensured by activating an inequality term. The actual inequality we used was $0.23p^2 \geq \det(\nabla^2\varphi)\det(\nabla^2 z)$ with an expectation that slightly narrower range can wipe out regions where the discriminant is not satisfied. In Figures 8–9 (a), the spots where the discriminant is violated are shown with red dots, and as shown in the figures, they disappear outside of a few isolated areas. The stress-aligned conjugate curve networks obtained using our tracing algorithm are also shown. Because the

inequality terms make the computation less efficient, we started with a smaller weight coefficient and increased it every 1000 steps. Obtain the solutions shown in figures 8 and 9 took more than 3000 steps.

(a) (b) (c)

Figure 8. (a) A stress-aligned conjugate net obtained by our algorithm, (b) a T/C shell, and (c) a stress function used to compute (b).

(a) (b) (c)

Figure 9. (a) A stress-aligned conjugate net obtained by our algorithm, (b) a T/C shell, and (c) a stress function used to compute (b).

7. Conclusions

We can solve a generalized eigenvalue problem to find a stress-aligned conjugate net. However, the generalized eigenvalue problem may not provide any solution in the regions where both surfaces give negative Gaussian curvatures. We have derived an inequality condition that ensures that the generalized eigenvalue problem provides a solution, and have extended the novel computational approach presented in [1] so that the method can simultaneously solve inequality constraints. As a result, a pair of shell and stress surfaces on which stress-aligned conjugate curves exist almost everywhere can be obtained by our proposed method, even when both surfaces give negative Gaussian curvature zones.

8. Future work

Although the form-found inequality-constrained mixed tension-compression shells of Figure 8 and Figure 9 are in equilibrium (to within 1e-4 in the L2 norm of the residual), and though they have real eigenvalues almost everywhere, the results, though correct within these limits, appear visually /

aesthetically rough. There are three potential reasons for this, all of which we intend to resolve in future work.

First, in the case of mixed tension-compression shells, the surfaces themselves can be quite complex in shape while still being in equilibrium and having real eigenvalues. This is a consequence of the much richer / more complex space of solutions available in the general mixed elliptic-parabolic-hyperbolic space of equilibrium shell shapes. Though corrugated / rippled solutions are valid from an equilibrium perspective, it is aesthetically desirable to smooth the solutions to remove ripples (while still satisfying equilibrium). Smoothed surface solutions will also naturally have less topologically and geometrically complicated stress- and flat-panel-aligned curve networks. Therefore, adding smoothing / filtering terms to the form-finding method of [1] is a key topic for future work.

Second, as noted in section 5.1, the penalty method used to enforce the inequality constraint (11) in the form-found shell results can lead to loss of accuracy. This numerical error may be partly responsible for the ripples of the solutions, in addition to the physical complexity of the solution space itself. Consequently, we plan on moving to more accurate inequality constraint enforcement technique in future work, such as the augmented Lagrangian method.

Finally, we note that the BTLS numerical solution method used in [1] and in this paper may have reached its limits when used to enforce the constraint (11). Specifically, the BTLS method is designed around bilinear problems specifically, while the constraint (11) is not bilinear. Although the results in this paper nonetheless achieve a sufficient level of accuracy for initial shape exploration and form-finding, higher accuracy may not be achievable without moving to a more general nonlinear equation-solving method.

Abstract

The Central Station Metro Works will deliver the most significant upgrades to Central Railway Station in decades, comprising an integral part of the NSW Government's Sydney Metro City & Southwest project. As the only underground station to be erected integrally within a live station environment, prioritisation of 'design for manufacture and assembly' (herein DfMA) and heritage interfaces, whilst minimising disruption to 270,000 daily commuters (pre-COVID), were the fundamental design drivers. This paper focuses on the heritage enhancement and DfMA approach championed in delivering the Grand & Northern Concourse Intercity cantilever slab and centrepiece canopy roof. The Intercity cantilever slab serves as a surface-level confluence point linking the new metro to suburban and Intercity platforms. The statement ~10-metre exposed-concrete cantilever features an organic double-curvature form and optimised reinforcement arrangement amidst a latticework of building services. Oversailing the Intercity cantilever slab and tracing the sandstone façade line of the heritage Sydney Terminal Building is the centrepiece canopy roof. The design of the steel-framed 40-metre-spanning propped cantilever was modularised, prefabricated, and preassembled, including services, fixtures, and finishes. This paper explores how a DfMA and user-centric approach to structural design and construction made viable 'open-heart surgery' within Australia's busiest railway interchange.

Keywords: case study, modular, preassembled, DfMA, sustainability, heritage, metro, railway, steel spatial structure

1. Introduction

1.1. Project scope

Sydney Metro is Australia's biggest rail infrastructure investment and will revolutionise the way our community navigates the city. By 2030, Sydney will have four metro lines, with forty-six stations and 113 kilometres of standalone metro rail. Sydney Metro City & Southwest will extend the Metro Northwest Line from the northern suburb of Chatswood to Bankstown in the city's south-west.

As part of the Central Station Metro Works (herein CSM), Laing O'Rourke, with its design and architecture partners, will deliver the most significant upgrades to Central Station in decades, comprising of an integral part of the NSW Government's Sydney Metro City & Southwest project. As the only underground metro station to be erected integrally within a live station environment, maintaining the operability of the railway interchange, and minimising disruption to commuters, was paramount. The scope of structural works includes the excavation and construction of the Sydney Metro platforms beneath existing platforms 13, 14, and 15 [1 & 4], the new 19-metre wide Central Walk concourse from a new entrance on Chalmers Street [3], escalators directly to suburban platforms 16 – 23, and a revitalisation of the Grand and Northern Concourse (herein GNC) entrance on Eddy Avenue [2]. paper focuses on the heritage enhancement and DfMA approach championed in delivering the GNC Intercity cantilever slab and centrepiece canopy roof.

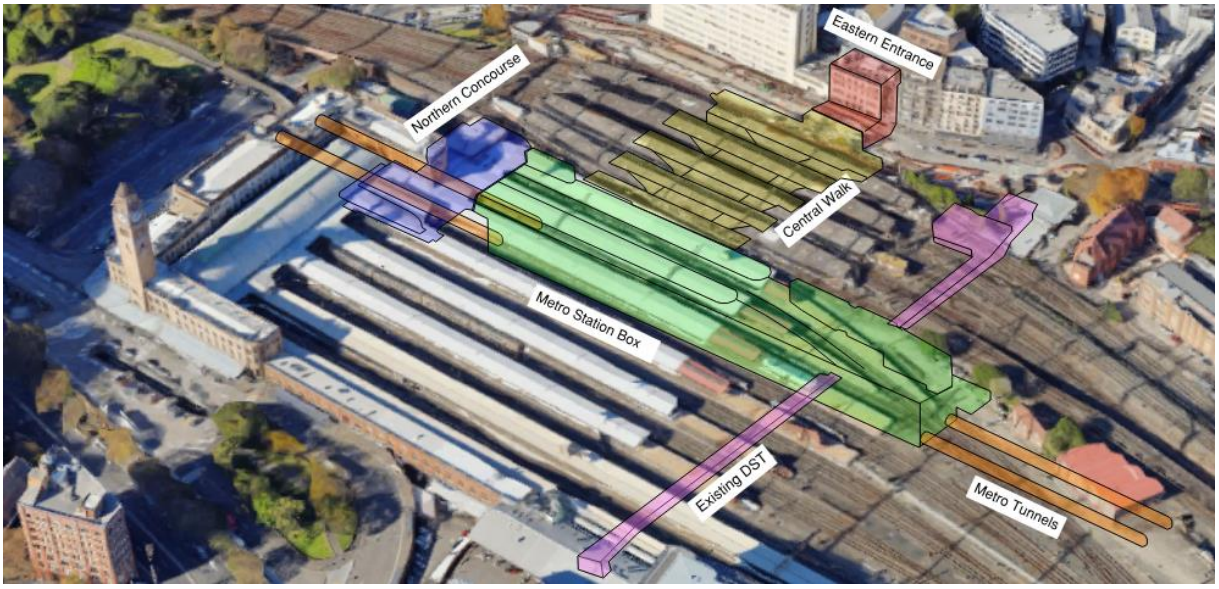

Figure 1. Project Scope, Annotated Aerial Site Photograph.

1.2. Heritage and site-specific constraints

The Central Station railway site is a state landmark, containing the original Sydney Railway Company grant, on which the first station and yards were opened in 1855. The heritage significance of the site, coupled with its complicated history of seemingly ad hoc developments and constrained inner-city location, demanded a sensitive and cross-disciplinary design approach. Furthermore, as a major infrastructure development, the project required a 120-year design life.

The GNC faced numerous constraints that required careful consideration in its design and construction. The most significant constraint was that the GNC needed to be constructed whilst the primary access to seven railway platforms remained operational. Furthermore, the GNC is situated over one of the most highly utilised commuter pathways within Australia's busiest railway station. It was not possible to have full public closure of the area during normal operation of the station for construction without any adverse impact to commuters. Therefore, designing for staged construction, speed of assembly, minimal temporary works and 'just-in-time' delivery was paramount.

The GNC is nestled between multiple new and heritage structures on all sides, each requiring careful consideration to ensure a seamless interface was achieved. It was essential to align the in-situ tree-head columns, precast colonnade, and, consequently, the primary canopy rafters with the existing and new Intercity and suburban platforms. The design also needed to facilitate an important view to the historic Central Station Clock Tower, which holds significant cultural and architectural value and was not previously visible from within this space.

Ensuring the safety of commuters and workers during the construction phase was a critical priority. In order to minimise disruption to the 270,000 daily commuters, the station needed to be handed over in a safe and secure condition after each night or weekend possession, ready for the daily influx of commuters. The workers had to navigate complex construction and installation tasks while adhering to strict safety protocols amidst time pressures and, at times, in conditions of high wind, rain, darkness, and extremes in temperature. Unlike construction within a vacant site, the weekend possessions and night works required considerable planning and the team needed to adapt to the changing conditions.

Managing tolerances in a precast, modular, or pre-assembled system is a meticulous task, particularly when it interfaces with in-situ concrete construction. On one hand, construction tolerances must be considered to enable site flexibility, while on the other hand, they must ensure the correct alignment and erection of the structure within acceptable tolerances. This balancing act demands accurate planning, precision in execution, and a comprehensive understanding of the construction process to avoid the need for major corrections and to ensure a successful outcome.

Considering its location and function, the structural elements of the GNC were required to withstand potential blast or train derailment loads. This constraint necessitated the careful consideration of various factors during the design process, such as the incorporation of redundant or stiffer elements, alternate structural load paths, and redistribution of loads post-yielding in these extreme scenarios. The challenge was to develop a design that not only met the functional requirements but also ensure a high level of safety and resilience for both the commuters and the surrounding infrastructure.

The steel canopy structure needed to be designed for disassembly and future extendibility, allowing for potential modifications or expansions in the future, embracing circular economy principles and reducing the risk of a premature end-of-life scenario. The constrained working area for pre-assembly of formwork or modules was another challenge, with the only available space being over the construction of the metro station box – a logistically complex area. Access to the site was limited to the Sydney Yard Access Bridge, which imposed spatial and weight constraints on the transportation of materials and equipment, necessitating careful planning, coordination, and, where possible, 'just-in-time' delivery to avoid any complications during the construction process.

1.3. Nature of the design

At the north entrance to Australia's busiest active railway interchange is the Northern Concourse, a new urban room positioned immediately to the south of Vernon's Grand Concourse. The Northern Concourse provides access between Eddy Plaza, the existing Intercity platforms, and the new metro platforms.

The scope of the works to the Northern Concourse includes the following;

- A new steel canopy roof, with glass walls enclosing the room,
- A new precast column colonnade at the intercity platform level to support the canopy,
- A new suspended concourse comprised of in-situ concrete at intercity platform level,
- A refurbished concourse at street level, which is largely supported on ground, and
- Associated sub-floor structures, retaining walls, and foundations.

Figure 2. Grand & Northern Concourse, Architectural Sectional Render.

Prioritisation of 'design for manufacture and assembly,' through modularity, was at the heart of the team's approach to delivering the complex structural designs and staging for the steel canopy roof, precast colonnade, and in-situ concrete Intercity concourse.

2. Intercity cantilever & tree-head columns

The statement ~10-metre, exposed-concrete cantilever at Intercity platform level features an organic double-curvature form and optimised reinforcement arrangement amidst a latticework of building services. The structural design team collaborated closely with the architectural and building services consultants to rationalise the organic form, minimising the extent of double-curvature geometries, which accommodated simpler modular reinforcement and formwork arrangements. This modular approach was further implemented in the rationalisation of the post-tensioning arrangement amidst a latticework of service pits and cast-in conduits. The cantilever formwork was comprised of plywood contours digitally fabricated using a Computer Numerically Controlled (CNC) router, while bespoke fibreglass moulds were fabricated to achieve the 'tree-head' form of the underlying supporting columns.

2.1. Modularisation of an organic architectural vision

The architectural vision for the Grand and Northern Concourse was to establish a world class entrance to the new metro station as an iconic urban room, which serves as a confluence point linking the new metro to suburban and Intercity platforms. The reference design for the Intercity cantilever, as shown on the left in Figure 3, met the functional requirement to improve pedestrian connections through the introduction of an Intercity level concourse. However, this design limited the aspirational performance of the lower concourse level as it obscured visibility of the canopy roof, restricted natural lighting, and introduced an underlying column grid that complicated wayfinding. The winning tender design proposed a cantilevered Intercity concourse, which achieved a column-free lower concourse level flooded with natural lighting. The monolithic cantilever is comprised of exposed concrete formed in an organic, curvilinear geometry and is supported on underlying 'tree-head' columns, so called due to the truncated conical form of their capital.

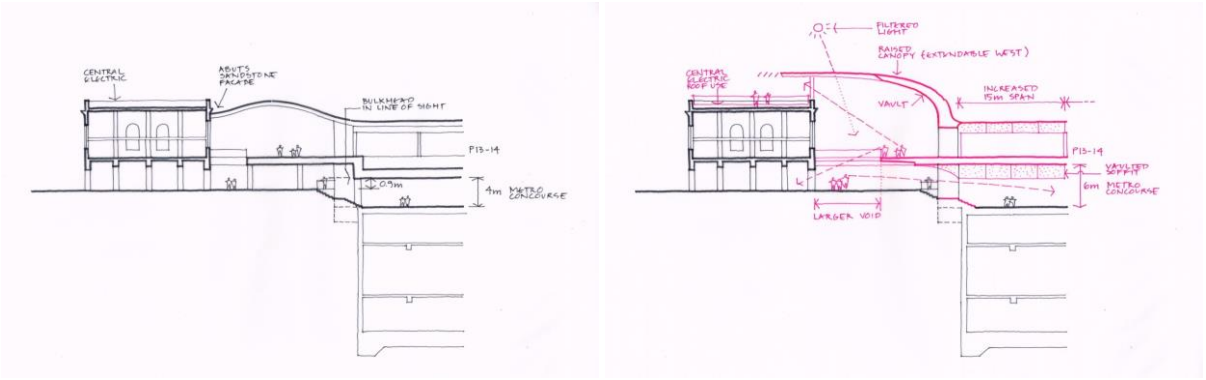

Figure 3. (Left) Reference Design Scheme and (Right) Winning Tender Design in Section.

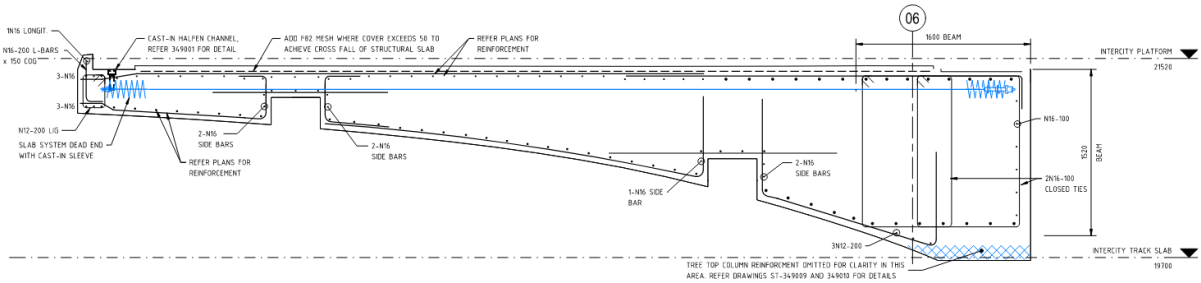

Figure 4. Typical Intercity Cantilever Profile in Section.

Early architectural designs of the statement cantilever were of highly multifarious geometries, with double-curvature forms generated extensively throughout the Intercity level. This variable geometry was highly impractical for structural design, fabrication, and construction. The structural design team

collaborated closely with the architectural consultants to rationalise the organic form, minimising the extent of double-curvature geometries to achieve the single curvature profile as denoted in Figure 4.

2.2. Description of the structural design

The cantilevered balcony protrudes approximately ten metres beyond the underlying tree-head columns and extends approximately 35 m along its leading edge in the east-west direction. The cantilever is supported by a 1230 mm deep beam running along the southern perimeter of the urban room and by two 2350 mm deep track edges beams running along gridlines G and J either side of the lift voids for north-south gridline locations). The cantilever is ultimately supported by two tree-head columns, located at gridlines G and J, and by the eastern and western curvilinear retaining walls.

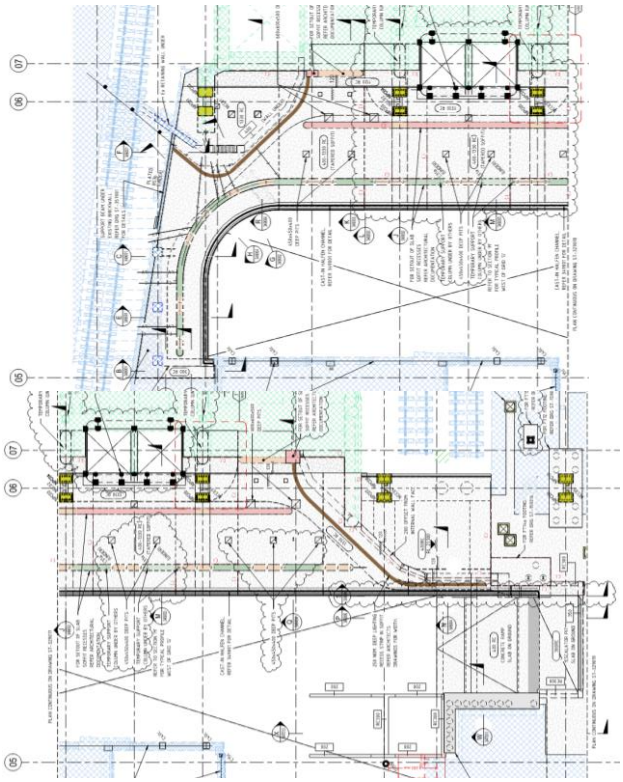

Figure 5. (Left) Eastern and (Right) Western Intercity Cantilever in Plan.

At gridlines G and J, the canopy colonnade is offset northward of the underlying tree-head columns by approximately 1.2 metres. This required a transfer structure, which was achieved by extending the track edge beams below the canopy colonnade in a tapered manner in alignment with the architectural intent.

The track edge beams were post-tensioned using multistrand tendons, which extend to a construction joint located approximately 2,000 mm south of the cantilever's leading edge. The cantilever was post-tensioned using monostrand 'flat duct' tendons, which generally extend between the cantilever's leading edge and the metro station box located to the south of gridline 7. Post-tensioning tendons have been arranged to minimise the differential displacements along the exposed perimeter of the cantilever by locally permitting and restricting deflection. Post-tensioning anchorages were concealed under the finishes using shallow pans to achieve the mass concrete architectural vision. Tendons have been extended into the platform level slab, where appropriate.

The Intercity cantilever has been modelled and analysed using finite element plate analysis in the CSi Bentley SAFE and Strand7 software packages. Linear, non-linear, and transient dynamic analyses were undertaken to assess performance against short and long-term functional criteria and construction staging requirements. Displacement studies have been carried out to consider the sensitivity of the

structural configuration to the placement of post-tensioning tendons, rotational stiffness of supporting columns and walls, geotechnical springs, and variability in material properties, such as creep and Young's modulus, in order to achieve an imperceptible leading-edge displacement. Furthermore, the design observed the prescriptive post-disaster recovery and protective design performance criteria, including consideration of alternate load paths and load redistribution in post-yielding scenarios.

2.3. Buildings services interfaces

Further to the organic architectural geometries, the design was complicated through the introduction of a series of recesses in the curved soffit, which would house lighting, electrical, and fire protection services. Services reticulations made in the cantilever soffit to accommodate sprinklers, lighting, and communications (PA) are located in two slots running parallel to the cantilevered edge. These lighting slots are visible within Figure 4 as the two recesses in the cantilever soffit. The slot nearest the leading edge is alternately 30 mm and 250 mm deep, with the key structural strength aligning with the shallow recess. The southern slot is consistently 250 mm. To accommodate the maintenance replacement strategy for the sprinkler pipes, concrete-encased pipes were placed inside conduits with clearances safeguarded to ensure straight lengths of pipe could be fed through. Along the southern edge, lighting and communications conduits are fed through the cantilever via services pits located at regular intervals throughout the cantilevered slab, which are 600 mm long x 600 mm wide, and extend to a depth of 500 mm below the top of the slab. The structural design team collaborated closely with the services consultants to design a modularised recess and pit arrangement to simplify conventional reinforcement and post-tensioning layouts, whereby post-tensioning ducts were 'bundled' either side of pits. The cross-disciplinary approach to design and prioritisation of stakeholder requirements balanced the technical design criteria and constructability constraints without compromising the architectural vision.

2.4. Temporary works & construction staging

2.4.1. Formwork & bespoke moulds for double curvature zones

While the geometry of the Intercity cantilever was rationalised to achieve a single-curvature profile, the tree-head columns and change in cantilever spanning direction required localised double-curvature forms. The cantilever is comprised of architecturally exposed concrete with a required formwork class of 2CX. Digital fabrication enabled construction of the bespoke geometries in alignment with the architectural vision.

At the eastern end of the Intercity level, the cantilever spanning direction changes from north-south to east-west as it wraps around the perimeter of the void. This creates a zone of double curvature where the single curvature profile of the cantilever in section wrapped around the circumference of the void in plan. The formwork in this zone was comprised of plywood contours digitally fabricated using a Computer Numerically Controlled (CNC) router, as shown in Figure 6. Each formwork component was physically numbered within the desired form for easy identification on site. The Intercity cantilever formwork was supported on a temporary flat deck.

Figure 6. Intercity Cantilever (Left) Double Curvature Formwork by Peri Formwork and (Right) Reinforcement.

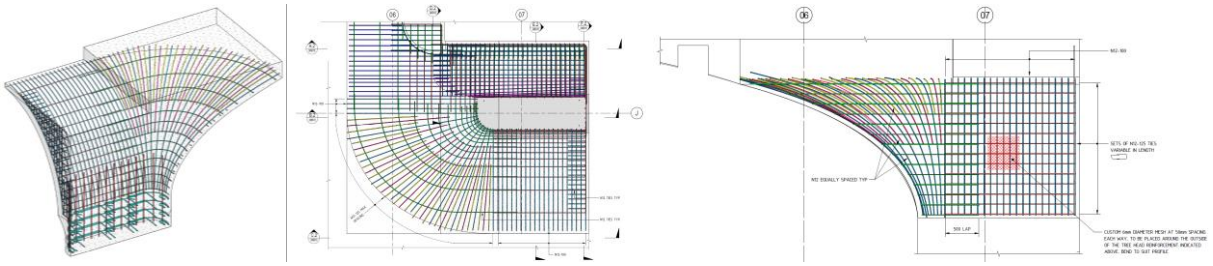

Figure 7. Tree-Head Column Reinforcement (Left) Isometric, (Middle) Plan, and (Right) Section.

For the underlying supporting columns, bespoke fibreglass moulds were fabricated to achieve the 'tree-head' form, as shown in Figure 8. The reinforcement latticework utilised easily workable 12 mm diameter low density grade D250N reinforcement to achieve the required forms, as shown in Figure 7.

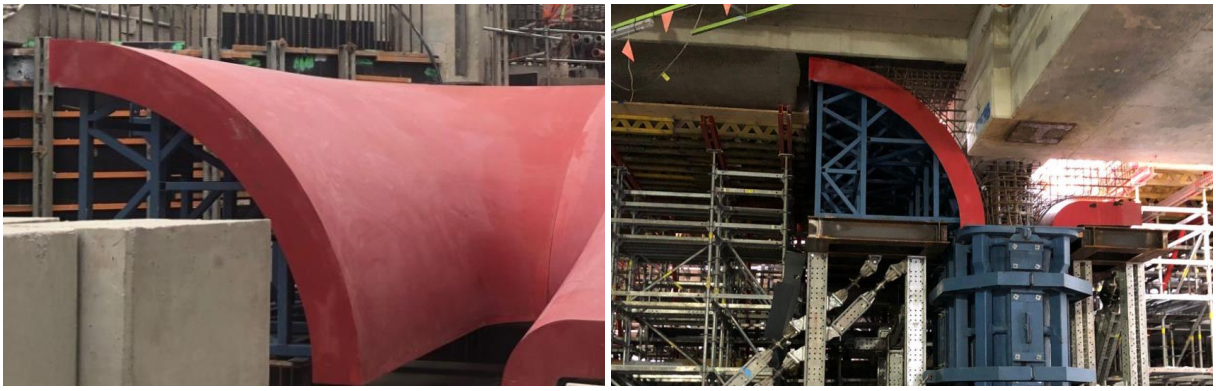

Figure 8. Tree-Head Column (Left) Moulds by Shapeshift and (Right) Temporary Works by Peri Formwork.

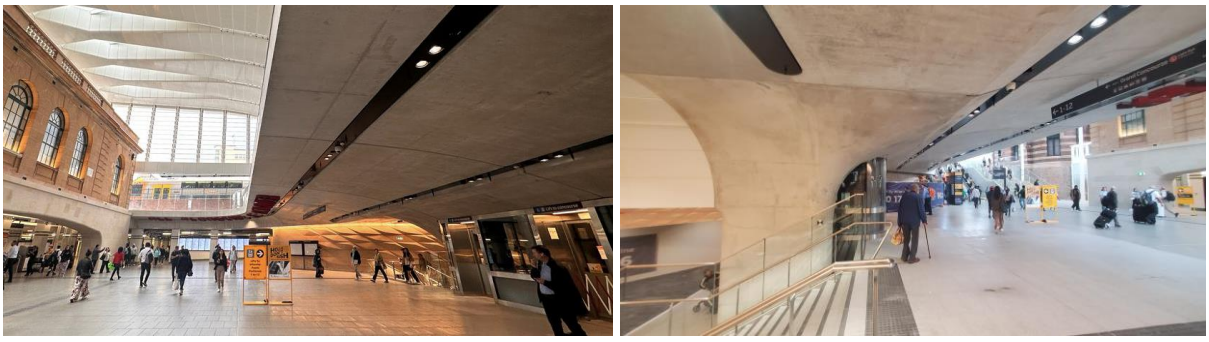
2.4.2. Construction staging within a live station environment

The station was to remain operational throughout construction, which required the Intercity cantilever to be designed to be poured in eleven discrete stages. This was largely driven by access requirements for stressing cables and staging regarding demolition of the existing lift and reinstation of the new lift. The staged construction of the Intercity cantilever took place over a period of over twelve months. In order to achieve a consistent colour across the multiple pours, the aggregate required for all pours was stored in the batching factory throughout the construction period.

2.4.2. As-built structural condition

The as-built condition of the Intercity cantilever structure is depicted in Figure 9, in which the cantilever soffit is viewed from street level looking towards the east in the left image and west in the right image.



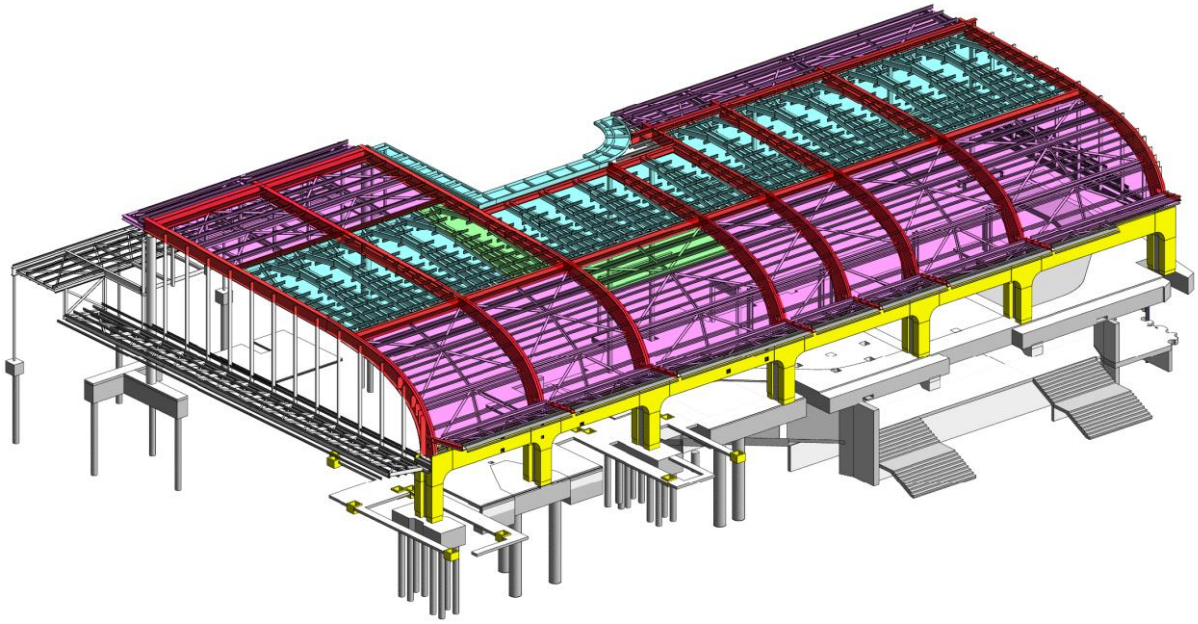


Figure 9. Intercity Cantilever Soffit (Left) Leading Edge and (Right) Tree-Head Columns.

3. Steel canopy roof

The northern concourse canopy roof is approximately 40 metres wide, 80 metres long, and 16 metres high. The propped cantilever steel structure features a curved aluminium outer cladding and 21 large kite-shaped skylights, which admit daylight into the new concourse, helping to create a clear, orienting space adjoining disparate parts of the station. The ceiling is a curved and discretised 30% porous aluminium cladding. The canopy consists of a primary frame of open section curved rafters and circular hollow section (CHS) columns. The secondary structure was modularised into fifty-eight preassembled and fully fitted out modules with all services and most of the soffit cladding installed off-site, weighing up to 9.2 tonnes. The structural system was optimised for speed in on-site assembly and was erected within a live station environment that remained functional during all stages of erection.

The roof is supported on its southern edge by a reinforced precast concrete colonnade sway frame above the platform level. The north edge is supported on tall, slender steel CHS columns. A portion of the canopy is supported by a steel transfer structure atop the heritage Central Electric Building. This transfer structure ensured that any loads from the canopy were able to be accommodated by the existing structure without the need for strengthening works. The steel roof is fully braced with all lateral loads resolved at the precast colonnade sway frame on the southern edge. The colonnade provides a fixed support to the main rafters, reducing deflections and creating improved efficiency.

Red indicates primary steelwork assembled on-site during night-time possessions. **Pink**, **blue**, and **green** indicate bays preassembled off-site.

Figure 10. Northern Concourse Structure, Primary Steelwork and Preassembled Modules.

3.1 Efficient construction through prefabricated modular construction

The 330-tonne northern concourse canopy is a grand and iconic structure that needed to be almost entirely erected within a staggered four-week period. To accomplish this, the design team developed an approach focused on optimising preassembled modules for rapid assembly. Through the use of Prefabricated Prefinished Volumetric Construction (herein PPVC), the team facilitated off-site assembly of the steelwork, glazing, cladding, fixtures, and services for the for the majority of the canopy.

Each of the 58 preassemblies were designed to incorporate only four simple connections to the primary steelwork. These connections were engineered to only have between two and four bolts, significantly reducing the time required working at height with over 90% of all steel connections undertaken off-site. This design consideration not only heightened the safety of the construction personnel but also

accelerated the erection process, ensuring minimal disruption to the station's daily operations. The prefabricated canopy roof was designed with an emphasis on disassembly and future extendibility, a forward-thinking approach that aligns with circular economy principles. The potential of this approach is evidenced in the full scale off-site pre-erection in *Figure 13*. The design and detailing of the canopy structure ensured it could be modified or expanded as needed in the future, ensuring its adaptability to changing requirements and conditions. By incorporating these concepts, the project team mitigated the risk of premature end-of-life scenarios and contributed to a more sustainable construction process. This is particularly critical for a canopy roof that is designed for an extensive 120-year design life.

Each component of the structure, including the preassembled modules had to be stable individually during lifting and after installation in their partly erected state. This was crucial as the station needed to be handed over in a safe and secure condition after each night or weekend possession, ready for the daily influx of commuters. This was achieved through designing bracing for each pre-assembled bay, which formed part of the global bracing solution when all the panels were installed but also provided stability during lifting. This was particularly critical for the large and delicate 14-metre-long, 2.5-metre-wide skylight modules, which had the glazing installed prior to lifting. A design approach was undertaken to improve the strength of the primary framing to reduce the amount of temporary works required and to ensure the part-erected structures were stable. Each of the fully modularised and pre-assembled steel framed panels required additional edge members, bracing, and strengthening of the primary structure, but enabled stable liftable pre-assembled modules, weighing up to 9.2 tonnes, that could be installed in under one hour on-site.

By adopting PPVC and off-site assembly, this project facilitated rapid on-site erection during the three weekend possessions of 48-hour periods available and the short night work sessions of 3-hour periods. During these times, the contractor, Laing O'Rourke and fabricator, Alfabs, had access to the required work areas while ensuring safe passage for commuters through alternative routes. This approach demonstrates the potential of integrating design and fabrication to overcome complex constraints in large-scale infrastructure projects.

Prior to Installation – January 2020 **Erection** – 5 September 2020 **Erection** – 12 September 2020

Figure 11. Aerial Photos Illustrating the Rapid On-site Erection of Northern Concourse Canopy.

In total, the northern concourse canopy was largely erected in just 250 hours of construction time on-site and has now become a world class ‘front door’ to the new metro station.

3.2 Creating a visually uniform appearance with a constrained primary structure

Through computational design techniques, the structural design and installation solution achieved regularly spaced skylights and a monolithic soffit appearance despite the irregular spacing of existing structures and, hence, the primary structure, which was typically spaced between 10 and 13 metres.

Figure 12. (Left) Preassembled Skylight Module, (Middle) Photograph of Canopy, (Right) Clock Tower.

The design process optimised several parameters, including the skylight width, the total number of skylights, the spacing between each glazed panel, and the distances between each secondary steel structure, all while striving to attain the largest possible skylight area. By determining the optimal combination of these parameters, it was possible to create twenty-one standard preassembled skylight modules with consistent spacing, resulting in a visually cohesive and harmonious architectural form for the skylights and soffits. The Rectangular Hollow Section (herein RHS) mullions and glazed louvers also frame an important view to the historic Central Station Clock Tower, which holds significant cultural and architectural value.

3.3 Balancing site flexibility and precise site assembly

Striking the right balance between installation, preassembly and fabrication tolerances was a critical aspect of designing and detailing the canopy structure. Insufficient tolerances could lead to challenges in installing the structure without locking in forces or displacements, while excessive tolerances might result in components shifting and moving during installation, making it difficult to accurately position the steelwork and potentially leading to delays and disruption associated with re-alignment or future modules potentially not ‘fitting’.

The primary structure, standing approximately sixteen meters above the ground, was considerably flexible. This characteristic enabled many of the modules to forego slotted connections or packing, which could otherwise have increased the risk of installing the steelwork out of tolerance. Therefore, in many instances the decision was made that the tolerances of standard bolt holes of simple connections would be sufficient and preferable for maintaining the required balance. For rigid connections where the structure was less flexible, slotted or oversized holes were introduced to provide an installation position tolerance of approximately ±15 mm. This strategy was put to the test during the pre-erection stage when the entire roof was assembled at the Alfabs Group workshop in Kurri Kurri (refer Figure 13 below). The pre-erection process served as a crucial validation of the design and detailing approach, confirming that the canopy could be successfully installed on-site within a staggered four-week period while maintaining the desired balance between tolerances.

Figure 13. Canopy Full Scale Pre-Erection at Alfabs Group's Workshop.

4. Precast concrete colonnade

The exposed precast colonnade supports the northern concourse canopy structure and the terminating overhead wires of the trains. Its alignment follows the existing platforms with columns at irregular spacings of up to thirteen metres and is approximately 80 metres in length and 5.4 metres in height. The colonnade also accommodates two full cable trays of services from the roof through to the Intercity cantilever slab and incorporates integral wayfinding signage. The columns provide a rigid support to the primary beams of the northern concourse canopy. They are a highly expressed, class 2CX concrete arch portal, which emulates some of the curves that are expressed throughout the historic station.

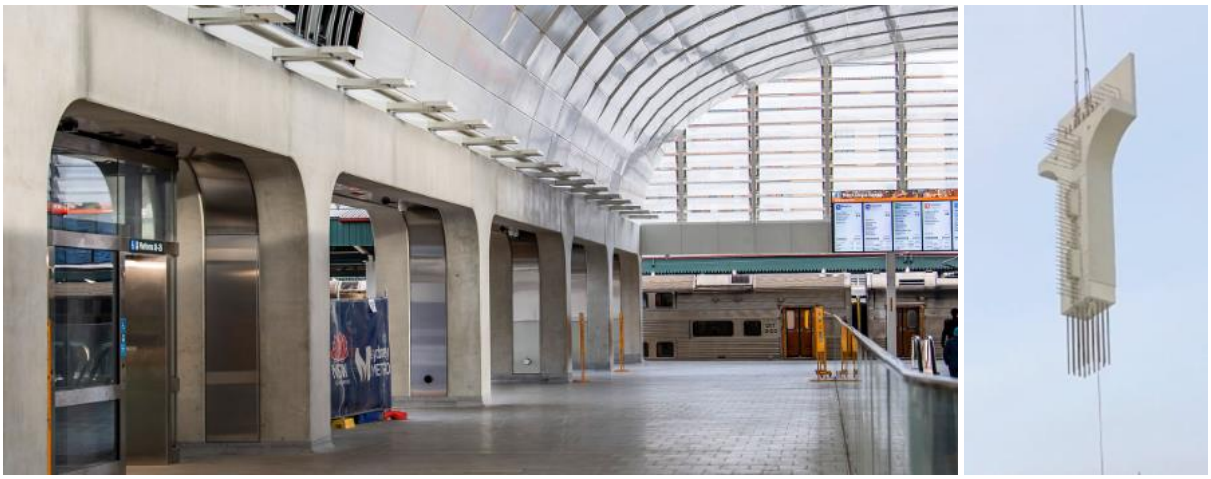

Figure 14. Precast Colonnade, (Left) Photo from East End of Intercity Cantilever Slab and (Right) Column Lift.

The precast colonnade was constructed within a staggered 32-hour period with minimal formwork and temporary works to ensure the station remained functional throughout construction. It also required sufficient tolerances between all precast elements and stitched steel reinforcement for rigid connections into the Intercity cantilever slab, under and between each segment. The discretisation of the precast elements was specifically designed for transportation and crane lifting limitations. The design effectively addressed crane and transport restrictions while achieving the goal of constructing the colonnade in just a few days, without reliance on temporary works beyond those required for positioning. Corrugated steel ducts were employed for reinforcement continuity, tolerance, and anchorage in both precast-to-precast connections and precast-to-in-situ footing connections. The structure was discretised and detailed such that there was a seating for each and every precast element and that it would be stable in the temporary state prior to the in-situ stitch pours. The in-situ pour of the beams were formed using 30 mm thick glass reinforced concrete (GRC), which could span prop-free and achieve the required 120-year design life. These in-situ concrete pours provided the necessary continuity for the structure to

behave monolithically, ultimately delivering an efficient and rapid construction solution for the precast colonnade with minimal disruption to the station's operation.

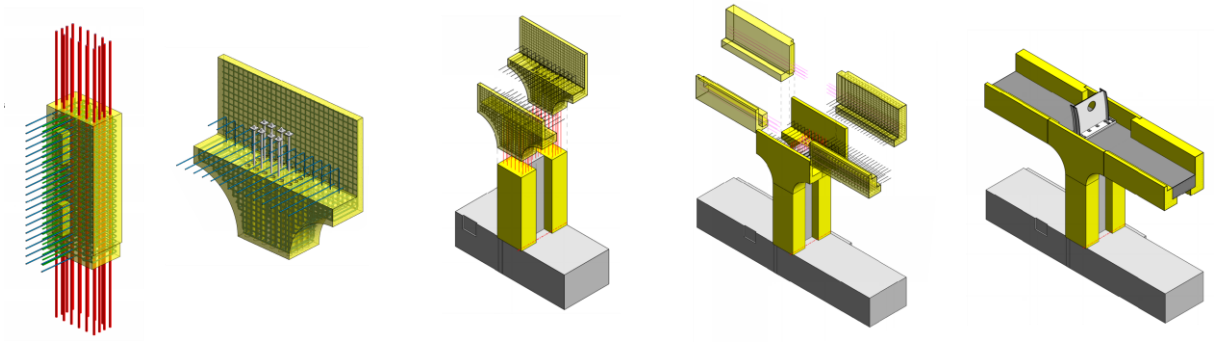

Figure 15. Installation Sequence of the Precast Colonnade.

5. Conclusion

As part of Central Station Metro Works, Laing O'Rourke, with its design and architecture partners, will deliver the most significant upgrades to Central Station in decades, comprising an integral part of the NSW Government's Sydney Metro City & Southwest project. The new Intercity cantilever slab serves as a surface-level confluence point linking the new metro to suburban and Intercity platforms. The statement ~10-metre exposed-concrete cantilever features an organic double-curvature form and optimised reinforcement arrangement amidst a latticework of building services. The cantilever formwork comprises plywood contours digitally fabricated using a Computer Numerically Controlled (CNC) router, while bespoke fibreglass moulds were fabricated to achieve the 'tree-head' form of the underlying supporting columns. Oversailing the Intercity cantilever slab and tracing the sandstone façade line of the heritage Sydney Terminal Building is the centrepiece canopy roof. The prefabricated, steel-framed propped cantilever spans 40-metres from precast colonnades towards the newly underpinned Central Electric Building. The DfMA approach and minimisation of on-site works ensured that Central's busiest commuter railway remained functional throughout the weekend possessions allotted to erection of the canopy and colonnade structures. These works have been likened to 'open-heart surgery' within Australia's busiest railway interchange.

Central Walk and the new escalators from platforms 16 – 23 opened in April 2023 with the new metro platforms becoming operational once Sydney Metro City & Southwest services commence in 2024.

Acknowledgements

The authors wish to make acknowledgement of Sydney Metro and Transport for New South Wales for undertaking Australia's largest public transport project, of which Central Station Metro Works forms an

integral part. Together with principal contractor, Laing O'Rourke, and ultimate client, Sydney Metro, Aurecon delivered the detailed design for the new and upgraded rail infrastructure comprising the Central Station Metro Works, in partnership with GHD and Atkins. In particular, the authors wish to thank Laing O'Rourke's Aston Williams, Channari Penh, Edward Labinski, Huw Griffiths, Lachlan McMaster, and Martin Bibb for their support and expertise during the design and construction phases of the project. Woods Bagot, John McAslan + Partners, and GHD delivered the architectural design.

Abstract

Awareness in the preservation and conservation of 20th Century architectural heritage in Mexico and particularly that of historic concrete shells have increased in the last decades. In a paper presented and published in the IASS2022 [1] the authors of this paper identified the main preservation challenges and opportunities that such heritage assets face locally and globally within the contexts of cultural heritage, circular economy, sustainability, and climate change. Building upon these findings, this paper will focus on the technology advancements related to digital tools and Non-Destructive Testing (NDT) and their potential to complement traditional methods in the assessment, documentation, and intervention of heritage buildings. To exemplify this, two research studies investigating different methodologies to evaluate the quality of reinforced concrete will be presented in this paper. These studies aimed to explore and advance the use of digital technology and NDT to assess the current state of the iconic Cosmic Rays Pavilion shell built by the architect Félix Candela in 1951. The Cosmic Rays Pavilion holds a significant architectural heritage value as it represents Candela's step-in stone to further develop some of the most ingenious and elegant 20th Century hypar shells worldwide and it is also part of the UNESCO heritage site of Ciudad Universitaria in Mexico City. The first study, a digital documentation workflow, was caried out by Sepideh Rajabzadeh from Carleton Immersive Media Studio (CIMS) and Mariana Esponda from Azrieli School of Architecture, Carleton Canada in 2019. This study was carried out to explore the use of emerging digital technologies to document and analyse if the Cosmic Rays Pavilion shell had suffered any damages after the 2017 earthquake. The second case study, conducted in 2022 by Dr. Alberto Muciño and Dr. Alejandro Leal, researchers at the Faculty of Architecture at Universidad Nacional Autónoma de México used NDT (ultrasonic pulse velocity (UPV) and sclerometer test) to assess the current condition of the shell's concrete. Both studies were also supported by traditional survey tools and methods. The analysis of these two studies will discuss the potential of using emerging digital and other NDT technologies as complementary tools to support a more efficient and sustainable preservation of 20th Century historic concrete shells.

Keywords: Félix Candela, historic concrete shells, preservation, conservation, sustainability, circular economy, digital technology, non-destructive testing

1. Introduction

During the mid-half of the 20th Century fast and significant developments in science and technology supported digital advancements such as digital media (software, digital images, digital video, digital data and database and electronic documents) which use has gradually grown for heritage buildings surveying and 3D modelling, thus resulting in new research methods and protocols. Since the 1970s

disciplines like archaeology started exploring the use of laser scanning, photogrammetry, advanced software for modelling, data analysis and computer-based visualization which is now recognised as an effective research method to assess heritage assets [2]. At the outset digital technologies were promoted as economic and time saving tools, recently they have also been identified as enablers of sustainability as they can reduce the use of materials, natural resources, and energy. As stated by the Unite Nations, digital advancement can support and accelerate achievement of each of the 17 Sustainable Development Goals [3]. However, the challenge in the field of heritage preservation remains in producing bespoke research methods and protocols adequate for each socio-cultural, economic, and geographic context. Furthermore, the use of digital technologies promotes circular economy in the field of built-heritage preservation in how we assess, document, and promote value in collaboration with stakeholders and the wider community. Digital technologies can also support to maintain and increase the functional, economic, and socio-cultural value of built-heritage assets for as long as possible. Heritage-built assets should be maintained and managed to support their reuse, re-adaptation and recycle, assisted using available digital technology.

Scientific and technological advancements have also supported the development of the Non-destructive evaluation (NDE) or Non-destructive tests (NDT) which are used to inspect, evaluate, or test constructive systems and materials' irregularities without causing damages or alterations to the serviceability of the analyzed structures [4]. The purpose of NDT is to assess the quality and integrity of structures' materials or assemblies without compromising their intended structural and functional performance. However, it is important to mention that some non-destructive testing methods can include invasive actions on the structure.

Whilst NDT methods have emerged as a response to detect and prevent structural damage and have been mainly driven by economics and safety, they also present circular economy advantages and they can be enablers of sustainability. As stated in the 'Guide to sustainability criteria in the conservation and restoration of immovable cultural heritage' [5] the use of NDTs can support saving materials resources by developing primary physical and/or mechanical properties analysis of structural components which can facilitate a minimal intervention in the cultural asset with the use of minimal resources. Furthermore, non-invasive NDTs can safeguard the structural integrity of the cultural asset during testing thus extending its value and serviceability. Some of the most common NDTs are sonic, ultrasonic, georadar, dynamic, sclerometers, thermography, etc. Some of the semi-destructive tests are the carried out by means of penetrometers, resistographs, flat jack tests, etc.

The methodology of NDTs for historic concrete shells is complex as it requires a multidisciplinary approach. As stated by Shull [6], a successful NDT must start with a good idea of what is that intended to be found which requires a conscientious knowledge of the geometry and construction methos of reinforced concrete shells as well as the physical and mechanical properties of reinforced concrete. A basic knowledge of how the various NDT methods work is essential to choose a method or a combination of methods. Furthermore, competent knowledge of the use, advantages, and limitations of the existing technology and for the particular case of reinforced concrete shells and their context is important 'we must be aware of the actual sensitivity of the equipment relative to the environment in which it is used' [7]. Also, competent knowledge of regulations and guidelines for the assessment and intervention of historic buildings for a specific context is required. It is important to mention that some of the most common non-destructive testing methods include invasive actions, which for the specific characteristics of thin shell reinforced concrete structures may not be the most appropriate. Shull [8], lists five levels to choosing an appropriate NDT method for a specific application:

1.- Understanding the physical nature of the material property or discontinuity to be inspected.

2.- Understanding the underlying physical process that govern NDT methods

3. Understanding the physical nature of the interaction of the probing field (or material) with the test material

4.- Understanding the potential and limitations of available technology

5. Considering economic, environmental, regulatory, and other factors.

To maximize the effectiveness of any NDT methods, it is paramount to have a good knowledge of the materials' properties and any potential issues/anomalies we are looking for such as voids, cracks, delamination, coating thickness, etc.

Through the application of NDTs it is possible to minimize the uncertainty of conventional primary assessments which by and large tend to result in unnecessary invasive interventions to heritage buildings. Furthermore, the non-destructive and non-invasive characteristic of some NDTs can safeguard the structural integrity and functionality of the cultural asset. As stated by Damazo [9] the use of NDTs can support a more effective decision-making process regarding the reuse, repair, repurpose or demolition and recycling of existing concrete structures. Furthermore, NDTs can be used prior to minimise the impact of any required destructive testing thus complementing it and making it more effective. Some of these destructive testing techniques include carbonation analysis, petrographic analysis, compression test, adhesion of the surface layers of the concrete (pull-of), moisture and density concrete test and coring [10]. The various efforts and interest of the international community of conservation experts to promote the implementation and application of NDT to concrete heritage are evident in the publications of the Getty Conservation Institute: *Conservation Principles for Concrete of Cultural Significance published in 2021* [11] and the Cadiz Document: *InnovaConcrete Guidelines for Conservation of Concrete Heritage,* ICOMOS published in 2021 [12]. It is also important to note that assessment of concrete structures through digital technology and NDTs are not substitute of traditional field research but are complementary.

2. Digital documentation and NDT of the Cosmic Rays Pavilion

2.1. The Cosmic Rays Pavilion, 20th century historic concrete shell

The Cosmic Rays Pavilion, located on the north-east of Ciudad Universitaria's campus in México City belongs to the complex of buildings that made up the original architectural scheme of Ciudad Universitaria built from 1950 to 1954, and listed as a UNESCO World Heritage Site in 2007. The Cosmic Rays Pavilion was one of the three pavilions (Van der Graaf Pavilion and the Gravitation Pavilion) that were built to support the innovative research activities of the Institute of Nuclear Physics at Unversidad Autonoma de Mexico new campus.

In 1951 Félix Candela worked in collaboration with the architect Jorge González Reyna, chief architect for the Institute of Nuclear Physics, to design and build a thin-shell reinforced concrete structure which had to comply with a thickness specification of approximately 16mm thick [13] to allow the pass through of cosmic radiation whilst providing a robust and secure shelter for the expensive and sensitive equipment. The final constructed roof "figure 1" was comprised of two saddle-shaped shells with a thickness of 5/8" (16 mm) at the crown increasing to 1½" (37mm) at the base [14]. Since this was Candela's first commissioned hyperbolic paraboloid (hypar) shell, he took further precaution against buckling and included three supporting arches (31 centimeters deep each) concealed under the shell and spaced at 5 metres. It is worth to note that due to the innovative nature in the construction field of reinforced concrete shells at that time, it was common for shell builders to advanced their knowledge through trial and error and experimentations on site which means that in some cases the current available construction drawings do not match with the final constructed shell. This poses a particular challenge when dealing with the conservation of heritage buildings and in these cases, NDT and digital technology can be very useful to corroborate construction drawings and assess the condition of a heritage building. The archival study and survey conducted by Cordero et al [15] demonstrated that all three stiffening arches had been designed, drawn, and built of equal height without considering that the lateral arches were short of height to meet the initially designed shell. Therefore, the shell's geometry was slightly

modified on site to resolve this anomaly, thus altering the final shape of the shell and in turn not matching with the existing construction drawings.

Figure 1. Cosmic Rays Pavilion, Ciudad Universitaria Mexico. Image: M.Mendoza, 2018.

The Cosmic Rays Pavilion is recognized for its historical associations and architectural values. Félix Candela was known to be one of the most innovative architects of the 20th Century specialised in thin shell reinforced concrete structures. With the Cosmic Rays Pavilion, Candela sparked international attention at the beginning of the 1950s and paved way for his practice to be further explored. Candela´s concrete shells are an important contribution Mexican modern architecture. Candela's ingenious use of the hyperbolic paraboloid geometry allowed the development of some of the most elegant thin shell concretes structures of the 20th Century while also achieving economic and structural design efficiency. Candela's hypar thin shell structures are also exemplary as they explored the synergy between form, function, and the inherent qualities of reinforced concrete to create very thin shells (thickness of as little as 15mm) thus minimizing the use of concrete and reducing carbon footprint.

2.2. Digital documentation workflow of the Cosmic Rays Pavilion concrete shell

In May 2019 Professor Mariana Esponda from Azrieli School of Architecture organized a student internship programme which included an in-depth research study and documentation of the Cosmic Rays Pavilion after the earthquake of September 2017. In collaboration with Sepideh Rajabzadeh, student leader from Carleton Immersive Media Studio (CIMS), develop the first digital documentation workflow for Candela's Cosmic Rays Pavilion. This research project was supported by The *New Paradigm New Tools for Architectural Heritage in Canada* (NPNT) research program and funded by the Social Sciences and Humanities Research Council of Canada (SSHRC). This documentation was undertaken to better understand the pavilion's structure, its evolution, and to assess if it had suffer any damages from the 2017 earthquake.

Followed by a traditional survey, material catalogue, condition assessment, and placement of targets markers on the pavilion, the Carleton team conducted a digital documentation of the pavilion using the CIMS workflow protocol "figure 2".

Figure 2. Photogrammetry workflow in Agisoft Photosan by CIMS, 2019.

Documentation began with the capture of exterior photogrammetry images using digital single-lens reflex (DSLR) cameras. Interior photogrammetric elevation photos were subsequently taken and combined in Agisoft Photoscan to create a point cloud, and which was then processed into a point cloud model. Exterior photogrammetry was also created using photos from the DSLR cameras and a drone. This equipment allowed assisted the data collection from the shell extrados, the site, and all exterior angles. The two-point clouds were then brought into Revit and combined manually. Since the interior walls were painted plain white without any noticeable texture, the team used more than usual number of targets to increase accuracy "figure 3".

Figure 3. Student from Carleton University collecting interior photogrammetry data of the pavilion using a handheld DSLR camera. Image: M. Esponda.

To ensure data was completed and accurate before traveling back to Canada, it was important to do a quality check of the photogrammetric models, data, and elevation photos using Bentley Context Capture and Adobe Photoshop as in Rajabzadeh et al [16]. The Cosmic Rays Pavilion was modeled in Revit using the point cloud model developed from the photogrammetric data attained on site and with Professor Esponda's supervision. This detailed point cloud allowed for an extremely high level of accuracy in modeling the Heritage Building Information Model (HBIM). The 2D drawings and 3D point cloud data were carried out at the CIMS Lab, Ottawa, Canada. By creating sections through point cloud at regular intervals, building elements could be modeled and adjusted to the point cloud within millimetres of accuracy. This method of modeling was particularly useful for the unique hypar roof structure and ultimately led to further discoveries, as in Esponda *et al*. [17]. The cross-reference between the collected data and observations recorded on site during the visit allowed to gain a more in-depth understanding of the endogenous and exogenous factors that have contributed to the current damages of the shell. Furthermore, the team developed a specific 'Statement of Significance' for the Cosmic Rays Pavilion including its important relationship with Ciudad Universitaria's main campus, which is listed as a UNESCO World Heritage Site, as in Esponda *et al* [18].

The preliminary objective for the project was to produce two sets of drawings from the existing pavilion using two methods: traditional and digital documentation. The two sets of drawings were then overlaid and compared with the original construction drawings by Candela and with the survey drawings developed by Cordero. This study helped to ratify Cordero´s initial findings to demonstrate that the dimensions of the shell had been modified during construction "figure 4" Rajabzadeh [19]. This comparative analysis demonstrated that compared to traditional survey techniques the use of contemporary digital technologies can provide significant advantages such as ease of access, speed in data collection and measurements´ accuracy.

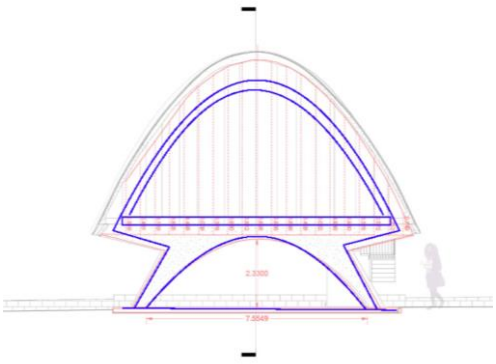

Figure 4. Comparison between 2D drawings by CIMS (grey), Cordero (red) and Candela's original construction drawing (blue). Image: S. Rajabzadeh (CIMS Lab).

Considering the three most significant earthquakes that have shook Mexico City (1985, 1999 and 2017) another aim of this research project was to identify any structural changes on the pavilion. While the team did not identify any damages to the building which could have been cause of seismic activity, the comparison between the digital model and the original construction drawings revealed that changes and deterioration observed in the building are mainly of anthropic nature as well as moisture penetration. These were identified and recorded during the site observations, including plaster stains, spalling, flacking, profile detachments, concrete spalling, and exposed rebar at the bottom of the shell's base. Corrosion of exposed reinforcement was also observed on one of the ground level arches supporting the shell and which requires prompt repair to avoid any further deterioration that may compromise the integrity of the structure, as illustrated in "figure 5" and further discussed in Esponda et al [20].

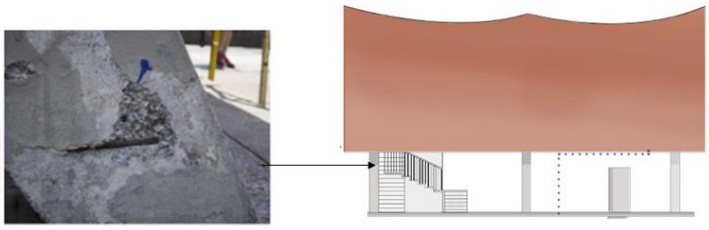

Figure 5. Condition assessment of the Cosmic Rays Pavilion. Image: Carleton Team, 2019.

One of the most significant findings through the analysis of the HBIM digital model by Rajabzadeh and in combination with the analysis of archival drawings was a significant surface-thickness difference between the intrados and extrados of the shell, showing a thicker surface on the extrados of the shell. This prompted further analysis of archival images of the pavilion in combination with the digital model. Moreover, the team lead by Dr. Esponda discovered a slight deviation in the curvature of the structure over time. Deeper analysis and an interview with relevant staff from the States Management and Conservation Directive, UNAM (Dirección General de Obras y Conservación, UNAM) corroborated the team's initial hypothesis to explain these anomalies. It was found that asphalt waterproofing layers had been gradually applied throughout the years without proper removal and cleaning of all previous waterproofing material thus adding thickness to the shell. Furthermore, there are no detailed maintenance or intervention reports which could provide information regarding the timeline, materials and methods applied to waterproof the shell or any other intervention as in Rajabzadeh et.al [21] and Mendoza et.al [22]. It is worth to note that this could not have been detected by solely relying on traditional documentation techniques. There were some valuable lessons learnt in using digital technology to document and assess the CRP and which arose from the fact that the main strategy was to rely on point-to-point correspondences for the software to merge the interior and the exterior point clouds. Later, it was understood that there was a lack of redundancy in the process. Although there were

thorough hand measurements taken by the team, no ground control points were collected to stitch the pictures together and which should have collected as precautionary measure in case of software failure.

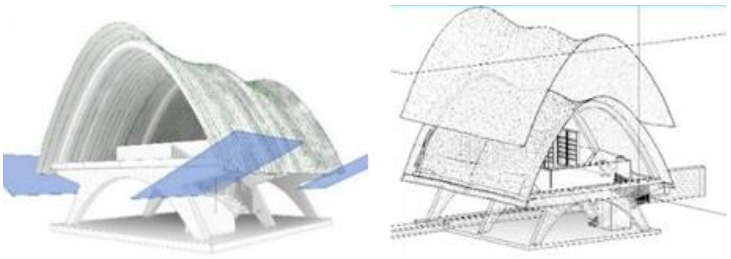

Figure 6. Exploded axonometric from Revit model to analyse the waterproof membrane and the concrete shell. Image: Rajabzadeh, 2019.

Despite the missing control points, the small size of the shell allowed for the interior and exterior point cloud data sets to be compiled manually. The target points were accurate to allow for a comprehensive point cloud data set of the pavilion to be created using photogrammetry. However, it is worth mentioning that for larger projects, collecting ground control points is necessary "figure 6" Rajabzadeh et.al [23]. It is also important to mention that while the use of a laser scanner could have produced a point cloud relatively faster, this was not accessible to the team at that time as they are a more expensive technology than DSLR cameras and drones as mentioned by Rajabzadeh et al [24].

Using photogrammetry technique assisted a faster visual assessment to identify which part of the building required immediate attention. Other advantages of the photogrammetry using DSLR versus laser scanners is its affordability and file size, files used in photogrammetry are considerably smaller than those obtained with a laser scanner, and which require more powerful computers to handle and more digital storage. Photogrammetry can be as accurate as laser scanner data collection, they both record the exact texture, condition, and circumstances of the sites. However, unlike laser scanners, DSLR cameras do not have an integrated GSP to collect control points and as a result it is more challenging to merge the two sets of data (interior and exterior) together. Another important lesson learnt was the consideration of lighting conditions for which it is best to record all data in one setting, as different lighting conditions (particularly daylight changes) can make it hard for the software to stich the pictures together. Although not always possible, it is best practice to remove all furniture and occupants from the space to be analysed to minimize the obstacles that restrict access to data collection.

Whilst using laser scanners and/or photogrammetry to assess heritage buildings are optimum as they use non-invasive and non-destructive techniques, they have a significant limitation as they are restricted to only record surfaces seen by the eye without being able to penetrate the surface to assess other physical or mechanical conditions of structural components. However, this limitation can be overcome by complementing laser scanner and photogrammetry assessments with other NDTs such as sonic, ultrasonic, georadar, dynamic, sclerometers, thermography, etc. One of the main advantages of using laser scanner and/or photogrammetry assessments for heritage buildings is that they apply non-invasive and non-destructive techniques protecting the integrity and value of the cultural asset.

2.3. Non-destructive testing of the Cosmic Rays Pavilion concrete shell

In 2022 Dr. Alberto Muciño and Dr. Alejandro Leal carried out a study to assess the current condition of the CRP's reinforced concrete using NDTs. This study was also presented at the Candela-Isler-Mütter Symposium, ETH, Zurich, Switzerland, 2022. The main reason for using the NDTs in this study was to comply with the specific assessment protocols required for heritage buildings such as the CRP. Two different NDTs were used in combination to maximise the reliability of results. The NDT methos used were the rebar location using the Proceq Profometer 200, combined with the surface hardness method

using a Proceq SilverSchmidt 8200 Tipo L. The guidelines used for the application and interpretation for the standard rebound were ASTM C805/C805M-13A y NMX-C. -192-ONNCCE-2018. To determine the correlation between resistance and rebound index it was necessary to build a control sample to be tested under simple axial compression and correlate the obtained resistances with the detected rebound index.

The project started with literature review analysing material from the archive: Archivo de Arquitectos Mexicanos, including architectural and construction drawings. This was followed by identifying and cleaning the testing areas (ideally, areas to be analysed with NDT should be identified in collaboration with the authorities in charge of safeguarding the cultural asset). For the purposes of this study square sections of (1000 mm X 1000mm were identified and labelled according to their north, south, east, and west orientation "figure 7". Once the areas of study were identified their surface was cleaned and any paint coating was removed to avoid any distortion of the sclerometer test readings of concrete carbonation.

Figure 7. Process of cleaning and preparation of the area where NDT was conducted. Image: A. Muciño.

It was relatively fast to obtain readings and data using NDTs. Overall, the study took three months and most of the time required was to clean and prepare the surfaces and set the scaffolding to take the instruments readings. However, the obtained results showed that to enhance the reliability of the study, the obtained data needs to be compared with results from control samples analysed in the laboratory and against existing literature.

It is important to mention that NDTs do not necessarily replace destructive ones but complement them. Non-destructive techniques can identify specific areas of a heritage building which may require further investigation and potential destructive testing to obtain samples to be analysed in the laboratory. The Mexican Construction Technical Standards for reinforced concrete structures acknowledges the use of destructive and non-destructive techniques to assess the quality of concrete structures or elements [25]. However, these standards have not yet established specific guidelines, protocols, methods, or criteria to use this technology for heritage buildings. Current building regulations need to be updated to provide adequate guidance and regulate the assessment and intervention of reinforced concrete heritage buildings. Such updates can assist professionals dealing with historic buildings and who may not be experts in conservation [26]. This is of particular interest if the construction sector wants to promote and advance the reuse and re-purpose of historic buildings as circular economy and sustainability strategies.

One of the main limitations of the study was that only the intrados of the concrete shell was analysed. To arrive at more reliable and holistic results of the integrity of the structure, testing of the extrados of the shell is needed not least because exposed to weather conditions, it is most prone to deterioration. The analysis carried out from the central and lateral testing on the shell's intrados showed a flacking in the shell's concrete. Furthermore, the sclerometer results showed that the resistance of the concrete is not optimum, and which shows that an adequate maintenance protocol and technique to keep the

concrete in the best possible conditions is needed. One of the important findings of this study was that the final built shell was thicker than what is cited in Faber's book, and which will support to rectify and advance existing literature.

After the non-destructive testing of February-March 2022, it became clear that the building needs further study, expanding the examination area to include not only the shells (upper structure), but also the slab and arches (lower structure). In addition, after collecting all the data it was evident that a bespoke protocol is needed at the outset of the assessment with a holistic approach to incorporate other complementary digital technology and to include other experts in the field.

3. Conclusion: submission of contributions

This paper presented the available technology (non-invasive and non-destructive) most used for the assessment of heritage buildings. The two studies presented in the paper aimed to develop a methodology to evaluate the concrete conditions of reinforced concrete shells using traditional and digital technology. The paper discussed the challenges and opportunities in the use of this technology for historic concrete shells such as the Cosmic Rays 20th Century historic concrete shells. The use of digital technology and other NDTs have the advantage of facilitating more holistic and accurate assessment of heritage buildings whilst maintaining their functional and structural integrity value. It is also important to note that the field research that complemented both studies was very valuable to make an initial visual assessment of the structure and materials' conditions such as concrete deterioration. Moreover, the use of the images collected and archived were crucial to better understand the complex geometry of the CRP and to ensure that it correlated with the data given by the digital tools.

One of the main limitations of the study relates to the NDTs. While it was possible to confirm the rebar location against available construction drawings it was not possible to identify and assess any potential corrosion. Furthermore, the surface hardness analysis of the shell's concrete was only applied to a designated area of the intrados and results may differ from those that could have been obtained from testing other intrados and extrados areas. Furthermore, another important aspect to consider as a limitation is the lack of archival information related to the shell's concrete mixture as well as the material and methods applied in the various waterproofing layers, and which have increased the thickness of the shell.

The analysis of these two preliminary and exploratory studies have prompted the authors of this paper to develop a third study in which traditional methods, digital media and NDTs will be carried out simultaneously to develop a more holistic protocol and approach as this paper demonstrated that they are complementary of each other and important when assessing heritage buildings. Furthermore, the paper has also discussed the potential of digital technology and other NDT techniques to support circular economy and sustainability strategies as they can reduce the use of materials, natural resources and energy and they can also safeguard the buildings structural integrity thus extending their heritage value and use.

In the last decade, concrete conservation research is progressing to find better solutions and to develop strategies to retain their cultural significance (aesthetic and technological) as well as to carefully assess modern concrete structures. Based on this process, the initial studies that we have done since 2018 in the Cosmic Rays Pavilion will allow us to identify key current issues on the concrete hyper, to understand how to assess the main damage, inherent environmental features and future threats, to recognize the main important challenges (socio-cultural, technical, economic, and sustainable) and to develop which best practice will be the most appropriate in conserving/intervening the concrete shells in Mexico.

We have based our thorough evaluation of the CPR following the Conservation Principles for Concrete Getty Conservation Institute [27] with the future intention of developing a sustainable conservation strategy and to create an inventory of other concrete shells built by Félix Candela and other architects

and shell builders in Mexico. We anticipate that the findings of this and future research will be of value to other researchers and practitioners around the world dealing with the conservation of 20th Century historic concrete shells as hitherto there is not consensus on the tools and methods on how to approach the conservation of 20th Century historic concrete shells. Future research will aim to consolidate and establish a protocol addressing the best conservation practices specific to the concrete shells built in Mexico and which could potentially inform the research and conservation of other concrete shells around the world. Some of the next steps will be to evaluate workmanship, maintenance records, materials deterioration (environmental characteristics and aggressiveness to concrete considering the specific context of Mexico City such as pollution levels, CO2 and other contaminants, exposure to sun, winds, rain), preliminary testing, structural evaluation and monitoring. Finally, future research can also include the us of the HBIM for seismic analysis and anticipate any damage scenarios and propose risk management strategies.

Abstract

This paper aims to clarify the linkages between various actors in the pioneering period of computational design by elaborating on the design and construction history of the Naiju Community Center, a complex free-form shell structure built in Fukuoka in 1994, designed by Japanese Architect Shoei Yoh (1940-). Yoh envisioned an undulated roof that resembles the moment a handkerchief is picked up. Early in the design process, he collaborated with Professor Gengo Matsui of Waseda University to study a woven bamboo dome, and eventually, decided to apply bamboo as the formwork of a concrete shell. The form was studied with computational models, then physical models were created using origami geometry, from which the coordinates of the surface were determined. For the structure, local engineer Kusaba Motoshige collaborated with Yoichi Minagawa of Kagoshima University, who analyzed the stresses in the shell using Finite Element Method. To design the formwork, Yoh referred to the properties of bamboo identified by Matsui's laboratory at Waseda University. Regarding the construction, the villagers worked together to weave a square bamboo net 22 meters per side. This net was lifted by a crane and formed a complex surface. The historical importance of the building lies in how the computationally-designed complex surface was constructed; not as a building on screen but as an actual structure. The key was the application of origami geometry, flexible bamboo formwork, the collaboration of experts, and construction with local participation.

Keywords: Shoei Yoh, Gengo Matsui, computational design, concrete shells, bamboo formwork, origami, form finding, local participation, historical structures

1. Introduction

In recent years, there has been growing momentum, both in Japan and abroad, to re-evaluate Shoei Yoh (1940-) as a pioneer of contemporary timber structures and as a pioneer of digital design [1]. As for timber, the Oguni Dome (1988), Japan's first large-scale timber structure, won the JIA 25-year award in 2018 and was also featured in the web media of the Architectural Institute of Japan in 2019 [2]. As for the digital, Yoh's projects such as Galaxy Toyama (1992), a pioneering architecture using parametric methods, were highlighted in the exhibition 'Archaeology of the Digital' at the Canadian Centre for Architecture in 2013 [3], while the exhibition 'Revisiting Shoei Yoh', which reassessed the digital design of Yoh, was held at the Australian Design Centre in 2021 [4]. The subject of this paper, the Naiju Community Center, is also a highly original work unlike any other of its time.

The Naiju Community Center (Figure 1) is a community center and nursery school built in 1994 in Chikuho Town (now Iizuka City), Fukuoka Prefecture, with an organic, three-dimensional curved concrete shell as its distinctive architectural feature. Yoh used origami geometry for its form-finding,

while his collaborators made full use of computational structural analysis. They also developed an ingenious construction method, using bamboo as formwork to create the complex curved surface. In order to explore the origins of today's architectural trend of integrating natural materials and computation, this paper provides a detailed historical study of the design and construction process of this building.

The research methodology of this paper is based on the analysis of a newly developed 'Shoei Yoh Archive' at Kyushu University and Shoei Yoh fonds at Canadian Centre for Architecture; primary interviews with Shoei Yoh and his collaborators (conducted in 2018-2021); and field surveys of Yoh's works in Kyushu region. These sources are utilized to achieve detailed insights into the development of the Naiju Community Center, a pioneering application of computational approaches to the innovative use of the bamboo-formwork concrete shell. To supplement the above primary sources, archival journal and magazine articles from the 1980s and 1990s are examined. These sources of data are triangulated and used to generate new historical insights into this missing part of Japan's architectural heritage.

2. Design process of Naiju Community Center

2.1. Bamboo as a building material

The design of the Naiju Community Center began in May 1993 at the request of Tatsuo Yoshinaga, the Mayor of Chikuho Town at the time. From the very beginning of the design, Yoh wanted to use bamboo as a building material. Yoh wrote in 1994; "The starting point for the Naiju Community Center was the idea of using bamboo, inspired by the bamboo shoot cannery in Chikuho Town" [5]. The origin of his inspiration for using bamboo can be pointed to the Yukinogawa Bridge (figure 2a), a bamboo-reinforced concrete structure in Oguni Town, Kumamoto Prefecture. Yoh came to know about this bridge when he was involved in a series of projects in Oguni Town in the late 1980s. He then designed Japan's first legal bamboo structures, the Bamboo Dome and the Tensegrity Shelter, at the 1989 Asian-Pacific Exposition in Fukuoka (figure 2b) [6]. This bamboo dome was realized in collaboration with the Gengo Matsui

Laboratory of Waseda University, which conducted structural experiments on bamboo. The application of bamboo as a building material in the Naiju Community Center can be considered as an extension of these efforts.

For Naiju, Yoh envisioned an undulated roof that resembles the moment a handkerchief is picked up, based on his design philosophy, 'in response to natural phenomena' [7]. To realize this form with bamboo, Yoh asked Professor Gengo Matsui to study its geometry and feasibility. Matsui proposed a dome-shaped structure made of woven bamboo net and conducted photoelastic experiments (figure 3). However, the local structural designer of the project, Motoshige Kusaba, was concerned about deformation due to external forces. Therefore, Yoh abandoned the use of bamboo as a structural material and instead conceived a concrete shell structure using bamboo netting as a formwork.

Left: Results of photoelastic experiments with different orientations of the bamboo framework, 23 June 1993. Right: sketch by Gengo Matsui on the shape of the dome top and the bamboo weave, 16 July 1993.

2.2. Form finding with physical models and origami geometry

In the initial design phase, the form of the building was studied mainly through model making. The first model was made using mesh blind fabric samples (Figure 4a). The model was made by placing a stick on cardboard as a base, placing the fabric on top of the stick, and then fixing its perimeter to the base with pins. This method of model-making is similar to the actual construction process of the building. Next, a model was produced using the same mesh fabric, with FRP coated over it. This model was used in the presentation to the town mayor, based on which the early 3D model and renderings of the project were likely produced (Figure 4b).

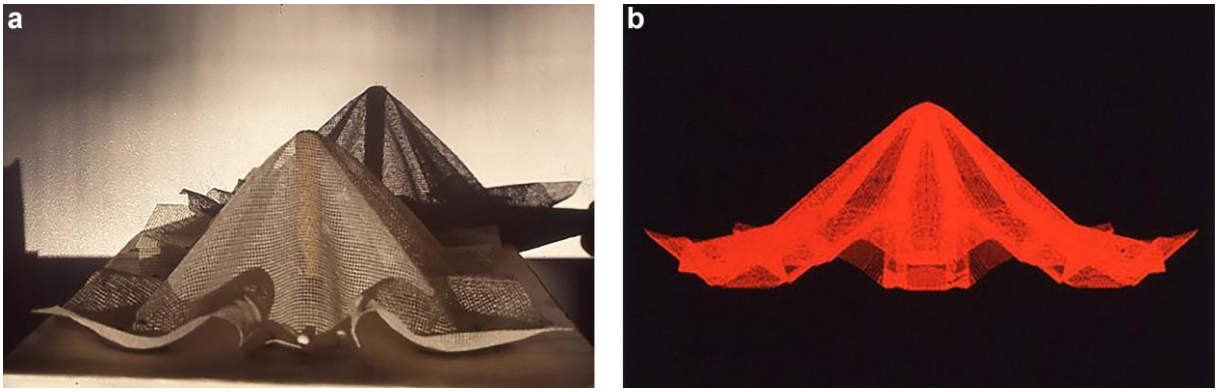

Figure 4. Physical model and rendering of Naiju Community Center at the basic design phase. Materials from Shoei Yoh Archive. (a) Photograph of the model in the basic design phase, 1993. (b) Rendering in the basic design phase, printed on paper, 1993.

After the first proposal was approved by the town, Yoh Design Office began detailed design work. To carry out structural analysis, it was necessary to know the coordinates of each part of the roof. For this, physical models were created using origami geometry (Figure 5a), from which the height of each part of the building, the position of the folds, and the height of the openings were examined, then the coordinates of the curved surface were identified based on the origami development diagram. Through studies using origami models, a major design change was made to add a skylight to the top of the building, otherwise, it would not have been possible to create a complex curved surface by folding a single square paper (Figure 5b).

2.3. Structural design

The structural design of the Naiju Community Center was carried out in collaboration with several structural engineers. As mentioned earlier, Prof. Gengo Matsui, who had collaborated with Yoh to design Bamboo Dome at the Asian-Pacific Expo, was involved in the initial conceptual stage, after which Motoshige Kusaba, an engineer who had communicated with both Yoh and Matsui, took over the overall structural design. Kusaba asked advice from Ikuo Tokuhiro, his mentor since his student days, regarding the structural analysis of the complex concrete shell, and Tokuhiro introduced him to Yoichi Minagawa, who was researching concrete shell structures at Kagoshima University at the time.

Based on the coordinates provided by Yoh design office in late July 1993, Minagawa modeled a 150 mm thick concrete shell and carried out a structural analysis using Finite Element Analysis Method (FEM). First, the structural model was divided into quarters, then a quarter was divided into 248 elements and 148 nodes, and analyzed in two cases: fixed loads and horizontal forces (Figure 6a, 6b). The results of the analysis were delivered in late September, upon which Minagawa and Kusaba calculated the concrete cross-sections and reinforcement arrangements. Reinforcement drawings were drawn using a development diagram of the origami model (Figure 6c).

3. Construction process of Naiju Community Center

3.1. Building by local people and local materials

Three rounds of bidding were conducted to determine the contractor for the Naiju Community Center. Two bids, one from a local general contractor and the other from a major general contractor in Japan, were unsuccessful. These general contractors assumed that the concrete shell formwork would be made by conventional methods, rather than the bamboo formwork specified by Yoh Design Office, and therefore their estimates were much higher than the budget. Thus, Yoh proposed that a third bidding round be held with local carpenters, which attracted five companies in the region. A local carpenter, Isao Kawakami, was ultimately selected as the successful bidder. Yoh explained his intention to ask a local carpenter to be the builder: “If you ask a local carpenter, the skills will remain (in the region). [...] The fact that the building was built by local people using local materials gives the community a sense of pride." [8] In response to Yoh's expectation, Isao Kawakami undertook an in-depth and thorough preparation for the construction that included making models and mock-ups on site to understand the complexities of the design (Figure 7).

Figure 7. Photograph of model and mock-up made by Carpenter Isao Kawakami. Materials from Shoei Yoh Archive. (a) On-site meeting around the model made by Kawakami, 1994. (b) Mock-up for testing concrete casting, 1994.

The details of the bamboo formwork were discussed around April 1994. First, it was decided to split the bamboo into eight strips. Next, two options for making the net were considered: bolting all the intersections of bamboo or weaving the split bamboos together (Figure 8a). Consequently, the idea of weaving bamboo was selected to reduce the amount of bolts. A 22m wide square net was composed of split bamboo, each approximately 5 m long, overlapped by 300 mm, and fixed with three bolts. The strength of the bamboo formwork was evaluated using data from structural experiments conducted by Gengo Matsui laboratory when designing the Bamboo Dome for the Asian-Pacific Expo.

On the initiative of Yoh Design Office, local people participated in the work of weaving the bamboo net. Yoh said: 'The work of weaving bamboo and constructing the formwork was done by the local people. We tried to leave traces of their hands, or rather the traces of everyone's sweat work''. [9] The collaborative process of weaving bamboo was a participatory design method. The work was carried out over a two-week period from the end of April to the beginning of May 1994, taking advantage of a Japanese public holiday period. Forty-six local residents, including junior and senior high school students, participated in the process (Figure 8b).

Figure 8. Bamboo net as formwork. Materials from Shoei Yoh Archive. (a) Mock-up of bamboo net with all intersections bolted together (not applied), 1994. (b) Local people weaving bamboo nets, 1994.

3.2. Forming a three-dimensional curved surface

The woven bamboo net was lifted by crane on 19 May 1994 and covered over a temporary support post erected at the center of the foundation (Figure 9). The temporary posts were made of steel, with a circular ring on its top to correspond with the design of the skylight, and steel cables were stretched from this ring to points on the foundations as guides to fix the perimeter of the netting in place.

Figure 9. Lifting bamboo net by crane, 19 May 1994. Materials from Shoei Yoh Archive. (a) Lifting bamboo net by crane. (b) Bamboo net on the temporary post. (c) Temporary post and steel cables.

After the bamboo net had been lifted onto the temporary post, the forming of the bamboo formwork began. The first step was to fix the bamboo formwork to the foundations. Next, supports were produced using timbers and steel pipe scaffolding. The bamboo net was only used to define the shape and does not carry the structure. This means that the shoring had to be inserted into the netting and withstand the load of the concrete. The forming work and shoring took place over a period of one month, from the end of May to the end of June (Figure 10).

In parallel with the construction of these supports, the temporary support post at the center of the building was jacked up. The temporary post was built lower than the maximum height on the design drawings and was gradually jacked up as the fabrication of the shoring and forming of the curved surfaces progressed. The intention of the jacking up was to tension the bamboo net and to pin and straighten the ridges to withstand the compressive forces of the shell. The jacking-up was carried out twice during the forming process, raising the post by approximately 60 mm from its initial position.

Figure 10. Forming process. Materials from Shoei Yoh Archive. (a) Lifting bamboo net by crane. (b) Bamboo net on the temporary post. (c) Temporary post and steel cables.

3.3. Concrete works

After the bamboo formwork had been formed and the shoring installed, the curved surfaces were sheeted, sprayed with urethane foam and rebar was placed according to the structural drawings (figure 11).

Figure 11. Roof works. Materials from Shoei Yoh Archive. (a) Sheeting work, July 1994. (b) Urethane foam spraying, August 1994 (c) Rebar placement, August 1994. Areas marked with red lines are single reinforcement, as they mainly transmit compressive forces.

For the concrete casting, advice was provided by Takao Yonemitsu of Ando Construction, who had worked with Yoh on previous projects such as the Glass Station (1993). Yonemitsu suggested that the concrete be poured in several stages, with the lower section, including the outer folds, being poured in the first stage. The intention was to stabilize the bamboo formwork and prevent overall deformation, to provide a scaffold for the upper concrete pour, and to prevent the central section from lifting. This suggestion was accepted, and the concrete was placed in five separate stages between 8 and 26 September 1994 (Figure 12). The fresh concrete used for casting was extremely hard with a slump value of 4-5 cm. In addition, reinforcing steel fibers, Dramix, were mixed into the fresh concrete to increase the cracking strength. After the pouring was completed at the end of September, the concrete roof was left to harden for two weeks. The steel temporary post was removed on 14 October. There was concern that the rooftop would drop under its own weight when the temporary post was removed, but measurements showed almost no change in height.

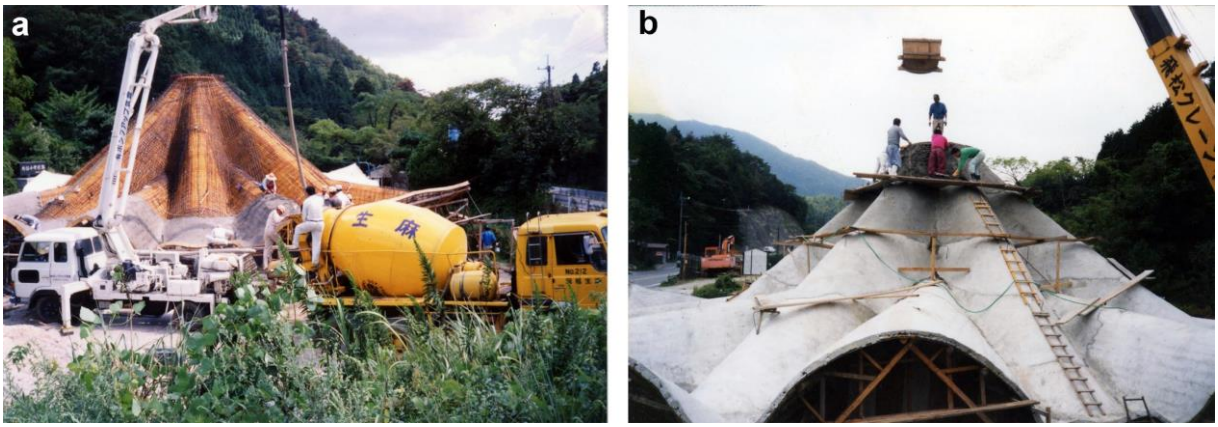

Figure 12. Concrete works. Materials from Shoei Yoh Archive. (a) First concrete placement, 8 September 1994. (b) Fifth (last) concrete placement, 26 September 1994. Fresh concrete was placed by hand in the box suspended by a crane. The fresh concrete was too hard to be placed using a pump truck.

3.3. Completion and after

Interior work began in mid-October; the roof was waterproofed in November and Naiju Community Center was completed in mid-December 1994 (Figure 13). Its inauguration ceremony was held on 12 December, at which children from the Naiju Nursery School, which will move to the Community Center, sang songs and performed in an ensemble. Mayor Nagayoshi expressed his hope that the new building would be "a catalyst for community revitalization" [10]. Naiju Community Center was thus welcomed by the town, but unfortunately, it was forced to close temporarily in 2001 due to the river pollution in the neighborhood. And it was closed in 2007 due to a decline in the number of users caused by depopulation. In 2023, Naiju Community Center still stands empty and quiet in the mountains.

Figure 13. Naiju Community Center nearing completion. Materials from Shoei Yoh Archive.

4. Conclusion and discussion

The design and construction process of Naiju Community Center was extremely advanced and unparalleled in its time and is unique and creative even from today's perspective, some 30 years after its construction. The study reveals that the unique idea of a free-form concrete shell using bamboo formwork was realized in collaboration with talented structural engineers Gengo Matsui, Motoshige Kusaba, Ikuo Tokuhiro, and Yoichi Minagawa. It is important to note that the origami models acted as a conceptual bridge between these structural engineers and architects, defining the geometry and coordinates of the surface, and therefore enabling computational analysis of its structure. This fact shows that physical models played an essential role in the pioneering days of computational design.

In terms of construction, despite the complexity and difficulty of the work, Yoh insisted on local craftsmen and community participation. Building by local people and local materials - this was the secret of success for regional architecture, which Yoh arrived at through his experience of designing timber structures in Oguni Town, Kumamoto. Naiju Community Center was realized by mobilizing the experience and connections that Yoh had cultivated in his design activities until then. In a sense, it proved to be the culmination of Shoei Yoh's architectural achievements.

Acknowledgments

The authors would like to thank Mr. Shoei Yoh, Mr. Motoshige Kusaba, Mr. Isao Kawakami, Mr. Toyohiro Kawakami, Mr. Hiroyuki Yageta and Mr. Takao Yonemitsu for their cooperation in the interviews. We also thank Iizuka City for giving us the opportunity to research the building in detail. A part of this research work is the result of a grant by JSPS KAKENHI Grant Number JP21K14334.

Translucent concrete shells in Ecuador

Mauricio LUZURIAGA*

* Universidad San Francisco de Quito
mluzuriaga@usfq.edu.ec

Abstract

In 1954, Felix Candela produced one of his most striking projects, the High Life Textile Factory in Coyoacán, Mexico City, built with his recognized inverted hyperbolic paraboloid umbrellas. Its uniqueness came from the way natural light filtered into the factory hall. Glass bricks embedded in concrete membranes allowed for light to flood the space below. Thin shells pierced with glass bricks are scarce however beautiful. From 1950 to 1960, *hormigón translúcido* or translucent concrete thin shells were produced in several Caribbean and South American countries. This paper hypothesizes that, contrary to experiences elsewhere, translucent concrete shells appeared in meaningful numbers with compelling aesthetic and constructive solutions in Ecuador. After a brief review of international and national examples, the study centers itself in works designed and build by architect Gilberto Gatto Sobral at Universidad Central del Ecuador in the capital City of Quito. The research encompassed an investigation never attempted before. Primary sources, entailing site visits, study of construction archives, and interviews were done to document the development of translucent concrete shells, an unheard-of feature in the history of Modern Architecture in Ecuador.

Keywords: translucent, concrete shell, glass brick, elliptic paraboloid, catenary vault, hyperbolic paraboloid, low-rise barrel vault, Gilberto Gatto Sobral

1. Introduction

Reinforced concrete system, patented by Françoise Hennebique and refined by Auguste Perret, initially leaned towards the production of straight porticoes. Impressive concrete shells appeared with hangars in Avord (1916) and Orly (1923) by Eugène Freyssinet. Transgressing the predominance of *angle droit* by Le Corbusier, the *Sao Francisco de Assis* church (1943) in Pampulha, Belo Horizonte-Brazil by Oscar Niemeyer, introduced sensuality to concrete shell structures. Similarly, diverging from the generalizing decree of universal applicability claimed the International Style of Phillip Johnson and Henry-Russell Hitchcock, "influential sectors of the modern movement around 1950 were ready to rebel against rectangular rectitude [through] the application of new thinking techniques to curvilinear structures" [1]. The Turin Exhibition Hall (1951) by Pier Luigi Nervi, also helped to lay foundations for the arrival of shells in the mid-20th century, such as the Kresge Auditorium (1955) by Eero Saarinen (Fig. 1), and the CNIT (1958) by Nicolas Esquillan. Organic shells were gaining notoriety to the point that Le Corbusier himself studied them at the Phillips Pavilion in 1958. However, the work of Spanish architect Félix Candela in Mexico was responsible for spreading the word worldwide. Candela was recognized for creating the thinnest existing reinforced concrete shell, for the Cosmic Ray Pavilion (1951) at the National University of Mexico in Mexico City. In 1958 Candela produced his masterpiece, Los Manantiales Restaurant.

Architectural Forum magazine baptized Candela as the *Wizard of the Shells* at the height of his unconventional production that predicted revolutionary possibilities for new architecture [2]. Candela's production, based on thin concrete shells, lasted twenty brilliant years. The inverted hyperbolic paraboloid (hypar) or inverted umbrella was used largely to roof markets, industrial sheds, and

warehouses. An inverted umbrella typically consists of a laminar shroud formed by four tympans. Each tympan is a hypar –a few centimeters thick– generated by two horizontal ridges at the edge and two opposite ridges descending to a lower vertex. The four hypars together are supported by a single central column inside which a rainwater downspout runs downward. A beautiful example of inverted umbrellas by Candela is the Coyoacán Market (1955) in México City (Fig. 2).

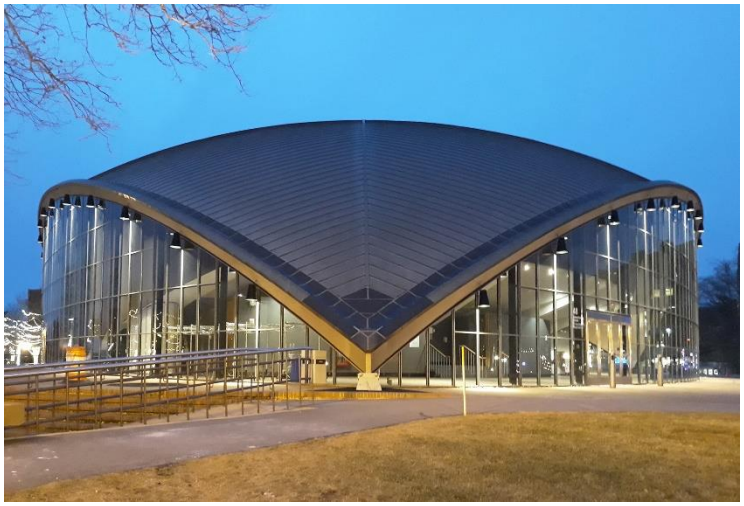

Figure 1: Kresge Auditorium (1955), MIT, Cambridge, Massachusetts-USA. Photo by the author, 2020. Figure 2: Coyoacán Market (1955), Mexico. Photo by the author, 2010. appropriate].

Hypar inverted umbrellas were replicated everywhere for its apparent ease of construction and economic feasibility –elements needed were: barely trained hands as workforce, available construction materials such as cement, sand, aggregates, water, wood poles and boards for simple scaffoldings, straight planks for falsework, reinforcing steel bars placed upon falsework. Once concrete was poured and cured, scaffolding was decentered and falsework removed producing a highly efficient double-curvature membrane.

2. Thin *shells* combined with glass bricks

One block North from the Coyoacán Market, Candela built the *High Life Textile Factory* (1954-1955). Unlike the market, at the factory he made an experiment –the utilization of glass bricks embedded in the shells to bring natural day light down to the factory hall. A revolutionary aesthetic emerged. The factory roof includes twelve identical hypars, 11.10 x 12-meter each, in a 3 x 4 layout. Since the umbrellas are tilted, they form rows of connecting hypars in one direction. Consequently, a continuous horizontal opening is created between rows and a sawtooth roof profile turns out. The horizontal openings are glazed with clear glass window bands. Most of the membranes were punctured with square *blocks de vidrio* –as they are called in Mexico– or glass bricks at a rate of 4.5 units/m^2 (Fig. 3). The result was a luminous space "as if there were no roof at all. But this brilliant mosaic provoked such heat and insulation problems that it was never repeated [3]" (Fig. 4).

International publication exposure for the *High Life Factory* started with an early article at *Informes de la Construcción* in 1956 [4]. Then it was featured in 1957 in a canonic book by Eduardo Torroja [5] where he predicted that these types of structural elements opened "a wealth of possibilities of all genres that […] are still kept hidden." In 1958 it was featured in an article titled Engineering of Excitement at The Architectural Review [6]. Six years later, the factory was included in the 1963 book *Candela/The Shell builder* by Colin Faber [7], followed by the German and Spanish versions of 1965 and 1970. The factory was renamed Cavalier Fashion Group but is now permanently closed. The building was put for sale, hopefully waiting for a buyer interested in its renovation and protection.

Figure 3: High Life Textile Factory, Coyoacán, 1954-1955. Photo: from *Candela und seine Schalen*, 1965. p. 124. Figure 4: High Life Textile Factory, as it looked in 2019. Photo: by the author.

Inventor Thaddeus Hyatt is credited with the creation of *Hyatt Patent Lights* [8], that consisted of round glass lenses, set into cast iron sidewalks, in 1845. Thus, glass bricks have been in used for a considerable time. Preceding the factory, glass blocks puncturing thin shells and slabs were visible in projects in several countries. In 1951, Max Borges Jr., purportedly used punctured shells (Fig. 5) at the dazzling conical segment shells covering the stage floor of *Arcos de Cristal*, a portion of Cabaret Tropicana in Havana, Cuba [9]. There are some examples in Caracas-Venezuela such as the *Santa María* building (1951) (Fig. 6), by engineer Arturo Luján with two spherical caps, one with a diameter of 8-meters and the smaller of 5.3-meters [10], or *Casa Sindical* auditorium (1954), by architect Henrique García Maldonado with one cap of 6-meters in diameter [11]. All these feature round glass bricks to flood with light helicoidal staircases, and hall spaces. A much larger case is found at *Banco de Descuento (1954)* in Guayaquil-Ecuador, designed by Karl Kohn. Its impressive dome has a diameter of 14 meters, covering a hall, staircase and balconies for what is now *Biblioteca de las Artes* or Library for the Arts (Fig. 7).

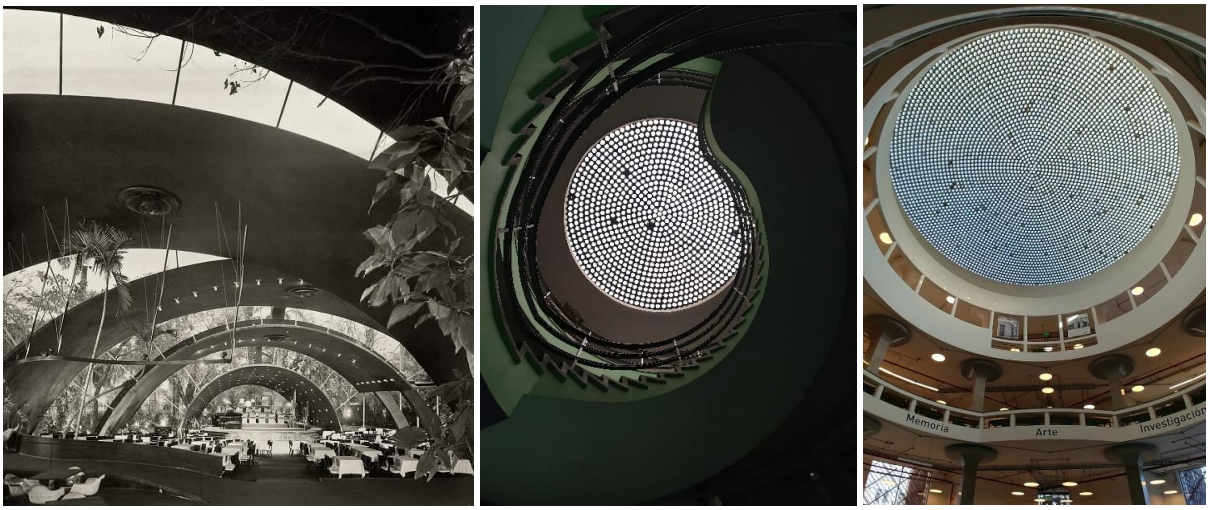

Figure 5: Tropicana Club Glass Arches, 1951. Havana-Cuba Photo: Muñis for Progressive Architecture. Figure 6: *Edificio Santa María*, 1951. Caracas-Venezuela. Photo: Lilia Tellez, 2022. Figure 7. Banco de Descuento, 1954. Guayaquil-Ecuador. Photo: Luis Paredes, 2019.

Another project with glass pierced hypars was built decades later at *Miller Bajo* car workshop (1977) in Las Palmas de Gran Canaria-Spain, a project by Luis López Díaz. There, "the lighting of the car workshop is done by means of 20 x 20 x 5-cm glass moldings, embedded in the central membranes and isolated from them with butyl sheets [12]. Yet, this paper concentrates on cases of thin shells pierced by glass blocks –translucent concrete– designed by one of the most important figures of Ecuadorian Modernity.

3. Gilberto Gatto Sobral (1910-1978) at *Universidad Central del Ecuador* (UCE)

Uruguayan architect Gilberto Gatto Sobral was invited by his fellow compatriot Guillermo Jones Odriozola to join him to develop several important commissions in Quito-Ecuador. He landed in the country in 1942 where he settled for the rest of his prolific life. In view of Jones departure from the country –due to ill health conditions– Gatto was appointed to bring to terms various of Jones' projects, such as the *Plan Ordenador de Quito* and the creation of the School of Architecture –commissioned by UCE authorities. Gatto was then chosen to start a Master Plan for *Ciudad Universitaria* (1947), which became his most achieved master piece. Facing times of professional uncertainty, he dared to bring Ecuadorian architecture into Modernity with an unmistakable architectural voice that gained the respect from local architectural colleagues. His academia-learnt rationalism, applied to the novel university campus, started with a coherent display of buildings adapted to a challenging topography. *Ciudad Universitaria* was the first large modern urban-architectural enterprise undertaken in the country [13]. It should be noted that *Ciudad Universitaria* in Quito began its construction just three years after *Ciudad Universitaria* in Caracas-Venezuela (1944), and two years before *Ciudad Universitaria de México* (1949), now *Universidad Nacional Autónoma de México*.

Gatto put in practice an "imaginative employment of reinforced concrete, (…) use of natural stones, brick, marble, including translucent glass blocks" [14]. He designed and built the first thin shell in the country for the Main Hall of the Central Administration building [15]. For the following years he proceeded to design various other expressive double curvature structures that work through form. Gatto, implemented a variety of translucent concrete shells at the School of Law; at the Institute for Materials y Static Testing; at the School of Agronomic and Veterinary Sciences; and at the School of Economy Library –presented herein as case studies in chronological order.

3.1 School of law –*Facultad de Jurisprudencia* (1952-1955)

The expression *hormigón translúcido* or translucent concrete was utilized for the first time on cross-section drawings for the main hall of the School of Law. Although this was just Gatto's second building at UCE campus, he experimented with glass brick shells as skylights to illuminate three different locations: the main hall which is also the *Paraninfo Che Guevara* auditorium foyer (Figs. 8 & 9), on top of a stairwell and above the school library. Unfortunately, the later skylight was condemned years ago because of humidity problems, and was not available for viewing.

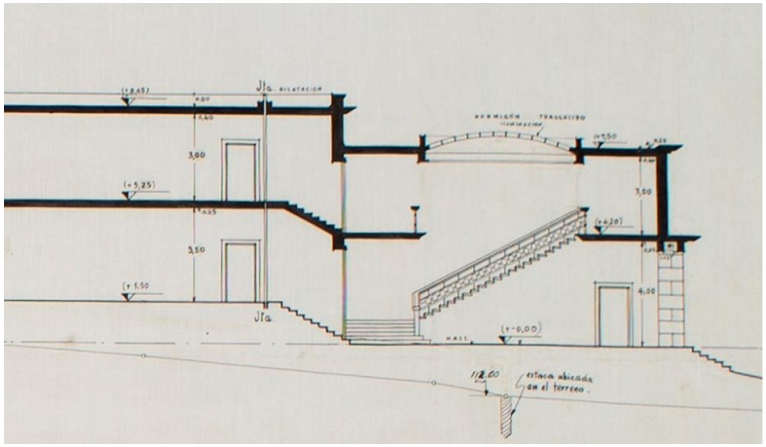

Figure 8: School of Law main hall and auditorium foyer. Photo by the author, 2023. Figure 9: Cross-section of main hall. Courtesy of *Fondo Documental de Arquitectura* UCE. Code FDA-FP-DP-JR-AR-006.

The hall translucent shell is a 5.9 x 5.9-meter elliptic paraboloid profusely pierced by glass bricks –1369 units were utilized at a rate of 39 units/m^2 (Fig. 10). The shell above the stairwell has more ample distancing between glass brick units. –only 224 glass bricks were utilized, using a combined pattern, at a rate of 7.5 units/m^2. Gatto proved that natural light effect can be balanced depending on where and how the translucent concrete was employed –very dense at the hall, and more separated at the stairwell (Fig. 11).

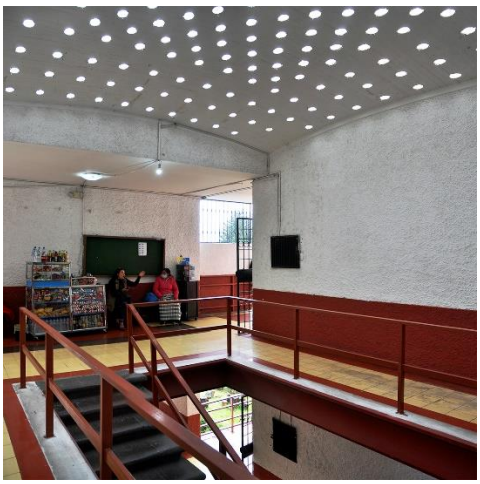

Figure 10: Close up of glass bricks above main hall/foyer. Figure 11: School of Law stairwell. Photos by the author, 2023.

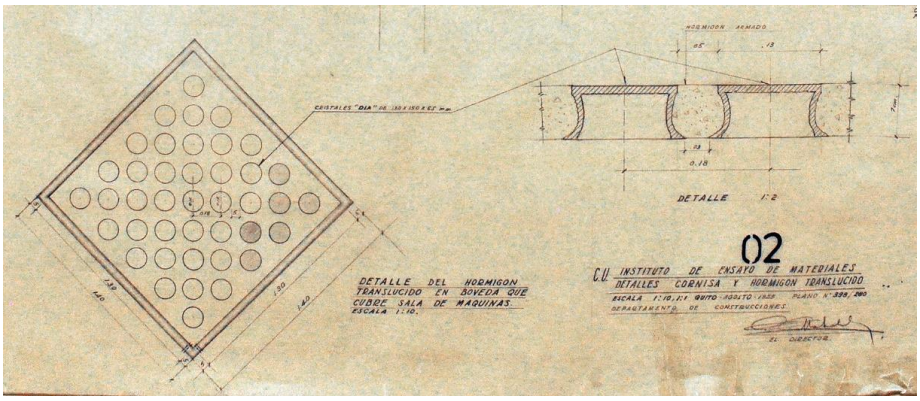
3.2 Institute for materials & static testing –*Instituto de Ensayo de Materiales y Estática* (1955-1958)

Gatto made a structural study along the lines of the Freyssinet and Nervi arched vaults, but also owing references to the Central Garage for National Public Assistance (1931) in Montevideo-Uruguay, designed by his university mentor Julio Vilamajó. The main engine room is a large catenary nave with 16 inverted concrete beams that protrude 25 centimeters from the extrados. 11-cm hexagonal tiles by *Ceramica Vaccari* from Ponzano Magra-Italy were used for exterior waterproofing. The inverted catenary rests on buttresses set 2.80 meters apart, rises 12.40 meters at the vertex and clears a free span

of 21 meters (Fig. 12). The shells are 6.5 centimeters thick with double steel armor. The UCE structure was calculated by engineer Eduardo Narvaez.

Figure 12: Institute for Materials and Static Testing, interior showing prefabricated skylight panels. Figure 13: Closeup of prefabricate skylight panel. 41 glass blocks are inserted in each frame. Photos by the author, 2022.

At the summit of the vault, three rows of 1.4 x 1.4-meter prefabricated skylight panels allow for mid-morning-to-midday light filter to the interior –avoiding afternoon sun (Figs. 13-14). Specifications call for "translucent concrete with *Cristales DIA*" glass blocks. Each round glass brick measures ⌀13-cm at the top, ⌀15-cm at the bottom, and is 65-mm thick, matching the slab thickness. At that time, newspapers and professional journals showed advertisements by AMSON promoting glass bricks made in Belgium (Fig. 15). Projects at UCE possibly used glass bricks acquired from local construction material importers.



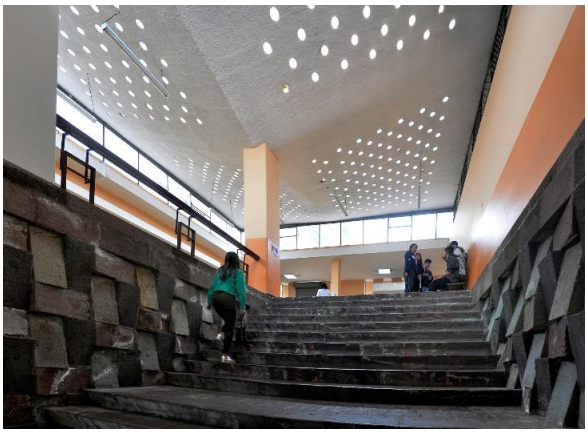


Figure 14: Translucent concrete detail. Courtesy of Physical Plant UCE. Figure 15: Belgian glass brick ad. From: Sociedad de Ingenieros y Arquitectos de Pichincha (SIAP) journal, no.8, march 1959:51.

3.3 School of agronomy and veterinary sciences –*Facultad de Ciencias Agronómicas y Veterinarias* (1959)

Gatto utilized glass bricks in 9 x 10-meter hypars for this building's main hall, gathering spaces and stairwells. He must have resorted to the 1956 *Informes de la Construcción* article for reference because other High Life Factory publications came into circulation only after this work began. He rose the level of inverted umbrellas higher than the surrounding walls to reveal their self-supporting nature. The expressive power, inherent to double curvature surfaces, was accentuated by the alignment of light dots that reaffirmed the generatrixes of the hypars, and thanks to natural light that, filtered by the cylindrical bricks, virtuously enhanced their spatial quality (Fig. 16). Seen from below, the lower surface of the

slabs was sprayed with mortar before being whitewashed and painted white, hiding the trace of wood falsework. It should be considered that, Quito is a city in the Andes mountain range, and the university campus is settled on the eastern slope of the Pichincha volcano. The temperature of the city in the fifties of the last century used to be mild. Regulating the temperature at selected spaces was achieved by translucent concrete as mechanism to obtain heat gain in tall and wide spaces of the building. Detail drawings specify the "Placement diagram of Paris-type, ϕ140 mm x 40 mm glass brick. (180 total units in this area)" (Fig. 17). However, only 111 units were actually placed on each tympan in a staggered pattern. Then, each hypar has 444 glass bricks placed at an average of 5 units/m^2.

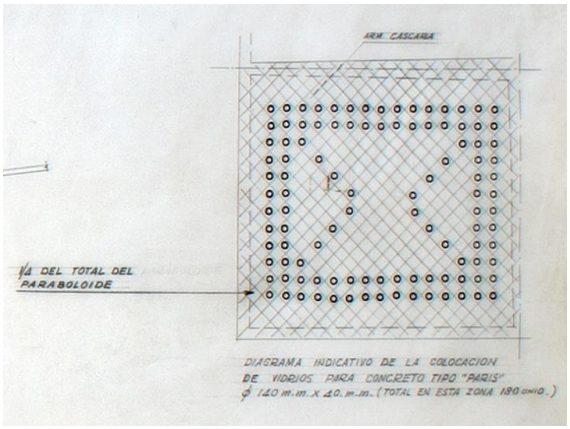

Figure 16: School of Agronomy and Veterinary Sciences Main Hall. Photo by the author, 2023. Figure 17: Glass brick placement diagram. Courtesy of *Fondo Documental de Arquitectura* UCE. Code FDA-FP-DP-AGVT-ES-304.

Thanks to a site visit to UCE campus facilities, a large stock of wooden crates containing unused glass bricks were found in a maintenance warehouse. These glass bricks are exactly as prescribed –ϕ140 mm x 40 mm, labeled *Val S$^{t.}$ Lambert—Belgique*. Its clarity is superb and enhanced by 12 bumps that act as lenses to multiply the incidence of light downwards (Fig. 18). A visual inspection showed that the membranes are bent at the corners, but are otherwise in good shape. Unlike the High Life factory in Mexico, sixty-six years after being built, these 'translucent concrete' hypars remain almost intact with only a small number of glass brick units damaged (Fig. 19).

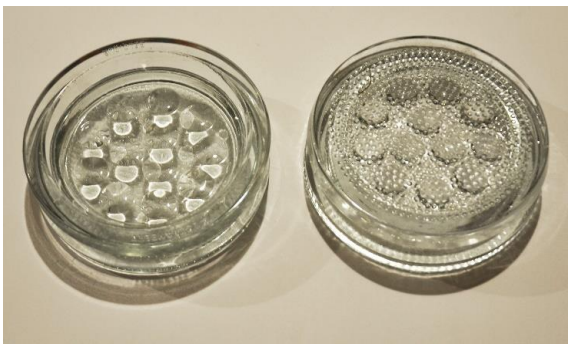

Figure 18: *Val S$^{t.}$ Lambert* Belgian glass bricks upside-down and upright. Figure 19: School of Agronomy and Veterinary Sciences hypars visited. Photos by the author, 2023.

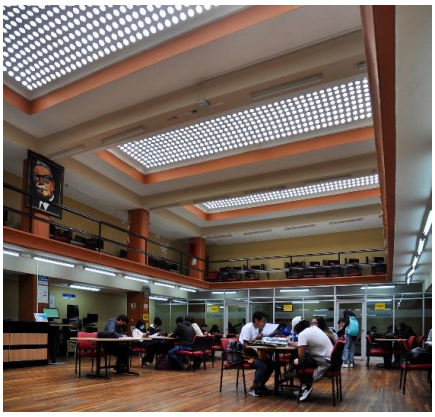
3.4 School of economy sciences –*Facultad de Ciencias Económicas* (1957-1959)

Four long low-rise barrel vault with sloping ends skylights are placed above the lecture hall and one additional barrel vault illuminates the book shelves' area at the School of Economy Library (Fig. 20). Different from previously considered cases, this location is not meant to illuminate circulation areas but a place for longer periods of stay –such as this lecture hall. Arguably, Gatto intended to create a space that improved study performance. Large sun-lit translucent shells, mimic the broad source of the bright sky with less glare. According to Lisa Heschong [16], contrary to artificial lighting, natural light with its varying intensity and full spectrum of colors –that change as sun rises and sets– have positive impact on people. Gatto explored these natural lighting options to trigger physical and mental sensations under this particular UCE library roof. By bringing bright natural light, he was looking for positive impact on improved task performance, health, and desired physiological and emotional responses.



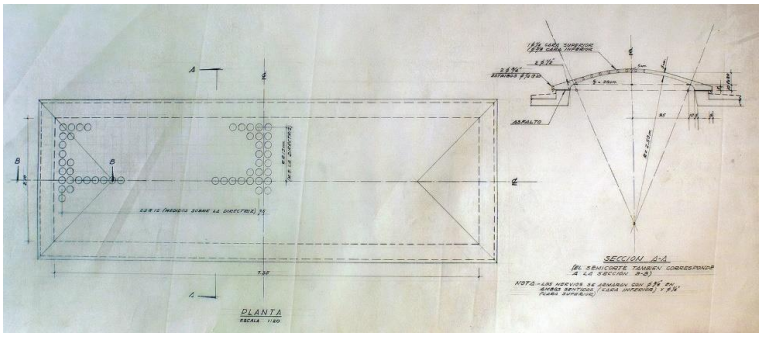


Figure 20: Soft/homogeneous natural light at School of Economy library lecture hall. Figure 21: Library low-rise barrel vaults with formed ends skylights seen from above. Photos by the author, 2023.

Each translucent low-rise barrel vault measures 2.10 x 7.35-meters and is traced with a 2.5-meter radius (Fig. 22), flooding the 5.2-meters high lecture hall below with homogeneous and soft lighting (Fig. 23). Each skylight has 585 glass bricks placed at 38 units/m^2.

4. Conclusion: submission of contributions

Use of translucent concrete shells punctured by glass bricks can be traced to Cuba, Venezuela, Mexico, Spain, and Ecuador, among other countries. Publications featuring the Hight Life factory in Coyoacán,

Mexico City may have informed the works of architect Gilberto Gatto Sobral at *Ciudad Universitaria* in Quito-Ecuador. Gatto left a legacy of fascinating cases of sky-lit translucent concrete shells in multiple formal, functional and structural configurations: elliptic paraboloids, catenary shells, hyperbolic paraboloids, and low-rise barrel vaults. Furthermore, he explored these natural lighting options as mechanisms to control air temperature and to trigger positive sensations on people using educational spaces. Studying these elements of Ecuadorian Modern identity will provide us with instruments to reinforce awareness on their patrimonial values and character.

Abstract

Pier Luigi Nervi was an engineer who contributed to the development of construction technology for reinforced concrete in Italy. The engineer is developing Hennebique and Monie system in Italy. Changes in the construction between the two system are due to the inadequate use of reinforcing bars and woods as a formwork, and a new construction technique called a prefabricated construction method has been used later. On the other hand, Nervi is engaged in the design of the pavilion of the World Exposition which was scheduled to be held in Rome in 1942, that is “Esposizione Universale Roma”. In this thesis I will deal specifically with “Arch of Emperor” in the EUR area. Its basic design is done by Adalberto Libera(1903-1963). Nervi is examining the structure and creating construction drawings. An arch of 200 meters in wide and 100 meters in height is considered. The arch is studied with concrete only without reinforcing bars. How did Nervi try to use a concrete as a structure of an arch in the state that he can not use steel bars? In addition, we will analyze a construction system which was considered at the time of construction in this paper. Then Nervi uses ferro-cement for his works after the world war II. Before the system, Nervi tried a plain concrete and a ferro-cement. While building resources cannot be used freely, the historical significance of making a monument of a huge arch with plain concrete is discussed in this thesis. Also this paper clarifies the process leading to Nervi’s ferro-cement construction in post-war.

Keywords: Pier Luigi Nervi, arch, EUR’42, reinforced concrete, reverse engineering, Adalberto Libera

1. Introduction

EUR 42 was an event scheduled for 1942 and was supposed to be a good experimental site for the expression of Italian fascist architecture (Fig. 1). Fascist architecture can be seen as a fusion of rationalist architecture with ancient Roman style in this paper, but it was actually built at the Livera conference hall (Fig. 2) and Mr. B's Colosseum (Fig. 3). However, the plan for the World's Fair in Rome was not limited to that, and a huge number of proposals were made centering on the main gate called the arch of the empire. Livera and Nervi are involved in the arch. The arch was also treated as a symbol of peace as "Pax Romana"[1]. In this paper, I would like to focus on the arch and consider the understanding of ancient Roman architecture by Nervi and Livera. From the viewpoint of research, the shape of the arch and the construction method. Furthermore, I would like to reassess the significance of this arch in EUR '42 (Fig. 4).

Research interests are Nervi's books and magazine articles, and Livera's memos. The method is to sort out each claim and compare what Nervi and Livera were looking for. By considering the results, we will clarify the significance of Nervi's claim and its ideas to the EUR plan. Previous studies include C.Greco[2], G. Neri[3], and R.Bologna[4], but none of them consider the significance of the arch of the empire. This study reassesses EUR'42 from the analysis of the arch. Nervi is also said to have been critical of the fascist regime after the war. However, until just before the end of World War II, he was

Copyright © 2023 by Satoru KIMURA, Toshiaki KIMURA and Yosuke KOMIYAMA. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

involved in a project that could be called a symbol of the fascist system, and this research provides an opportunity to learn about Nervi's thinking at the time.

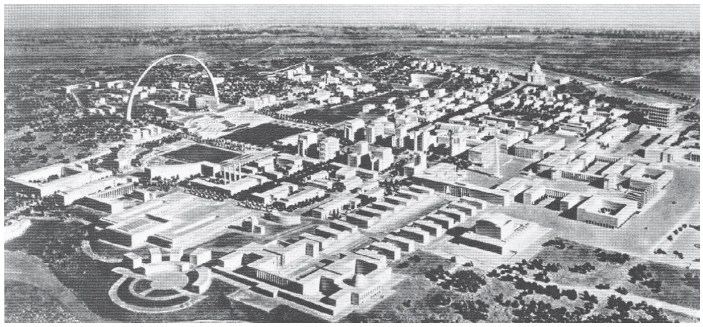

Figure 1. Overall image of the E'42 plan

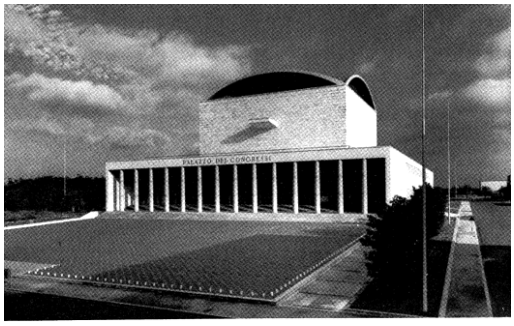

Figure 2. EUR conference hall

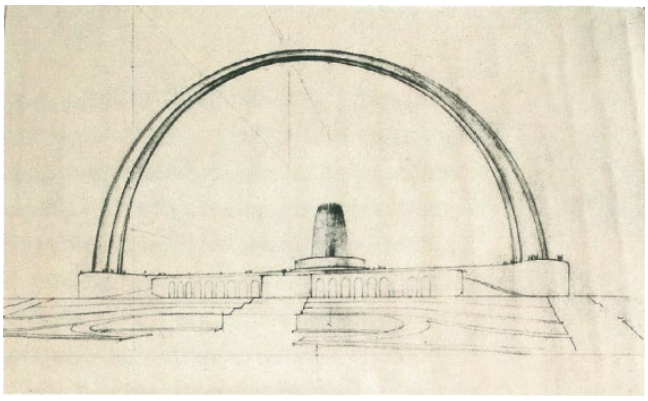
Figure 3. EUR Civilization Hall



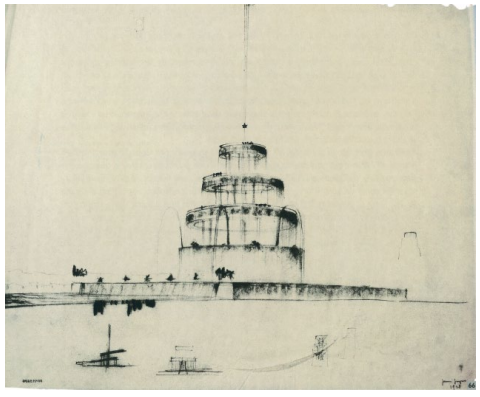


Figure 4. Sketch of the imperial arch

2. Nervi's involvement in the EUR'42 project

As I said in the background, Nervi is involved in three plans centered on the arch of the empire(Fig.5, Fig.6, Fig.7). Looking at those proposals, a parabolic arch is used. In the arch of the empire, a semi-circular arch was pro-posed by Libera, but since Nervi took the initiative in designing the three plans described here, Nervi's intention is directly expressed. A parabola is clearly more effective than a semicircle in terms of building a large roof, but Nervi is planning a large parabolic roof in RC.

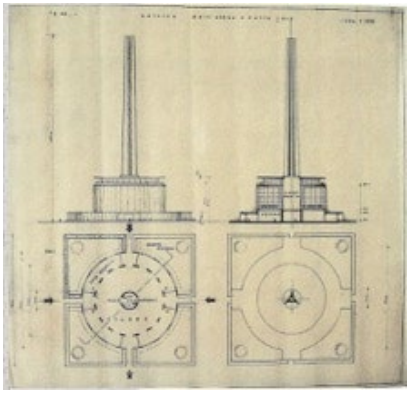

Figure 5 (left). Perspective(A) of pavilion with water and light

Figure 6 (center). Perspective(B) of same Project

Figure 7 (right). Perspective(C) of same project

It is being considered in the Pavilion B plan planned for EUR'42 (Fig. 8). On the other hand, Plan B was a circular plane with a diameter of 70 m, and the same size as the above-mentioned circular hangar was examined (Fig. 9). In the hangar plan, the roof support member provided in the center of the circle has a rigid frame structure, while in the B plan, the arch is extended. In addition, in the hangar plan, the center of the plane was the warehouse, while in the center of the B plan, an external space is provided, and some improvements can be seen.

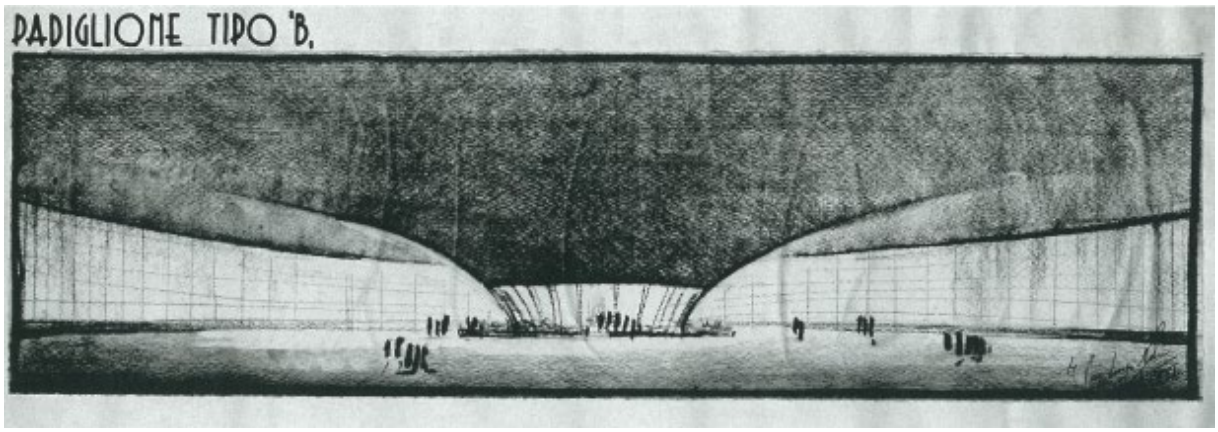

Figure 8. Perspective for pavilion of exhibition hall

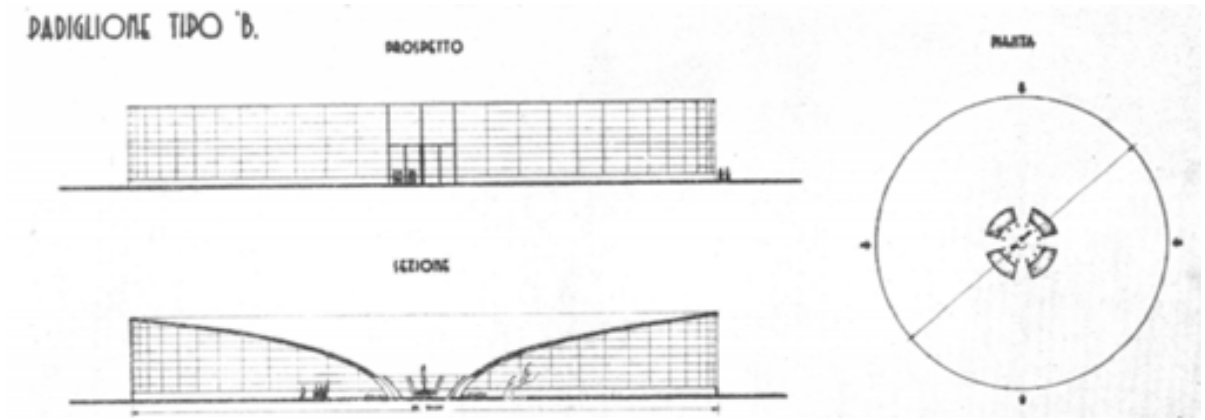

Figure 9. Elevation and plan for pavilion of exhibition hall

3. Remarks on the shape of the arch

If you look at the memorandum about Livera's arch (Fig. 10), you can see that five things are written * 3. They are (1) the cross section of the axis that constitutes the arch is elliptical, (2) the major axis of the ellipse is 1.5 times the minor axis, and (3) the lengths of the base, middle, and top. It was the length of the axis and the minor axis, (4) the radius of the arch, the dimensions of the inscribed and circumscribed circles, and (5) the height of the base. It should be noted that the arch looks like an elevation, and although the arch's cross section in the lateral direction is elliptical, the entire elevation is a perfect circle with a radius of 100 m.

EUR was selected as the new city of Rome as the main venue of the Expo, and Livera has left an actual work called the EUR conference hall. The conference hall used flat and elevation symmetry and colonnades at the entrance. On the other hand, it can be said that the arch of the empire was trying to express fascist architecture with a semicircular arch instead of a parabola as a form. Nervi also made the following criticisms while designing the implementation of the arch designed by Libera. Beyond all

relations to stable facts, the unnaturalness of this form, due to the abstract ideas formed in advance in the designer's mind, gave all the works non-concrete features [5].

This shape" in the quote is exactly the arch of the empire. Nervi also points out that Livera's arch proposal emphasizes morphology over structural safety.

“In special and exceptional cases, it is a characteristic that can be a sensory element (...), but there is no doubt that it has a completely unpleasant appearance [6]”

While criticizing the elevation in this way, he has left a detailed view (Fig.11). From this, it can be seen that there was another form that Nervi should aim for. Also in his own book, Nervi also discusses the example of an ideal bridge, comparing the two bridges. “A quick observation of these two bridge schemes reveals that voluntary obedience to static laws is a condition of aesthetic success(Fig.12&Fig.13). Type A is statically unhappy and aesthetically unhappy” (Fig.12). As the quote suggests, Nervi has a negative opinion about the shape of the bridge using a perfect circle, while the parabolic shape is ideal.

Figure 10. Libera’s sketches and notes on the arch of empire

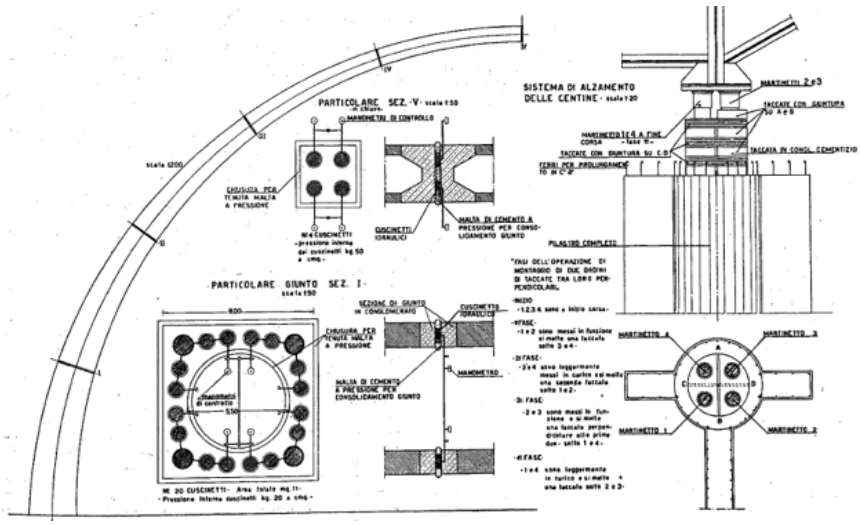

Figure 11. Detail of connects of same arch

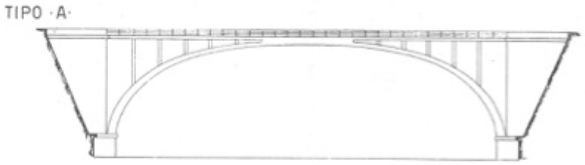

Figure 12. Type A of an ideal bridge

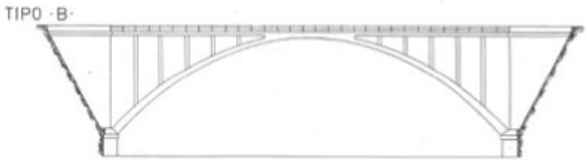

Figure13. Type B of an ideal bridge

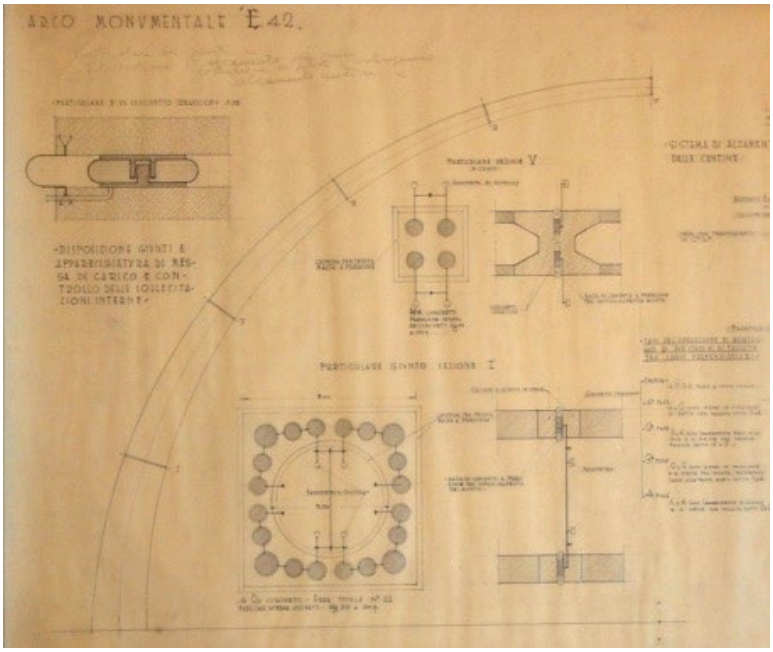
4. Consideration



Here, based on the contents of the previous chapter, we will consider three points: form, material, and history. First, Nervi unilaterally criticized Livera's empire arch proposal for form, but there is something in common between the two. They are about the size of the arch and the materials that make it up. The size of the arch is a perfect circle with a radius of 100 m, and even if you look at other sketches and drawings, there are no plans for different dimensions or ellipses, so the two people agreed on this size and form.

It is probable that an agreement was reached on the use of Roman concrete as the material to be constructed. In addition to Livera and Nervi's proposals, other architects' proposals for aluminum and iron were also being considered [6]. In response to that proposal, the two may have been conducting a

more detailed examination of the construction of unreinforced concrete. Also, it may have been trying to form the style of ancient Rome at that time.

Next, regarding materials and construction methods, Nervi is studying for construction (Fig. 14). We tried to form an integral arch with unreinforced concrete by dividing half of the semicircular arch into five and providing ribs at each connection. The cross section of the arch is a perfect circle.In addition, Nervi has commissioned an experiment on a scale model in collaboration with Professor Oberti of the Polytechnic University of Milan (Guido Oberti, date of birth unknown) (Fig. 15). It has been confirmed that collapse does not occur due to wind pressure or its own weight [7]. As they were considered, it was really aimed at construction.

From here, we will consider how Livera and Nervi perceived rationalist and fascist architecture. The results are shown in Table 1. Livera used symmetry and low rise arches in rationalist architecture such as the EUR conference hall. On the other hand, for fascist architecture, the symmetry is similar, but a semicircular arch is assumed. Furthermore, regarding materials, it was considered desirable to use RC and steel frames as rationalist architecture. And, as fascist architecture, he probably thought that unreinforced concrete, which is Roman concrete, was suitable.

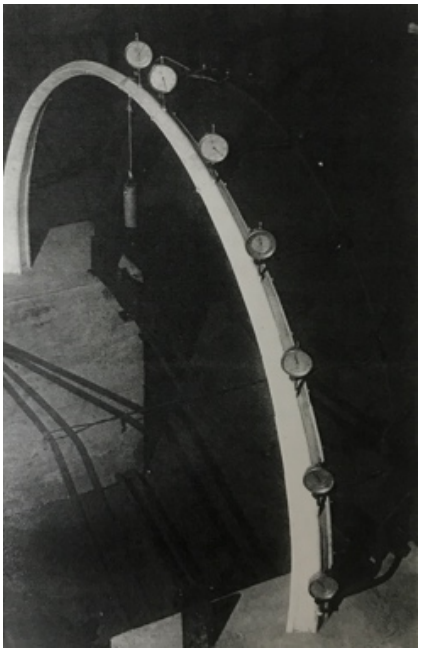


Figure 14 (right). Detailed view of the empire arch by Nervi (in CSAC)
Figure 15 (left). Obertis Structural Experiments on the Arch of the Empire .

5. Conclusion

Nervi wanted to build a parabolic arch rather than a semi-circular arch, while considering the detailed view of the semi-circular arch proposed by Libera as an empire arch. This is because Nervi prefers something that is structurally rational and highly workable, rather than a symbolic one that represents the authority of the ancient Roman Empire.

Nervi is also considering inheriting traditional construction methods for its arches. He is being considered for construction without rebar, and it is believed that he replaced Roman concrete with the construction method of the time. In that sense, it can be said that Nervi sought his own method of form and construction, with reference to what was used in the ancient Roman Empire. Livera planned to quote the ancient arches as they were, but Nervi did not. In other projects in EUR, shell shapes in RC were

considered, and it seems that they were looking for a shape as RC instead of a semicircular arch as a stone.

Furthermore, in the examination of the construction method, it is closer to the Monier type construction method instead of the Hennebique type, showing the sprouting of postwar ferro-cement. Construction with unreinforced concrete, which does not even have a main bar or band bar, has the same idea as the postwar Nervi system in that ribs are provided and the structure is segmented. In the future, I would like to consider the significance of Nervi's ferro-cement architectural works.

Acknowledgements

I have browsed the original drawings at the Parma University Library (Centro Studi e Archivio della Comunicazione, CSAC). In addition, MAXXI provided drawings and photographic data. I would like to express my gratitude.

Abstract

Heinz Hossdorf (1925-2006) was an exceptional engineer. His research and work included very different fields, such as small-scale physical model tests, electronics, structural engineering, architecture, computer applications, three-dimensional CAD (ITS-10), revolutionary calculation methods such as the Finite Element Method, and the development of new materials [1]. For Heinz Hossdorf, model statics was well on the way to overcoming its conventional cumbersomeness through the sensible integration of electronic calculating machines as process computers in the test sequence and to increasing the reliability of the experimentally recorded data to perfection through the use of modern measurement technology. The reinterpretation of the measured values into statements of interest to the engineer, which was associated with laborious calculation processes, was easily mastered by the computer [2]. This paper gives an overview of the wide range of hybrid statics, which Heinz Hossdorf used to achieve technological progress in the field of civil engineering. The materials used and the measurement methods will be analysed, and the question of what influence they had on the planning of the structures will be answered.

Keywords: physical models, FEM, concrete shells, computer statics, new material, electronics.

1. Introduction

Since ancient times, scale models have been used to study physical processes in the real world, to understand the laws of nature, and to make them usable for humans. At the end of the 15th century, Leonardo da Vinci used physical models to study the bending behaviour of elastic beams with different spans. Later, in the 20th century, physical models were indispensable for civil engineers and architects to check the load-bearing capacity of unconventional and innovative structures [3].

Heinz Hossdorf used physical models from the beginning to check his theoretical assumptions for constructive designs. What distinguished him from other civil engineers of his time is that in 1967 he was one of the first to use the computer to automate the whole process of testing physical models. In the 1980s, his lab developed a 3D modelling program that accessed a central model, automatically generated its plans and views, and managed masses in a database [1]. This so-called ITS-CAD system is what is nowadays called BIM.

2. The engineer Heinz Hossdorf

Heinz Hossdorf (Fig. 1.) was born in Wiesbaden (Germany) and grew up in Basel (Switzerland). Hossdorf began his civil engineering studies in 1946 at the Federal Institute of Technology (ETH) in Zurich and, after his intermediate diploma, completed an internship at a shipyard near Antwerp (Belgium). He finally continued his studies at the TU Aachen in 1950, but at the same time began working as a structural engineer at the Rudolf Hascha engineering office in Basel, so he didn't finish his

studies and soon worked full-time there. Already during his time as an employee in the engineering office, Hossdorf felt the cooperation with architects fruitful and his interest in designing his own constructions was awakened. Hossdorf finally founded his own engineering office in 1953, seeking constructive solutions in harmony with the new technological working methods, building materials and construction processes. Therefore, he opened his own private laboratory for experimental statics in Reinach (Switzerland) in 1957 to introduce the tools of the second half of the 20th century's electrical revolution into civil engineering and enhance model statics technologically. In combination with new technologies, experimental statics was to become a modern contemporary medium for structural design and planning. This was also to be achieved through numerous contacts at a national and international level with people and institutions in the field of model statics. His laboratory became internationally renowned for combining physical models with the possibilities of using new electronic computers in engineering, called hybrid statics. In 1966, his laboratory moved to a new building in Basel, where Hossdorf, in addition to his projects as a civil engineer in collaboration with architects, increasingly conducted modelling studies for external colleagues. He also gave lectures on model testing at the ETH Zurich between 1967 and 1969. At the same time, he prepared his book “Modellstatik” (Model Statics), which was published in 1971 [4].

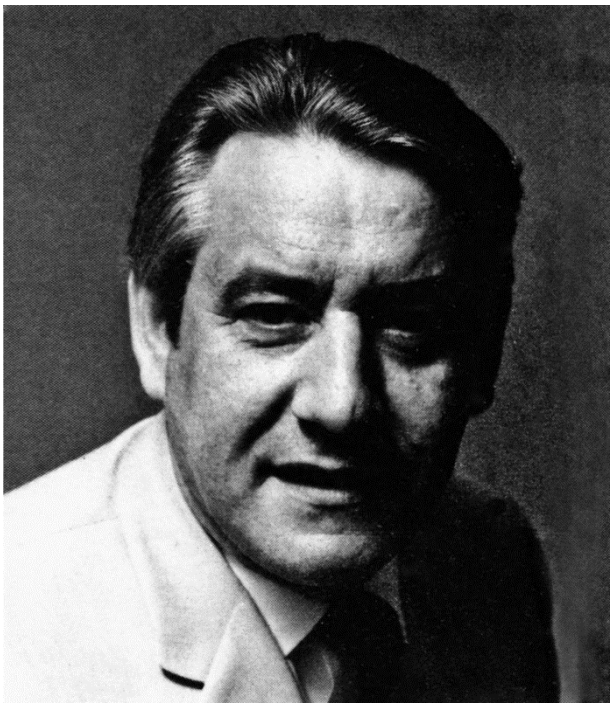

Figure 1. Portrait of Heinz Hossdorf (Bauverlag BV GmbH) [6].

In his publication “Modellstatik”, which Hossdorf understood as a textbook, he further emphasised integrating electronic data processing into physical model tests, in addition to the classical model statics. He was convinced that this was an opportunity to establish the method of model statics, which in his opinion, was not always taken seriously by his engineering colleagues as a fully adequate and practicable tool. The book presents the purpose of model statics, different types of applications and the historical development at the beginning. This is followed by separate chapters on the theoretical principles and the experimental techniques, where the possibilities of materials, experimental set-ups, measurement techniques, etc., are explained. The fourth chapter deals with the computer in model statics and shows the contemporary and possible uses of hybrid statics. In the end, a chapter entitled “Documentation” contains examples from all over the world of projects that have been investigated with the help of experimental model tests. The diverse examples are intended to provide an instructive reflection of engineers' possible applications and ingenuity. Most of the information and documentation on these

model tests was requested by Hossdorf himself directly from the persons involved. Hossdorf benefited from his effective international network of persons and institutions in the field of model statics. Among the institutions and persons requested were the Laboratorio Nacional de Engenharia Civil in Lisbon (Portugal), the University of Southampton (United Kingdom), the Istituto Sperimentale Modelli e Strutture in Bergamo (Italy), the Laboratorio Central in Madrid (Spain), the University of Tokyo (Japan) and the Polish engineer Waclaw Zalewsky, all of whom were known to him personally and perhaps even in close contact [5].

Convinced of the potential of digital object modelling, his laboratory concentrated on this topic and the development of corresponding software from 1974 onwards, so no experimental model tests were carried out there anymore. The laboratory eventually became CAD-Systems AG, which, in addition to development and research, also carried out the first training courses on CAD-Systems in Switzerland. After various holdings and financial difficulties, the company had to be abandoned in 1983. In 1984 Hossdorf emigrated to Madrid and continued consultancy work there, e.g. for Expo 92 in Seville. Hossdorf returned to ETH Zurich in 1996-1997 as a guest professor at the architecture department [4].

Hossdorf became known, among other things, for his shell structures, as he was born at a time when shell construction and prestressing technology were gaining importance. The physical parameters limited the design freedom for shell structures, and theoretical principles were only available for simple, regular geometries. For this reason, only a few architects were concerned with shell construction, but at this time, a number of structurally designing engineers emerged, including Heinz Isler, Pier Luigi Nervi, Eduardo Torroja, Felix Candela and Eladio Dieste, in addition to Heinz Hossdorf. Due to the lack of analytical principles and as the computer technology was not fully developed, Hossdorf resorted to model statics. He carried out load tests on scaled models and determined forces, deformations and strains, allowing him to deduce stress curves in the model and the actual structure. Increasingly, he also used the computer to evaluate and present the measurement results and recognised its potential early on. Ahead of his time, Hossdorf failed to find the financial and human resources to develop a practical CAD system or finite element calculation programs on virtual models, which are now part of the engineer's routine [6].

3. The laboratory for experimental statics

The central tasks of Hossdorf's laboratory were research and development of modelling techniques, as well as the practical application of model statics, especially for external projects for architectural and engineering offices. In this function, the laboratory was a popular excursion destination for students and teaching staff. The laboratory consisted of a mechanical and electronic workshop (Fig. 2) and an experimental laboratory. In the workshop, the models for the experiments were built, and new modelling techniques were developed. The experimental laboratory was equipped with mechanical experimental technology, electronic measuring equipment and a computer. Some circuits were designed there to control the experimental technology using a computer so that specific load cases could be carried out under computer control. The experimental laboratory also had a robust floor on which the models were tested. Results could be output as classical computer printouts or in graphical representations utilising specially developed programmes. Hossdorf saw the success of the application of model statics in the international use of the method, as in England, Germany or, especially emphasised by Hossdorf, at Cornell University in the USA. Hossdorf expressed the following basic idea concerning model statics in an interview: “It is our concern to simply see the truth. Man often tends to prefer to believe in a theoretical line of thought which flatters him rather than to want to find out the bitter truth through experiment [7].”

Figure 2. Workshop of Heinz Harsdorf's laboratory (Walter Grunder) [4].

4. Personal and institutional networks

One of Hossdorf's closest confidants was Kilian Weiss, who was employed as a student assistant in Hossdorf's laboratory during the 1958 semester break. After finishing his studies, Weiss was permanently employed in Hossdorf's office in 1963 and took care of the day-to-day business there. Weiss took over the duties in the office and became a partner in the renamed Hossdorf and Weiss engineering office in 1972 until Hossdorf left the office in 1978 so that he could devote himself entirely to the development of CAD systems. Nevertheless, the two kept in touch until Hossdorf's death. Even before leaving his office, Weiss had taken over many tasks so that Hossdorf could concentrate on working on the models and further developing hybrid statics, although the office naturally benefited from their application. In the laboratory, Léon Beuret, as head, took care of the ongoing processes and also disburdened Hossdorf. Beuret also further developed, for example, tensioning devices for strength models made of prestressed micro-concrete. In addition to the model tests, manual calculations were carried out for individual details, to check the results internally for plausibility. Hossdorf and his staff were in close contact with other model test facilities, such as the laboratory of José Antonio Torroja in Madrid, but an external check of the test results was hardly possible. The architects' trust in Hossdorf and his methods were decisive for many projects; only in this way could a constructively holistic design be developed together. This trust was always crucial to Hossdorf, who preferred creative collaboration over a bottle of red wine to the daily office routine so that statics and construction could become part of the architecture [8].

His close relationship with Spain was established as early as 1954 after Hossdorf published an article on a possible solution for the construction of the third Devil's Bridge as part of the Gotthard Road as a prestressed structure made of purely natural stone in the "Schweizerische Bauzeitung". The construction principle proposed by Hossdorf aroused the interest of Eduardo Torroja and his Instituto de la Construcción y del Cemento, so initial contacts were made with Spain, and a meeting with Eduardo Torroja followed. Eduardo Torroja's statics analysis method using physical models inspired Hossdorf, and he benefited from Eduardo Torroja's reputation and existing network. A close friendship also developed with Eduardo's son, José Antonio Torroja. This friendship even led so far that after the end of the physical model tests in Hossdorf's laboratory in 1978, a large part of the equipment was taken over by the Faculty of Civil Engineering at the Technical University of Barcelona, which was just being established, under the direction of José Antonio Torroja. The transfer and correct use of the equipment was accompanied by Hossdorf himself, thus ensuring the transfer of knowledge. In Barcelona, the method was mainly used in teaching and was part of the curriculum at least until the 2000s. A couple of engineers, together with Hossdorf and José Antonio Torroja, founded the company Digitec AG in 1974, which set itself the task of rationalising engineering work with the help of computer programmes [4].

From his office and laboratory practice, Hossdorf established many, often fruitful, contacts with architects and firms with whom he could realise several projects over longer periods. These contacts often gave Hossdorf great freedom in his constructive solutions, including, for example, the architects Otto and Walter Senn, Hans Beck and Heinrich Baur, Vischer Architects and Felix Schwarz and Rolf Gutmann. As Hossdorf increasingly concentrated on software development, he also sought contact with corresponding experts, which also led to contact and friendship with the physicist and computer scientist Peter Dietz, who was able to provide further help, especially in questions of process control [4].

5. What is hybrid statics?

Hybrid statics was used in Heinz's laboratory in the 1970s to calculate complex structures or to check previously made calculations. The experimental setup in which a computer is integrated into symbiosis with a physical test and measurement facility to form a monolithic technical unit, Hossdorf called hybrid statics. At that time, Heinz Hossdorf was of the opinion that the computer, by tailoring the computational processes to finite element analysis, would be particularly useful in elastic beam statics for plane structures that had been difficult to capture until then. He was critical of the computer's penetration into other areas of structural analysis. He saw the increased computation time from the third power of unknowns in the inversion of matrices and the size of the computers of the time as the limiting factors. He nevertheless predicted the great potential of computers, but only in a symbiotic relationship with the physical measurement model. This symbiotic relationship makes use of the strengths of both components. The computer is in a dialogue with the physical model [2]. The control and regulating devices, which are attached to the model, send analogue data to the computer, which converts these in fractions of millionths of seconds into numerical values, and vice versa, also gives them to the models. The computer is able to make controlled decisions based on the results of complex data analysis in fractions of a second.

Hossdorf describes the computer as a mindless, oversized athlete, capable of indefatigable patience to perform arithmetic operations at high speed and to repeat them any number of times. The physical model has inherently complementary properties. As a material world component, the model knows basically everything (Fig. 3). The physical reality is, by nature, its own. Only it has no language to communicate its experiences to us.

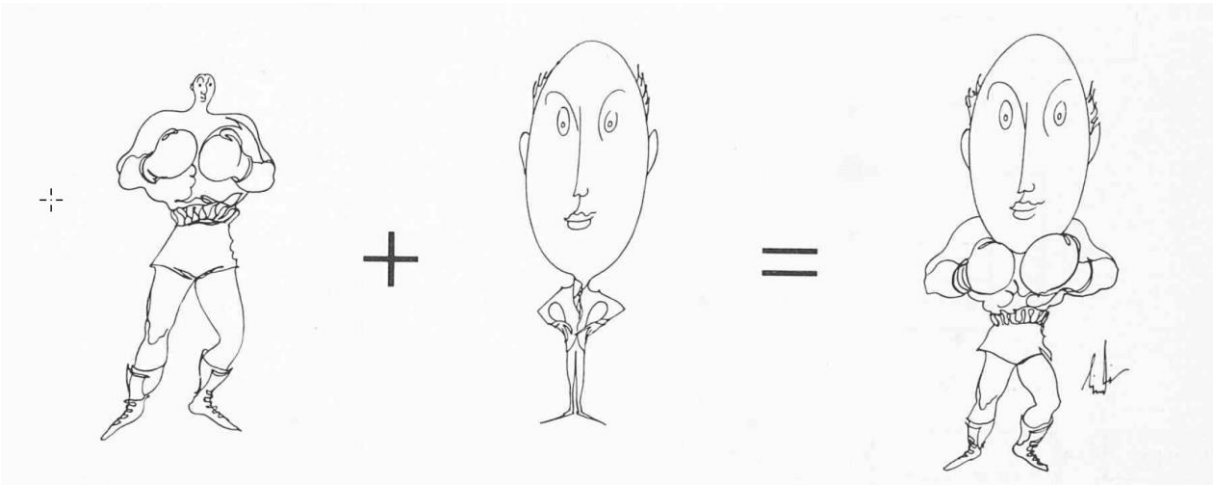

Figure 3. "Hybrid statics – the optimal symbiosis between the workaholic but mindless digital computer and the omniscient but mute analogue model." (Caricature of the well-known illustrator Lindi in an article in the Schweizerische Bauzeitung. 1965) [5].

The whole process of carrying out a hybrid model experiment on a physical measurement model may be described as follows: In the first step, the model is produced. This is often made up of thousands of individual parts, some of which have been specially manufactured and assembled by hand onto an individually tailored test frame, sometimes over days or weeks. After the first part, which is already very time-consuming, has been completed, measuring sensors must be attached. Some of these are also custom-made. This is followed by the load test. For the load test, multiple weights, whose distribution is calculated and each of which is weighed, are attached to the model at a great expense of time. This leads to the fact that one tries to simulate as few load cases as possible. Simultaneously, the measurement is made, which is also very time-consuming, which leads to the tendency to keep the number as small as possible. After the monitored deformations and forces, the evaluation follows. This also must be done manually and consumes additional time. Hossdorf tried to save time and material in the first step, so a modular substructure was made in his laboratory, where the different measuring instruments were mounted [4]. For more or less plane structures, a program-controlled loading device (Fig. 4) was used for the first time in Heinz Hossdorf's laboratory. With this experimental equipment, many of the negative factors from the previous paragraph can be eliminated. This loading carriage can approach any model coordinate with 0.1 mm accuracy. The load can be chosen arbitrarily and applied as often as required. Time-consuming weighing and application of weights are eliminated. For a medium-sized bridge, 100 measuring points can quickly accumulate. With 100 load positions, 10,000 measured values are available. However, it can also run into the hundreds of thousands. Thanks to the computer, the evaluation of these data and the conversion into data that the engineer can use can be done in a few minutes and not in days or weeks, as was previously the case. The read-out values are stored on punch cards. So the inevitable human errors in reading, transmitting and calculating the values are eliminated. Temperature differences or changed bridge voltages can be avoided by calibration measurements as often as required. A xy recorder connected to the system graphically recorded the data on paper [5].

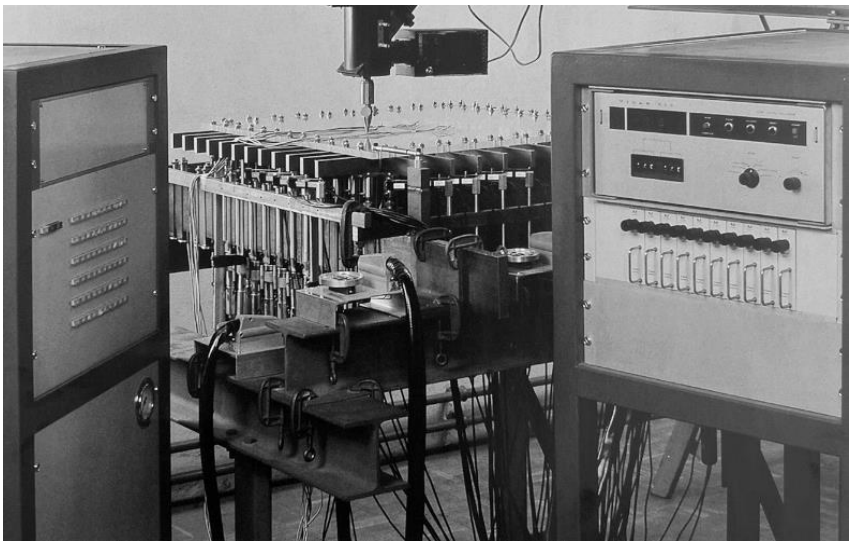

Figure 4. Automatic device for the loading of mostly planar structures [4].

6. Material use

If, as a layman, you see the acrylic resin measuring models, you probably ask yourself why the measuring model was cast from acrylic while the later structure is to be made from reinforced concrete. Of course, the most accurate analogy would be a model made of the same material as the later structure. To understand the use of materials in the models, it is necessary to understand a little about their properties and the principles of the theory of elasticity. The theory of elasticity presupposes a homogeneous continuum, which will be difficult to find in real building materials. Attempts were made to build models from similar rheological materials with similar Young's modulus. The prerequisite was knowledge of the stress-strain diagram and Poisson's ratio, which is the effect of the error effect from the deviation of the transverse contraction coefficient. Also crucial in this context are the principles of Hook's law, which states that the strain depends linearly on the acting force.

Hossdorf saw major problems using micro-concrete since many factors, such as water content and aggregates, can influence the properties. The so-called scale effect also makes micro-concrete a rather poorly suited modelling material. An example of this is the altered proportions of a component's edge and cut surface. The relationship becomes apparent when the area-volume ratio is considered. The area increases quadratically while the volume increases cubically. These differences in the proportion of surface area and interior are neglected in the engineer's usual design methods. Still, in smaller models, they may well carry more weight and must be considered accordingly. “The larger the test specimen compared to the individual “grain”, the smaller the scatter of the measured values. For example, the usual test specimens for concrete have a linear expansion of only about ten times that of the largest individual grain. It would be inconceivable here to reduce the size of the test specimens even further if one wanted to speak at all of a statistical mean value for the interaction of the overall structure. For the same reason, it is impossible to make small models of concrete without at the same time reducing its fine structure [9].” Hossdorf considered acrylic resin a good model building material to simulate concrete elements. Besides the material characteristics, he also saw many advantages in preparing and conducting the elastic tests with acrylic resin. It was easy to process and quickly formed into the desired shape. It is transparent, making it easy to see the weak points in the joints. And it was easier to accurately position the strain gauges on top of each other, which made the measurements more accurate [1]. Since the density of the plastic is much lower than that of concrete, the lack of weight had to be weighted down with weights distributed as evenly as possible to compensate [5].

For his experiments, Heinz Hossdorf did not rely solely on the available materials [5]. In his opinion, there was no perfect material for his model experiments, so he tried to develop more suitable materials

on his own. To do this, he examined various materials, such as plastics, and mixed them with additives such as araldite and aluminium powder [1].

Table 1. Overview of hybrid models tested in Heinz Hossdorf's laboratory. This table is only an excerpt and does not claim to be complete.

Building	**Location**	**Tests**	**Material**	**Year**
University Library	Basel, Switzerland	Elastic tests	Acrylic resin	Appx. 1964

7. Example of a hybrid test

Today the 183 m high building, the second tallest in central London, is called Tower 42. It was built from 1971 to 1979 according to plans by the office of the Swiss-British architect Richard Sieffert as the headquarters of the National Westminster Bank and completed in 1980. The structural principle is a reinforced concrete core clamped into the foundation, from which reinforced concrete brackets cantilever at different heights up to 42 m. Before constructing the physical model, a statics model was calculated by computer. However, since the bracing and cantilevers make it a geometrically complex structure difficult to understand, the commissioned engineers Pell, Frischmann and Partners decided to use Hossdorf's laboratory to conduct a model test that would help to understand the data from the computer analysis [4]. The 1:50 scale acrylic resin model (Fig. 5) was fitted with 200 strain gauges whose output was stored on magnetic tape. This data provided the input for analysis software on a main-frame computer [1]. The data obtained in the experiments were thus digitally preserved, and the results were still reproducible even if the model was lost. Today, over 40 years later, models are predominantly used digitally and no longer hybrid.

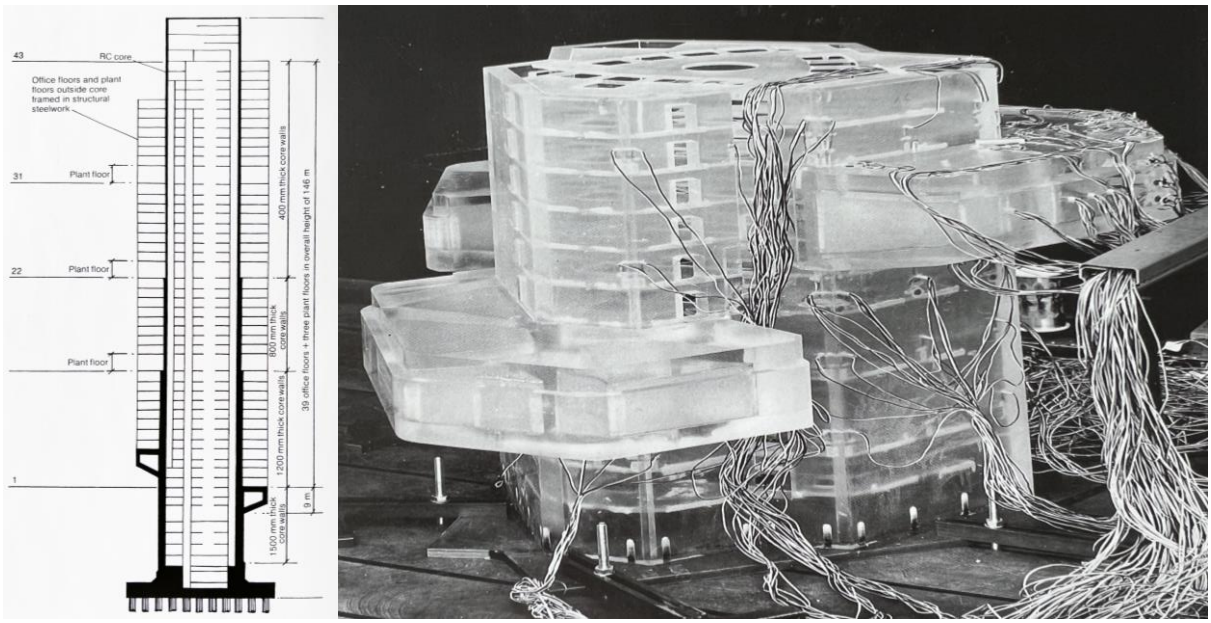

Figure 5. Section and acrylic model of the National Westminster Bank building [4].

8. Comparison of hybrid model and FEM

A comparison of the hybrid models with today's FEM programmes would be very interesting, but is difficult due to several factors. First of all, the data situation has to be mentioned, especially the results obtained by means of the hybrid models. In the sources, mostly only methods and the static system itself are described. Calculated results were only found in graphical tables Hossdorf himself devotes only one page in his nearly 300-page autobiographical work to the comparison of classical computer statics vs hybrid statics [4]. Next, data quality and contextualisation must be considered. The available results, as in Fig. 6, only make it possible to read approximate values. Besides the line width, it remains open where exactly the value indicated by the triangle lies. The most important missing links are the applied load as well as the exact place where it was applied to.

The fact that it is comparatively difficult to obtain data may have to do with the fact that in Switzerland it is not necessary for engineers to record the calculation for buildings being constructed. The authors are currently trying to find contemporary witnesses in order to locate documents that would make it possible to carry out an extensive comparison.

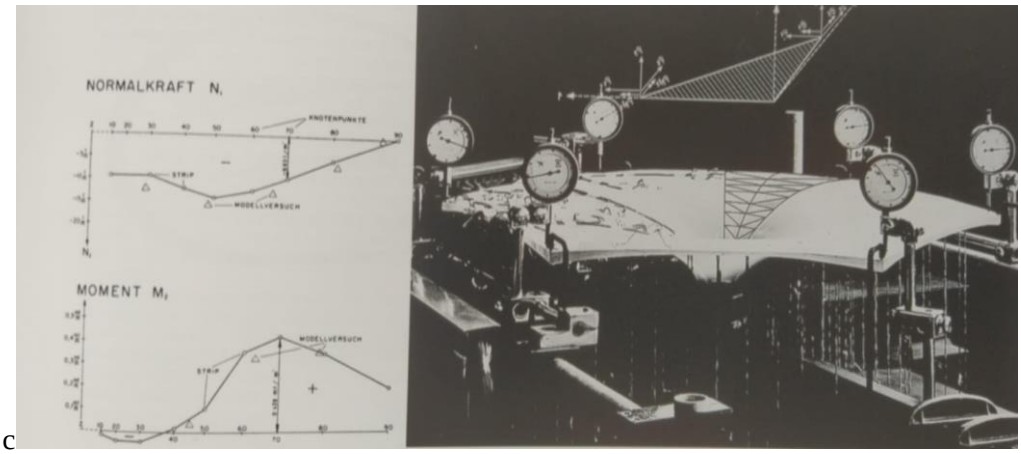

Figure 6. Vergleich Ergebnisse FEM des Strip Programmes und physisches Modell[4].

9. Conclusion and outlook

Hossdorf recognised the potential of the computer as a tool but also as a communication medium very early, which is why he tried to make the use of physical models economical and improve them by optimising their production and measurement technology while at the same time, he wanted to enable the use of virtual models. Hossdorf finally abandoned the physical models altogether which could be a reason that the authors know nothing about the whereabouts of Heinz Hossdorf's models. Since many of the models were tested to the point of destruction or were no longer of importance, and the test facility was dissolved, we must assume that there are, unfortunately, no surviving specimens left.

It is, therefore, all the more important to document the great treasure of knowledge contained in the surveyed witnesses of model testing and to make it available to the public. In order to generate the greatest possible benefit from the surviving physical models found, our results are to be made available to the public as far as possible. This is done within the framework of an ongoing research project, “Last Witnesses”, funded by the German Research Foundation (DFG). For this purpose, an open database is generated, which is fed not only with basic data such as the name of the model, the model scale, the engineer(s), the institute or company, the date of the model, the origin of the model, the current location of the model with contact details, the dimensions of the model, the materials of the model, the description of the model, the location of the project, the date of the start and completion of the project but also with the recorded data of the models and the material stored in archives such as photos, plans and calculations (Fig. 6). However, less common data are also available, such as point clouds and textured polygon meshes. These were acquired in the course of a retro-digitization of still-existing objects and are to be processed into a common web format and made accessible on a homepage within the framework of the research data infrastructure for objects (NFDI4Objects).

Abstract

Structural design of a public library with single-layered lamella shell roof is introduced in this paper. The building is 76 meters by 66.5 meters in planer size, with four floors and one basement floor. There are a large reading room through the ground floor to the third floor, which is continuously connected by step-floors and slopes. The large reading room named “Great Hall” is covered with flat roof, which is supported with dome shaped lamella shell structure. The planer shape of lamella dome is ellipse. The members of dome structure are arranged diagonally in two directions to form a diamond-shaped grid. Since there are no circular members, the dome doesn’t have the properties of a triangular grid dome, and is closer to the stress state of arch. The members are jointed with pin-joint because the joint details would be simple, and vertical members are arranged at the intersections of the diamond-shaped grid and connected to the bending rigid members of the flat roof. The elastic buckling strength of the roof structure has 8 times strength as design load.

Keywords: metal spatial structure, lamella shell, lattice shell, buckling strength of dome structure

1. Introduction

Structural design of a public library with single-layered lamella shell roof is introduced in this paper. The building is 76 meters by 66.5 meters in plain size, with four floors and one basement floor. There are a large reading room named “Great Hall” through the ground floor to the third floor, which is continuously connected by step-floors and slopes, and has circular grid. The basement floor was used for closed stacks, and the structural grid is rectangular. The grid of upper ground floor is different from the basement floor, and it is an important issue of this structural design. The most important issue is a structural design of roof covering the Great Hall.

Figure 1. Outer View.

2. Structure of the building

Figure 4 shows the structural section of the building. A base-isolated structure was adopted to enhance seismic safety and to maintain its function as a library after an earthquake. The basement floor is a rigid-frame structure with seismic resistant walls, and the beam of the ground floor is used with steel reinforced concrete and steel. While the structural frame has a rectangular grid for the basement floor, the structure of the upper floor is used a steel rigid frame with an elliptical grid. Therefore, the structural grid is not matched as the grid of the basement in some areas, and steel columns are placed on the steel beams of the ground level. Because the rigidity of the steel frame upper the ground level is not sufficient to act as isolation structure, the concrete confined steel pipe columns (CFT column) are arranged at the perimeter. Stair-stepped steel beams and stepped slabs are used for floors and slopes.

3. Structural System of the roof

3.1 Structure design process of the roof structure

Various types of structure for the roof of the reading room were considered in the schematic design phase. The plan of the room was rectangle in shape, and the center of the roof should rise in an elliptical shape. The elliptical dome is 42.2 meters by 34.2 meters in planer size A bridge across the room was required to be placed in the center of the room. Various ideas for the bridge and the roof structure were considered. Figure 5 shows several combined ideas for the bridge and roof structure. At first, we considered to use the central bridge as a keel structure to support the roof shown in figure A) or B).

A) Bridge: Suspen-arch, Roof: BSS B) Bridge: Tree shape structure, Roof: Simple beam

C) Roof: BSS D) Roof: BSS and slant Coolum

Figure 5. Structural Ideas of the Bridge and the Roof.

For the roof structure, beam string structures (BSS), truss structures and tree shape structures were considered. A truss structure and a beam string structure don't cause horizontal reaction; therefore, it is easy to be supported by the under structure. In this case the center of the roof is convex downward. However, sufficient height in the center of the room was required from an architect aspect. The structure like a dome and an arch were studied to satisfy the architectural request.

The final structural idea is shown Figure 6, which is an irregular single-layer lamella dome with a diamond-shaped grid of members arranged diagonally in two directions in an elliptical plane, topped by the roof support structure. The ratio of rise-span is 6.5 as shortage direction and 8.9 as longitude direction. The feature of this grid is not existing circumferential members, so it does not have the properties of a triangular grid dome (shell). It is closer to the stress state as a collection of arches (Figure 7). The arrangement and size of members were determined by manual design based numerical analysis.

To simplify the joint details, the members are connected used pin-joints. In this case, it is unstable against unbalanced vertical and horizontal loads, so post members are provided at the intersections of the diamond-shaped grid and connected to the bending rigid members of the top roof. It is important to deal of the thrust in this structure. It is efficient to arrange the arch members down to the floor level to transfer the axial force, but this was not possible due to the architectural plan. Therefore, the arches are supported by columns, and diagonals members are placed at the opposite side of the column for axial to transfer axial force to the roof (Figure 8). The thrust is resisted by the ring-like restraint effect of the surrounding roof slab.

3.2 Member Shape and Joint Detail

The feature of this structure is that many members are existed and jointed with various angles at the intersection point. Therefore, a universal joint system was required. Steel pipe is the most effective member for axial force, but when bolt joints are used, gusset plates must be used at the end of members, and may breaks visually continuity of the member (Fig.9A). If T-shaped members or angle shaped members are used back-to-back, and are fastened with bolts directly to gusset plates, visual continuity can be maintained (Fig.9B). But bolts at the joints will be visible. An original detail was proposed for this project. The angle members were assembled with the corners facing outward, and were attached the plates on the inside of the members at the both ends. When they were bolted to the gusset plates (Fig.9C), the continuity of members were realized used this method (Fig.10). The size of angle section member

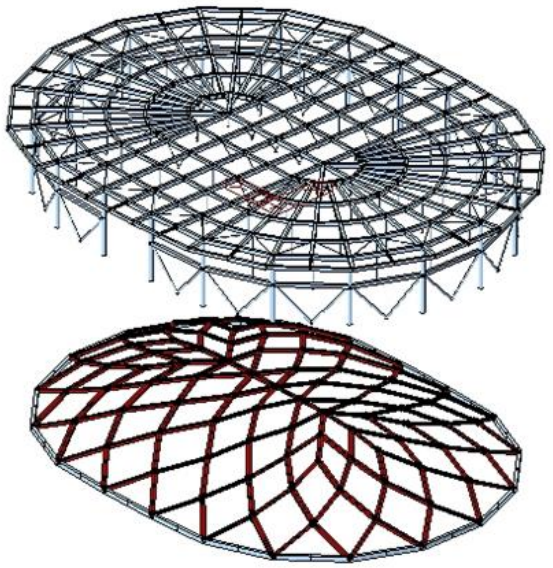

Figure 6. Structural Ideas of the Roof.

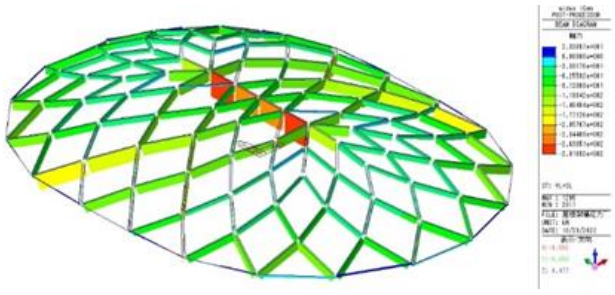

Figure 7. Stess Analysis Result of the vertical load.

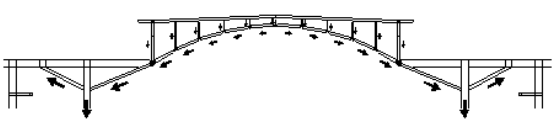

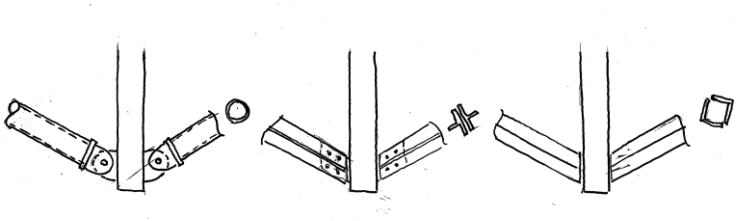

Figure 8. Stress Flow.

is 150 mm x 150 mm. Since the gusset plates are attached to members at various angles, the plates were welded to vertical steel post members. The ends of the members were chipped on one side when they were joined (Fig.11), and a cover plate was welded after the bolts were fastened (Fig.12). After completion, the members are distinctive box-shaped with emphasized edges. The members of rooftop are H-shaped beams.

4. Buckling Strength Evaluation of the Roof

The site is height snowfall area, and the amount of snow depth for design is 215 cm depth. Buckling load evaluation of the roof was important for this project. The buckling strength is dominated by the

A) Pipe B) T Shaped C) Angle

Figure 9. Diference of joint shape.

Figure10. Continuity of Members.

Figure11. Before Bolt Fasteing.

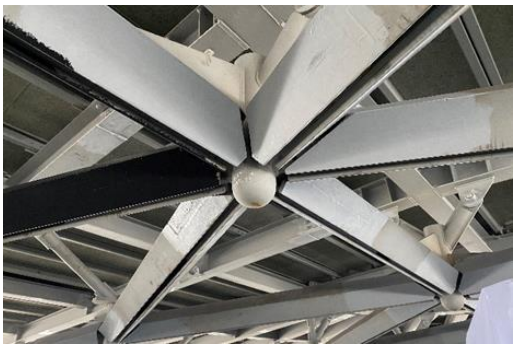

Figure12. After Bolt Fasteing.

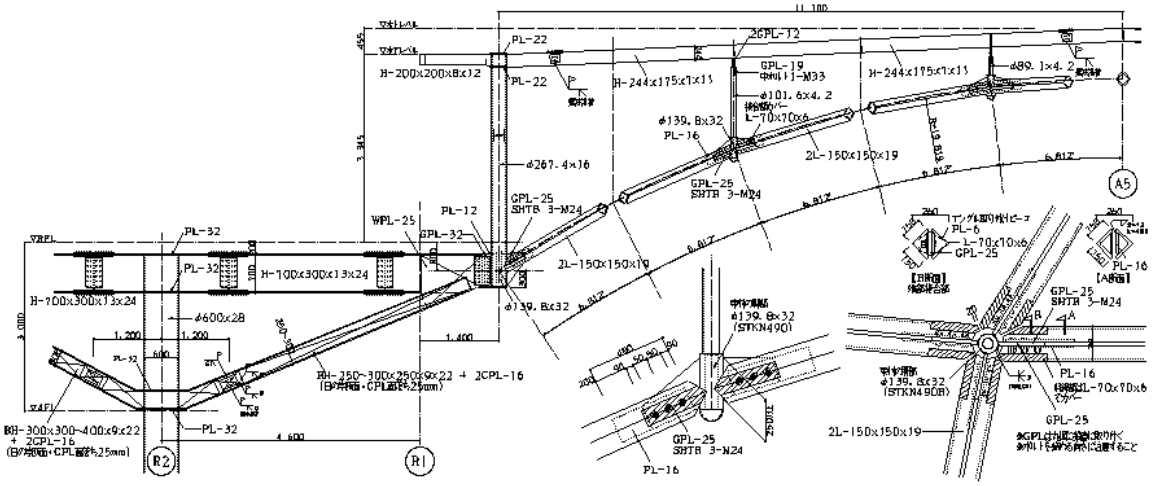

Figure13. Structural Detail Lamella Dome and Roof.

minimum amount of member buckling strength and shell-like buckling strength. The member buckling strength is calculated using buckling length of each member. The shell-like buckling strength is investigated by the method included Report of Activity of IASS WG8[1)]. Firstly, elastic buckling analysis was performed. When the generalized slenderness ratio λ_c is defined Eq. (1), the buckling strength of axial member is defined Eq. (2), (3) by the design code for allowable stress design of steel structure defined by AIJ.

$$\lambda_c = \sqrt{N_y / N_{cr}^{el}} \tag{1}$$

N_y: yield force, N_{cr}^{el}: elastic buckling load

$$\text{for } \lambda_c \leq 1.29 \qquad N_{cr} = \left(1 - 0.24{\lambda_c}^2\right)/\left(1 + 4{\lambda_c}^2/15\right) N_y \tag{2}$$

$$\text{for } \lambda_c \geq 1.29 \qquad N_{cr} = 1/\left(1.2{\lambda_c}^2\right) N_y \tag{3}$$

The buckling strength depend on the rotational stiffness of the joint and the bending stiffness of the roof beam. The joint is assumed pin connection in this structure; therefore, the top roof beam is important element to enhance buckling strength (Figure 14). Figure 15 shows the first buckling mode. The buckling mode is not individual member buckling of lamella dome but the anti-symmetry mode of the arch. The amount of the elastic buckling load was confirmed to be about 8 times that of the vertical design load. The generalized slenderness ratio λ_c defined Eq. (1) is 0.769, and the value of N_{cr}/N_y is 0.741. On the other hand, the value of N_{cr}/N_y for the buckling strength depended on the member buckling is 0.313. As a result, the buckling strength depends on the member buckling, and the safety factor is 0.59 for the buckling against vertical load.

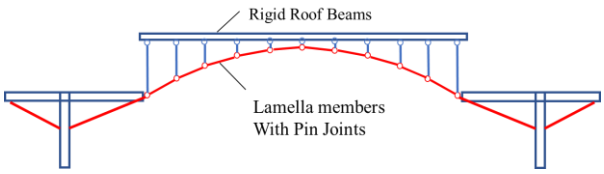

Figure 14. Relation Lamella Members and Beams.

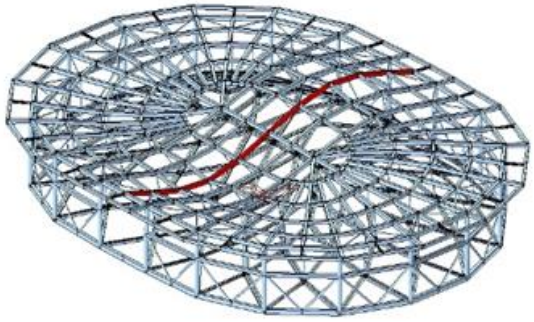

Figure 15. 1st Buckling Mode.

5. Conclusion

A structural design of a distinctive roof with single-layered lamella shell is introduced in this paper. Lamella dome structure without circumferential member acts like arch, and its joints are used pin joint. It is important for this project to handle the thrust force and to enhance buckling strength of pin-jointed arches with the flat roof beams. Distinctive feature of structure was realized by using combination of angle members.

Abstract

In this paper, prediction models of the nonlinear buckling load calculated by the geometric nonlinear analysis are constructed by supervised learning for lattice shells composed of steel pipes. Then, structural optimization was performed using the obtained prediction models. Specifically, shell shapes with high nonlinear buckling loads are generated in realistic computational time by solving optimization prob-lems in which nonlinear buckling load calculations are replaced by the obtained prediction models. The effectiveness of the proposed method is verified through several numerical examples.

Keywords: lattice shell, form finding, machine learning, geometric nonlinearity

1. Introduction

In recent years, with advances in analytical techniques, optimization methods have been introduced into the field of architectural engineering, and there has been many studies of obtaining optimal shell shapes, cross-sections, or topologies with high structural rationality [1-3].Since most of those previous studies are intended for use in the early stages of structural design, structural performances are usually evaluated only in the linear elastic range. However, shell structures can be affected by geometric nonlin-earity, so optimization that takes structural performances only in the linear elastic range as the objective functions is not necessarily optimized for actual structural performances. Although the computational morphogenesis proposed in previous studies has usually complex and free form, such structure requires large computational cost to carry out geometric nonlinear analysis. Therefore, if the structural behaviour in the linear-range diverges from that of nonlinear-range, it may be necessary to modify the structural form obtained by the previous optimization methods considering only linear range through repeated trial and error with huge computational time. It is difficult to directly consider the geometric nonlinearity in the process of computational morphogenesis due to the problem of computational cost. On the other hand, machine learning, a type of artificial intelligence, has been applied to structural optimization in recent years to shorten optimization time and reduce computational cost [4-5].

Therefore, in this study, a prediction model of geometric nonlinearity is constructed using machine learn-ing, and the geometric nonlinear analysis that is repeatedly performed in the structural optimization pro-cess is replaced by this prediction model in order to solve the computational time problem and extend the structural optimization methods to the nonlinear range.

2. Method for creating analytical models

The nodal cordinates of shell structures are discretized by a B-spline surface with $(I+1)\times(J+1)$ control point nets. The vector of x-,y- and z-coordinates of each control point is denoted by q_x, q_y and q_z as follows:

Copyright © 2023 by Shinnosuke FUJITA and Yuma YABUUCHI. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

$$\begin{aligned}
\boldsymbol{q}_x &= \begin{bmatrix} q_{x,00} & \cdots & q_{x,0J} & \cdots & q_{x,I0} & \cdots & q_{x,IJ} \end{bmatrix}^\top \\
\boldsymbol{q}_y &= \begin{bmatrix} q_{y,00} & \cdots & q_{y,0J} & \cdots & q_{y,I0} & \cdots & q_{y,IJ} \end{bmatrix}^\top \\
\boldsymbol{q}_z &= \begin{bmatrix} q_{z,00} & \cdots & q_{z,0J} & \cdots & q_{z,I0} & \cdots & q_{z,IJ} \end{bmatrix}^\top
\end{aligned} \tag{1}$$

If the number of nodes is n, the nodal coordinate vector r is expressed as follows:

$$\begin{aligned}
\boldsymbol{r} &= \begin{bmatrix} \boldsymbol{x} & \boldsymbol{y} & \boldsymbol{z} \end{bmatrix} \\
\boldsymbol{x} &= \begin{bmatrix} x_1 & \cdots & x_n \end{bmatrix}^\top \\
\boldsymbol{y} &= \begin{bmatrix} y_1 & \cdots & y_n \end{bmatrix}^\top \\
\boldsymbol{z} &= \begin{bmatrix} z_1 & \cdots & z_n \end{bmatrix}^\top
\end{aligned} \tag{2}$$

Is this case, the nodal coordinates are discretized as follows:

$$\begin{aligned}
x_k &= \sum_{i=0}^{I} \sum_{j=0}^{J} q_{x,ij} \boldsymbol{B}_{i,N}(u_k) \boldsymbol{B}_{j,M}(v_k) \qquad (k = 1, \cdots, n) \\
y_k &= \sum_{i=0}^{I} \sum_{j=0}^{J} q_{y,ij} \boldsymbol{B}_{i,N}(u_k) \boldsymbol{B}_{j,M}(v_k) \qquad (k = 1, \cdots, n) \\
z_k &= \sum_{i=0}^{I} \sum_{j=0}^{J} q_{z,ij} \boldsymbol{B}_{i,N}(u_k) \boldsymbol{B}_{j,M}(v_k) \qquad (k = 1, \cdots, n)
\end{aligned} \tag{3}$$

where, u_k and v_k is the parameter corresponding to the nodal coordinate of the $k-$th node. $B_{i,N}(u)$ and $B_{j,M}(v)$ are the B-spline basis functions. N and M are the orders of the functions.

3. Prediction methods using machine learning

Neural network that is a type of machine learning is used to predict nonlinear buckling load factor of shell structures. A neural network is a computational graph made by connecting differentiable transformations, as shown in Fig. 1, and consists of three layers an input layer, an middle layer, and an output layer. In Fig. 1, the nodes represented by circles contain numerical values, and the vertical set of these nodes in called a layer. The first layer represents the input variables for prediction, and is called the input layer.

As shown in Fig. 1, when the relationship between input vector and output vector are nonlinear, it is necessary to transform the output vector to the input vector in the middle layer nodes. The function to perform this transformation is called an activation function, and in this paper, we use an activation function called Reacted Linear Unit (ReLU) [6].The ReLU is a function as shown in Fig. 2, and is represented by the following equation:

$$\mathrm{ReLU}(a) = \begin{cases} a & \text{if}(a \geq 0) \\ 0 & \text{else} \end{cases} \tag{4}$$

ReLU is a function that always outputs 0 when the input is negative and outputs the same value as the input value when the input is positive. By repeating the above calculation until the output layer node becomes 1. the predicted value y can be obtained.

When the number of learning data is N, the neural network determines the parameter vector W obtained by the following equation:

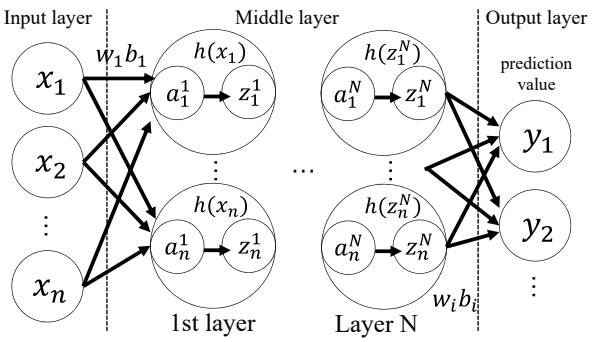

Figure 1: Neural Network calculation flow

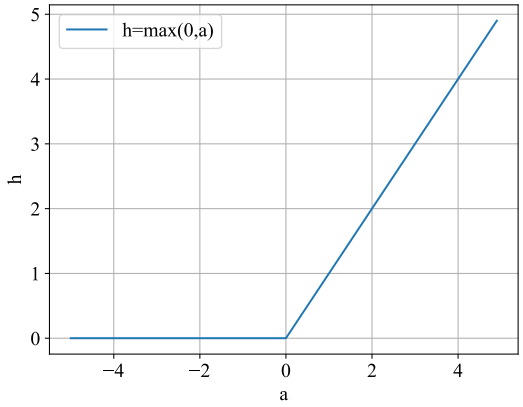

Figure 2: ReLU

$$\underset{\boldsymbol{W}}{\text{minimize}} \quad \text{MSE} = \sum_{n=1}^{N} (t_n - y_n)^2 \tag{5}$$

$$\boldsymbol{y} = \begin{bmatrix} y_1 & \dots & y_n \end{bmatrix}$$
$$\boldsymbol{t} = \begin{bmatrix} t_1 & \dots & t_n \end{bmatrix}$$

N : Number of data
W : Parameter vector
$\boldsymbol{y}$: Prediction value vector
$\boldsymbol{t}$: Target value vector

By inputting the obtained parameter vectors and the input variables of the prediction model, the predictions of the prediction model can be obtained.

Neural networks are built using Keras [7], a high-level neural network library written in Python that can be run on TensorFlow [8].

4. Prediction model building

In this paper, nonlinear buckling load facotor is considered as the objective function for geometric nonlinearity. The nonlinear buckling load factor, which is repeatedly required during shape optimization, is predicted by a neural network. The calculation of the nonlinear buckling load factor takes into account the initial shape imperfections corresponding to the linear first buckling mode obtained from linear buck-ling analysis. First, linear buckling analysis is performed on lattice shells created by randomly placing control point *z*-coordinates. Then, initial shape imperfections based on the first-order buckling mode are applied to those shells with an amplitude of 1/1000 of the span. Subsequently, a geometric nonlinear analysis is repeatly performed on those shells with initial shape imperfection to generate training data.

The nonlinear buckling load factor is calculated by incremental analysis based on the arc-length increment method. Linear buckling analysis and geometric nonlinear analysis are performed using Opensees [9].

5. Formulation of optimization problems

In this paper, four multi-objective optimization problems are considered in problems (6) to (9). In these optimization problems, the nonlinear buckling load factor is maximized under volume constraints, in addition to minimizing the linear elastic strain energy, as is often carried out in conventional optimization approach. To examine the correlation between the nonlinearity of the equilibrium path and the prediction accuracy, (the prediction values of) the nonlinear buckling load factor are defined as $\lambda^{\mathrm{p}}_{1/100}$, $\lambda^{\mathrm{p}}_{1/50}$, $\lambda^{\mathrm{p}}_{1/25}$, and $\lambda^{\mathrm{p}}_{1/20}$ for displacements up to 1/100, 1/50, 1/25, and /20 of the span, respectively, which are the objective functions for problems (6) to (9). An overview of how nonlinear buckling load factor are defined and an example of a load-displacement curve for a geometry in the learning model are shown in Fig.3 and Fig.4. In this study, λ^{p} is defined as the load factor at the point when the tangential stiffness turns negative, but if no buckling point exists within the specified displacement range, λ^{p} is defined as the load factor at the point when the maximum specified displacement is reached. Therefore, note that in cases with small displacement reference ranges, such as $\lambda^{\mathrm{p}}_{1/100}$, the structure may not yet have buckled. Optimization calculations are performed using MIDACO [10], a multi-objective optimization solver that uses ant colony optimization, a type of heuristic method.

$$\begin{aligned} &\underset{\boldsymbol{q}_z}{\text{minimize}} && \begin{cases} -\lambda^{\mathrm{p}}_{1/100} \\ f \end{cases} \\ &\text{subject to} && \begin{cases} V \leq \overline{V} \\ -5.0 \leq \boldsymbol{q}_z \leq 20.0 \end{cases} \end{aligned} \tag{6}$$

$$\begin{aligned} &\underset{\boldsymbol{q}_z}{\text{minimize}} && \begin{cases} -\lambda^{\mathrm{p}}_{1/50} \\ f \end{cases} \\ &\text{subject to} && \begin{cases} V \leq \overline{V} \\ -5.0 \leq \boldsymbol{q}_z \leq 20.0 \end{cases} \end{aligned} \tag{7}$$

$$\begin{aligned} &\underset{\boldsymbol{q}_z}{\text{minimize}} && \begin{cases} -\lambda^{\mathrm{p}}_{1/25} \\ f \end{cases} \\ &\text{subject to} && \begin{cases} V \leq \overline{V} \\ -5.0 \leq \boldsymbol{q}_z \leq 20.0 \end{cases} \end{aligned} \tag{8}$$

$$\begin{aligned} &\underset{\boldsymbol{q}_z}{\text{minimize}} && \begin{cases} -\lambda^{\mathrm{p}}_{1/20} \\ f \end{cases} \\ &\text{subject to} && \begin{cases} V \leq \overline{V} \\ -5.0 \leq \boldsymbol{q}_z \leq 20.0 \end{cases} \end{aligned} \tag{9}$$

6. Numerical examples

For numerical examples, the lattice shells with pin support all around shown in Fig. 5 is considered as an analytical model. The analytical model consists of a 15×15 grid with a square plane of 40 m on a side and a rise of 10 m. The shape is discretized by a 3rd-order B-spline surface with 7×7 grid control net. The cross section of all members are steel pipes with an external diameter of 267.4 mm and a thickness of 6.0 mm. For each member, the unit weight, Young's modulus, and Poisson's ratio are set to 77kN/m^3, 205GPa, and 0.3, respectively. Symmetry is taken into account in this study, with the z-coordinate vector of control point in the one-fourth region as design variables and the other z-coordinate vector of control point determined dependently from symmetry. The condition for stopping the optimization calculation by MIDACO is when the calculation time reaches 12 hours. Computation was carried out on 4.20GHz Intel i7-7700K processor with 64GB RAM.

7. Machanical performance to be predicted

In this study, the nonlinear buckling load factor $\lambda^{p}_{1/100}$, $\lambda^{p}_{1/50}$, $\lambda^{p}_{1/25}$ and $\lambda^{p}_{1/20}$ is predicted by the neu-ral network. First, 90,000 learning models and 5,000 test models with randomized control point z-coordinates of the analytical model in Fig. 5 are prepared while one-fourth symmetry condition is maintained. The prediction accuracy of the prediction model is evaluated by the 5,000 test models. Prediction accuracy in this study refers to the ratio of the true value λ^{true} divided by the predicted value λ^{p} that falls within the range $0.9 \leq \lambda^{true}/\lambda^{p} \leq 1.1$. Adam [11] is used as the optimizer to solve the Eq. (5), and its learning rate is set to 0.0001. Hyperparameters are validated using a total of 4 combinations; 5 middle layers; 32 and 64 batch sizes; and 100 and 200 epochs. Create a prediction model using the hyperparam-eters with the lowest MAE for the test model.
The accuracy of the prediction model through 5,000 test models are shown in Table. 1 and Fig. 7. The results of the training showed that the hyperparameters with 5-layers, 32 batch size, and 200 epochs had the highest prediction accuracy for $\lambda^{p}_{1/50}$, $\lambda^{p}_{1/25}$ and $\lambda^{p}_{1/20}$, 5-layers, 32 batch size, and 100 epochs for $\lambda^{p}_{1/100}$, respectively. Fig. 7 shows that the prediction accuracy is more than 80 % for any output function, and the predicted value for the true value is generally within 1.0.

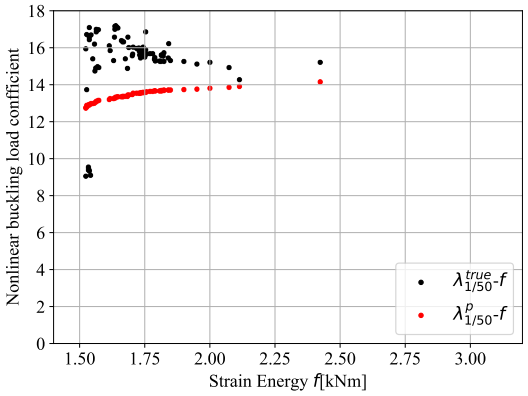
8. Shape optimization result



The pareto front of the multi-objective optimization results from problem (6) to (9) is shown in Fig. 8. The figure shown the pareto front of λ^{p}-f at optimization, together with λ^{true}-f for which a geometric nonlinear analysis was performed on the pareto front solution. From the figure, prediction value tend to be underestimated relative to true value.

The form with minimum strain energy and maximum true nonlinear buckling load factor in the pareto front is shown in Fig. 10 to Fig. 13. As a comparison, the shape with single objective optimization of strain energy is shown in Fig. 14.

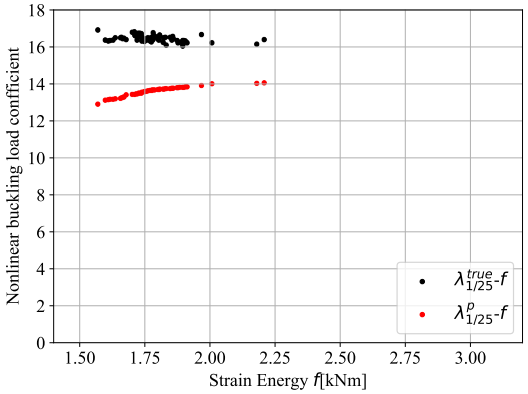


Fig. 8 shows a summary of the pareto front for true values and strain energy. The figure shows that the true values and strain energy are generally in a trade-off relationship, with the true nonlinear buckling load factor being at most about 1.5 times higher than the initial shape.

9. Conclusion

In this paper, the nonlinear buckling load factor and shape optimization using the prediction model. The results showed that the predicted values during optimization were underestimated relative to the true values, but there was generally a trade-off relationship between the strain energy of the pareto front and the nonlinear buckling load factor. Thus, shape optimization that accounts for geometric nonlinearity can be achieved by using machine learning. However, further study is needed as it takes a great deal of time to create a learning model.

Abstract

In a context of simultaneous rising global temperatures and increasing urban density, the need to build additional floor area while reducing the building sector's environmental impact is extremely pressing. Reusing existing structural elements, such as the foundations, presents an opportunity to significantly reduce the carbon emissions associated with constructing a building. This paper presents and deploys a method that demonstrates how designing different superstructures, constrained by the capacity of an existing foundation, leads to different utility. The impact of occupancy, materiality, and efficient structural design on potential floor area is demonstrated, which can vary up to 90 percent, for an office, for example. The impact of these combinations on embodied carbon is also demonstrated, as well as the fact that materiality does not preclude carbon competitive solutions if they are designed efficiently.

Keywords: design for reuse, superstructure design, foundations, embodied carbon, urban development, algorithmic design

1. Introduction

The building stock is expected to increase by over 40% in the U.S. over the next 30 years, due to population and gross domestic product growth [1]. At the same time, current processes required to construct buildings, including material extraction and manufacturing, contribute over 10% of global carbon emissions, annually (often called embodied carbon) [2]. Structural materials, such as concrete and steel, have the ability to last up to 200 years if properly maintained [3] and also embody the majority of a buildings' carbon [1]. This suggests that existing structural elements have the capacity to be reused, to limit the carbon emitted while constructing new buildings.

1.1. Motivation

Despite this potential, the average lifespan of buildings is about one-third of that timeframe in North America [4], [5] and much less in other locations such as South Korea and China [6]. In a study of over 200 building demolitions, nearly 90% were motivated by three criteria: 1) urban redevelopment due to (market driven) changing land values, 2) a lack of maintenance of non-structural elements leading to an undesirable physical condition, and 3) a lack of suitability for current needs (relating to program and building services) [5]. In the case that a building needs to be replaced, or if a site is redeveloped to increase density, foundations have the potential to be reused.

This paper presents and deploys a method to quantify the potential floor area and the resulting embodied carbon for various construction systems, utilizing an existing foundation (Section 2), following a review of relevant literature (Section 1.2). Four floor systems are studied (See Figure 1): 1) flat reinforced concrete (RC) two-way floor with RC frame, 2) shape-optimized one-way RC floor with RC frame, 3) composite steel deck and RC floor (steel deck) with steel frame, and 4) cross-laminated timber (CLT) floor with timber glulam frame. Where applicable, these systems are designed for three program

(occupancy) types: 1) multifamily residential, 2) office, and 3) light manufacturing. This study demonstrates and discusses how designing different superstructures, constrained by the capacity of an existing foundation, leads to different utility. The total floor area is evaluated, as well as the normalized embodied carbon and normalized structural mass for the respective combinations (Section 3).

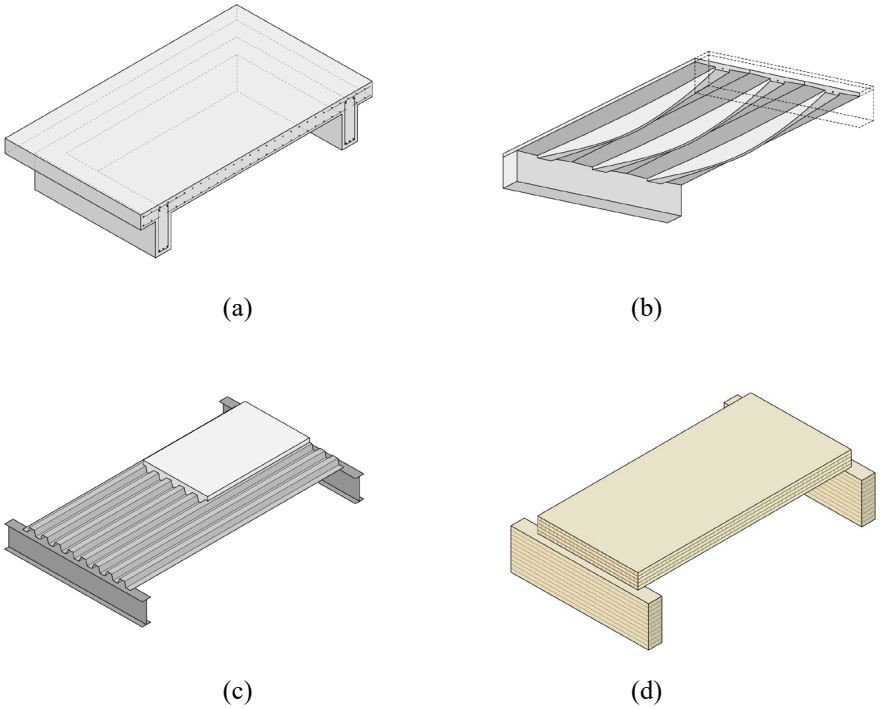

Figure 1. Superstructures being evaluated include: (a) Flat reinforced concrete (RC) two-way floor with RC frame, (b) Shape-optimized RC floor with RC frame [image adapted from Ismail and Mueller [7]], (c) Composite steel deck and RC floor with steel frame, and (c) One-way CLT floor with timber glulam frame

1.2. State of the art

Increasing the longevity of structural elements has the potential to significantly reduce resource demand and emissions. For example, in the United States, increasing longevity of cement-based materials between 1900 to 2015 by 50% could have led to 14% less greenhouse gas emissions [8]. One opportunity to reduce resource consumption in construction is to reuse existing foundations, which are both resource intensive and extremely difficult to remove, particularly in congested urban sites [9].

An example of a building that utilized this approach is 1 Triton Square in London. Originally designed by Arup in 1995, the building was refurbished by Arup in 2021. Primary structural elements, including the foundations and parts of the existing superstructure were maintained, supporting a roof addition and floor infill. The refurbishment saved an estimated 35,000 tons of concrete, 840 tons of reinforcing steel, and 340 tons of structural steel, with the foundation reuse accounting for 25% of the total saving [10]. Using global average embodied carbon coefficients (See Sec. 2.3), the savings from the foundations alone can be estimated at 1.9 million kg CO_2e. The added cost saving (43%) and speed of construction (30% faster) were also noted (Arup, 2023).

Another approach to reducing carbon emissions is to efficiently allocate structural material only where it is necessary. Significant research has been developed by architects and engineers demonstrating the material savings that can be achieved for reinforced concrete floors [7][11][12]. This approach demonstrates that there is room for improvement in reducing the embodied carbon of business-as-usual structural systems across all common material systems.

2. Methodology

To evaluate the embodied carbon impact and utility of reusing existing foundations to support various structural systems, the following methodology is used (See Figure 2).

2.1. Conceptual overview

An existing foundation with a known capacity per column is assumed to be located on a site for re-development. Four gravity load-resisting structural systems -- 1) Flat RC two-way slab with RC frame, 2) Shape-optimized one-way RC slab with RC frame, 3) composite steel deck and RC floor (steel deck) with steel frame, and 4) cross-laminated timber (CLT) floor with timber glulam frame -- are designed for multifamily residential, office, and light manufacturing program using physics-based calculations. This paper references the 2018 International Building Code [13] with the code considerations outlined in Table 1.

Once the superstructures are designed, the systems are evaluated to determine the total floor area that can be built in the respective materials for a given foundation capacity. At the same time, structural material quantities (SMQs) are quantified and used to compare normalized structural mass and to calculate the relative embodied carbon (kg CO_2e/m^2) of each design to compare their environmental impact. Different combinations of occupancy, superstructure materiality, and foundation capacity are evaluated.

2.2. Superstructure design

Design of the superstructure begins with the floors. The one-way spanning steel deck and CLT floors are the most constrained elements in their systems, due to the number of prefabricated parts used in their construction. Design of the structural frame follows, as secondary beam spacing is dictated by the allowable span of the floor system and sizing is based on floor loading. The method presented simulates the design process of a practicing structural engineer using existing construction systems, and accounts for the minimum material necessary to satisfy the design loads and applicable building codes outlined in Table 1. Sound transmission, including impact, is not considered.

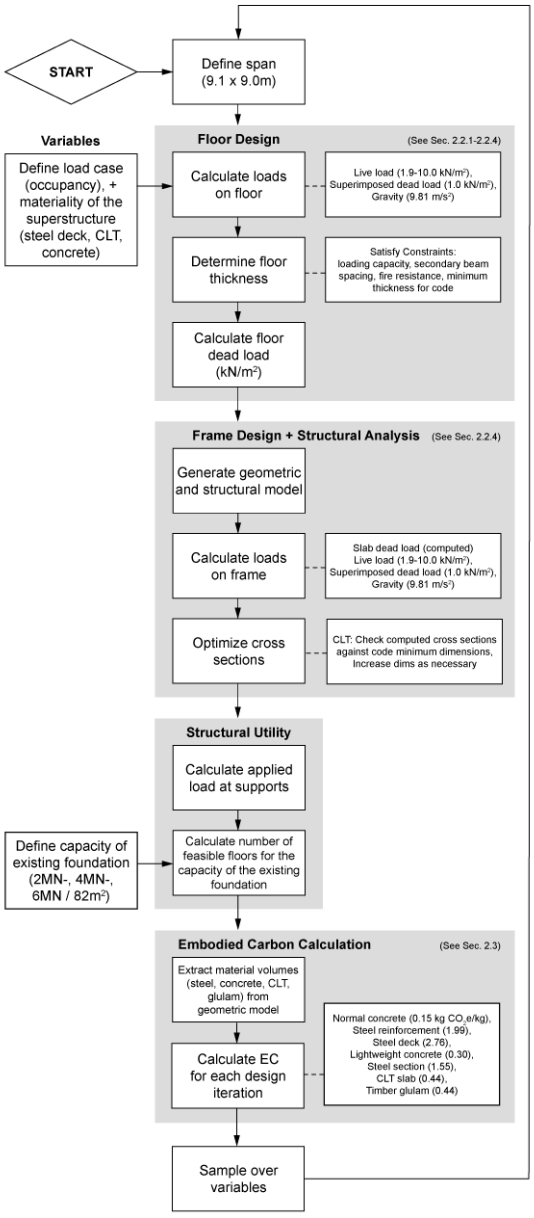

Figure 2. Methodology to evaluate the embodied carbon impact and utility of reusing existing foundations to support various structural systems

For all of the materials being evaluated, the floors are designed for a typical office bay, 9.1 x 9.0m (See Table 4), as office buildings have a shorter lifespan on average when compared to other occupancy types [6]. For all combinations, the roof and its supporting beams are not included in the analysis.

2.2.1. Flat reinforced concrete floor design

A two-way spanning RC slab (non-prestressed) is designed using typical normal weight concrete and reinforcing steel (See Table 5 for material properties). The slab thickness and area of steel is calculated to satisfy ACI 318-19: Building Code Requirements for Structural Concrete [14] using first principles. The RC floor and frame design workflow used in this paper was developed by Sory, Lyu, and Mueller [15] [16]. The resulting dead load for all floors is noted in Table 3.

2.2.2. Shape-optimized reinforced concrete floor design

A one-way spanning shape-optimized slab is designed to satisfy code [14] using the constrained optimization method developed by Ismail and Mueller [7]. This method reduces structural material where it is not required to reduce the slabs overall mass and embodied carbon. Designs are optimized for each for the loading conditions outlined in Table 1.

2.2.3. Steel deck floor design

The one-way spanning steel deck is designed following technical guidance from Vulcraft [17]. To satisfy the superimposed dead load and required fire resistance, a total composite floor depth of 15.88 cm, deck type 3VLI22 (the lightest allowable deck), and lightweight concrete is selected. For the bay size being studied (9.1x9.0m), secondary beams are spaced at 3m (3 span) to satisfy the 3.5m maximum unshored

clear span. This build up is typical of North American construction, and results in a ULL capacity of 46.1 kN/m^2, far exceeding the necessary capacity.

2.2.4. CLT floor design

The one-way spanning CLT floors are designed following technical guidance from Nordic [18] and checked against the minimum dimensions prescribed by code. To satisfy the design loads outlined in Table 1, the minimum dimensions outlined in Table 2, and the minimum material, secondary beams are spaced at 4.5m and a double-span 105-3s floor slab [18] is selected. This floor has a thickness of 10.5cm, satisfying code; however, the fire-resistance rating from the manufacturers is only 30 minutes, compared to 120 minutes for the steel deck floor. Due to the significant discrepancy, a double-span 175-5s floor slab [18] is also studied, which has a thickness of 17.5cm and a fire-resistance rating of 120 minutes. The CLT floors are not designed for light manufacturing occupancy, as the live load exceeds the allowable capacity of the material.

Table 2. Minimum dimensions of heavy timber structural members from Table 2304.11, 2018 IBC due to fire requirements [13]

Element	**Minimum width** (cm)	**Minimum depth** (cm)
Columns	17.1	21.0
Beams, girders	12.7	26.7
Floors	-	10.2

2.2.4. Structural frame design

Following the floor design and secondary beam spacing, the structural frames are designed to satisfy the loads described in Table 1 and Table 3, as well as the minimum dimensions from Table 2 for the timber glulam frame. The overall configuration of the frame is described in Table 4.

Table 3. Calculated floor dead load by materiality of structural system for structural frame design

Floor system: total thickness	**Occupancy**	**Floor dead load** (kN/m^2)	**Frame dead load**
RC two-way flat slab: 27.2 cm	Residential	11.94	Computed automatically
	Office	12.74	
	Light manufacturing	18.50

Steel deck (7.6 cm) with lightweight structural concrete: 15.88 cm	Residential, Office, Light manufacturing	2.17	
CLT: 10.5 cm	Residential, Office	0.53	
CLT: 17.5 cm	Residential, Office	0.88	

Table 4: Configuration used for structural frame design

Primary span (m)	**Secondary span** (m)	**Column height** (m)	**Secondary beam spacing** (m)		**Primary bays** (#)	**Secondary bays** (#)
			Steel frame	**Timber frame**		
9.1	9.0	4.0	3.0	4.5	2	5

Karamba3D is used to efficiently select the cross-sections of the structural frame for the configurations being studied. Beams and girders are designed for a deflection limit of 3.8cm (span/240) for all materials and constrained to a depth of 110cm for the concrete and glulam frame to fairly compare the depth against that of steel sections. The allowable beam depth is increased to 133cm for the glulam frame when the building reaches 26-35 floors, as a depth of 110cm is not sufficient.

Glulam member widths are extracted from Table 3.7, Standard Net Finished Widths for Structural Glued Laminated Timber and depths increase in increments of 38mm, the standard lamination thickness of typical softwood species, according to APA – The Engineered Wood Association [19]. The members are checked against the minimum dimensions prescribed by code (Table 2), and the minimum allowable cross-section is selected.

For steel and timber frames, column dimensions are sized to increase material efficiency and reduce in cross-sectional area for each floor, due to the discretized nature of these systems. For the RC frame, uniform column dimensions are designed for the largest required cross-section for every five floors, due to the desired continuity of the material.

Once the frame members are efficiently sized, the number of floors for each material system is sampled (up to 35 floors), tracking the total structural mass, the maximum reaction forces at the column locations and the structural material quantities. The number of floors that can be built for each system for a maximum reaction force of 2-, 4-, and 6 MN/82m^2 tributary area is reported as well as the structural material quantites for the respective designs.

2.3. Embodied carbon comparison of RC, steel, and timber superstructures

Structural material quantities (SMQs) are tracked during the design of the superstructures discussed in Section 2.2. These material quantities are extracted and multiplied by their respective density and embodied carbon coefficient (ECC) (See Table 5) to determine the environmental impact of the designs. The ECCs represent the amount of carbon (CO_2e) emitted during LCA Stages A1-A3 (cradle to gate) according to EN 15978:2001. World average ECCs are used from the Inventory of Carbon and Energy (ICE database) [20], due to the reliability of these values [21]. For materials not included in the ICE database (structural lightweight concrete), the global average value is used from the Embodied Carbon in Construction Calculator (EC3) tool [22]. Carbon storage is not considered for timber elements, due to the range in values present in the literature.

Table 5. Material properties for structural design and embodied carbon calculations. ECCs are from the ICE database* [20], unless otherwise noted** [22].

Floor system	**Material**	**Embodied carbon coefficient*** (kg CO2e/kg)	**Density** (kg/m^3)	**Strength** (Mpa)
RC	Concrete (normal)	0.15	2400	slab, beam: 34.5 column: 55.1
	Steel reinforcement	1.99	7850	415
Steel deck	Steel deck (hot dip galvanized)	2.76	7850	
	Concrete (lightweight, structural)	0.30**	1762	
	Steel mesh (reinforcement)	1.99	7850	
	Steel section	1.55	7850	
CLT	CLT floor	0.44	513	
	Timber glulam	0.44	513	

Embodied carbon and structural mass are normalized by square meter of built floor area and reported against the total number of floors that can be constructed, for comparison.

3. Results

The total number of floors that can be supported by an existing foundation with a capacity of 2MN, 4MN and 6MN/82m^2 and the normalized embodied carbon (EC) is shown in Figure 3 for flat concrete, shape-optimized concrete, steel and timber superstructures designed for residential, office, and light manufacturing occupancies (where applicable).

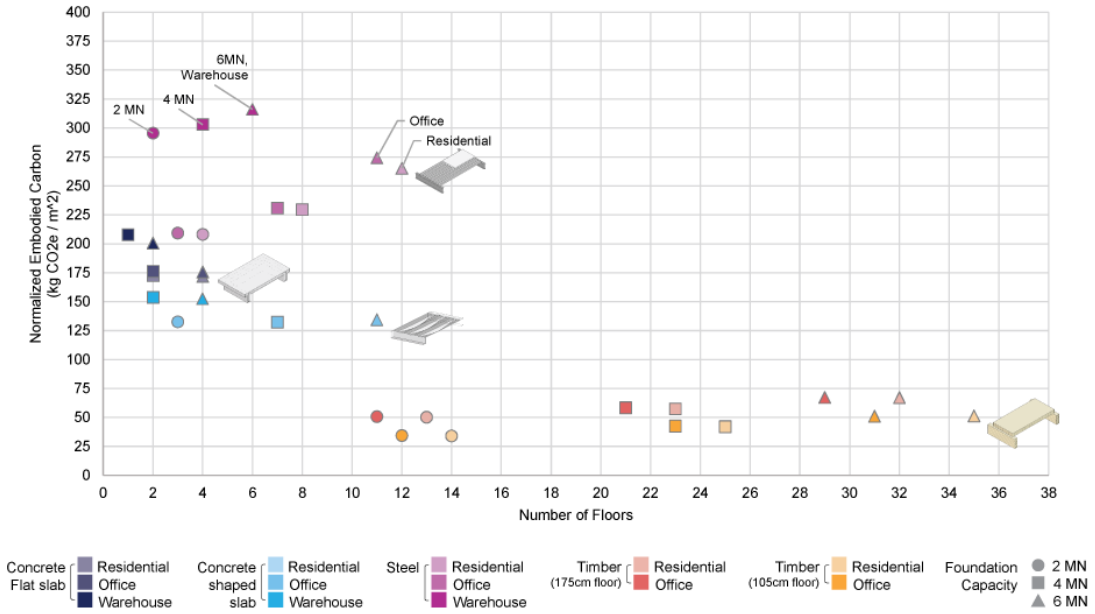

Figure 3. Normalized embodied carbon and allowable number of floors for flat concrete, shape-optimized concrete, steel, and timber structures designed for a foundation capacity of 2-, 4-, and 6MN/82m^2 tributary area

As one might expect, the normalized embodied carbon for the timber superstructures is significantly lower than the steel and concrete superstructures, supporting the same loads. This can be attributed to the low normalized structural mass as well as the low embodied carbon coefficient for glulam and CLT. The normalized EC values for the flat concrete structures are around 10-25% lower than those of the steel structures due to the relative carbon intensity of steel sections as well as the increased cement content (and resulting EC) from using lightweight structural concrete for the floors. It should be noted that for the flat concrete system, the additional mass precludes it from achieving a factored column load of 2MN for the tributary area studied. However, the shape-optimized RC floor (designed for office loading) saves around 60% of the embodied carbon from the steel system for the same load and can achieve the number of floors.

As the live load increases from residential program to warehouse program, the quantity of structural material required to support the additional live load leads to a significant increase in embodied carbon for the business-as-usual steel and flat RC systems. For example, a steel residential and office building designed for a 4MN foundation can reach 8 and 7 floors, respectively, for 230 kg CO_2e/m^2. For the same foundation capacity, a steel warehouse can reach 4 floors, for 303 kg CO_2e/m^2. By utilizing material efficient systems in these scenarios, a significant amount of carbon can be saved.

For the two CLT slabs studied, intuitively, the normalized EC increases, and the number of achievable floors decreases for the 175cm thick CLT floor from the 105cm thick CLT floor. However, the additional thickness doesn't significantly alter the utility of the 175cm system, compared to the 105cm system, while providing significantly higher fire resistance (120min compared to 30min).

The normalized structural mass relative to the normalized embodied carbon values for the same designs are shown in Figure 4.

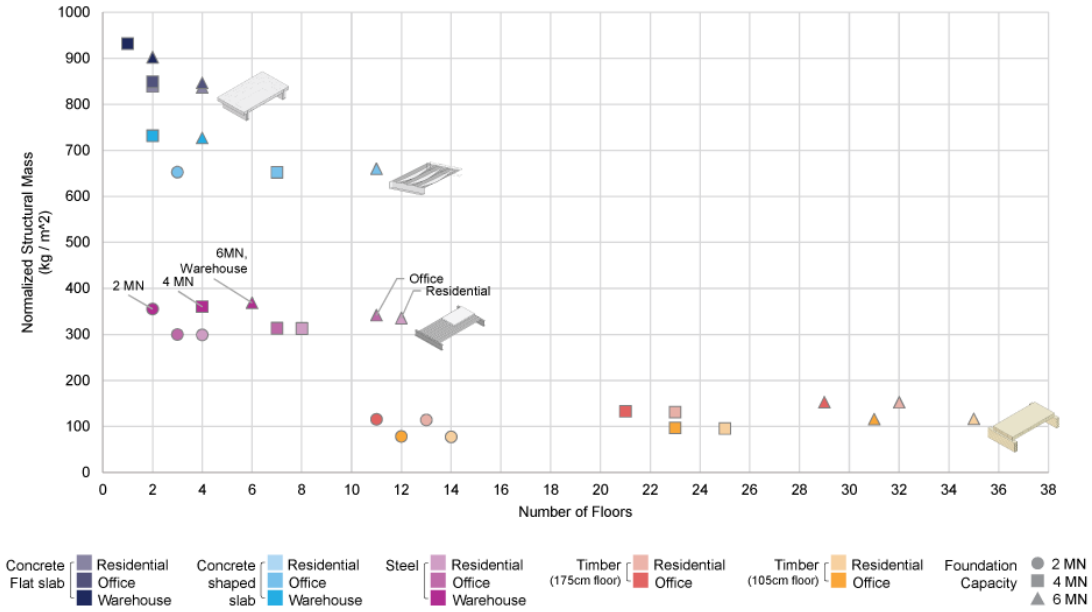

Figure 4. Normalized structural mass for concrete, steel, and timber structures designed for a foundation capacity of 2-, 4-, and 6MN/82m^2 tributary area

CLT floors have a significantly lower normalized structural mass (kg/m^2) than typical steel deck and RC floors (See Table 6). This contributes to the ability to build more floors in timber for the same maximum column load, all things remaining equal. For lower allowable column loads (4MN/82m^2) one can build three times the number of residential floors in timber compared to steel and shape-optimized RC floors, and twelve times the number of flat RC floors. However, if a more material efficient steel system is developed, the normalized mass may bring it closer to the timber systems shown here.

The total mass of the flat concrete system is significant, at three times the values for steel and nine times the values for timber. A shape-optimized RC slab brings this total mass down by one-third. If the shape-optimized RC floor is compared to a one-way flat RC floor, this shift could be even more significant.

The normalized structural mass and normalized embodied carbon for an office designed for a foundation with a capacity of 4MN is compared for each structural system in Table 6.

Table 6. Structural system utility for an office designed for an existing foundation with a 4MN capacity

Floor system: number of floors	**Max applied column load** (MN)	**Total floor area** (m^2)	**Structural Mass** (kg)	**Normalized structural mass** (kg/m^2)	**Total embodied carbon** (kg CO_2e)	**Normalized embodied carbon** (kg CO_2e/m^2)
RC flat: 2	3.78	1,638	1,575,900	962	335,090	207
RC shape-optimized: 7	3.95	5,733	36,99,063	652	750,824	132
Steel deck: 7	3.63	5,733	1,797,200	313	1,322,500	231
CLT, 10.5cm: 23	3.96	18,837	1,820,500	97	801,014	43
CLT, 17.5cm: 21	3.88	17,199	2,280,500	133	1,003,400	58

Normalized mass quantities are closely aligned to previous bottom-up structural design for the steel and timber systems [23] [24], however, the flat RC system is roughly double that of the same studies. This may be attributed to the fact that the studies referenced utilize one-way ribbed slabs for a 9m span, reducing the material volumes for the floors themselves as well as the beams required for 2-way systems. The normalized mass quantities for the flat RC system are more closely aligned (albeit slightly lower) with the median value in the top-down analysis of 59 concrete buildings conducted by De Wolf *et al.* [25]. While this paper doesn't include the structural material quantity of the lateral load resisting system, it is assumed that a comparison is still warranted given the low rise of the structures considered.

However, the shape-optimized RC floor becomes more competitive when evaluating the tradeoffs of this system compared to the others. For example, although the normalized mass is double that of the steel system and six times that of the timber system, the normalized embodied carbon is almost half of the steel system. Additionally, the shaped RC system is designed for warehouse loading, which is not possible in the timber system.

A summary of the normalized structural mass and normalized embodied carbon for all the design combinations are shown in Figure 5.

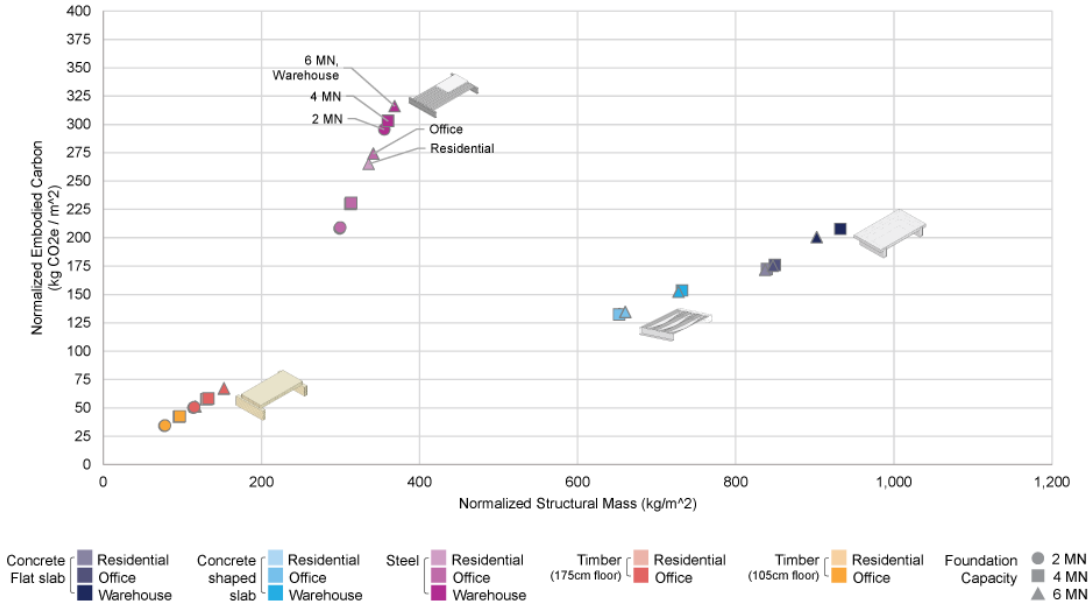

Figure 5. Normalized embodied carbon and normalized structural mass for concrete, steel, and timber structures designed for a foundation capacity of 2-, 4-, and 6MN/82m^2 tributary area

4. Conclusion: Summary of contributions and potential impact

This paper aims to encourage reuse of existing structural materials to limit carbon emissions associated with new construction. Acknowledging the fact that urban redevelopment often necessitates building a new superstructure, the utility of existing foundations is determined for flat concrete, shape-optimized concrete, steel, and timber structural systems to evaluate the environmental impact and total allowable floor area of the respective systems, if a new superstructure is warranted.

The utility of the timber systems is best exemplified in Figure 3, both in terms of applicability and limitations. Compared to a steel system, one can build three times the number of floors in timber for only two-thirds of the total embodied carbon. However, as high live loads cannot be supported by CLT floors, their use is limited to occupancies such as residential and office. CLT also incurs a cost premium over reinforced concrete for the same span and faces limited supply volumes [26]. The trade-offs

between the various systems warrant further exploration, especially when CLT floors are not possible due to loading, cost, or material sourcing limitations.

Business-as-usual steel and flat slab concrete systems are both massive and can have a high environmental price. However, shape-optimizing these systems can have a significant impact on their applicability, allowing them to be more competitive when evaluating the tradeoffs against the other systems. For example, although the normalized mass of the shape-optimized RC floor is more than both the steel and timber systems, the normalized embodied carbon is almost half of the steel system. Additionally, the shaped RC system is designed for warehouse loading, which is not possible in timber.

4.1. Limitations and future work

In this paper, lateral load-resisting systems are not included in the structural material quantities. It is assumed that lateral stiffness is not the controlling factor for the concrete and steel designs sampled [23]. However, the additional height of the timber structures may necessitate the inclusion of the lateral systems in the overall EC evaluation.

Additionally, in terms of total carbon emissions, whole life carbon emissions (beyond LCA stage A3) and the thermal performance of the structural materials is not accounted for. Thermal mass of the concrete and steel systems has the potential to improve operational performance of a building during use, which requires further study.

Lastly, the majority of the systems studied in this paper, with the exception of the shape-optimized RC floors, are indicative of business-as-usual construction methods, which often sacrifice material efficiency for speed of construction. There is potential to reduce the structural material quantities of these systems by utilizing efficient geometry, which may bring the respective designs closer to one another for both normalized mass and EC. Significant work has been done in this area for reinforced concrete floors, however an opportunity exists to reduce the mass and embodied carbon of traditional steel deck systems. Using less material intensive and lower cost systems is particularly relevant where timber is not readily available, or the cost premium precludes it from being used.

4.2. Concluding remark

In a context of simultaneous increasing global temperatures and increasing urban density, the need to provide additional floor area while reducing the AEC sector's environmental impact is extremely pressing. By reusing existing building foundations, significant carbon savings can be achieved. Additionally, understanding the constraints of these elements and designing a superstructure that maximizes their utility will be key in achieving this objective. The method presented in this paper aims to encourage designers and engineers to minimize the embodied carbon associated with urban development by rethinking business-as-usual construction methods and demonstrating the utility of various superstructure designs constrained by reusing existing foundations.

Abstract

A lot of the most consequential building design decisions are locked in during the early-design phase. However, lifecycle assessments are commonly conducted later in the planning phases where the analysis has limited potential to meaningfully affect the design. It would be ideal to front-load this analysis into the early-design phase, however, this is challenging since project information at this stage is limited and the design process is fast-paced. This paper addresses this challenge by creating a user-friendly webtool for indicative lifecycle assessments to be used during the concept design phase. Existing research has resulted either in sophisticated software with maximised functionality but limited practicality for early design or point solutions that often lack the interdisciplinary approach necessary to achieve truly sustainable outcomes. This tool is novel in that it addresses both embodied and operational emissions, and both the main structural and façade elements, while considering the margin of error associated with early-stage assessments and reaching carbon neutrality. It does so as a web-based tool that provides integrated access to expertise through a highly accessible interface with near real-time feedback. A unique contribution of the tool is a design automation algorithm that auto-sizes structural members based on a first-principles approach.

Keywords: parametric design, user-friendly, lifecycle assessment, carbon neutrality, embodied carbon, operational carbon, agile development, energy modelling, environmental flows, concept design

1. Introduction

Over the past decades, sustainable building design has focused mainly on operational emissions, that is, those associated with the day-to-day running of the building. With increasing progress on the energy-efficiency of HVAC systems and high-performance facades, as well as the increasing decarbonisation of energy grids, the significance of embodied emissions associated with the manufacture and transport of building materials has risen. Sustainable building design should therefore consider lifecycle assessments (LCA). In other words, estimating both operational and embodied carbon emissions.

Some of the most impactful building design decisions are made in the early project stages [1]-[3]. At this point, engineering analysis is commonly limited, while architects are left to make many design decisions based on tacit knowledge rather than data-driven insights. It is difficult to significantly change the design after a town planning permit has been lodged, since this process solidifies design expectations with legal and financial ramifications should the initial design have to be reworked. The issue here is that the town planning permit tends to lock in the structural system and overall envelope design, both of which are the greatest contributors to lifecycle emissions [4].

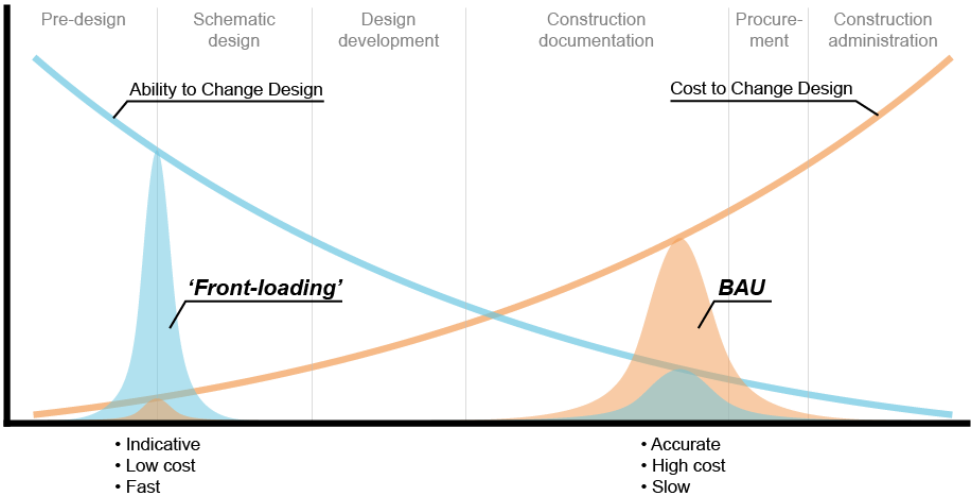

Figure 1. A "MacLeamey" curve as it applies to LCAs. (Adapted from [5])

LCAs are commonly only conducted in the late planning phases. This is a problem as design changes become increasingly costly as the project proceeds, hence the analyses have limited potential to meaningfully affect the design (Figure 1). Sustainable building design could be facilitated by 'front-loading' LCAs into the early design phase, but this is challenging since project information at this stage is limited and the design process iterative and fast-paced. This is a common dilemma that plagues all aspects of early design and is one that computational designers typically seek to alleviate by developing algorithms to automate processes and decrease the effort needed to conduct analyses, or by using new types of tools and visualisation techniques to enhance design processes, or sometimes even by developing custom software. Compared to other contexts, conducting LCAs for buildings is more challenging due to the long lifespans of buildings, their complexity, and the multiplicity of stakeholders involved throughout their design and operation [6]. Any effort to conduct these kinds of analyses in the early-design stage must be accompanied by an understanding that the results will necessarily be indicative rather than accurate calculations. These intrinsic error margins should not become a roadblock to considering sustainable design from the project outset; the uncertainties just need to be expressed clearly and quantified where possible [7].

While several academics have proposed various theoretical frameworks (e.g., [8], [9]) to tackle the challenges in conducting early design LCAs, there are now also numerous consultancies that have developed digital tools for use in practice. This is an emerging field with direct potential impacts on the sector with the largest contribution to worldwide emissions [4] and therefore warrants deeper research attention. An analysis of the currently available tools shows a diversity in terms of the approaches and methodologies followed, the types of user input they require, the scope of carbon-related design tasks and disciplines considered, and the solution maturity. A lot of the existing tools appear to be in the beta phase of their development (e.g., [10]-[13]) which demonstrates that this is an emerging field in the industry. Some tools are specifically intended for browsing existing material emissions databases and therefore require an existing geometry model (e.g., [10], [12], [14], [15]), while others allow the user to input top-level geometric data (e.g., building width and length, etc.) and the tool then auto-sizes all building elements to estimate material volumes (e.g., [11], [13], [16]-[20]). Tools tend to focus on a specific discipline, typically producing an informed estimate either of the embodied carbon of the structure or the façade; a search conducted by the authors did not reveal an early design tool within this space that considered operational carbon.

There appears to be a gap in research to create a tool that:

- Holistically estimates emissions across all major contributors

- Assesses embodied carbon of the structure and façade as well as operational carbon
- Auto-sizes structural elements in the early design stage where a sophisticated geometric model (e.g., a reliable Revit model) may not be available for determining material quantities
- Allows exploring the interdependencies between upfront façade emissions versus lifecycle emissions through operational energy consumption

2. A cross-disciplinary tool

2.1. Aim

The aim of this research was to create a user-friendly design tool for conducting indicative, early-design stage LCAs and allowing a broad user group to compare design options holistically, for the goal of reducing lifecycle emissions in building design. A focus of this tool was to enable user groups beyond sustainability experts to make informed decisions and communicate these to clients, while establishing a technological framework that retained flexibility for individual domain specialists to maintain and update algorithms and calculations.

2.2. Requirements

To achieve their aim, the authors developed a webtool called *Aurecon Buildings Carbon sketcher* (ABCs). The name was chosen deliberately to indicate the specific intent for using it to design buildings rather than other asset types. 'Sketcher' intends to signal to the user that it is aimed at producing indicative estimates in schematic design, thereby distinguishing itself from other tools that conduct specific calculations to determine accurate results for compliance purposes in the later stages.

To fulfil the purposes of an early stage LCA tool, the authors gathered the following requirements from key stakeholders and domain experts within their home organisation to be addressed by the tool:

- Consider the 'big-ticket items' in terms of lifecycle emissions and reaching carbon neutrality that can be assessed with information levels available in early design. In other words, consider operational emissions from energy use as well as embodied emissions for the main structural and façade elements, but exclude items that are unknown in the early design stage and have a lesser impact on carbon emissions, like interior finishes and furniture.
- Make the tool accessible for a wide stakeholder group by minimising dependencies and user knowledge of third-party software, and without requiring users to install specialist software environments on their local computer hardware.
- Build it in a modular way from several domain-specific modules that can be maintained over time by subject matter experts from different disciplines.
- Design the tool in a way that caters to about 95% of Aurecon building projects in terms of allowable geometric complexity and building usages.
- Design the tool for a user group consisting of environmentally sustainable design (ESD) consultants, mechanical, structural, and façade engineers.
- Assume the user does not have a detailed geometric model when using the tool. That is, the tool should auto-size structural elements based on the overall building massing.
- Develop ways to communicate to the user that the estimates generated by the tool are indicative and convey a margin of error.

In essence, the overarching requirement for the development of the tool was to enable interdisciplinary design exploration to generate holistic low emission strategies in the early building design stage.

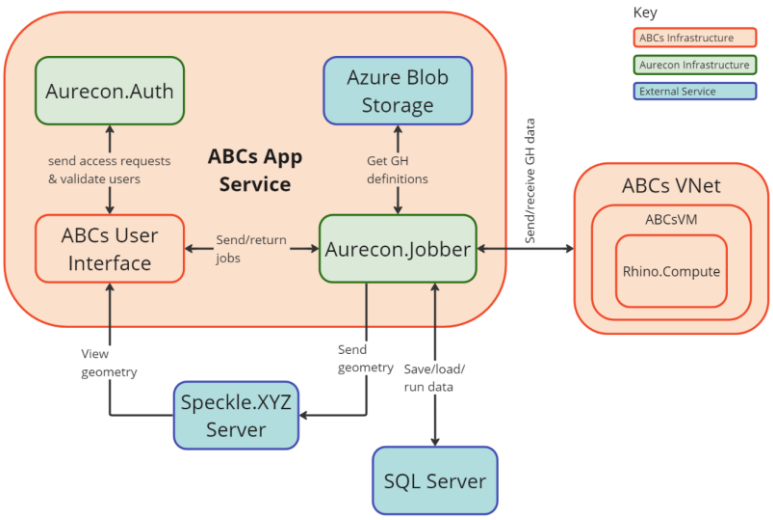

Figure 2. Overall software architecture and Grasshopper definitions contained within ABCs.

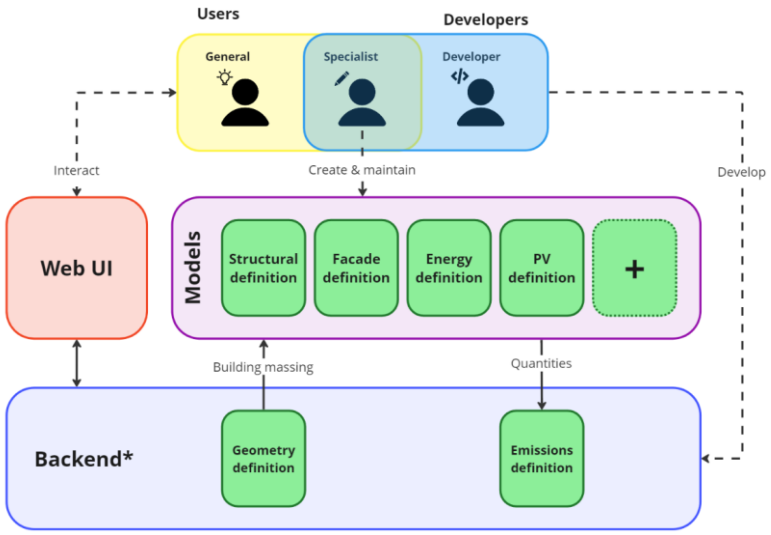

Figure 3. Developing, maintaining, and interacting with the tool. *See Figure 2

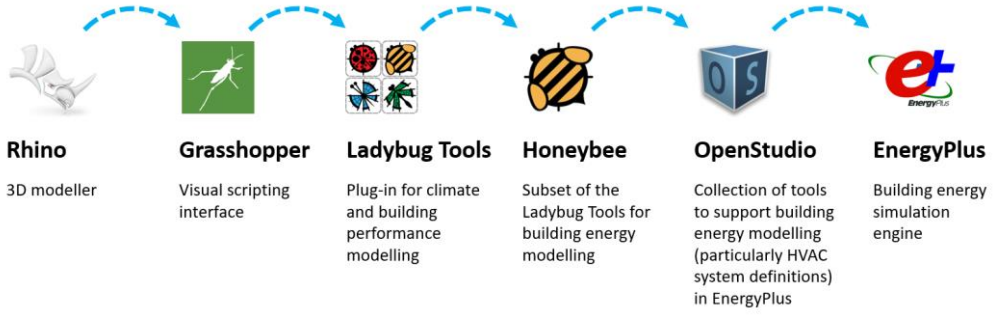

Figure 4. Software used for energy simulations.

2.3. Software architecture

ABCs consists of several Grasshopper definitions that run within Rhino.Compute. The definitions are provided inputs from a browser-based application built on the Blazor framework that uploads the results through a REST API hosted in the cloud. The Blazor application utilizes Speckle to provide the to the user an interactive 3D viewer with metadata. The Telerik for Blazor package is used to provide interactive web elements for the user to input design parameters, and to generate charts that the user can interact with to interrogate the results (Figure 2).

The development of ABCs was a joint effort between software engineers developing the "backend" of the tool, and domain experts creating calculation models (Figure 3). This includes a Grasshopper definition to create the building massing geometries (see Section 2.5), and one for applying the appropriate emissions factors to the corresponding building material and energy quantities (see Section 2.10). There are several domain-specific Grasshopper definitions that cover calculations relation to different disciplines impacting lifecycle emissions: structural element sizing (see Section 2.6), facade element sizing (see Section 2.7), energy modelling (see Section 2.8 and Figure 4), and on-site energy generation modelling (see Section 2.9). These Grasshopper definitions were created and are being maintained and extended by domain experts within the organisation who have appropriate computational design skillsets.

2.4. UI/UX

ABCs was designed to have a highly accessible and easy-to-use user interface and user experience (UI/UX), enabling a broad user group extending beyond computational designers, sustainability experts, and engineers. Rather than automating an existing process [21], the webtool proposes novel affordances that democratise and demystify the relationship between early-stage design decisions and emissions. In doing so, the webtool not only provides key insights to impact design, but also clearly illustrates relationships and sensitivities, supporting users to further develop their understanding of LCA and ESD.

During development, the authors conducted frequent demonstrations of ABCs' UI/UX design to collect feedback from subject matter experts. This helped design a highly accessible and easy-to-use tool. For example, the team discovered that one of the main roadblocks preventing from people using an earlier version of ABCs was that it had been built purely as a Grasshopper tool. As a result, ABCs was built as a webtool that does not require any installations or specialised domain knowledge to use. It has a job management system in which the user can create '*projects*'; each project can have several '*studies*', and each study can have several design '*options*' to be compared in a dashboard view side-by-side (Figure 5). Clicking on a design option from a study page brings up the main UI (Figure 7).

The main UI consists of two columns: user inputs on the left and result visualisations on the right. The columns are sub-divided into logical sections that clearly differentiate between different disciplines; input sections including 'Building', 'Structure', 'Façade', 'Shading', 'Materials', and 'Operation', and output sections including 'Geometry', 'Embodied Carbon', 'Operational Carbon', and 'Carbon Neutrality'. The interface does not freeze while waiting for simulation results to be produced; instead, the visualisation sections that are awaiting data are blurred out until the results become available while the user can keep navigating the UI. It includes an interactive Speckle 3D viewer displaying the structural, façade, and PV panel geometries.

The UI/UX was designed to convey the inherent uncertainties in early-stage LCA analysis. This was done by including a welcome page, guided tour, and documentation that describe the intent, assumptions, and limitations of the tool. Result data is expressed in round numbers so as not to convey a false sense of accuracy [7]. As described in Section 2.10, embodied carbon is calculated using 'high', 'medium', and 'low' scenarios that are displayed side-by-side in the UI for the user to consider the variance of environmental impact across different materials.

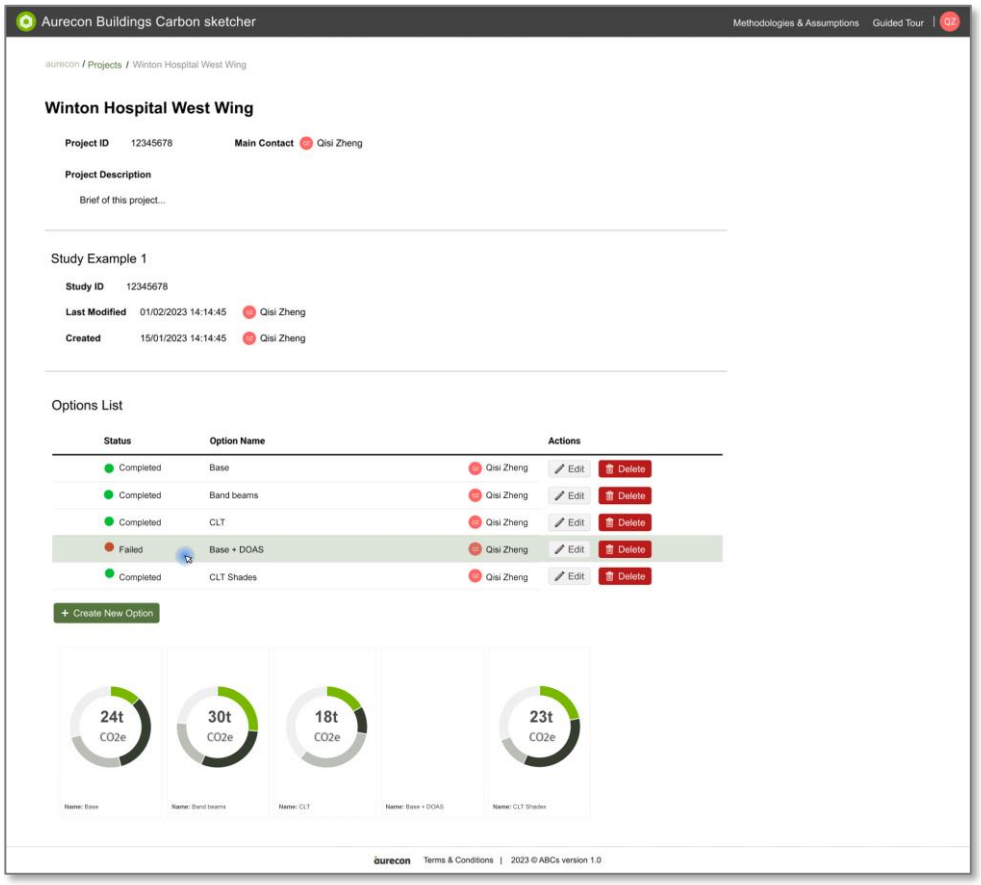

Figure 5. ABCs' "Study" viewer to compare design options at a top level.

2.5. Geometry definition

The first Grasshopper definition to execute within an ABCs run is one that generates the overall building massing as a closed polysurface. Users have three options to describe the building shape (Figure 6): for box-shaped buildings they can enter purely numeric parameters, for buildings that can be described as a vertical extrusion of an irregular footprint the user can upload a polyline defining the footprint, and for more complex building shapes they can directly upload a closed polysurface.

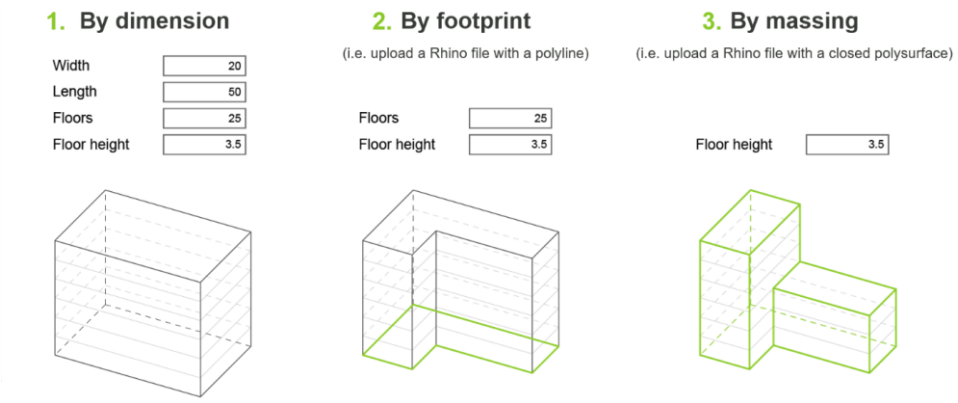

Figure 6. The 3 options to describe building shapes in ABCs.

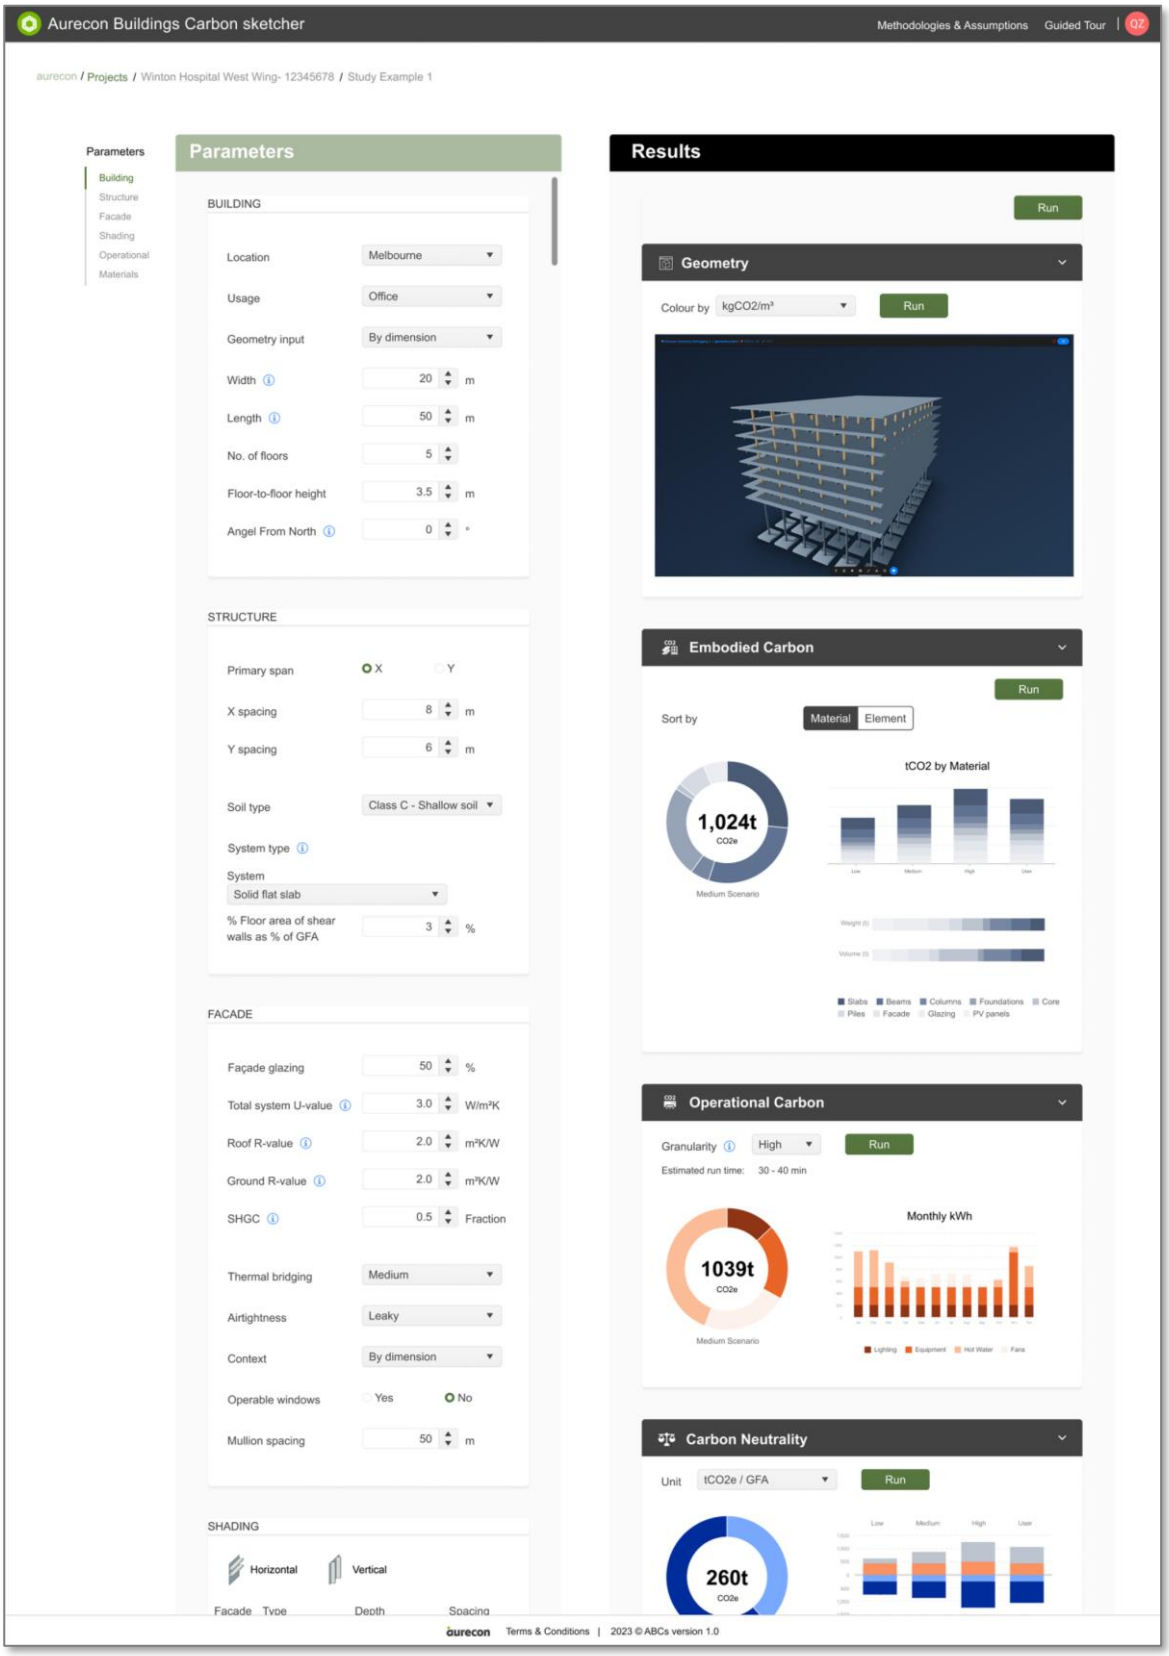

Figure 7. ABCs web UI. Each parameter panel reflects a Grasshopper definition executed with Rhino.Compute.

2.6. Structural definition

A particular contribution of the tool is a design automation definition that auto-sizes structural members based on a "first-principles" approach. That is, based on the building shape and user inputs it determines the applicable loads and slab thicknesses using basic formulas and look-up tables from various standards and supplier catalogues. Once the slab geometries are generated, it applies a similar approach to the beams, then the columns, and lastly the foundations and shear walls. The resulting geometries are sent to the Speckle viewer for visualisation in the web UI; the material quantities are sent to the Emissions definition (see Section 2.10) to calculate embodied carbon.

2.7. Façade definition

ABCs includes a simplified façade embodied carbon calculation that takes several user inputs to generate an estimate of various material volumes for a curtain wall façade (aluminium, glass, and rockwool) and sends these results to the Emissions definition. The curtain wall framing elements are sized using preliminary wind load calculations following building Australian standards. Mullions are sized assuming a simply supported condition, comparing the calculated deflection to an assumed deflection limit. To satisfy the resulting minimum required second moment of inertia (I-value), the definition selects a mullion and transom profile from a set of typical off-the-shelf products. ABCs allows considering vertical and horizontal aluminium shading fins by allowing users to define their spacing and depth for each cardinal direction. All extrusions are assumed to have a wall thickness of 3 mm which is common for curtain wall façades. The insulation, spandrel, and glass material volumes are calculated based on the user's window-to-wall ratio and thermal performance input.

2.8. Energy definition

This definition runs an energy simulation using Ladybug Tools and EnergyPlus, and outputs the estimated annual operational energy consumption data to the Emissions definition (see Section 2.10). It also generates a wireframe of the façade to be visualised in the web UI.

The building mass is segmented into floors and thermal zones, band windows are applied (assuming a curtain wall façade), and shading elements are added as 2D surfaces based on the respective user inputs. User-defined thermal envelope properties are passed into the construction definitions. Thermal bridges are considered by applying a degradation of the thermal properties of these constructions as per the methodology used in the LBT2PH plug-in for Grasshopper. ABCs allows users to choose one of several building usages, based on which ABCs sets a default list of heat load assumptions. ABCs also allows users to pick from several HVAC templates. Finally, the user can pick a trade-off between accuracy and speed by means of a 'granularity' setting that modifies several of the simulation parameters and geometry creation processes (see Figure 8).

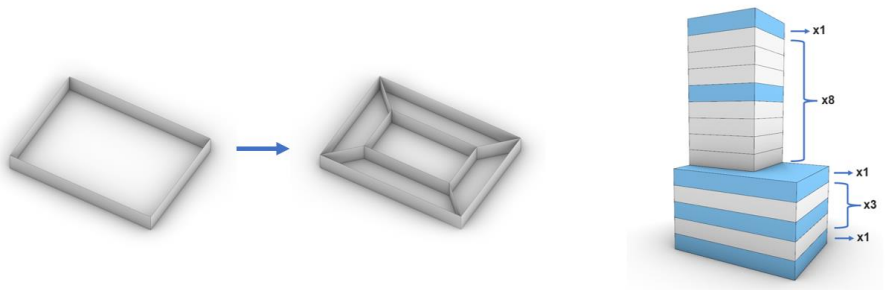

Figure 8. Examples of energy modelling simplifications. Left: ABCs allows either considering each floor as a single thermal zone, or as a core and several perimeter zones. Right: Only unique floors are considered.

2.9. Photovoltaic definition

This definition isolates all roof surfaces, populates them with PV panels and runs a simplified calculation of energy generation using Ladybug Tools. It assumes common panel dimensions, tilt angles, spacings and capacities. The annual, cumulative incident solar radiation on the panels is determined using the Ladybug Tools, the results of which are scaled by an assumed panel efficiency to estimate energy generation. It sends the energy results to the Emissions script (see Section 2.10) and the PV panel geometries back to the web UI for visualisation in the geometry viewer.

2.10. Emissions definition

This script collects all material and energy consumption quantities calculated in the other definitions and applies carbon factors to estimate lifecycle emissions. Given the tool's intent to be used in early design, the authors limited the tool's scope to the lifecycle assessment (LCA) phases A1 (raw materials supply), A2 (transport), and A3 (manufacturing) for the embodied carbon calculation, and phase B6 (operational energy) for the operational carbon calculation. All units are given in weight (kg or t) of equivalent carbon dioxide (CO_2e).

To give the user an idea of the variance in embodied carbon within different material types, the ABCs results section shows "High", "Medium", and "Low" scenarios. The corresponding embodied carbon values were determined by selecting representative products from various suppliers' environmental product declarations (EPDs). To estimate the operational energy emissions, ABCs multiplies the annual energy outputs from the Energy definition (see Section 2.8) by the carbon intensity of the electrical grid of the region of the selected project location. ABCs considers the targets set by the governments of the different regions across Australia and New Zealand to decarbonise their grids by increasing renewable energy sources in future. While it is not guaranteed that these targets will be met, the authors deemed this scenario more suitable than assuming that the current energy mixes will not change in future, which would lead ABCs to convey the false impression that reducing embodied carbon has little impact over the building lifecycle. The purpose of ABCs is to generate insights by comparing options; not to conduct a precise LCA which would be impractical in early design.

The "Carbon Neutrality" section of the web UI simply shows the how much of the lifecycle emissions can be offset by on-site energy generation through PV panels, and therefore what the remaining difference is that would need to be offset by other means in order to reach carbon neutrality.

3. Reflections

Our analysis led to several general insights and lessons learnt regarding the development of early-design lifecycle assessment tools. These are described in the following sub-sections.

3.1. Design strategy vs. design

The current use of lifecycle analysis in building design is limited to the late stages of the design process, where the results of the assessments have limited potential to meaningfully impact the design. Early design assessments have the potential to be much more valuable, however at this stage the design process is fast-paced and information limited. Adopting parametric modelling for lifecycle assessments in early design can create opportunities to explore design options more comprehensively and generate insights. Importantly, however, the designer must understand that the purpose of these design investigations cannot be to obtain a fully accurate and reliable prediction of actual lifecycle emissions. Instead, the value lies in generating insights that can inform an overall design strategy rather than a finalised solution.

3.2. Carbon reduction is a group effort

Many current solutions for carbon reduction in building design are point solutions targeting a specific discipline. However, truly sustainable and low-carbon design tends to be the result of holistic design strategies and cross-disciplinary optimisation. Introducing a design feature that is low-carbon for one

discipline may cause a detriment to another discipline. For example, while introducing shading fins might reduce operational cooling energy emissions, these fins tend to be constructed from aluminium that is so high in embodied carbon that it might not pay off over the building lifecycle. Therefore, any tool developed to address this issue should consider a cross-disciplinary approach.

3.3. Flexibility vs. accuracy

While the previous insight suggests increasing the complexity of a tool to address LCA in early design, there is an important trade-off that developers should consider: the usability and extensibility of the tool on the one hand, and on the other hand, attempting to optimise the tool's accuracy by increasing the complexity of the tool's parameters and calculations. Through the development process of ABCs, the authors have found that the former often outweighs the latter. That is, it is recommended to focus on developing the tool to allow for interdisciplinary considerations and co-development, to produce a flexible tool that allows developing design strategies and creating insights, rather than hyper-focusing on a precision that is unrealistic to achieve given the nature of early design.

3.4. Build tools that can grow

ABCs' software architecture allows for a novel approach to maintenance, future development, and governance. Firstly, ABCs implements each discipline specific embodied-carbon definition as a stand-alone algorithm that obeys a designed schema. The advantage of this is that the platform becomes easily extendable with new models to produce increasingly accurate predictions as other disciplines develop strategies for calculating carbon. The extendibility of the platform can be achieved with minimal developer engagement meaning that extensions are not only easy to implement but allows for anyone with a low level of programming knowledge to contribute to the software. This becomes increasingly important as individuals with a high level of specific disciplinary knowledge do not always have high-level programming experience. This allows for a simplicity in engaging and working with collaborators and maintain disciplinary definitions. Secondly, disciplinary specialists have a degree of ownership and responsibility over their contribution to the software platform. This includes changing and updating the model, maintenance, and testing for accuracy. The value of such a distinct set up is that the individuals with the knowledge to produce and check the outputs of the algorithms are the individuals producing the algorithm.

Thus, the governance and ownership of the tool allows for individual actors to contribute to carbon reduction in whatever way they can. Although the definitions produced to give carbon results for ABCs are not necessarily novel, the capacity to allow these disparate disciplinary definitions to conglomerate into a more *inclusive* and *complete* calculation is. Rather than having to engage a series of disciplines and depend upon their time and hardware, ABCs provides access to this expertise in a real-time, dynamic environment using modern web-development frameworks and remote computing to make this analysis as accessible as possible.

4. Conclusion

Reducing both up-front and operational emissions in the built environment has become increasingly crucial, as it accounts for a significant portion of global emissions. However, the industry faces a complex challenge due to a variety of factors. Firstly, operational emissions depend on local conditions, such as climate, site characteristics, and the emission intensity per kWh of the regional power grid. Secondly, in a global economy, the up-front emissions for the same material can vary greatly. Lastly, the technical and interdisciplinary expertise required to define a low-emission building can be overwhelming.

Without an interdisciplinary approach and a tool that considers the specificities of each project, it is difficult to develop a low-carbon strategy that properly considers the project context. By focusing on major carbon contributors and understanding the interdependencies between different fields, the tool

proposed by the authors within the current research aims to establish a solid foundation in the early design stage for low-emission buildings.

The research led to several more general conclusions on developing early-design lifecycle assessment tools. For example, their purpose should likely be to inform a design strategy rather than a finalised design; developers should accept that the results will be indicative and design a user interface that illustrates margins of error. Most development decisions will be related to finding an acceptable trade-off between flexibility and accuracy. Importantly, carbon footprint reduction is best tackled as an interdisciplinary design practice.

5. Future research

The authors seek to deepen the research in future by considering the following factors:

- Increase functionality and options: For example, include other façade and structural system types, and the embodied carbon of services.
- Revised carbon factors: Replace the current indicative carbon factors by ones based on an extensive data analysis of large LCA databases; also include other emissions metrics.
- Benchmarking: The ability to get an LCA "score" for a given design option (e.g., using [22])
- Cost: Considering the cost impact of different design features.
- Machine learning: ABCs logs all design options ever simulated by its users. Once a sizable database has been generated, the authors intend to use it to generate new insights and conduct predictive modelling to decrease simulation times
- Horizontal extension: The authors intend to create variations of tools like ABCs but geared toward other markets and asset types. The way that ABCs has been developed (see Section 2.3) specifically facilitates reuse and extension of this kind

Autarkic office boat

Arno D.C. PRONK*

* Eindhoven University of Technology
Vertigo 9.35 Postbus 513 5600 MB EINDHOVEN
a.d.c.pronk@tue.nl

Abstract

The autarkic office boat accommodates a small office with about 10 to 15 employees. The office has a total area of 120m2 divided over 2 floors, both of which are 60m2 in size (5.6m wide, 11m long). It is possible to choose your own office setup. In addition, there is meeting room with an area of 25 M2 and an archive room. The roof of the boat is curved and has photovoltaic cells. The archive is located at the bottom of the office boat with a limited floor height. The size of the archive is 15m2. Other areas in the boat are a reception, the toilets, a pantry and an installation room. For the realization of this design we tried to realize the following objectives: Autarkic, Environmental friendly, Reliable Attractive and Affordable. With this project we would demonstrate an example to show that it is possible to combine high environmental requirements, and an attractive affordable space.

Keywords: autarkic, office boat, energy, eco-friendly

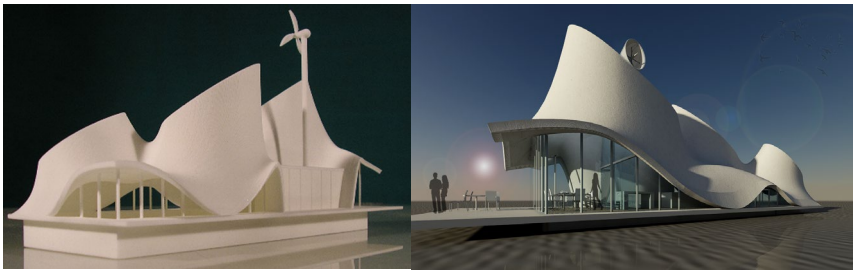

Figure 1 and 2. Design for an autarkic office boat

1 Starting points

With the realization of this room, we started with the following objectives:

1 Autarkic

2 Environmentally friendly C2C

3 Reliable

4 Attractive design

5 Affordable

With this autarkic office boat we have strived for an optimal combination of these objectives. With this project wants to show that it is possible to combine high environmental requirements with an attractive design and affordable space.

1.1 Installation concept

The installation concept is based on three pillars:

1. energy generation
2. energy storage
3. energy consumption

By efficiently combining these three pillars with the situation, use and architecture, the aim is to achieve an optimal and affordable installation [2].

Copyright © 2023 by Arno D.C. PRONK. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

1.2 Energy generation

On the water, depending on the situation, there is soon 40% - 60% more wind than in the built environment. Due to the economical installation and the relatively large supply of wind, the size of the wind turbine can be limited. When there is no wind, the office boat is supplied with energy by the PV cells that are directed at the sun at an angle of 36 degrees. The ratio between wind and solar energy is on average 60% - 40%. A fully electric solution was chosen because it has the highest efficiency with the best price/quality ratio.

1.3 Energy storage

The principle is based on the storage of heat/cold. This storage is equipped with PCM panels (Phase Changing Materials). The storage with the PCMs provides heat storage in the winter and cold storage in the summer. The buffer makes it possible to significantly reduce the power to be reduced. For example, a heat pump of only 2.3 kW is sufficient. In the event of a large supply of energy by wind turbine and/or PV cells, the cold/heat buffers will first be filled. Storage of energy in batteries will take place to a limited extent; surplus energy can be made available to the grid. The extraction of energy from the grid will only take place if too little energy is generated over a longer period of time and the accumulated buffers have been used. Such a situation can occur in the winter months, for example in case of fog in combination with a frost period, as a result of which there is no energy generation, combined with high consumption.

1.4 Energy consumption

The energy consumption of the office boat will be limited as much as possible by ensuring a low surface, good insulation, heat recovery, energy efficient devices, using buffers and offering a local 48 VDC electricity grid in addition to the usual 230 VAC electricity grid.

2 Technical solutions

2.1 Ventilation, heating and cooling

A modern office anno 2011 must be sustainably heated and cooled. The heating and cooling of the office boat are tailored to the Dutch climate. The climate in the Dutch winter situation is characterized by two situations:

• A very cold non-cloudy day with relatively much sunshine (diffuse and direct) and a lot of nocturnal radiance.

• A cold cloudy day with relatively little sunshine, mainly diffuse solar radiation, but less nocturnal radiance.

In the summer, the design is tailored to a period with a lot of sun with high temperatures. The architecture of the boat allows for smaller openings and overhangs on the south and larger openings on the north, limiting the cooling load. Furthermore, the high spaces of the *cones* act as natural storage that can be used as a heat or cold buffer depending on the weather forecast.

2.2 PCM

The abbreviation "PCM" stands for the Phase change material. The PCM is used for the melting and solidification of material. At this phase transition, a lot of energy is absorbed or released. Converting a material from solid to liquid costs 80 times more energy than heating the same amount of material 1°C. The phase transition material consists of paraffin or saline solutions. The phase transition can be set to a predetermined temperature, e.g. 18°C or 40°C. This makes it possible to buffer a large amount of energy at a given temperature. If the room temperature is higher than the melting temperature, the PCM underfloor heating cools the room until all pcm has melted. If the room temperature is lower than the melting temperature, the PCM underfloor heating heats the room until all the PCM is solidified. This process takes place without the need to use moving parts such as compressors, heating pumps or similar

installations. A 10 mm thick PCM-panel has the heat-accumulating capacity of a 300 mm thick concrete slab. By using this heat-accumulating capacity, it is possible to reduce the installed power for the office boat by 50%. This can be achieved by anticipating the desired temperature in the living areas in combination with the weather forecast, for example in the summer night cooling and in the winter night heating. (In doing so, cheap and widely available energy is used in the winter night of the electricity grid) This building installation concept has been translated into affordable system concepts, as described in the scientific journal *Bau Bionik* (O.A. University of Saarbrücken)

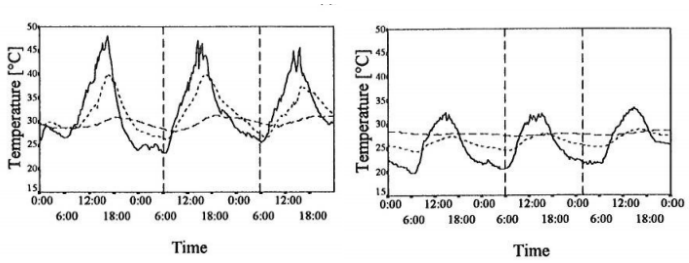

Figure 3. Temperature graphs

Measurement results free field

Dense line = outside temperature

Dotted line = Temperature in the semipermeable membrane

Dashed line = Measuring temperature in the conditioned room

The graph shows the dampening effect of PCMs in combination with anticipatory floor cooling and heating in the office boat. An additional advantage of the application of PCM floor heating and cooling is that particularly high insulation values are superfluous, resulting in less material use and a manageable investment.

2.3 Air-water electric heat pump

The application of PCMs is combined with the application of a new generation air-water electric heat pump as well. The required pump has a thermal capacity of only 2.3 kilowatts. This is half of the required power. (It can be compared to a refrigerator whose condenser is used to heat in winter and to cool in summer.) For hot water production, instead of a flow-through device, such as a combi boiler, an indirectly heated hot water boiler is chosen. This is connected to the electric air-water heat pump and a heat recovery of the heat from waste water.

2.4 Electricity

The summer is characterized by many sun and heigh temperatures. In winter the temperatures are low but there is more wind. We will use electricity in the winter months mainly from the wind and during the summer mainly from photovoltaic solar cells. A hybrid combination between Pv-cells and an urban wind turbine (UWT) will be a better solution than only using PV cells or UWTs. Even if the low efficiency of UWTs is taken into account, a hybrid combination remains the best solution in the Netherlands. We have opted for a hybrid solution in which 60% of the energy is supplied by wind turbines and the remaining 40% by PV cells. This combination delivers an average of 14 kWh (e) / summer day and 21 kWh (e) / winter day.

For the electrical installation we opt for direct current (DC) at 48 Volts, because DC has many advantages compared to alternating current AC. For example, DC motors are more efficient and DC does not suffer from electricity, which means that AC grids are oversized. Furthermore, solar panels, fuel cells and wind turbines all supply DC. In conventional situations, these are all converted into the

usual 230 volt AC. The conversion from DC to AC occurs some loss. To avoid the loss it is better to chouse for DC. Due to the lower voltage we need thicker cables. By choosing 48 Volt DC, the efficiency improves by 20%, so we have to install fewer solar cells and can choose a smaller wind turbine with less nuisance for surrounding neighbors. Nowadays, electrical appliances can be purchased in various places that operate on 24 or 48 VDC. We split the electricity distribution into 24 VDC (measurement and control installation), 48 VDC (mechanical installation) and 230 VDC (external energy demand).

The office boat must be able to bridge a cycle of 1 day. To bridge the requested period, we assume the worst situation for our system: a cloudy, windless winter day. Then the energy demand is the highest, while the energy production is the smallest. The energy that is needed is provided by a collection of batteries with a capacity for this day. If the weather forecast predicts a second day with the same weather type, the buffers will be replenished by using night power from the electricity grid. Such a situation will occur several times a year. Sizing the buffers over a period of several days is possible but requires disproportionate investments in batteries, PV cells and UWTs. In addition, night power is available and the Netherlands has a good electricity grid. We assume that the boat is used 6 days a week for a period of 12 hours per day. From 8 a.m. to 8 p.m.

The dimensioning of the installation complies with the applicable Dutch and European standards. For the dimensioning of the design, the performance criteria are derived from the following current standards:

- The Dutch Building Decree.
- The Dutch and European standard NEN-EN 15251, criteria for indoor conditions including thermal, air quality, light and sound.
- The heating capacity is calculated according to the Dutch and European standard NEN-EN 12831, heating systems in buildings, method for calculating the design heat load.
- The cooling load is calculated according to the Dutch standard NEN 5067, the cooling load calculation of a room.
- The electrical installation must comply with the Dutch standard NEN 1010.

3.Installations

3.1. Introduction

The design of the installations is based on the following innovations:

- It is an orientation-dependent design to prevent an excessive cooling load. Contrary to what has been propagated so far with regard to zero energy houses or passive housing: 'use passive solar heat on the south façade as much as possible', this does not apply to offices. Due to the internal heat production, cooling in offices is a much bigger problem than heating.
- The office is not only ventilated and heated but also sustainably cooled. Anno 2022 this is desirable for thermal comfort. By responding to this need, residents will be prevented from purchasing an energy-consuming electric air conditioner themselves in the future.
- Part of the office is conditioned by PCM underfloor heating and cooling.
- Furthermore, the office boat is equipped with a new generation of reversible electric air-water heat pump of 2.3 Kilowatts. This is only possible in combination with PCM underfloor heating and cooling.
- It is an 'all electrical solution' in which new calculation rules have been developed to achieve an ideal hybrid electricity production.

- Out of efficiency, it was decided to apply a local 48 VDC electricity grid. This leads to an efficient improvement of 20 percent compared to a 230 VAC electricity grid. By massively realizing the switch in the Netherlands from the current 230 VAC grid to local 48 VDC electricity grids, it would be fairly easy to achieve these environmental objectives.
- The excessively thick insulation packages of up to 30 to 40 centimeters, as is also proclaimed for zero energy houses and passive housing, are superfluous in the given design. Here, only optimal insulation is provided.

We have strived for a simple thought-out and robust installation concept. By equipping the office boat with 60m^2, 10 mm thick PCM underfloor heating and cooling panels, the installation can be greatly simplified without having to compromise on comfort. This allows us to offer a solution that is both affordable and robust.

3.2. The mechanical installation

3.2.1 Room ventilation

The ventilation installation must ensure a healthy indoor climate. In addition, we do not want to lose energy as a result of ventilation. That is why an HR-WTW unit is used.

Total net floor area 103.8[m^2]Including the overflows we round this off to 116[m^2]

According to the Building Decree, the minimum ventilation flow rate is 0.7[ltr/(s.m^2)]=2.5[m^3/(h.m^2)].

The size of the HR-HR-WTW unit then challenges 116 [m^2]*2.5[m^3/(h.m^2)]=rounded 290[m^3/h].

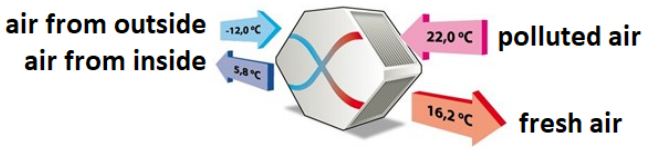

Figure 4. WTW unit

3.2.2 Space heating and cooling

On the basis of the international standard NEN-EN 15251, Criteria for indoor conditions including thermal, air quality, light and sound, a thermal comfort performance Roman II is chosen. This concerns an adaptive indoor temperature of at least 20 degrees Celsius at an outside temperature of -10 degrees Celsius and an operative indoor temperature of 26 degrees Celsius at an outside temperature of +30 degrees Celsius.

In the office boat, the offices and kitchen are covered with innovative PCM underfloor heating (a patented Dutch invention) while the other rooms are covered with conventional underfloor heating.

3.2.3. Warmwater production

The average drinking water consumption of a four-room house is 280 liters per day. For an office, this is much lower. That is why we explicitly opt for an indirectly fired hot water boiler of 160 liters. The hot water supply is provided with a water-saving tap and heat recovery from the waste water. The 160 liter boiler is connected to the 2.3 Kilowatt innovative air water electric heat pump.

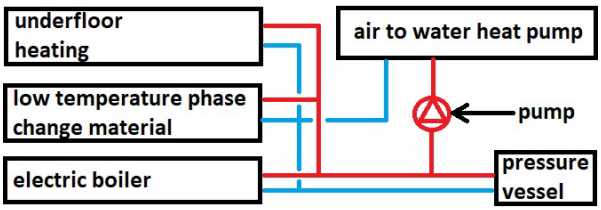

Figure 5. Installation scheme

3.2.6. Electrical installation

When comparing alternating current (AC) and direct current (DC), the following stands out:

• A brushless DC motor is more efficient and easier to control than an AC motor. The smaller fans, pumps and compressors are already equipped with DC motors as standard. The return improvement is approximately 15%. Motors are equipped with transformers and rectifiers for the conversion of 230 VAC or 300 VAC from the grid to the required DC voltage of the motor for example 24 or 48 VDC. The loss factor for this is approximately 5% to 10%, which largely cancels out the efficiency improvement of the engine.

• Photovoltaic solar cells, fuel cells and wind turbines equipped with synchronous DC generators produce 'automatically' DC electricity. Nowadays this 12 or 24 or 48 VDC is still converted to 230 or 300 VAC by means of transformers and invertors. The loss amounts to approximately 5% to 10%.

• Alternating current and ac grids have another thing called 'reactive power'. Due to capacitive and inductive action, the current 'runs in front of or behind the voltage', so that the maximum power is not available. Because of this reactive power, an AC network must be oversized. This 'loss' is indicated by a cosine phi of 0.85. On the other hand, DC grids must be equipped with batteries that also have a loss factor of 10%.

• Because the voltages of DC grids are lower than for AC networks, the cable thicknesses increase and it is necessary to switch from a 'central box network' to a 'star network' with direct power supplies of all components. Furthermore, only local networks are applicable. Electricity grids as Thomas Edison already proposed and made around the turn of the century from the 19th to the 20th century.

The efficiency improvement that occurs by opting for a local 48 VDC grid instead of a 230 VAC is then: η_accu-η_motor η_gelijk η_cos φ η_invertor=0.9-0.9*0.95*0.85*0.95≈21[%].

Furthermore, in 2010 computers can already be purchased on PV solar energy. With the latest development of integrated computers on solar energy through PV cells is an interesting development because it combines all the advantages of direct current. Nevertheless, we opt for a split electricity distribution in the boat, namely:

• 48 [VDC] for the mechanical engineer installation.

• 24 [VDC] for the measurement and control system and

• 230 [VAC] for white and brown goods.

It is also striking that the electricity consumption of a one person household is approximately 60% of a four-person household. So the dimensioning of the sustainable electricity supply depends on the occupancy rate of the office boot. Nevertheless, we opt for a decentralized electricity production per office boat consisting of:

• A UWT power of 4.5[kW]

• 12[m^2] PV cells.

This combination produces 14[(kWh(e))/day] under summer conditions and 21[(kWh(e))/day] under winter conditions. This fits the electricity demand of a four-person family. This hybrid combination forms a self-regulating electricity production unit.

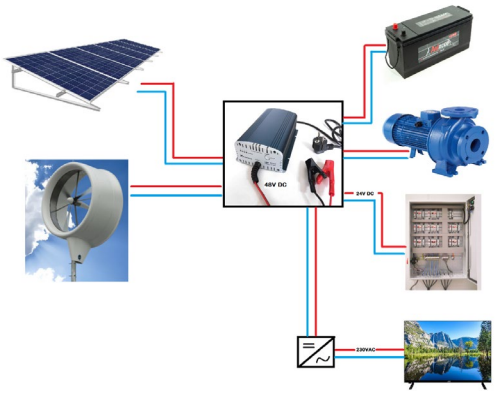

Figure 6. Electrical installation

3.2.7 Red un dance, risk and robustness

The installation must bridge a time period of 7 days! What does this mean?

The worst design day is: A cloudy, not too cold winter day with windless weather. Then the largest electricity demand occurs and the electricity production is the smallest.

The wind turbines are stationary. The maximum electricity production through PV cells is then 12*0.11*(90*16)/π=0.60 [(kWh(e))/d] while the electricity demand is 21[(kWh(e))/d].

Under the condition that the clouds and the windless weather persist for 7 days (this is in principle an unrealistic assumption) and the office is occupied with 4.0 people during these days, the PCM buffer will also be completely discharged. This results in a daily storage capacity of: (21,000-600)/48=425[Ah/d]. This time 7 days and that is 7*425≈3.000[Ah]

In the calculations we have assumed 12 m2 of PV cells. Due to the robustness of the design, we assumed an area of 20 m2.

3.2.8. Operation of installations

3.2.8.1. Mechanical engineering installation

• The ventilation installation. A natural air supply through pressure-controlled outside air grilles and a mechanical air exhaust fan executed as a variable volume system. Air flow rate 290[m^3/h]

Operation: It draws air in outside and carries air inside In the Heat Recovery installation (WTW), the heat is exchanged between these two streams with the indoor air transferring the heat to the incoming outside air.

Energy consumption: 0.9 [kWh/d]

Maintenance: The filters must be changed every 6 months

• The conventional space heating. all other rooms are equipped with conventional underfloor heating and cooling approximately 60[m^2] with a heating capacity of 40[W/m^2] total 2.4[kW]

Operation: The air that runs along the radiator is heated by the radiator. The air rises and the room passes through a pressure difference.

• The innovative space heating. The office and meeting rooms are equipped with an innovative PCM underfloor heating and cooling also approximately 60[m^2] with a heating capacity of also 40[W/m^2] total 2.4[kW]

Operation: PCM stands for phase changing materials, these materials change from solid to liquid at a certain temperature. For this transition, the material needs a lot of energy, which is achieved because the outside temperature rises. If the outside temperature drops again, the material will transfer its heat back to its surroundings.

• Hot water production. An indirectly fired hot water boiler of 160[ltr]

Operation: The central heating water of the boiler flows through a heat exchanger in the boiler and thereby indirectly heats the water in the boiler. As a result, a very high hot water yield can be achieved.

The heat and cold production. A new generation of reversible electric air water

heat pump with a heating capacity of 2.4[kW]

Operation: The heat is extracted from the outside air, this heat is released to the water circuit of the office boat. This heat is brought to temperature together with an indirectly fired hot water boiler for heating.

Energy consumption: for heating is = 6,5[kWh/d]

Maintenance: cleaning 1 time a year.

3.2.4. Water production

Water for the flushing of toilet is obtained by collecting rainwater. In case of a shortage of rainwater, surface water can be absorbed. Drinking water is obtained by connecting to the water network or bunkering water in a water tank. In every port, water can be obtained from a bunker boat.

3.2.5. Cleaning waste water

For the cleaning of the waste water, we opt for the direct cleaning of the waste water by a pre-treatment in a skeptical tank by means of an anaerobic pre-cleaning and a after switched aerobic after cleaning, so that the cleaned waste water can be discharged into a central swimming pool and from there can flow to the surface water. A separate cleaning of the pool water with chlorine is therefore no longer necessary. See the diagram below.

3.2.6. Drinkwater and wastewater production

• Helophyte filter

Operation: The helophyte filter is a filter where the bacteria in the reeds purify the water. This way of filtering removes a lot of waste from the water, but it is not yet enough to be used as drinking water. It can be used to discharge it to the surface water or as a flush of water in the toilet.

Maintenance: check the pipes 1 time a year, mow the green 1 time every 2 years in the spring.

• Sceptic tank

Operation: In the septic tank, the waste water from the toilet enters a tank, in this tank one part settles and another part floats on the water. The sludge that lies on the bottom digests by a slow process with bacteria. Not all matter is digested, which is why it still has to be emptied every so often.

Maintenance: Some chemicals should not be in the septic tank. Such as bleach, unblocking agents, strong descaling agents, alkaline agents, medicines, oils, cooking fat, pesticides and paint.

Furthermore, it must be emptied every 5 years by a sewer cleaning company.

• Fat separator

Operation: Grease traps are mandatory for catering establishments, snack bars, butchers, bakers, etc.

In the grease trap, the waste water comes from the shower, sink, kitchen and washing machine. The water gets in here and vertical bulkheads ensure that the water stops, the fat therefore floats above. The water can then be discharged back to the helophyte filter.

Maintenance: With a floating layer of 16cm of fat, it can be emptied.

• Pumps and pressure vessels in the system:

Operation: The pumps and pressure vessels ensure in the water pipe system that the water is pumped around and that it can expand at high temperatures.

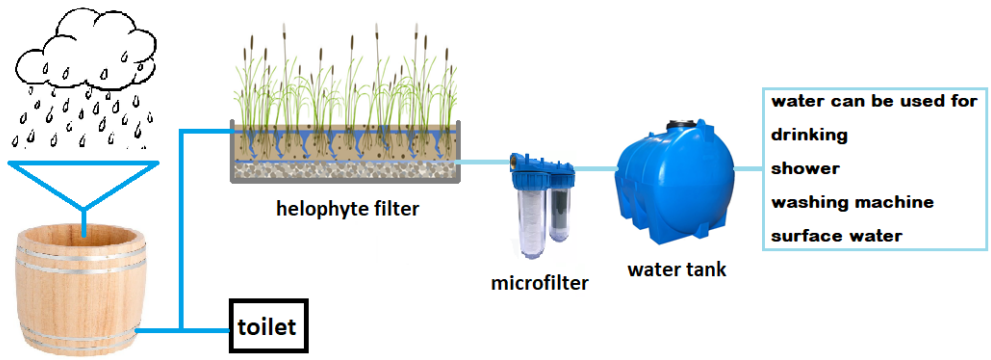

Figure 7. Cleaning waste water

4. Material

The office boat is constructed from sustainable materials.

4.1 How can sustainability be measured?

Daniël Tulp's [1] graduation report (The possibilities for the Cradle to Cradle concept in Dutch housing APR 2009 4416) explains how he arrived at the scores of the various materials. These have been taken up in this report. The concept of sustainability is also described here[3].

4.2 Inventory of which building materials / parts are needed for the boat

• Mezzanine floor (European oak or poplars)

• Insulation (sheep's wool, hemp, expanded stool or flax insulation)

• Glass (HR+)

• The characteristic shell construction is made of composite based on flax and cork which is processed with a natural resin.

• Floor covering/laminate

• Finishing/stucco/tiles

• Construction boat itself (concrete box)

As an alternative to the concrete barge , a standbarge or pontoon can be taken for the office boat. This is filled with a light and durable filling material such as blast furnace slag.

4.3. NIBE waste scenario

The NIBE [4] waste scenarios (Netherlands Institute of Building Biology & Ecology) give a picture of the current recycling practice, but do not have the potential that the materials have in the future in the field of recycling. Therefore, they are an important indicator, but will need to be supported by other data. The NIBE waste scenarios are based on discard scenarios used in the eco-quantum 2.0 from 2002 (developed by founding build research).

Table 1. Nibe waste scenario

material	specification	reuse	recycling	burning	dumping	material	specification	reuse	recycling	burning	dumping

4. 4. Possibilities to apply C2C materials

Wood fiberboard

This product is made without the addition of binders and is therefore completely biodegradable. Wood fiberboards are boards of waste wood that are made into insulation boards by a process of fiberization under humid conditions and without added binders or adhesives, making the material suitable for composting. The nature plus quality mark has been awarded to this product, which offers a certain guarantee for the low environmental impact. Further study of this German quality mark could provide more insight, but has not been included in the research of D. Tulp.

Oak parts (93.8%)

European oak is a very hard softwood that, due to its long service life and because it can be used untreated as façade cladding, has a very favorable score in the c2c instrument. But due to the scarcity and price almost no longer used as façade material. Oak wood is harvested in forests and not in plantations.

Sheep wool insulation (63.2%)

Due to the use of pesticides in herding sheep, biodegradability may be a problem. After the use of the sheep wool, based on the NIBE waste scenario we assume that 5% will be dumped and 95% will be burned. According to NIBE, the sheep wool insulation blankets have the lowest environmental load of all insulation materials. It has a thermal conductivity coefficient of 0.0412 W/mK, which means that a thickness of about 105mm is required for an Rc value of 3m²K/W.

However, the sheep wool insulation material are often treated with pesticides against mold formation. However, this stands in the way of biodegradability and affects the social and ecological aspects.

Expanded cork insulation (77.8%)

Expanded cork insulation is biodegradable and no artificial means are added for fire safety and mold prevention. Based on the NIBE waste scenario 5% dumping, 95% burning.

The cork, which comes from sustainably managed forests, can be harvested from a tree for around 10 years, after which the cork is taken into an autoclave. This increases the resistance to biological degradation and no additional resources need to be fed to it. The product is still susceptible to rot in the long run, so it is believed to be biodegradable.

Flax (insulation) (76.4%)

Flax (insulation) is biodegradable if binders based on organic products are used. When growing flax, it is possible that pesticides are used to protect the harvest. These products are inferior to biodegradability and social and ecological aspects. Growing the crop in monocultures is not conducive to biodiversity and, if scaled up, can disadvantage the food supply.

Organic cultivation does not use chemical pesticides and will therefore have less or no influence on biodegradability and social and ecological aspects. Synthetic resins are used as a binder, but also on the basis of an organic product.

NIBE waste scenario 5% dumped, 95% burning

HR Glass (85.4%)

Glass can be recycled into a similar product provided that no films or material coatings are mixed in it.

In the NIBE publication, glass is not assessed as a separate material. The only clue given is an exterior door made of HR++ glass in an aluminum frame, which also includes the pillars and sills. Therefore, for the absence of toxicity, the emission profile from the GPR Building database was used. Pure glass can be recycled, but glass with metal coatings, foil or reinforcement will have to be dumped or burned.

Aluminum(68.1%)

Aluminum is one of the materials in which it is technically possible to produce the same product in the next cycle. The properties of aluminum (homogeneous, mono-material, no alloy, low melting temperature) make it extremely suitable for recycling without loss of quality. When anodizing aluminum, a protective oxide layer is applied to the aluminum with the help of an electrolysis. This makes no difference to recycling

NIBE waste scenario 5% dumped, 5% burned, 90% recycling

Anhydrite cast screed (41.0%)

The material becomes contaminated additives and physical mixing with these substances and possibly the interfaces of other products ensures that only inferior recycling is possible. Anhydrite is hydrated gypsum (CaSo4) that was already used as a binder during the construction of the Egyptian pyramids.

NIBE waste scenario 5% dumped and 95% recycling.

4.5 lifecycle costing

Table 2. Lifecycle costing

material	realisation	Price, euro	live span	transport	demolition	dumping	recycling	burning	Score

Abstract

New structures can be designed from existing steel elements at lower cost and with dramatically lower carbon emissions when compared to conventional steel structures. This paper establishes more certainty about the supply of steel elements, quantifies potential carbon and cost savings, and identifies the variables that most impact such savings to better enable designing steel frames. This work first outlines why reusing gravity beams and columns is particularly advantageous via a state-of-the-art overview of the steel value-chain. Next, a high-level material flow analysis is conducted for three of the largest steel-producing markets globally, indicating that the quantity of the existing steel heavy section scrap covers 140% of the demand for imports of steel. A partial LCA utilizing a comparative cut-off method is then performed coupled with a cost estimation, which demonstrates a potential for around an 87% reduction in carbon emissions from steel reuse instead of recycling. Based on the findings of the partial LCA, a factor analysis is performed with both a stochastic sampling and nine real building projects to identify the variables impacting carbon cost associated with reuse. Structural weight was found to have the largest impact on reuse emissions, followed by number of elements, and then transportation distance. This paper then proposes strategies for practitioners to deploy reused elements in their designs.

Keywords: salvaged materials, uncertainty, life-cycle design, steel, unknown material quantities, circular economy, reuse of structural components, gravity beams and columns, structural design, Hangai prize applicant

1. Introduction

In today's steel value chain, heavy section steel is extracted from buildings and stockyards, remelted with other steel sources, reformed, and remanufactured to create new heavy sections and other products. Figure 1(a) depicts structural steel elements sold to scrap collectors and remelted before the end of their usable life. An alternative to remelting viable heavy section steel is element reuse. Figure 1(b) demonstrates a recent example where 83 metric tons of steel from an existing project were dismantled, stored, refurbished, and reused to construct a new building.

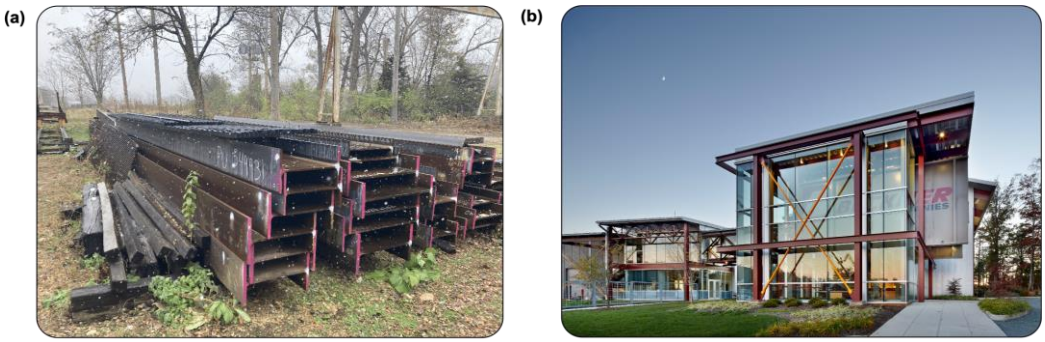

Figure 1. (a) Surplus steel destined for a scrap yard. (b) 83 tons of salvaged steel (in red) used in a new facility [1]

The structural system typically accounts for 50-60% of embodied carbon, and the majority of buildings are demolished before the end of their maximum usable life [2, 3]. The climate crisis demands an acute transformation of the way we source and design the built environment. Reducing the carbon of structural systems will markedly reduce the overall environmental impact of the construction sector and help meet IPCC 2050 goals [4]. One strategic pathway to reduce the embodied carbon in structures is to incorporate reuse of salvaged materials into the structural design process [5].

This paper focuses on gravity beams and columns, due to their loading conditions and structural weight in buildings. The paper clarifies the opportunity for steel reuse in three ways: 1) Characterizing steel component demand with reused building stock supply (scrap market/percentage of whole building components); 2) Establishing the cost and carbon savings potential of component reuse; and 3) Understanding the variables and factors that most affect the cost and carbon savings potential of component reuse of structural frames.

1.1 Reuse of structural steel elements

Steel building structures typically have the highest embodied carbon impacts when compared to masonry, wood, concrete, and reinforced concrete projects [6]. Reuse of steel elements in buildings has been identified as a strategy to cut industrial emissions [7]. Steel structures often have a far shorter service life than its capacity allows [3]. Reusing structural steel gravity elements bypasses the recycling step that is standard practice in most steel supply chains; circumventing the recycling process of steel components leads to the avoidance of high energy costs and carbon impacts, in addition to alleviating new pressures on the steel supply chain [8]. Today's structural steel supply chain is experiencing high carbon impacts, increased demand and growing impacts of more copper contamination in structural steel supply chains [9, 10].

While designing with salvaged structural steel is a beneficial alternative for structural engineers to reduce embodied carbon in the built environment, there are still many barriers that inhibit designing with reused gravity elements in buildings at scale. Uncertainty surrounding element availability and opportunity cost are two of the largest concerns about implementing reuse [11].

1.1.1 Existing use cases

The reuse of structural elements has existed as a building practice since antiquity. Steel reuse specifically has become increasingly present in recent building projects. The steel depicted in Figure 1(b) was obtained from both a 58-foot-long truss bridge, and 15-foot steel plate girders used in a collegiate stadium [1]. Steel tubes have been reused as load bearing elements in Colorado and London [12, 13]. Additional analyses have demonstrated how to utilize used transmission line towers as space trusses [14]. Several projects, such as Holbein Gardens in the UK, reuse structural frames [15].

2. State of the art

Figure 2 details the structural steel industry's current best practices for steel making, wherein structural steel is taken as scrap from demolished buildings or surplus in stockyards, recycled, melted down, mixed with other scrap, reformed into heavy sections, fabricated, and then erected on a new project. This figure does not detail additional inputs to the system such as heavy-section imports. Additionally, throughout the supply chain, surplus steel returns to scrap before being used structurally. The use of salvaged steel prior to remelting would modify this value chain.

2.1 Understanding the steel reuse value chain

Despite avoiding steel waste via recycling, current literature indicates emissions reduction targets set by the IPCC will not be met with current "best steel-making practices" alone, and limited research highlights potential for Circular Economy independence in the U.S. steel sector [18].

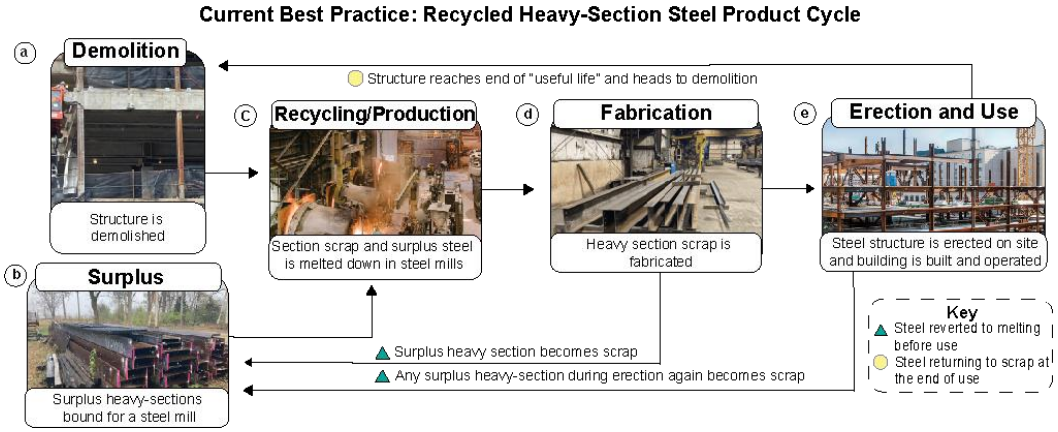

Figure 2. Current Best Practices for Steel Making. (a) Steel structural demolition (b) Surplus, unused steel sold for scrap(c)Recycling and Production [16] (d) Fabrication facility (e) Erection and Use Phase [17]

2.1.1 Material flow analysis and demand projections in literature

A commonly identified barrier to steel reuse is the lack of understanding about supply and demand of structural steel [11, 19]. Existing literature anticipates global steel consumption will grow [9] but does not estimate demand for heavy section steel specifically. Additional literature identifies other factors affecting steel supply including copper contamination in steel recycling [10].

High level Material Flow Analyses (MFAs) have been conducted for global and local steel supply chains that identify end-use sectors for steel and identify steel losses associated with melting scrap steel [18, 20, 21]. Material efficiency is also discussed in the context of strategies to reduce demand. Additionally, doubling product lifespan is noted to halve life-cycle steel demand and initial energy input [20]. While structural steel is discussed through the lens of end-use sectors, a more specific MFA understanding the specifics of structural steel elements availability has yet to be realized.

2.2 Opportunity cost and carbon savings of reuse

Estimates of the carbon emissions of reused steel have been achieved primarily through case study analyses conducting a whole building LCA of a specific building project, or by utilizing hypothetical geometries that compare traditional building design to design for reuse. Three papers specifically estimate the embodied carbon associated with structural steel reuse, whereas other work has estimated reuse savings from other material types, discussed further in [14, 22, 23, 24]. Existing Environmental Product Declarations (EPDs) also calculate Embodied Carbon Coefficient (ECC) values for recycled and reused structural steel. This paper estimates new embodied carbon values and compares them to the literature values.

Like carbon estimations, the cost of specific building projects with reused elements are compared with traditional structures. Under certain conditions, steel reuse demonstrated cost savings [25]. Another paper found steel reuse to cost minimally more than traditional construction but exhibited much larger risk [22].

2.3 Variables impacting carbon of reuse

While aforementioned literature estimates emissions, little is known about the high-level supply chain and design factors that influence the emissions associated with reuse. Various works analyze performance criteria including procurement risk, construction techniques, environmental impacts and project costs, structural performance, topology optimization influence on reuse rates, and geometry [22,

23, 26]. Such works primarily understand reuse through the lens of reuse rate, instead of its general impact on cost and carbon implications, which is analyzed here.

3. Understanding supply and demand

Having a robust understanding of the nature of available and projected heavy section scrap stock helps designers discern what elements are available for reuse in their building projects. This section seeks to characterize steel recycling trends in four steel producing markets. It also seeks to understand the current state of heavy-section scrap availability, production and demand in the US.

3.1 Methodology

Understanding the distinction between recycling and reuse is essential for comprehending the potential benefits of reuse. Recycling steel is enabled by the use of an Electric Arc Furnace (EAF). The two global primary methods for new steel production are the use of Blast Oxygen Furnaces (BOF) and EAF. Prevalence of EAFs in different markets enables overall recycling rates (defined in section 3.1.1). 3.2.1 breaks down the BOF and EAF utilization in four of the ten largest steel producing markets, their subsequent reuse rates, and the implications they have for reuse.

A Material Flow Analysis (MFA) aggregates units of physical data pertaining to the extraction, production, transformation, consumption, recycling, and disposal of materials [27]. A high-level MFA for new and scrap steel heavy sections is carried out in this analysis that focuses specifically on the inputs (imports), outputs (exports), production of new steel, and supply of scrap steel in the United States (US). This MFA therefore takes the form of an abbreviated physical input-output analysis for new and scrap heavy-section steel. Similarities across like steel value chains allow the primary takeaways from the US high-level MFA to be applied to additional markets with similar steel value chains.

3.1.1 Variables for analysis and data sources

The component of the material flow analysis focused on process flows for four markets: Japan, US, Germany, Brazil. These markets were selected out of the top ten crude steel producers because they spanned four continents and represent disparate steel ecosystems. The EAF and BOF breakdown represent the amount of steel produced with each process defined above. More specific to structural steel, the MFA primarily focused on total heavy new heavy section consumed, and total heavy section scrap generated. Data for the high-level material flows in section 3.2. came from two public data sources: the World Steel Association and the US Geological Survey [28, 29, 30].

3.2. Results and discussion

3.2.1 Characterizing market processes and abbreviated material flow analysis

Japan, USA, Germany, and Brazil are all within the top ten Steel Producers globally. China produces ten times the amount of steel as Japan. China produces around 90% of steel in a BOF. The US, also a top producer, has a robust EAF system, with a 93% recycling rate for structural steel [31]. Brazil, Japan, and Germany all utilize predominately BOFs.

While section 3.2.1 made the United States' EAF ecosystem clear, an important aspect of understanding reuse potential is characterizing scrap supply and new element demand. Figure 3(bi) demonstrates inputs, outputs, and demand of new structural steel shapes, and figure 3(bii) demonstrates inputs, outputs, and steel structural shape scrap generation. The data points depicted also include fabricated shapes. Figure 3(b) demonstrates that the total domestic structural scrap quantity could displace the number of new shapes we import by over twofold. The total generation of scrap is less than the consumption of new structural steel sections. That being said, the quantity of generated scrap is around 80% of the quantity of consumed new steel structural sections, including imports. Further analysis is needed to determine actual displacement potential on a granular level.

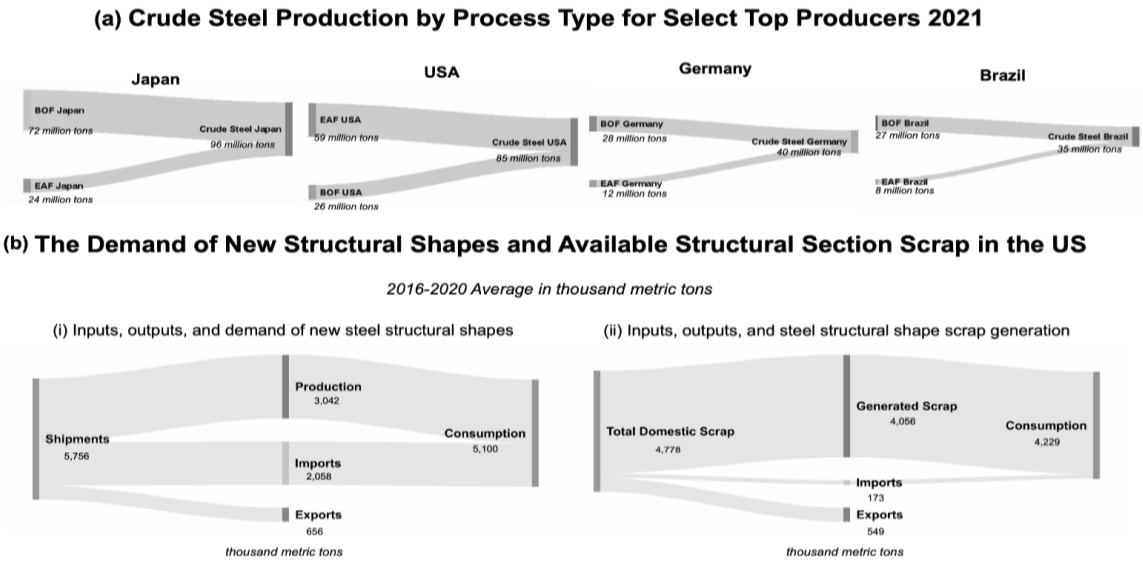

Figure 3.(a) Characterizing steel production processes in different markets for Electric Arc Furnace (EAF) and Blast Oxygen Furnace (BOF) [28] (b) Understanding supply and demand in the US Structural Steel Ecosystem [29, 30].

4. Opportunity cost and carbon savings

Quantifying the magnitude of potential savings is an essential part of the case for reused frame structures. This section explores the potential carbon and cost savings associated with reuse.

4.1 Methodology

4.1.1 Environmental impact assessment

One challenge of evaluating the potential for reuse is how to compare carbon emissions between reuse and recycling to ensure a like-to-like comparison. There are numerous methods for calculating the carbon emissions of reused structural steel elements. The methods mentioned in literature are characterized in Table 1.

Table 1. Different Methodologies for Reuse Impact Assessment in Literature

Methodology	Governing body	Summary	Consideration of Whole Building LCA	Consideration of future reuse potential (Reusability, multiple use cycles)	How many Lifecycles considered?	Production/Demolition Impacts distributed across multiple life cycles?	Sources
Module D, 100:0, "Cut-off Method"	European EN15'804, ISO14040	Places all production impacts in the first use cycle	Y	Y	>2	N	De Wolf 2021 [32], Vares et al 2019 [22], Kupfer et al 2022[23], Brutting et al 2019 [14]
Module D, 0:100, "End of Life Method"	European EN15'804, ISO14040	Places all production impacts in the last use cycle	Y	Y	>2	N	De Wolf 2021 [32], Vares et al 2019 [22], Kupfer et al 2022 [23]
Distributed Allocation	PAS-2050, BSI	Impacts of production, demolition divided across all lifecycles	Y	Y	>2	Y	De Wolf 2021 [32], Vares et al 2019 [22], Kupfer et al 2022[23], Brutting et al 2019 [14]
Market- Based Approach	European Commission 2012	Only A:100-A is analyzed (Cradle to gate)	N	N	2	N	Vares et al 2019 [22]
Modular-Based Approach	CEN	Modules A--C, Module D shows benefits beyond the system boundary	Y	N	2	N	Vares et al 2019 [22]
Comparative LCA	N/A	Only the difference (like displaced scrap)	N	N	2	N	Yeung et al 2016 [24]

One of the primary distinguishing characteristics of the methodologies is the consideration of a whole building LCA. Most methodologies consider at least Module A(A1-A3) of a building LCA. Another differing characteristic of the possible methodologies covers how many total building life cycles the analysis considers. All the LCA methods enable the consideration of more than two life cycles,

including the first use lifecycle, second, and third. The boundary conditions are demonstrated in Table 1. This is like the Cut off approach in that demolition impacts are accounted for in Module A, but differs as the end-of-life impacts after the second life cycles are not considered.

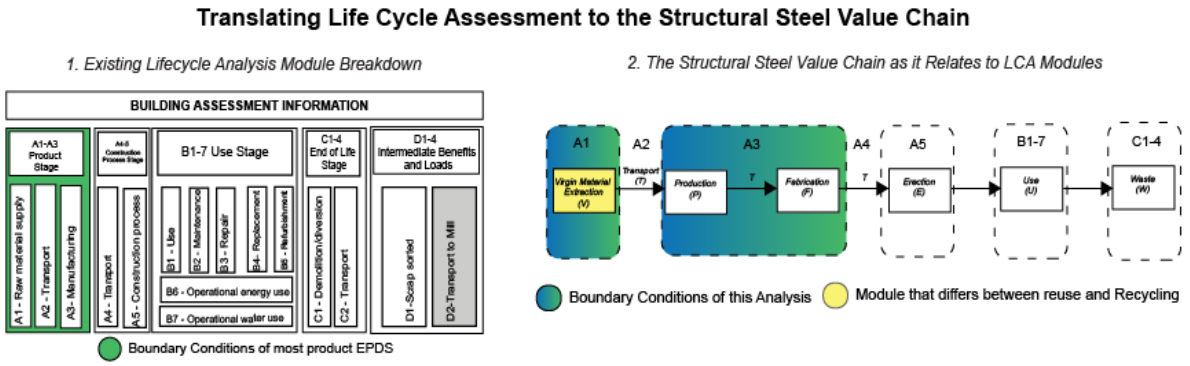

Figure 4. Translating Life Cycle Assessment to the Structural Steel Value Chain [33]

This analysis implements a comparative, cut-off method LCA approach. The LCA used in this analysis sets the boundary conditions spanning the end of the first use lifecycle (Modules C3-4& D1-4) to the beginning of the second use cycle (A1-A3). As demonstrated in Figure 4., the module that differs between reuse and recycling is A1. In the reuse scenario, this analysis places the deconstruction impacts in Modules C3-4 & D1-4 from the previous use cycle into A1 of the new use cycle. In other words, the "Raw Material Supply" for reused structures are just the deconstruction processes and transportation associated with demolition. This was also done for several other EPDs and reuse case studies [14, 23].

This breakdown is depicted in Figure 4. The latter approach will also aid the factor analysis explored in section 5. Additionally, the carbon coefficients for each approach are also compared with the carbon coefficients and factors found in literature exploring other methods of reused elements. The calculations and methods are outlined in Table. The Reuse LCA is also compared against reuse values found in existing heavy section EPDs produced by AISC and the ICE database, and an existing reuse EPD [34, 35, 36]. Additional literature where these methods were utilized, and more carbon estimation methodologies can be found in [37].

$$\Sigma\, Total\ Emissions_{Salvaged} = m_{elements}(Ecc_{cutting}) + m_{elements}(Ecc_{hoisting}) + m_{elements}(Ecc_{grinding}) + m_{elements}(Ecc_{transport}) + m_{elements}(m_{elements}) \quad (1)$$

$$\Sigma\, Total\ Emissions_{Recycled} = m_{elements}(Ecc_{EAF}) + m_{elements}(Ecc_{transport}) + m_{elements}(Ecc_{fabrication}) \quad (2)$$

The partial LCA conducted in this paper includes an inventory, and a subsequent Environmental Impact Assessment. The first step in the IA was to determine which subprocesses to include in phase A1 for reuse. Existing literature has identified several subprocesses associated with deconstruction, including the two utilized in this paper: hoisting and cutting. These subprocesses are evident in equation 1, which demonstrates the equations used for reuse. The A2 value for this paper was determined by averaging transportation coefficients defined by the GHG protocol, and an initial distance of 70 km, as that is the distance utilized in existing EPDs. The GHG protocol and transportation coefficients are better defined in [37]. The A3 value for this paper LCA was obtained from existing recycled steel EPDs in order to conduct a like-to-like comparison. Equation 2 details the processes included in these calculations. Exact energy consumption values used in this LCA are outlined in [37].

4.1.2 Cost estimation

There are three primary methods of estimating cost values in literature: stakeholder interviews, case study costing, and utilizing existing cost databases. Stakeholder interviews obtain specific cost

estimates, often via surveying [38]. Several analyses have estimated construction cost differences from the deconstruction of a specific building. This analysis utilizes RSMeans data to estimate a cost differential between recycled and reused steel. RSMeans is a database containing ~92,000 validated line items for construction cost data [39]. The equations used for cost comparison estimation of recycled structures versus reused structures can be found in equations (3) and (4). Given that this is a comparative cost estimation, only the cost premiums of building deconstruction and labor are considered, along with hard material costs of salvaged and recycled steel.

$$\Sigma\, Costs_{Recycled} = m_{elements}(C_{Material\,Steel}) \quad (3)$$

$$\Sigma\, Costs_{Salvaged} = m_{elements}(C_{Material\,Steel}) + m_{elements}(P_{DecProct}) + m_{elements}(P_{DecLabor}) \quad (4)$$

4.2 Results and discussion

4.1.1 Environmental impact assessment

Figure 7(a) demonstrates the comparison of carbon coefficients for reused steel in literature, EPDs, and the LCA conducted in this paper. All values have boundary conditions from A1-A3. The result of this paper's LCA is a carbon coefficient for reuse of 0.255 kg co2/kg. This can be compared with the literature average for reused steel, which is 0.267 kg co2/kg steel. The only known public EPD for steel reuse detailed the carbon coefficient as 0.045 kg co2/kg steel. Figure 4.6 compares these values with literature and EPD values for recycled steel. This comparison demonstrates an average of an 87% reduction in emissions from reusing steel versus recycling steel. These coefficients are further employed in section 5.

The results of this analysis make a compelling argument for reuse; significant reductions in carbon can be achieved by reusing structural steel versus recycling. While the existing reuse EPD demonstrated lower emissions on average than the literature and this paper's LCA, all three reuse values demonstrate lower carbon than recycled steel. The EPD for recycled steel also demonstrated lower carbon values, making the delta attributed to reuse only minimally lower than literature LCAs. This is likely due to the nature of EPDs, wherein the material supplier often produces the EPD. Notwithstanding, all values reflect a potential for carbon savings and reuse.

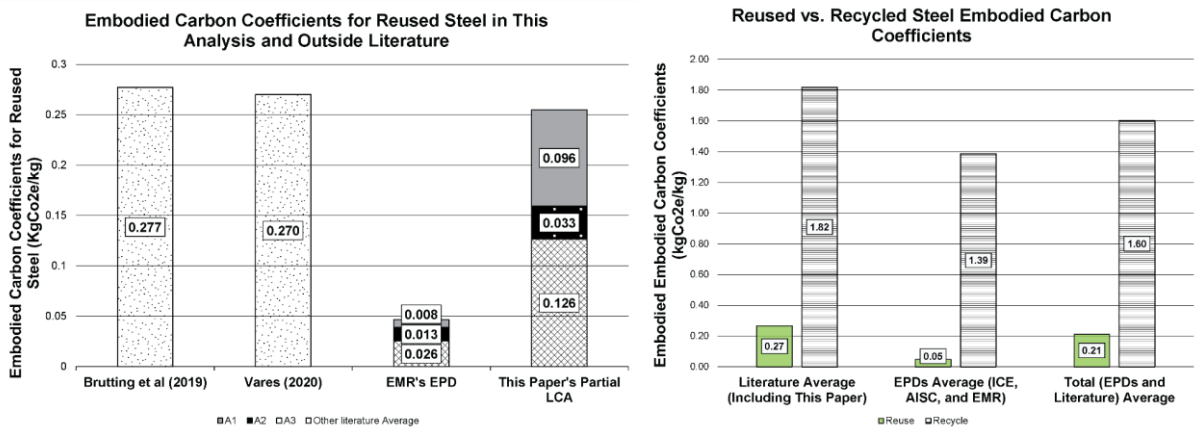

Figure 7. Embodied Carbon Coefficients for Reused Steel from This analysis and outside literature

4.2.2 Cost estimation

Based on calculations governed by equations (3) and (4), the material costs associated with reused material, deconstruction, and the labor premium for reuse sum to $538/ton of salvaged steel. In contrast, raw material costs for new steel are around $4635/ton of a new steel section. This indicates dramatic cost savings potential from reuse based on the delta between new and salvaged material costs. This

analysis is limited in that it only considers material, deconstruction, and labor costs. The calculations do not account for storage and additional refurbishment costs. Additionally, travel and gasoline costs were not considered in this calculation. Material costs are incredibly volatile, and future exploration is needed for line-by-line cost estimating, forecasting, and risk assessment.

5. Variables impacting carbon of reuse

It is evident from section 4 that several variables impact the emissions associated with reuse. The question of which variables most impact carbon emissions is addressed in this section. Predominantly, the most significant variables emerge from the inventory analysis, which accounted for both process and quantity values. Such variables are examined in this chapter and include: travel distances, structural weight, and the number of elements in a project.

5.1 Methodology

5.1.1 Stochastic sampling

Given limited data availability, the factor analysis required a random sampling method varying the number of elements, structural weight, and transportation distance to create a sample of 500 data points. In order to isolate one variable, averages of the building projects used in section 5.1.2 were utilized for the other data points not being sampled. The averages were ~800 kilometers, ~5,500 kg of steel, and ~2,500 elements. The random sampling of the number of elements varied from 50 to 5,000 elements, 1,500 to 10,000 kg for structural weight, and 3 to 1,600 km for transportation distances. These ranges were selected based on thinking surrounding the typical design of a structural steel bay, in addition to typical travel distances of the steel to different projects.

5.1.2 Real building projects

While the stochastic sampling reveals trends in how building characteristics could impact emissions associated with reuse, much can be learned about applying the ECCs to real building projects, such as general understanding about carbon per area of a reused steel structure, a known industry metric that is beneficial when comparing reuse to other sustainable building methods [6]. To carry out this analysis, the Steel Solutions Center at AISC provided data for nine real projects depicted in Figure 9(a) [40]. The Steel Solutions Center provided information about framing plans, location, element sizes, areas, and element types. Across all nine projects there was a range of ~600 to 4800 km, ~30 to 3000 metric tons, and 70 to 4000 elements.

5.2 Results and discussion

5.2.1 Stochastic sampling

Figure 8(a) indicates recycling is impacted more by structural weight than reuse. The analysis demonstrates significantly more emissions are produced as structural weight increases. Reuse has minimally more emissions as structural weight increases, depicted in 8(a). Transportation also impacts emissions minorly when compared to structural weight. The large gap in Figure 8(b) can be attributed to the process difference between melting and scrap. The slope in 8(b) is the same across process types because the method for transportation emissions used the same factor. The recycling method is not impacted by the number of elements in this analysis, only reuse. Element number showed a minimal increase as the number of elements changed, though the rate of change was minimal when compared to distance and structural weight. This indicates there is less concern pertaining to refurbishment, cutting, and selective deconstruction of materials regarding carbon emissions. The factor analysis indicates that the structural weight associated with recycling plays the largest role in emissions reduction.

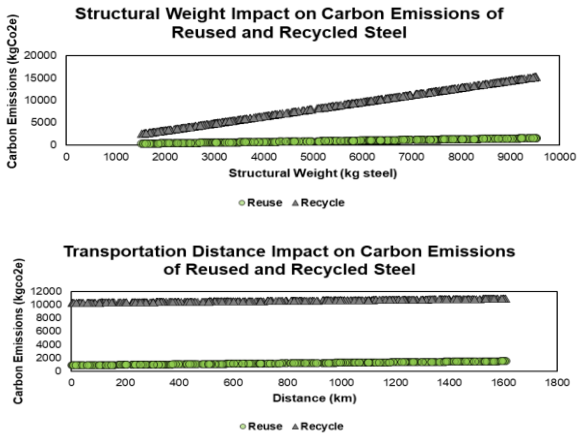

Figure 8. Estimating Emissions of Reused and Recycled Steel: (a) Structural Weight (Transport distance of 800 km) (b) Transportation Distance (Average structural weight of 5.5 tons of steel, 2,500 elements).

5.2.2 Real building projects

All building projects exhibited lower emissions when reused steel carbon coefficients were applied. There was a direct, linear correlation between more weight and more emissions (evident in Figure 9), whereas there was not an entirely linear relationship when the number of elements varied. The average carbon for reused building structures was 98.4 kg CO2e/M^2, whereas an average of 119.4 kg CO2e/M^2 was presented for recycled steel structural systems. Reused steel ranged from 15.9-459.1 kg CO2e/M^2 for reuse and 54.8-476 kg CO2e/M^2 for recycling. This indicated an average 23% reduction in GWP (emissions per square meter) by using reused steel. This delta differs from reductions outlined in section 4.2.2. likely due to the higher transportation distances (average of ~2,580 km) instead of 73 km which was used to calculate a comparable reused steel EPD. Additionally, understanding carbon in relation to floor area leads to greater variability in GWP than in a generalized ECC because of individual project differences. The carbon values for each project Figure 9 also depicts a literature benchmark for business-as–usual steel buildings that have been databased, with a GWP ranging from approximately 250 to 600 kg CO2e/M^2. This benchmark is higher than the ranges for reused and recycled steel for all projects but one, likely due to the benchmark's inclusion of the entire structural system

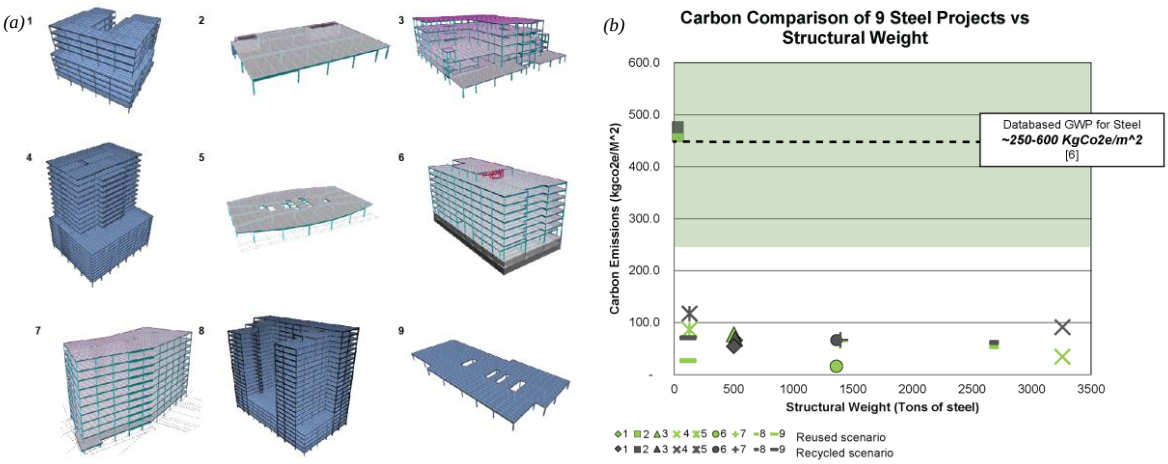

Figure 9. (a) Nine steel structures obtained from the Steel Solutions Center (project identifiers not included)(b) Comparison of 9 Steel Projects

6. Conclusions

This paper has three primary takeaways regarding the reuse of gravity beams and columns in buildings: 1. There is existing supply potential for utilizing structural section scrap in markets where the EAF recycling system is robust; 2. Across literature, industry EPDs, and an additional LCA, reused steel has lower carbon emissions than recycled steel and lower material costs; 3. Structural weight most demonstrably influences emissions associated with structural system steel reuse.

More specifically, this preliminary analysis indicates available scrap could meet most of the scrap demand in markets with a large presence of EAF. Further analysis is needed at a more detailed level for each market. There is potential for 87% greenhouse gas emissions reduction by using reused steel. Structural weight had the largest impact on reuse emissions. Across all variable changes, reuse still had lower emissions than recycling, and recycled steel is impacted much greater by structural weight than reused elements. Given the results of this analysis, layout complexity, quantity, and carbon impacts of refurbishment are less of a concern for structural designers when compared to the impacts of recycled steel. Figure 10 presents the future best practice for reuse, one where heavy section scrap is deconstructed from an existing building, refurbished, and reused in a new structure. By adopting this practice, structural designers could aid in decoupling structural steel design from additional carbon and cost implications associated with reprocessing.

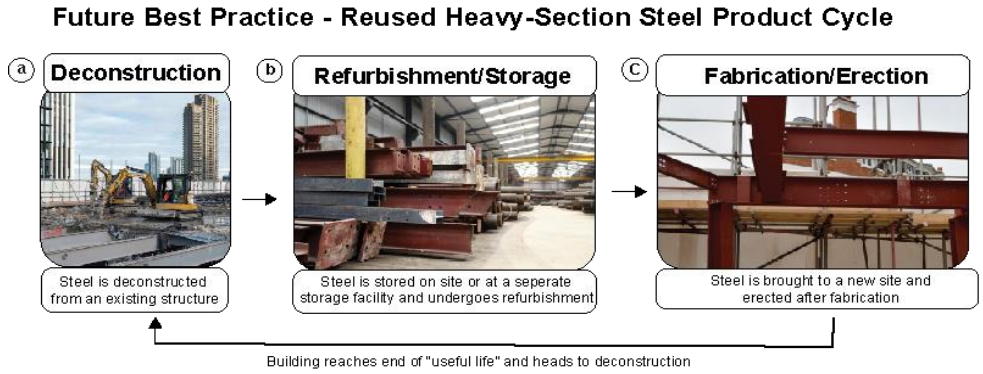

Figure 10. Future Best Practice: Reused Heavy-section Product Cycle. (a) Elements are deconstructed from a building. (b) Elements are refurbished and stored. (c) Elements are fabricated and erected on a new site [15].

7. Acknowledgments

This work would not have been possible without funding support from the National Science Foundation Graduate Research Fellowship Program. Thanks to the MIT Climate and Sustainability Consoritum. The authors are grateful to the AISC Steel Solutions Center for providing data for Section 5 of this project.

Abstract

Structural systems are a significant contributor to buildings' embodied carbon and reusing structural elements in new load-bearing applications is one strategy to reduce this impact. However, integrating this approach into existing design workflows without affecting design freedom is challenging. New computational tools like Phoenix3D, a plugin for Grasshopper within the Rhino3D environment, are intended to help master this task. This paper extends current research developments of Phoenix3D by integrating the tool into a more flexible multi-objective optimization framework. Hence, the outcomes obtained from Phoenix3D are employed as an objective function in the optimization workflow. This enables designers to move from a mere assignment operation on a predetermined structural system to a more comprehensive approach, wherein alternative design options are thoroughly investigated. Two case studies are conducted here to showcase this extension's effectiveness: (1) a theoretical study that compares generated designs with established typologies; and (2) a real-world application of the proposed tool to design a façade system using only reclaimed steel elements. Results show that adequate design solutions are found in real-time and interactively for the same stock of reused structural elements. Not only does Phoenix3D turn component reuse constraints into new circular design opportunities, but it also reduces the detrimental environmental impact of a structure and therefore allows the establishment of a more sustainable building culture.

Keywords: computational design, interactive design, optimization, reuse, circular design

1. Introduction

The construction industry is responsible for substantial global greenhouse gas emissions, resource exploitation, and waste generation [1]. To mitigate these adverse effects and decrease the detrimental environmental impact (DEI) of constructed buildings, one possible solution is to adopt a circular economy approach, which involves reusing structural components to construct new buildings.

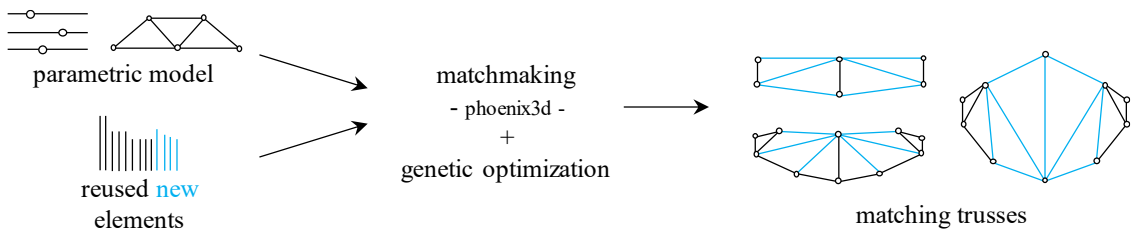

Figure 1. Matchmaking of truss structures for a given stock of reused and new elements

With a few exceptional cases, this approach is not commonly used in current building practices. One of the reasons for this is that reusing structural components demands an inversion of the conventional design approach, as the synthesis of a structural system (including topology and geometry) must comply with the geometric and static characteristics of the available elements. As a result, this leads to challenges in the regular construction process. One solution to this issue is using computational tools that assist architects and engineers when designing from a fixed inventory of elements. An early approach of such computational tools was presented by Fujitani and Fujii [2], who optimized plane frames of fixed topology subject to given elements of known length and cross-section. Kim and Kim [3] used genetic algorithms to optimize embodied carbon, weight, and cost of frame structures made from a stock of reclaimed elements. Bukauskas et al. [4] developed a strategy based on heuristics to form-fit a supply of wood logs to statically-determinate trusses. Brütting et al. [5] presented structural optimization techniques based on mixed integer linear programming (MILP) to design truss and frame structures from reclaimed steel elements. Huang et al. [6] employed the Hungarian Algorithm to design wooden geodesic domes from a stock of elements. Additionally, they briefly compare various algorithmic formulations for reuse-driven design in computational tools. In previous work, Warmuth et al. [7] introduced the computational tool **Phoenix3D** which optimally assigns reclaimed and new elements from a given stock to target truss designs. This tool was built upon a MILP formulation and was later extended with a Best-Fit heuristic to accelerate result generation.

To further open up the design possibilities of stock-constrained design, this paper introduces an extended method to generate design alternatives when working with a given stock of elements. Rather than solely assigning stock elements to a pre-defined structural system, this method enables interactive design with the available stock components. The method's general workflow is depicted in Figure 1. The input consists of a parametric model and a stock of both reclaimed and new elements, which are fed into an optimization framework. This framework utilizes a combination of Phoenix3D and genetic optimization algorithms to modify the parametric model and to optimally assign stock elements to the design. As a final step, the framework produces several truss structures that make optimal use of available stock elements. Section 2 elaborates on the algorithms of Phoenix3D and the genetic optimization process. Furthermore, Section 3 features a theoretical case study that compares generated structures with established typologies and a real-world project that illustrates the practicality of this framework.

2. Method

2.1 Phoenix3D

Phoenix3D is an open-source tool to design optimum truss structures made from a stock of new and reclaimed elements. In the tool, the assignment of stock elements to a design brief is formulated as a discrete optimization problem.

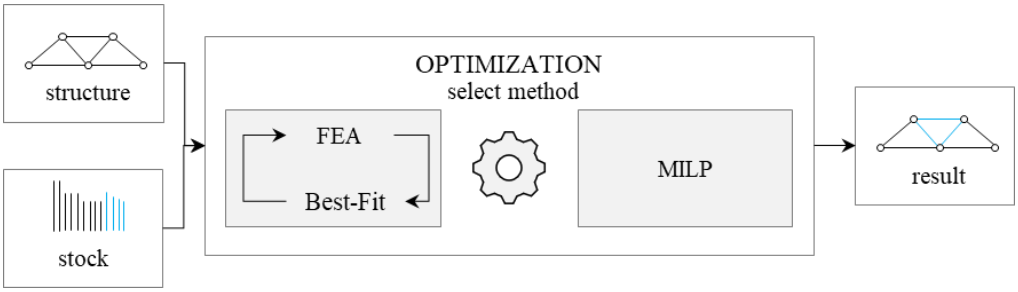

Figure 2. Workflow of Phoenix3D

It is implemented by the authors based on previous research in the field [6]. The core of Phoenix3D is molded by two optimization algorithms: (1) a MILP formulation that delivers globally optimal results

but is computationally expensive, and (2) a Best-Fit heuristic combined with a linear-elastic finite element analysis (FEA) of first order that delivers just close-to-optimal results but in real-time and with low computational costs. The objective function is to minimize DEI, computed by a Life-Cycle-Assessment (LCA). Details for the implementation of the optimization algorithms as well as the LCA, can be found in [7, 8]. The workflow of the tool is illustrated on Figure 2. An initial structure serves as input to which reusable stock elements are assigned, as well as newly-manufactured elements. Subsequently, users can select which of the two optimization algorithms should be employed to assign the stock elements to the structure optimally. As a result, the structure with the assigned stock elements is displayed, including statistics about the run optimization. Among these are the DEI in $kgCO_2eq$ and the cut-off waste in kg. Cut-off waste occurs when reclaimed elements from the stock must be cut to fit a target position in the intended design. In general, it is worthwhile to minimize the amount of cutoff waste and employ reclaimed elements as they are to enable an additional cycle of repurposing.

2.2 Global optimization framework

As outlined in Section 1, the proposed framework employs a genetic optimization algorithm to produce trusses that match a given stock of reclaimed elements. The overall workflow is illustrated on Figure 3, which starts with the definition of a parametric model. For the case study in Section 3.1, the parameters, i.e. the design variables, include the number of bays, the direction of diagonals, and the nodal coordinates of the design brief. A stock of reclaimed and new elements is provided, all made of steel S235. Furthermore, various circular cross-sections are available, with both reclaimed and new elements ranging from diameters of 10 mm to 100 mm with steps of 10 mm in between. For each cross-section of reclaimed elements, six pieces of length 3.0 m are available.

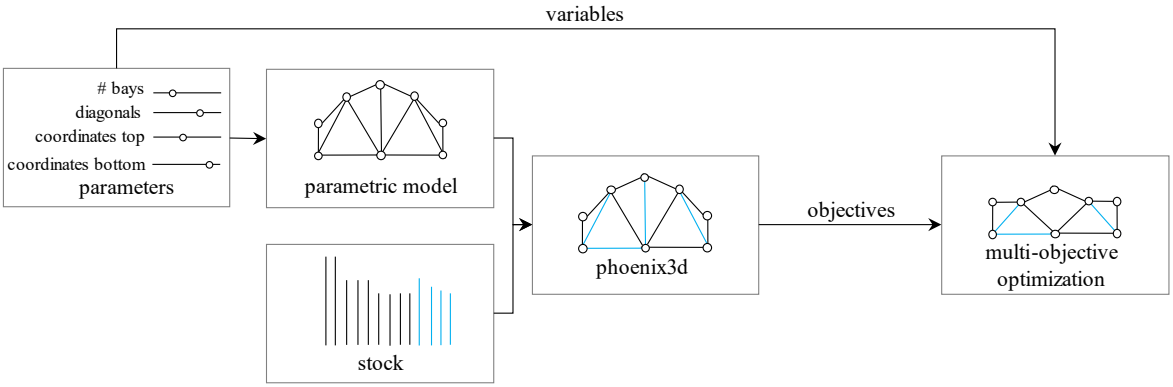

Figure 3. Workflow of the presented framework

Despite Phoenix3D's ability to optimally assign stock elements to an already specified structure, modifying the topology and geometry of the design brief opens up the solution space by allowing the design to adjust to the characteristics of the reclaimed elements from the stock. Since the model is parametric, this can also be regarded as an optimization problem where the model's parameters serve as design variables, and the calculation of DEI and cut-off waste in Phoenix3D act as objective functions to be minimized. Wallacei [9], an evolutionary optimization and analytic engine for Rhino/Grasshopper [10], is the primary tool for this overarching optimization.

3. Case studies

3.1 Theoretical case study

The theoretical case study setup is illustrated on Figure 4. The design boundaries in which the parametric truss is generated are presented on Figure 4a. To simulate a loading scenario, a line load of 15 kN/m is assumed, and the self-weight of each bar is applied at its respective end nodes. In addition, Figure 4b

displays a benchmarking truss optimized by employing the Best-Fit heuristic to minimize DEI solely. Three well-known truss typologies, a Warren truss, a Pratt truss, and a Howe truss, are shown in Figure 4c. The corresponding metrics for these trusses, such as their DEI in $kgCO_2eq$ and their cut-off waste in kg, are given in Table 1.

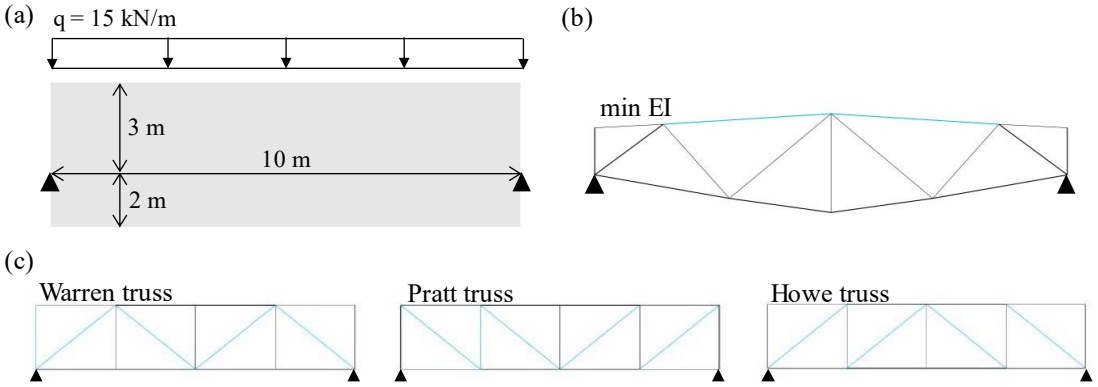

Figure 4. Matchmaking of well-known trusses with optimal trusses for minimization of DEI

Table 1. Results for the trusses from Figure 4

	min DEI	Pratt truss	Howe truss	Warren truss	(5a)	(5b)	(5c)	(5d)
DEI [$kgCO_2eq$]	41	83	67	70	55	46	44	43
Cut-off [kg]	8	27	18	17	0	1	2	4

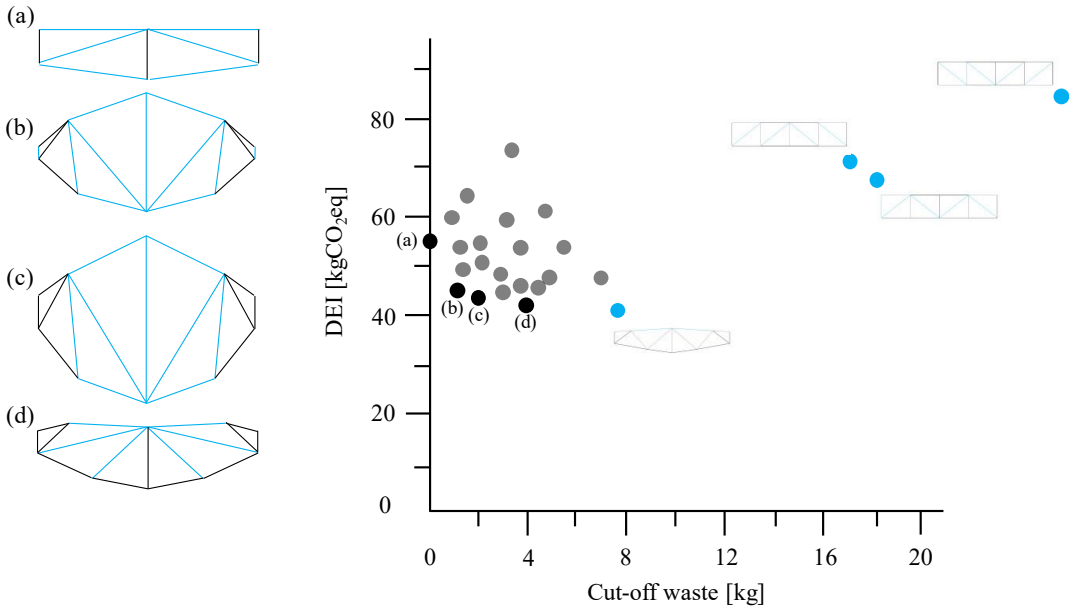

Figure 5. Pareto front with selected samples subject to the minimization of DEI and cut-off waste

Table 1 shows that the benchmark DEI is 41 $kgCO_2eq$, which results in a cut-off waste of 8 kg. The three truss structures have DEI values ranging from 67 $kgCO_2eq$ to 83 $kgCO_2eq$ and also generate significant amounts of cut-off waste, ranging from 17 kg to 27 kg. The goal of the optimization is to generate truss structures that are more suitable for the given stock, with the ability to reduce cut-off waste and ideally outperform the three standard trusses in Figure 4c in terms of DEI. Therefore, a multi-objective optimization is set up for two objective functions: minimizing DEI and cut-off waste. Selected results from the multi-objective optimization are presented on Figure 5. The Pareto front of the optimization is represented by black dots, non-optimal solutions by grey dots, and the trusses in Figure 4 by blue dots. The four Pareto-optimal solutions (Figure 5a-d) are displayed to the left of the graph. As shown in Table 1, all generated trusses have a significantly lower DEI than the three trusses in Figure 4c, ranging from 43 kgCO2eq to 55 kgCO2eq. Moreover, their cut-off waste ranges from 0 kg to 4 kg, indicating that the identified solutions are more suitable for the stock than the initial truss structures.

3.2 Façade Primeo Energie Kosmos

The real-world project presented in the following involves designing and constructing the façade for the Primeo Energie Kosmos in Münchenstein, Switzerland. The design intent was to obtain a tree-like façade structure of complex geometry. Reclaimed steel elements from obsolete electric masts were to be used, which had already been dismantled and inventoried.. The available stock contains 1’361 linear elements with a total length of 4’329 m ranging from 1.4 m to 6.2 m. Figure 6 shows a scatter diagram of the in total 125 different stock element groups.

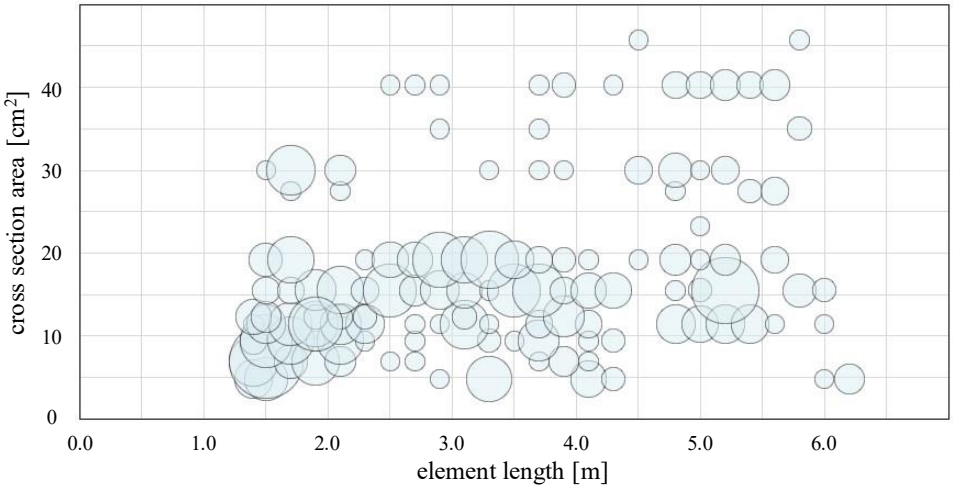

Figure 6. Stock composition

Most elements are either circular hollow sections or L-sections, an excerpt of which is pictured on the top left of Figure 7. In the following step, the available inventory was imported into Phoenix3D to be used for the assignment optimization. After applying the method described in Section 2, a range of design variations was generated; the eventually selected one is shown at the bottom left of Figure 7. Following several iterations, the final solution was established. An added advantage of working in the Rhino/Grasshopper environment was that detailed component drawings could be generated

automatically, which could be directly delivered to the steel fabricator. The construction of the façade was completed in fall of 2022, Figure 7.

Figure 7. Realized facade system based on the proposed method

4. Conclusion

This paper introduced an extended framework for the reuse-driven design of structural systems based on the parametric design tool Phoenix3D for Rhino/Grasshopper in combination with a genetic multi-objective optimization algorithm. A theoretical case study has been developed to generate different design alternatives from one stock of structural elements. Moreover, the framework was used to design a real-world application, the façade of the Primeo Energie Kosmos in Münchenstein, Switzerland.

Regarding design flexibility, future investigations will further expand the range of applicability to frame structures. Moreover, the developed Best-Fit heuristic will be improved to generate more accurate results when compared with a MILP-based implementation. This allows for more real-world applications and emphasizes integrating reuse strategies into conventional structural design workflows.

Abstract

The ever-increasing use of glass in load-bearing applications has led to concern about the effects of sustained loads on its strength. Ample experimental data is available on short-term strength of various types of glass. However, the short-term strength cannot be used directly in the design of structural components because the nominal strength decreases with time as a result of environmentally-assisted subcritical crack propagation. The load duration factor has been introduced to account for the dependence of strength on sustained loading, but a more comprehensive understanding of long-term strength is needed to guarantee the reliability of glass structures. This paper proposes a strength-prediction model based on stress corrosion theory to account for the effects of temperature, humidity and loading rate on crack growth parameters. An empirical power-law function is used for two types of stress histories: constant stress (life-time service condition) and constant stress rate (laboratory test condition). The relationships between applied constant stresses and lifetime, applied stress and stress/strain rate, and the proposed load duration factor are analyzed and quantified. The results of the model are validated using a large set of available data for various load durations and are compared with international standards. The results demonstrate that the proposed model provides accurate predictions of the long-term strength of structural glass.

Keywords: structural glass, long-term strength, load duration factor, life-time service condition, laboratory tests condition

1. Introduction

The use of glass in architecture has a long history, from its use in traditional windows to modern glass curtain walls. Because of its versatility and transparency, glass has become a major building material, second only to concrete and steel. In recent years, there has been an ever-increasing use of glass in load-bearing structures such as beams, columns, and stairs. However, its use has increased despite insufficient understanding of its long-term strength, a critical factor in the design of load-bearing structures. Laboratory testing (mostly constant stress rate, as shown in Figure 1(a)) provides short-term strength values that are useful for estimating the initial nominal resistance of a glass component, but they may not accurately reflect the long-term behaviour under sustained loading (constant stress, as shown in Figure 1(b)).

Glass, a nominally elastic-brittle material, contains large numbers of microcracks on the surface introduced by manufacturing and processing. When subjected to tensile stress and exposed to atmospheric environments, these microcracks propagate subcritically as a result of a chemical reaction between glass and water molecules. The subcritical extension under sustained load is referred to as static

Copyright © 2023 by Siyi YI, Suwen CHEN and Roberto BALLARINI. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

fatigue, or stress corrosion. If one or more of the surface cracks extend to critical lengths, the structural component can fail catastrophically. Therefore, the apparent (nominal) long-term strength of glass is lower than the short-term strength that is typically measured in the laboratory. Numerous studies have been conducted on time-dependence of glass strength using lifetime tests, in which the constant load is applied and time-to-failure is measured. The results have consistently shown that the glass strength decreases with increasing service life.

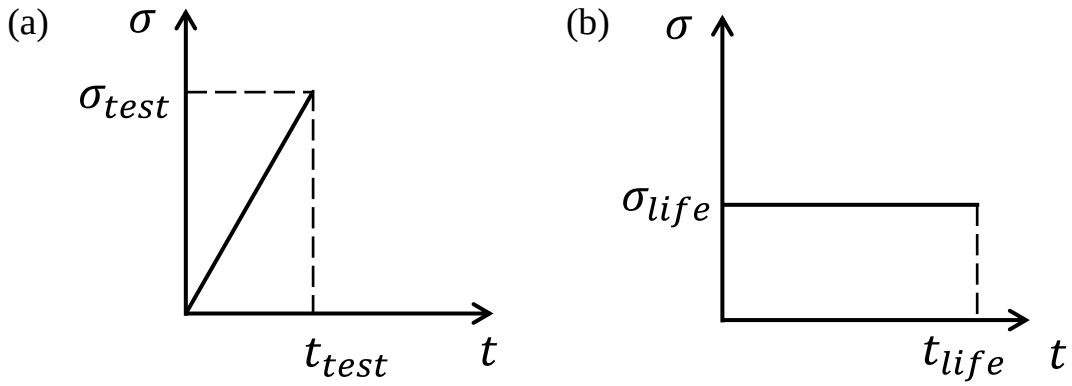

Figure 1. Two different stress histories: (a) stress history under laboratory tests condition (constant stress rate), (b) stress history under life-time service condition (constant stress).

The load duration factor k_{mod} has been introduced to consider the influence of subcritical crack propagation on glass strength, and is widely used in various standards. k_{mod} is defined as the ratio of long-term strength to short-term strength. The short-term strength is obtained by testing a certain number of specimens and performing a statistical analysis of data. The characteristic bending strength of soda-lime-silica glass is specified as f_k = 45 Mpa in EN 572-1[1]. Figure 2 presents the different methods used to determine k_{mod} in various standards. When the design lifetime is known, European [2], American [3], Australian [4] and Italian [5] standards provide formulas for calculating k_{mod}. When the designe lifetime is unknown, Chinese [6] and Australian [4] standards offer values of k_{mod} for corresponding lifetimes. However, as shown in Figure 2, the Chinese standard sets a very conservative k_{mod} value of 0.3 for design lifetimes greated than 10 minutes. Moreover, the formulas for calculating k_{mod} in other standards do not account for the effects of stress history and environment, and therefore may lead to unsafe designs.

To address this gap in knowledge, a novel approach is presented here to assess the long-term strength of structural glass through laboratory tests. Drawing from stress corrosion theory, an empirical power-law function is introduced to characterize subcritical crack propagation that quantifies the effects of temperature, humidity, and loading rate on crack growth parameters. The effectiveness and reliability of the model is demonstrated through a comparison of its results with international standards and available data.

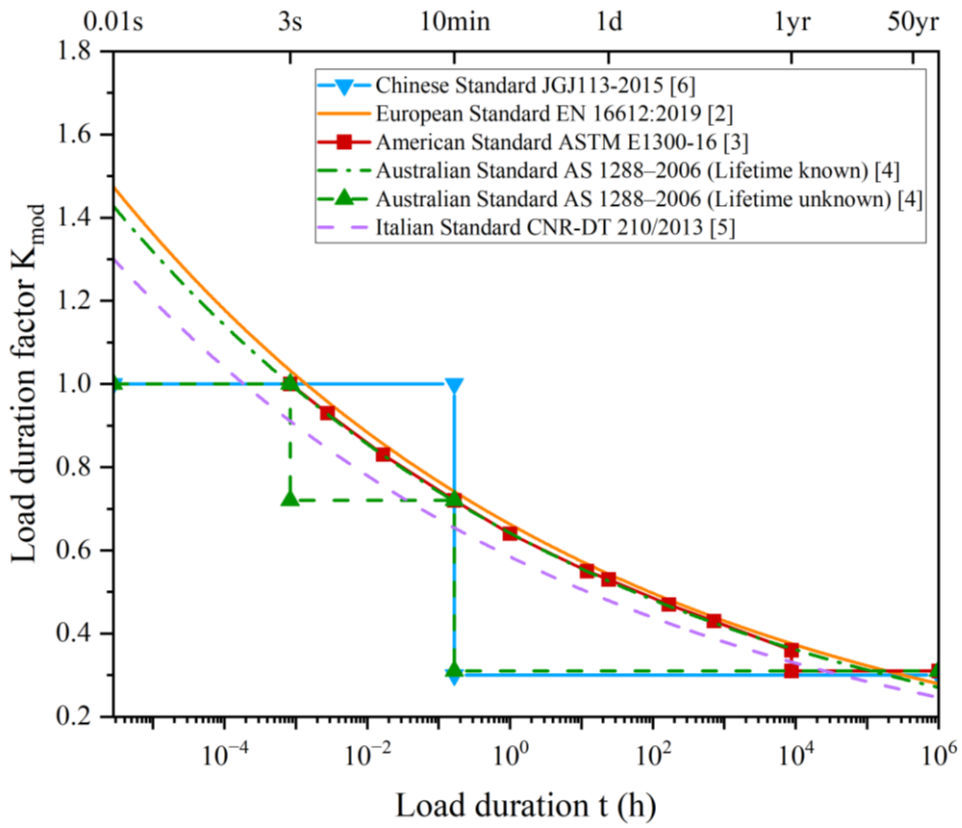

Figure 2. The determine methods of k_{mod} from different standards

2. Subcritical crack propagation

Glass is essentially an elastic and perfectly brittle material. Therefore, the cracks that are inevitably introduced on its surface by the manufacturing process and processing procedures can be modelled using Linear Elastic Fracture Mechanics (LEFM). LEFM assumes that a crack subjected to pure tension (Mode-I) will extend when the stress intensity factor K_{I} (a parameter that depends on the loading and crack length, or possibly another characteristic dimensión of the specimen) reaches the critical value K_{IC} (the fracture toughness). Under load-control the crack will propagate catastrophically when $K_{\mathrm{I}} = K_{\mathrm{IC}}$. However, it is also posible for a crack to propagate subcritically at values of K_{I} less than K_{IC} if the glass is exposed to a humid environment. This because the applied stress combines with a chemical reaction between the glass and water molecules to break the bonds along the crack front, thus effectively increasing the crack size. The crack velocity associated with this static fatigue (or stress corrosion) phenomena is determined by the stress intensity factor.

2.1. Relationship between crack velocity and stress intensity

Figure 3 illustrates the relationship between crack velocity v and K_{I} for a typical glass. When K_{I} exceeds the threshold K_{th}, the crack will begin to grow subcritically at a rate that depends on K_{I} (region I). In region II the crack velocity v is affected by relative humidity, but is independent of K_{I}. The velocity in region III returns to K_{I}-dependence and can be as fast as 0.001 ~ 1 m/s. When K_{I} reaches K_{IC}, the glass element fails catastrophically. In general, for the design of glass load-bearing structures which will withstand long-term loads, the mechanical behaviour of glass in region I is of interest.

For the case of brittle materials, an empirical power-law function[7] is usually used to describe the relationship between crack velocity and stress intensity in region I:

$$v = \frac{da}{dt} = v_0 \left(\frac{K_I}{K_{IC}}\right)^n \tag{1}$$

where v_0 and n are the linear and exponential crack velocity parameters, respectively. On the logarithmic scale (Figure 3), v_0 represents the ordinate of K_{IC} and n is the slope.

Here it suffices to summarize the fracture mechanics of two-dimensional configurations (plane stress or plane strain) under pure tension. As such, the crack front (a line) reduces to a crack tip (a point). The stress intensity factor K_{I} is usually written as:

$$K_I = Y\sigma\sqrt{\pi a} \tag{2}$$

where Y is the geometry factor, σ is the tensile stress perpendicular to the crack plane, and a is the crack depth.

Combining Equations (1) and (2), with the assumption of constant n and negligible K_{th}, leads to:

$$\int_{a_i}^{a_f} a^{-\frac{n}{2}} da = \frac{v_0 (Y\sqrt{\pi})^n}{{K_{IC}}^n} \int_0^{t_f} (\sigma(t))^n \, dt \tag{3}$$

where a_i is the initial crack depth, and a_f is the crack depth at failure, t_f is the time-to-failure.

In Chapter 3, Equation (3) is utilized to derive the crack resistances for two different stress histories. By considering the effects of temperature, humidity and loading rate, we will establish a relationship between these two crack resistances, enabling us to assess the long-term strength of glass based on the short-term strength obtained from laboratory tests.

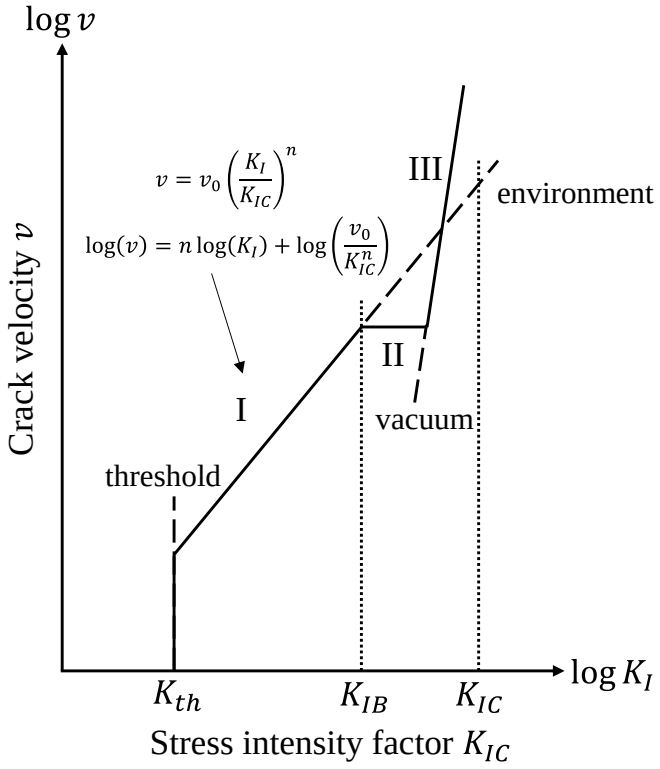

Figure 3. Relationship between crack velocity and stress intensity factor for glass

2.2. Quantification of the model parameters

To establish the relationship between life-time service condition and laboratory tests condition, it is crucial to analyse the effects of environment factors and stress history as well as to quantify the model parameters.

2.2.1. Geometry factor

Generally, the geometry factor Y is dependence of the crack geometry, the crack depth, the stress field applied and the geometry of glass element. However, the crack depth is too small in comparison with the thickness of glass element, so the dependence of the geometry of crack is the most significant. And it is assumed that Y is constant during the crack propagation. For surface cracks away from edge, Y = 1.12[8, 9] is commonly taken. For edge cracks caused by processing, it is reasonable to simplify as half-penny or quarter-circle cracks, and Y =0.722[8-10].

2.2.2. Fracture toughness

Fracture toughness K_{IC} is regarded as a material constant, which is only dependence of material itself (for example, the chemical composition of the material). Table 1 lists experimentally measured K_{IC}, and shows that K_{IC} = 0.75 MPa·m$^{0.5}$ is a reasonable assumption for soda lime silica glass in all applications.

Table 1. An overview of experimentally measured K_{IC} for soda lime silica glass

Source	K_{IC} (MPa·m$^{0.5}$)
Wiederhorn[11]	0.82
Atkins and Mai[12]	0.78
Gehrke et al. [13]	0.78
Mencek[14]	0.72~0.82
Ullner[15]	0.76

2.2.3. Crack velocity parameters

Crack velocity parameters v_0 and n are both affected by the temperature and humidity of the ambient environment. v_0 is also influenced by loading rate. Increases in temperature and humidity accelerate the chemical reactions between glass and water molecules, and in turn increase v_0 and decrease n [11, 16, 17]. Haldimann[8] established a linear crack velocity – stress rate relation based on experimental data, as depicted in Figure 4. On a double logarithmic scale, v_0 exhibits an approximately linear relationship with stress rate. For the typical loading stress rate of 2 MPa/s used in many laboratory test standards, v_0 is approximately 10 μm/s. By performing a linear fit (R^2=0.89) on the data points in Figure 4, the value of v_0 can be calculated for different loading stress rates $\dot{\sigma}$:

$$\log v_0 = -0.56 \log \dot{\sigma} + 1.27 \tag{4}$$

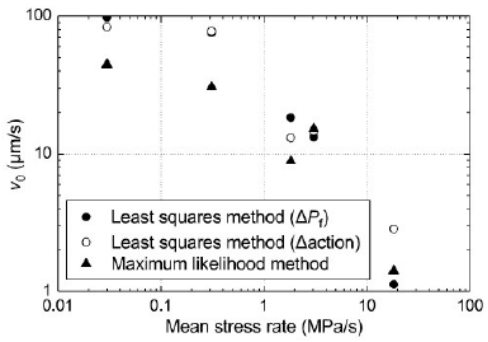

Figure 4. Curve of v_0 in relation to stress rate[8]

An overview of proposed v-K_I relations is shown in Figure 5, with the corresponding v_0 and n shown in the legend. The experimentally measured n is in the range of 14.77 ~ 21.5, and it is generally accepted that the use of n =16 [8-10, 18] is reasonable and conservative for most environmental conditions. The experimentally measured v_0 varies greatly due to its dependence on loading stress rate. However, with comprehensive consideration of environment and loading conditions, a reasonable range of 4.5~8.2mm/s can be used for load-bearing glass components. Haldimann[8] suggested that for general applications, v_0 = 6mm/s may be used as a conservative assumption; for glass elements that are permanently immersed in water, a higher value of e.g. v_0 = 30 mm/s might be required.

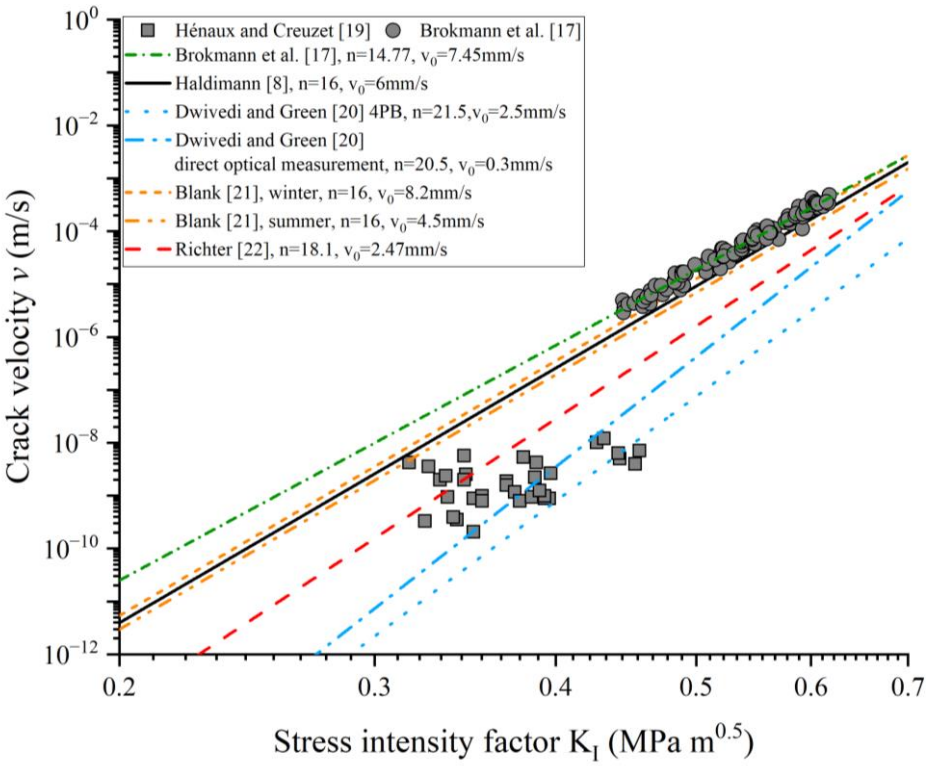

Figure 5. An overview of the v-K_I relations and crack growth data

3. Crack resistances under two different stress histories and the interrelationships

Equation (3) is now utilized to derive the crack resistances for two stress histories, and the relation between them will be established based on the parameter quantification in Chapter 2.

3.1. Laboratory tests condition (constant stress rate)

In laboratory tests the applied stress typically increases linearly with time. That is, the loading stress rate $\dot{\sigma}$ is constant, so that $\sigma(t) = \dot{\sigma}t$, as illustrated in Figure 1(a). Equation (3) becomes:

$$\int_{a_i}^{a_{test}} a^{-\frac{n}{2}} da = \frac{v_0 (Y\sqrt{\pi})^n}{{K_{IC}}^n} \int_0^{t_{test}} (\dot{\sigma}t)^n \, dt \tag{5}$$

with a_{test} defined as the crack depth at failure. Assume n to be constant and integrate Equation (5), yields

$$\frac{2}{n-2}\left({a_i}^{\frac{2-n}{2}} - {a_{test}}^{\frac{2-n}{2}} \right) = \frac{v_0 (Y\sqrt{\pi})^n}{{K_{IC}}^n} \cdot \frac{{\sigma_{test}}^{n+1}}{(n+1)\dot{\sigma}} \tag{6}$$

When the time-to-failure is more than 0.01s, the size of the critical crack at the end of the test can be assumed to be much higher the initial size [9]. Thus, the interrelationship between applied stresses of two identical cracks under identical conditions, loaded at different constant sstress rates $\dot{\sigma}_1$ and $\dot{\sigma}_2$, is obtained:

$$\frac{\sigma_1}{\sigma_2} = \left(\frac{\dot{\sigma}_1 v_{02}}{\dot{\sigma}_2 v_{01}}\right)^{1/(n+1)} \tag{7}$$

When under the standard stress rate of $\dot{\sigma_0} = 2$ MPa/s, the linear crack velocity parameter v_{00} =0.01mm/s. And values of v_0 for different loading stress rates $\dot{\sigma}$ can be calculated by Equation (4). Thus, the interrelationship between applied stresses of two identical cracks under identical conditions, loaded at standard and other constant stress rates $\dot{\sigma}_0$ and $\dot{\sigma}_1$, is obtained:

$$\frac{\sigma_1}{\sigma_{\dot{\sigma}_0}} = \left(\frac{\dot{\sigma}_1 v_{00}}{\dot{\sigma}_0 v_{01}}\right)^{1/(n+1)} \tag{8}$$

Equation (8) can also be expressed by strain rate, $\dot{\varepsilon}_0$ =2.86×10^{-5} s^{-1} ($\dot{\sigma_0}$ =2 MPa/s for elastic modulus E= 70 GPa[1]):

$$\frac{\sigma_1}{\sigma_{\dot{\varepsilon}_0}} = \left(\frac{\dot{\varepsilon}_1 v_{00}}{\dot{\varepsilon}_0 v_{01}}\right)^{1/(n+1)} \tag{9}$$

3.2. Life-time service condition (constant stress)

In the case of life-time service condition, the applied stress is commonly constant, $\sigma(t) = \sigma_{life}$, as illustrated in Figure 1(b). Equation (3) can be expressed as:

$$\int_{a_i}^{a_{life}} a^{-\frac{n}{2}} da = \frac{v_0 \left(Y\sqrt{\pi}\right)^n}{{K_{IC}}^n} \int_0^{t_{life}} {\sigma_{life}}^n \, dt \tag{10}$$

with a_{life} being the crack depth at failure under life-time service condition. Assume n to be constant and integrate Equation (10) to obtain

$$\frac{2}{n-2}\left(a_i^{\frac{2-n}{2}} - a_{life}^{\frac{2-n}{2}}\right) = \frac{v_0 \left(Y\sqrt{\pi}\right)^n}{{K_{IC}}^n} \sigma_{life}^n t_{life} \tag{11}$$

When the time-to-failure is greater than 0.01s, the interrelationship between applied constant stresses and lifetimes of two identical cracks under identical conditions is also obtained:

$$\frac{\sigma_1}{\sigma_2} = \left(\frac{t_2}{t_1}\right)^{1/n} \tag{12}$$

Thus, the applied constant stresses under different lifetimes can be normalised to a relative applied stress σ_{t_0}:

$$\frac{\sigma_1}{\sigma_{t_0}} = \left(\frac{t_0}{t_1}\right)^{1/n} \tag{13}$$

There are different values of t_0 used in standards and researches, e.g., 0.67s [5], 1s [8], 3s [3, 4, 8], 5s [1] and 60s [8, 18].

3.3. Assessing the long-term strength through laboratory tests

Assume the exponential crack velocity parameter n to be constant (n =16) for both laboratory tests condition and life-time service condition, and the linear crack velocity parameters are v_{0t} and v_{0l} respectively. For two identical cracks, the interrelationship between strength under laboratory tests condition σ_{test} and life-time service condition σ_{life} can be obtained:

$$\frac{\sigma_{life}}{\sigma_{test}} = \left(\frac{v_{0t}\sigma_{test}}{v_{0l}(n+1)t\,\dot{\sigma}}\right)^{1/n} \tag{14}$$

For convenient application, the long-term strength σ_{life} can be assessed through short-term strength obtained from standard laboratory tests ($\dot{\sigma} = \dot{\sigma}_0$ =2 MPa/s), and $v_{0t} = v_{00}$ =0.01mm/s. In the case of life-time service condition, v_{0l} = 6mm/s. The value of σ_{test} can be adopted as the characteristic bending strength f_k = 45 MPa, which is specified in EN 572-1[1]. Thus, the modified load duration factor k_{mod} can be obtained:

$$k_{mod} = \frac{\sigma_{life}}{f_k} = \left(\frac{f_k}{600(n+1)t\dot{\sigma}_0}\right)^{1/n} \tag{15}$$

4. Comparison of the model predictions with test data

A large number of laboratory strength tests have been conducted on glass using various methods such as three-point bending, four-point bending, coaxial double ring bending and uniaxial tensile tests. The tests data have been collected in [23]. Those tests are conducted under different constant stress rates. Remarkably, all the test data align with Equation (9) quite well, which considers the influence of stress rate on linear crack velocity parameters v_0, as demonstrated in Figure 6(a).

A significant amount of lifetime test data has also been gathered in [23] where the applied constant load and time-to-failure are recorded. This type of test closely simulates the life-time service condition and the specimen is typically loaded by dead-weight or through universal testing machine. Notably, all the data fit Equation (13) very well, as shown in Figure 6(b). Here t_0=1s is selected.

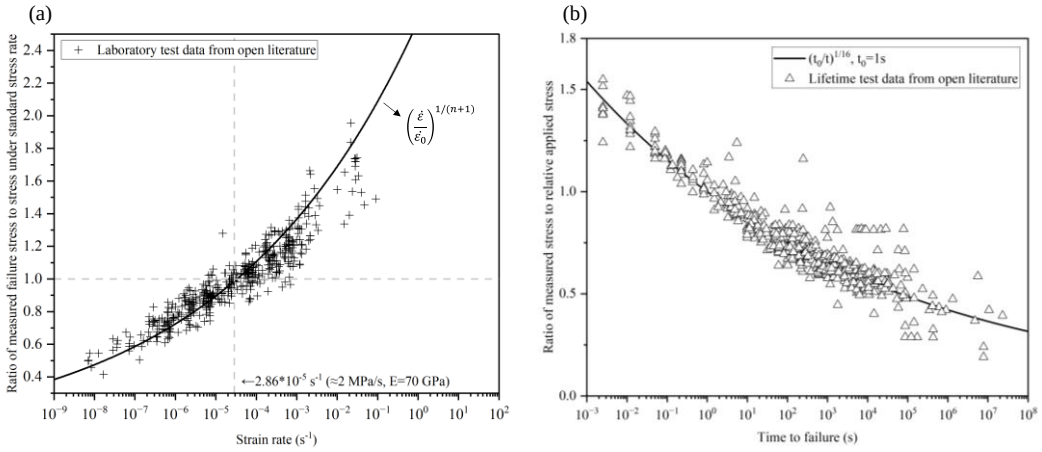

Figure 6. Comparisons of (a) Equation (9) and (b) Equation (13) with test data.

The lifetime test data are also compared with the proposed load duration factor k_{mod}, as shown in Figure 7. It can be observed that almost all the lifetime test data are above the proposed model. Most international standards use Equation (13) with different values of t_0 to assess the long-term strength, which may lead to unsafe design. This indicates that the proposed k_{mod} is safe enough to predict the long-term strength of glass through short-term strength obtained from standard laboratory tests.

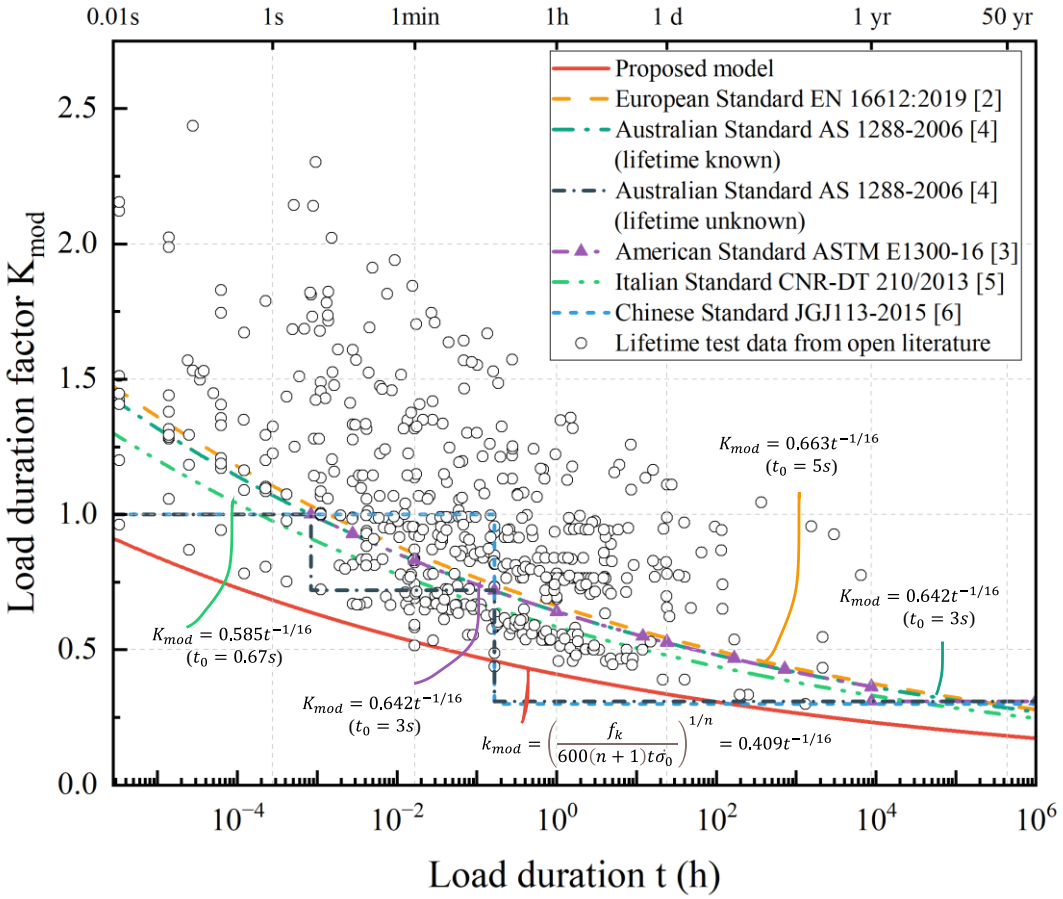

Figure 7. Comparison of proposed k_{mod} with test data

5. Conclusions

This paper proposes a predictive model for the long-term strength of structural glass that relies on short-term strength data obtained from laboratory tests. The model is motivated by the limitations of existing methods for determining the load duration factor k_{mod} from international standards. This paper addresses these limitations by developing a modified k_{mod} that considers and quantifies the influences of environment and stress rate on crack velocity parameters. The proposed model is verified against a large data set of laboratory test data for various load durations, and the results are compared to the international standards. It is demonstrated that the proposed model is more capable of converting short-term strength under different stress/strain rates, normalise the applied constant stresses under different lifetimes to the relative applied stress, and predict the long-term strength through short-term strength obtained from laboratory tests. It is concluded that the proposed model provides a safe and reliable method for assessing the long-term strength of structural glass, and offers promise improving design of load-bearing glass structures.

Abstract

Creep exists in the prestressed cables in spatial structures such as cable nets and cable domes. The occurrence of creep in structural elements leads to stress relaxation, resulting in a degradation of global stiffness or even failure of the entire structure. Therefore, it is critical to accurately predict the creep behaviour of structural members such as steel cables in structural design and assessment. To investigate this issue, this paper compares two methods for precisely predicting long-term creep behaviour in steel cables: a physical model based on viscoelastic theory and a neural ordinary differential equation (ODE)-based data-driven approach. Neural ODE is a powerful machine learning tool for governing equation discovery or approximation. Different from other neural network-based methods, Neural ODE learns the changing trend from measured data by approximating the derivative of the input-to-output transform rather than abstractly seeking the underlying relation between input and output, which enables it to generate a more accurate prediction. Furthermore, Neural ODE can not only learn the creep constitutive equation, but also flexibly integrate other physical information such as the diameters of cables into the model, which shows the evolutionary capability of the model. Based on the experimental data of a long-term creep test in previous research, prediction performance of both methods will be compared in this study. The Neural ODE framework possesses several advantages compared to the physical model method for directly fitting the creep constitutive equation: Firstly, the creep prediction of Neural ODE will be more accurate because it learns the changing trend of the data, while the accuracy of physical model is based on the assumed form of the constitutive equation and quantity of measurement data; Secondly, Neural ODE framework is more general because various parameters of steel cables can be considered and integrated into the framework.

Keywords: neural ODE, machine learning, creep behaviour, steel cables, cable structures, structural assessment

1. Introduction

Steel cables are a fundamental component of many engineering structures, ranging from bridges and towers to cranes and suspension systems. The long-term creep and stress relaxation behaviours of steel cables under tension have considerable implications for the reliability and safety of these structures. Accurate predictions of the creep deformation of steel cables are, therefore, a prerequisite for improving the design of these structures [1, 2].

Creep and stress relaxation are two important phenomena that are exhibited by viscoelastic materials. In general, creep and stress relaxation are different manifestations of the same mechanism under different conditions [3]. Creep is a particularly important concern for steel cables that are subject to

sustained tension. Over time, the length of a steel cable can increase significantly due to creep deformation, which can result in a loss of tension, reduced structural performance, and even failure. The precise nature of the creep deformation can depend on a range of factors, including the magnitude and duration of the applied load, and the composition and microstructure of the material itself. Stress relaxation, on the other hand, can also have significant implications for the long-term behaviour of steel cables. If a steel cable is stretched to a certain length and then held in that position, the stress on the cable will gradually decrease over time. This decrease in stress can result in reduced structural performance and can contribute to the potential for failure of the structure as a whole.

Given the importance of creep and stress relaxation in determining the long-term behaviour of steel cables, it is crucial to develop accurate methods for predicting these phenomena [4, 5]. By doing so, engineers and designers can make more informed decisions about the structural integrity of their designs and can take steps to mitigate the potential for failure over time. Different branches of neural networks are used to predict structural creep. For example, artificial neural networks [6] and recurrent neural networks [7] are used to predict creep behaviour in masonry structures. Convolutional neural networks are used to model creep and shrinkage in concrete structures [8]. However, there lacks studies on creep prediction of steel cables using machine learning methods.

In this research paper, two different methods are introduced to predict the long-term creep behaviour of steel cables: a physical model [4] based on viscoelastic theory [3] and a machine learning approach known as Neural Ordinary Differential Equation (Neural ODE) [9]. The physical model is a well-established method that describes the time-dependent behaviour of materials under stress by considering the inherent viscoelastic properties of the material. On the other hand, Neural ODE is a recent development in the field of machine learning, which has shown great promise in learning dynamic systems [9, 10].

The main objective of this study is to compare and evaluate the performance of these two methods in predicting the creep deformation of steel cables. We will use experimental data from previous studies [5] to calibrate and validate our models. Additionally, we will discuss the potential of combining these two methods to enhance the accuracy and efficiency of the prediction process.

The results of this study will provide valuable insights into the long-term behaviour of steel cables under tension and may help to improve the safety and reliability of engineering structures that rely on steel cable components.

2. Methodology

In this section, we will discuss two ways to describe the time-dependent creep constitutive model. The first method is physical model based on viscoelastic theory, which is commonly used. The second method is a data-driven machine learning method called Neural ODE.

Both methods can be utilized to describe the creep behaviour of steel cables by extrapolating from the limited data obtained within a short period of time. The aim of learning the creep constitutive equation is to predict the long-term creep behaviour of these steel cables in order to accurately evaluate the structural performance, with particular regard to the creep effect; this is important due to the difficulty of obtaining measurement data. To assess their effectiveness in fulfilling this purpose, the predictive performance of both methods will be evaluated in the subsequent section.

2.1. Physical model

The application of a physical model rooted in viscoelastic theory is well-suited for establishing the nonlinear relationship between the strain and stress exerted upon steel cables due to the creep effect. The construction of typical models embodying the principles of viscoelastic theory incorporates both ideal elastic elements and viscous elements, i.e. the springs and the dashpots. The relationship between stress and strain can be represented by Eq. (1) and Eq. (2) for springs and dashpots, respectively.

$$\sigma = E\varepsilon \tag{1}$$

$$\sigma = \eta \frac{d\varepsilon}{dt} = \eta\dot{\varepsilon} \tag{2}$$

Complex models, such as the Maxwell model and Kelvin model, may be constructed to describe the creep property of diverse viscoelastic materials by integrating multiple basic elements in either a parallel or series configuration. A typical Kelvin chain model is shown in Figure 1. The constitutive model of this Kelvin chain model is succinctly conveyed by the differential equation expressed as Eq. (3):

$$\sigma + p_1\dot{\sigma} + p_2\ddot{\sigma} + \cdots + p_n\sigma^{(n)} = q_0\varepsilon + q_1\dot{\varepsilon} + q_2\ddot{\varepsilon} + \cdots + q_n\varepsilon^{(n)} \tag{3}$$

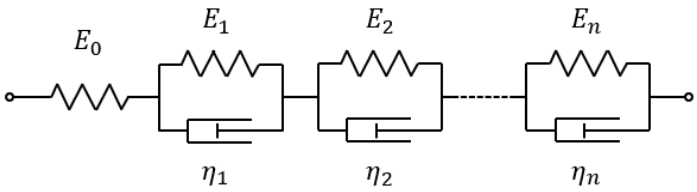

Figure 1. A general Kelvin chain model

By applying Laplace transformation to Eq. (3), it gives the relationship between total strain and applied constant stress:

$$\varepsilon(t) = \frac{\sigma_0}{E_0} + \sigma_0 \sum_{i=1}^{n} \frac{1}{E_i}\left(1 - e^{-\frac{t}{\tau_i}}\right) = \varepsilon_e + \varepsilon_{cr}(t) \tag{4}$$

Then, the expression of the total creep strain can be derived as:

$$\varepsilon_{cr}(t) = \sigma_0 \sum_{i=1}^{n} \frac{1}{E_i}\left(1 - e^{-\frac{t}{\tau_i}}\right) = \sum_{i=1}^{n} \phi_i\left(1 - e^{-\frac{t}{\tau_i}}\right) \tag{5}$$

It should be noted that Eq. (5) is derived from a Kelvin model with three basic unit, which is a parallel combination of a spring and a dashpot. The values of the relevant parameters are obtained through measurement data and may vary depending on the specific model chosen and the quantity of data available, potentially impeding the accuracy of predictions derived through this formulation. Careful attention to parameter selection and model choice is therefore paramount in ensuring the reliability and validity of results obtained from this approach.

2.2. Neural Ordinary Differential Equation (Neural ODE)

Neural ODE has raised significant attention in recent years for it provides a new insight into the relation between neural networks and differential equations. Neural ODE is a variant of Residual Networks (ResNets) [11]. In ResNets, the states of a system can be expressed by hidden layers of neural networks. The state of layer *t*+1 can be obtained from the state of layer *t* through a function $f(\cdot)$:

$$h_{t+1} = h_t + f(h_t) \tag{6}$$

This process can be regarded as a numerical integration with a time step $\Delta t = 1$:

$$h_{t+1} = h_t + f(h_t)\Delta t \tag{7}$$

By taking the limit of Δt to approach zero, Eq. (7) can be transformed from a discrete form into a continuous ordinary differential equation with respect to time *t*:

$$\lim_{\Delta t \to 0} \frac{h_{t+1} - h_t}{\Delta t} = \frac{dh(t)}{dt} = f(h(t), t) \tag{8}$$

The differentiable function $f(\cdot)$ is the derivative of the hidden state $h(t)$, which can be parameterized by deep neural networks (DNNs) as $f(h(t), t, \theta)$. θ represent the trainable parameters, i.e. weights and biases, in the DNNs. It is the core idea of Neural ODE that modelling a dynamic system using DNNs in the format of an initial value problem of an ODE:

$$\dot{h}(t) = f(h(t), t, \theta) \qquad h(t_0) = h_0 \tag{9}$$

As a powerful function approximator, DNNs can learn the derivative, i.e. the dynamics, of the states of the concerned system from data. To train the DNNs, the loss function can be constructed by:

$$L_{total} = \sum_{i=1}^{n_m} \left| h(t_0) + \int_{t_0}^{t_i} f(h(t), t, \theta) dt - u_m(t_i) \right|^2 \tag{10}$$

By minimizing the loss function, the parameters of the DNNs can be optimized and updated during the training process. At the same time, the DNNs will be finally trained as a surrogate model of the time derivative of $h(t)$.

Neural networks such as artificial neural networks [6] have been applied to predict creep by learning the creep itself. In this study, however, we try the newly emerged Neural ODE framework. The advantage of Neural ODE is its superior curve-fitting accuracy provided by the key idea of Neural ODE, which is to learn the underlying dynamics of the system rather than learn the structural response itself. On the other hand, Neural ODE is a data-driven method, which means it learns the dynamics from data. Thus, the effectiveness of learning and the accuracy of prediction highly depend on the quality of the data.

3. Creep constitutive model

In this section, we present an evaluation of the predictive accuracy of two methods, previously discussed. The evaluation process includes two steps, whereby the measurement data is obtained from a long-term creep test. In the first step, we use the measurement data of 2,000 hours to model the creep constitutive equation derived from viscoelastic theory and train the DNN-based Neural ODE model. In the second step, the fitted physical model and learned Neural ODE model will be used to predict the creep behaviour of 9,000 hours, and their performance will then be assessed.

3.1. Physical model

To fit the time-creep strain curve depicted in Figure 2, a Kelvin chain model comprising one spring and three spring-dashpot units was selected. The elastic behaviour is represented by the spring, while the viscoelastic behaviour is mimicked by the three units. The scatter chart in Figure 3(a) illustrates the time-creep strain relationship. It is worth noting that only 2,000 hours of data was employed to establish the model, while the remaining data was utilized to evaluate the predictive performance. The resulting creep constitutive model can be adequately fitted and expressed as follows:

$$\varepsilon_{cr}(t) = \sum_{i=1}^{3} \phi_i \left(1 - e^{-\frac{t}{\tau_i}}\right) \tag{11}$$

in which, $\phi_1 = 1.41 \times 10^{-2}$, $\phi_2 = -1.39 \times 10^{-2}$, $\phi_3 = 1.17 \times 10^{-4}$, $\tau_1 = 2.17 \times 10^{1}$, $\tau_2 = 2.15 \times 10^{1}$, $\tau_3 = 7.98 \times 10^{2}$. Figure 3(b) presents a comparison between the fitted curve and measured data. Additionally, Figure 3(b) illustrates the prediction obtained from the physical model concerning time-creep behaviour over the interval between 2,000 and 9,000 hours. The physical model exhibits a reasonable agreement with the available data, albeit portraying a tendency towards horizontal progression, which means it cannot predict the changing tendency of the curve well. The relative error at *t*=9,000 h is 7.23%, and the average error of prediction is 4.17%.

The limited suitability of the physical model for prediction, despite being appropriate for modelling the time period of the available data, is attributed to uncertainty in the selection of model components and

the quantity of data utilized. The accuracy of the model is dependent on the amount and quality of the data used. In situations where data is inadequate, the model may fail to capture the complete trajectory of data fluctuations, thereby affecting the reliability of predictions.

Figure 3. The time-creep strain relation

3.2. Neural ODE

The implementation of Neural ODE for learning the creep constitutive equation from limited data will be detailed in this subsection.

First, a DNN was designed to serve as the primary component of the Neural ODE framework. The DNN features two hidden layers, each of which comprises 40 neurons. Given that the DNN's architecture exerts a significant influence on the learning process, trials were undertaken to optimize this feature. Various choices exist for the activation function [12], including ReLU, Sigmoid, and Tanh. In this study, we utilized Tanh, which performs the nonlinear transformation for every hidden layer. The inputs of the DNN are the time variable, *t*. If additional factors such as the steel cable's diameter and stress level are considered, the DNN easily accommodates other inputs accordingly. The outputs of the DNN will be the derivative $f(t)$. In contrast to other machine learning methods, the DNN in the Neural ODE framework learns the derivative of the time-creep strain curve, which represents the fundamental dynamics of the creep effect, as opposed to merely the curve itself. The transformation through the DNN can be represented explicitly as follows:

$$y_i = \sigma(W_i \cdot x_{i-1} + B_i), \qquad 1 \le i \le n \tag{12}$$

in which, x_{i-1} and y_i are the input and output of *i*th layer, respectively; W_i and B_i are matrices for weights and biases; σ is the nonlinear activation function.

To construct the loss function, an ODE solver is required to compute the integral term in Eq. (10). The ODE solver can be built based on numerical integration methods such as Runge-Kutta method and Gaussian quadrature. Chen [9] proposed an adjoint sensitivity method-based ODE solver, which can significantly reduce the memory cost. Then, the total loss function can be computed by:

$$L_{total} = \sum_{i=1}^{n_m} |h(t_0) + ODESolver(f(t), t_0, t_i, \theta) - u_m(t_i)|^2 \quad (13)$$

After calculating the total loss, the DNN can be trained to learn the derivative $f(t)$ during the training process. The training of a DNN involves the use of two critical algorithms, forward propagation and backpropagation. Forward propagation performs the critical function of taking an input and proceeding through the neural system to generate an output. On the other hand, backpropagation computes the gradient of the loss function concerning each neuron in the network. This gradient is then utilized to update the weights and biases of the network via an optimizer method such as SGD, L-BFGS, Adam, or RMSprop, among others. For this study, Adam will be employed to train the model, with a fixed learning rate of 0.01. Training will be stopped once the model reaches a certain iteration number or when the loss value has become stable. The learned derivative of the data will be leveraged to make predictions, and the overall Neural ODE framework is displayed in Figure 4, with the image depicting the convergence of the total loss throughout the training phase shown in Figure 5.

The prediction in the entire time period is shown in Figure 6. The relative error at *t*=9,000 h is 2.90%, which is smaller than that of physical model (7.23%). The average error of prediction is 2.19%, and it is also better than physical model (4.17%). This result shows the ability of Neural ODE in learning time-dependent behaviour and generating accurate long-term predictions.

3.3. Comparison of the physical model and Neural ODE model

The observation from Figure 3(b) and Figure 6 reveals that the physical model and Neural ODE model effectively fit the measurement data until 2,000 hours. However, the Neural ODE model outperforms the physical model in terms of predictive performance. It is worth mentioning that both models have potential areas of improvement.

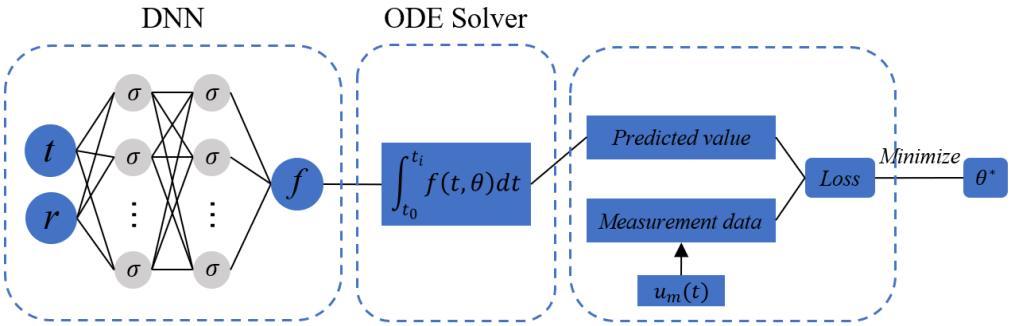

Figure 4. The Neural ODE framework

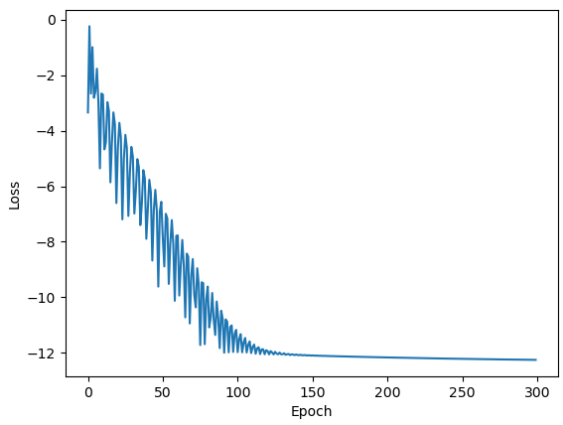

Figure 5. The training loss curve

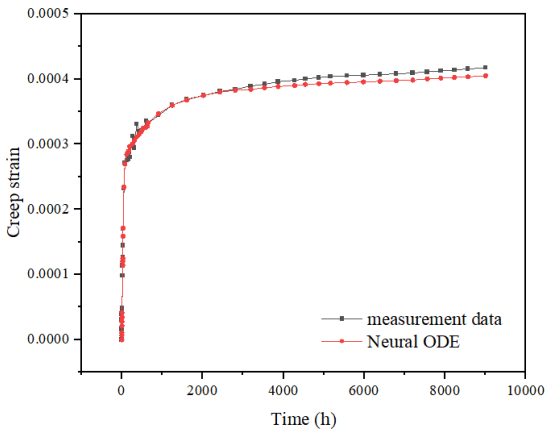

Figure 6. Comparison of time-creep strain curves

4. Conclusion and discussion

The accurate prediction of creep behaviour in steel cables is crucial for the structural design and assessment of spatial structures such as cable nets and cable domes. This paper presents a preliminary study on creep behaviour prediction. Two methods including physical model based on viscoelastic theory and a Neural Ordinary Differential Equation (Neural ODE)-based data-driven approach are investigated and compared.

Compared to the physical model method that derive the theoretical creep constitutive equation from viscoelastic theory and fit the equation directly, Neural ODE possesses several advantages such as more accurate prediction through learning the changing trend of the data, which is the underlying dynamics of the creep behaviour, and being more general by considering different parameters of steel cables. The results show that Neural ODE owns good extrapolation capability and is suitable to learn time-dependent properties and dynamics of structural systems.

In addition, the performance of Neural ODE can still be further improved. For example, Neural ODE is a data-driven approach, whose prediction accurate highly relies on the quantity and quality of the measurement data. However, the measurement data is sparse, and even hard to get in many cases. Therefore, prior physical knowledge like the theoretical creep constitutive equation can be integrated to facilitate computation and enhance the accuracy in the future work.

Abstract

Large-span spatial structures are widely used as public facilities. In order to ensure the safety and durability of the structures and protect the lives and property of the occupants, it is necessary to monitor the health of large-span spatial structures. Sensor placement is important for structural health monitoring. Since large-span spatial structures have complex shapes and a large number of members and nodes, research on optimal sensor placement can effectively address many problems associated with excessive and inappropriate placement. The sensors placed effectively should be sensitive to changes of the structural condition, which can provide enough information. In this paper, a novel method of sensitivity analysis based on the static characteristics of large-span spatial structures is proposed. The key members that are sensitive to load changes and govern the structural mechanical property are identified by the method to arrange sensors. This sensitivity analysis method was applied in the Ouhai Olympic Centre Stadium to place stress sensors. The monitoring data successfully reflects the condition changes of the structure during construction and ensured structural safety, showing the effectiveness of the method.

Keywords: large-scale spatial structure, structure health monitoring, optimal sensor placement, sensitivity analysis

1. Introduction

Large-scale spatial structures are widely used in public facilities such as airports, railway stations, and stadiums, but the potential safety risks cannot be ignored [1]. To ensure the safety of structures and provide early warning of potential risks, structural health monitoring (SHM) systems are widely used. The optimal sensor placement (OSP) method is one of the key parts in the design of an SHM system. Due to constraints such as site conditions and economic conditions, only a relatively small number of sensors can be placed in limited locations [2]. Therefore, sensor placement has a significant impact on the effectiveness of monitoring data collection.

Many methods have been proposed for OSP. Some dynamic characteristic-based methods include the modal assurance criterion-based method [3], the effective independence method [4], the kinetic energy method [5], and the singular value decomposition method [6]. By analyzing different data features in the dynamic response information collected by sensors, changes in structural health due to damage or degradation can be obtained. Some static characteristic-based methods based on strength [7], sensitivity [8], energy [9], redundancy [10], and susceptibility [11] analysis have also been proposed. By placing sensors on key members, their properties can be analyzed in time to obtain the stress state of the whole structure and provide early warning.

The OSP should be based on the stress properties features of structures, consider the key processes of different construction methods, and the mechanical properties of different structural members. Large-scale spatial structures have various structural systems, complex construction methods, and different kinds of members [7]. The response of a structure is mostly through static stress and deformation, and

Copyright © 2023 by Yiqun WANG and Yaozhi LUO. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

the effect of the structure varies under different loads. In addition, large-scale spatial structures are super-stationary and have a high degree of redundancy. The "domino effect" may be triggered when some key members with high sensitivity fail, resulting in the successive buckling of the members arranged in parallel or bearing the same directional load, eventually leading to the destruction of the whole structure [12]. For this reason, strain monitoring based on static characteristics is necessary for large-scale spatial structures. In this paper, the OSP is carried out from structural static characteristics, and a sensitivity-based analysis method is introduced. The members with obvious stress changes under load changes were first selected by load sensitivity analysis, and self-sensitivity analysis was further carried out to select the key members with high influence on the structural stress state during damage. The sensors are placed according to the selected key members. This method is used to design the sensor placement scheme of the Ouhai Olympic Centre Stadium. Based on the collected real-time data, the stress conditions of the key members are promptly analyzed and the safety status of the structure is evaluated.

2. Sensitivity analysis method

2.1. Load sensitivity analysis

The structural load sensitivity analysis is based on the member load sensitivity analysis, which concerns the relationship between load changes and member response. During its operational life, a large-scale spatial structure is subjected to various environmental factors such as snow load, wind load, and temperature effect. The response of different members will vary under the influence of different variable loads, this response is represented by stress and nodal deformation.

Under linear conditions, when a particular type of load is applied, the greater the change in a member's stress, the more sensitive the member is to that type of load. A member whose stress changes significantly with the change in load is defined as being sensitive to that type of load.

The load sensitivity I_{Li} of a member is defined as follows:

$$I_{Li} = \frac{SZ_i}{SZ_{max}} \tag{1}$$

$$SZ_i = \left|\gamma_{wind} S_{wind,i} + \gamma_{snow} S_{snow,i} + \gamma_{temp} S_{temp,i} \cdots\cdots\right| \tag{2}$$

Where SZ_i is the comprehensive load sensitivity coefficient of member i; $SZ_{\max}$ is the maximum value in SZ_i; $S_{wind,i}$, $S_{snow,i}$, $S_{temp,i}$ is the load sensitivity coefficient of wind load, snow load or temperature effect of member i; γ_{wind}, γ_{snow}, γ_{temp} is the load influence weight coefficient, the highest is 1 and the lowest is 0.

Since the probability of occurrence of different environmental loads is different and the magnitude is a random variable. To facilitate the comparison and calculation between different environmental loads, it is necessary to define the probability of occurrence and the range of values of environmental loads. The definition of the sensitivity of a member to a certain type of load is proposed as follows: if the wind load (snow load, temperature effect) on the structure changes from the design value of 50 years to the design value of 100 years, the amount of stress change Δs_i in the member is the sensitivity coefficient of the member to this load. The calculation formula is as follows:

$$S_i = \Delta s_i = s_{i100} - s_{i50} \tag{3}$$

Where s_{i100}, s_{i50} is the stress of a member i under a certain type of load taking the design value of 100 years and 50 years; the type of load can be wind load, snow load, temperature effect, and others.

2.2. Self-sensitivity analysis

The structural self-sensitivity analysis is based on the member self-sensitivity analysis, which concerns the relationship between member damage and structural mechanical property. The component self-sensitivity is the degree of effect on the safety evaluation index of structures when member damage occurs. The current simulation of member damage is performed by weakening the cross-sectional area of the member [13], and this method is also used here to simulate the effects of member damage on the structure.

Structural displacement and member stress are controlling factors in structural design, these two factors can be used as response indicators to consider the effects on the structure after member damage [14]. Since the change in these two factors after the damage is positively correlated [15], either one of them is analyzed as a response index with the same results. The maximum change in structural displacement is used here as the output parameter.

The self-sensitivity I_{Si} of a member is defined as follows:

$$I_{Si} = \frac{R_i}{R_{max}} \tag{4}$$

$$R_i = \left| \Delta_{max}(i) \right| \tag{5}$$

Where R_i is the maximum response of the structure after the section weakening of member i; $R_{\max}$ is the maximum value in R_i; $\Delta_{max}(i)$ is the maximum displacement change of the structure before and after the section weakening of the member.

3. Optimal sensor placement based on sensitivity analysis

A square flat grid structure is used as an example for sensitivity analysis and selecting key members with high sensitivity for sensor placement. The grid plan size is 30m*30m, with a thickness of 3m, the number of grids in both directions is 10, and each side of the grid is 3m, as shown in Figure 1.

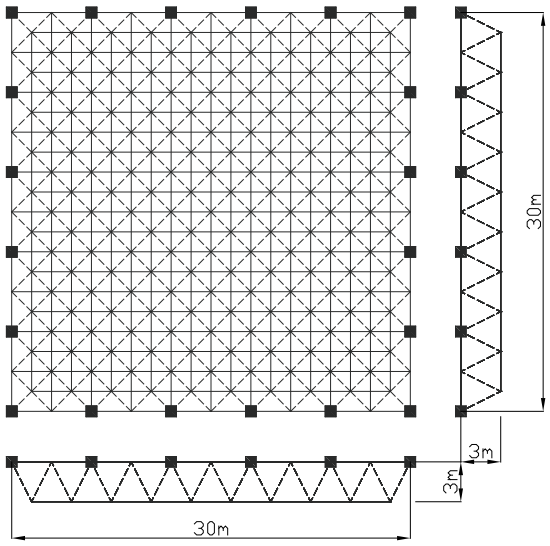

Figure 1. Square flat grid structure

The load sensitivity analysis was carried out on the calculated model and the values taken for the load and weight coefficients are shown in Table 1. The load sensitivity of each member is calculated and sorted. The results of the calculation are shown in Figure 2. The members with the top 15% of the load

sensitivity orders are selected and shown in Figure 3. The minimum load sensitivity of these members is close to 0.8.

Table 1. Load and weight coefficients

		Dead load	Liveload	Wind load	Download	Temperature effect
Load	50 years	0.3 kN/m2	0.5 kN/m2	0.45 kN/m2	0.45 kN/m2	-20℃~+30℃
	100 years			0.5 kN/m2	0.5 kN/m2	-22℃~+32℃
Weight coefficients				0.4	0.4	0.2

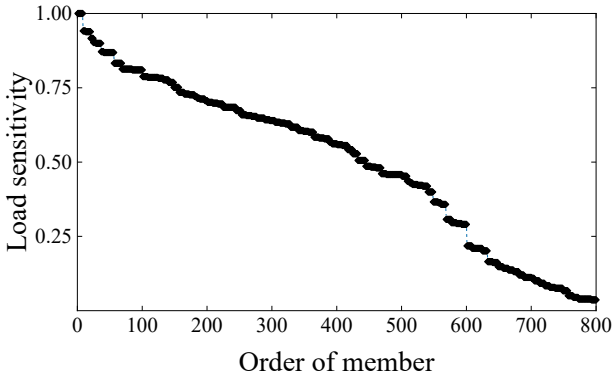

Figure 2. Load sensitivity distribution

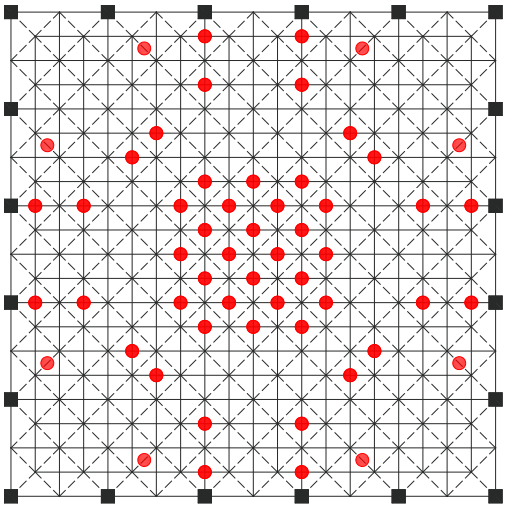

Figure 3. Diagram of the members to be selected

The members selected by the load sensitivity analysis are subjected to the self-sensitivity analysis. The cross-sections of these members are weakened by 50%. The self-sensitivity of each member is calculated and sorted. The results of the calculation are shown in Figure 4. The members with the top 20% of the self-sensitivity orders are selected and shown in Figure 5. These members are the key members with high comprehensive sensitivity, sensors should be placed on them.

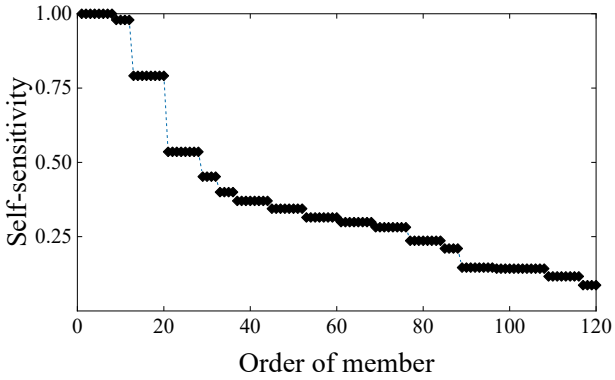

Figure 4. Self-sensitivity distribution

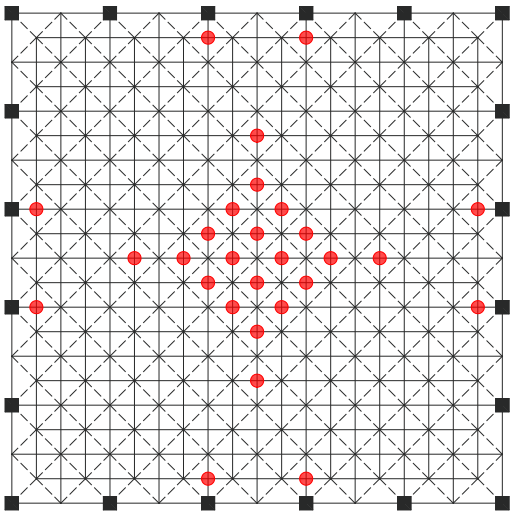

Figure 5. Diagram of the key members

4. Application on the Ouhai Olympic Centre Stadium

The Ouhai Olympic Centre Stadium is one of the competition venues for the Hangzhou 2022 Asian Games. The roof of the stadium is crescent-shaped, with an outer circle radius of approximately 223m and an inner circle radius of approximately 176m. The structure is supported by concrete columns on the outside of the grandstand and tubular steel columns on the perimeter. As the structure has a large span and a special shape, the mechanical properties and construction program of the station are very complicated. To monitor the structural condition and ensure safety, the SHM system is applied at the beginning of the structural construction. The sensitivity analysis based on the actual forces on the structure was carried out for the sensor placement, as shown in Figure 6.

The key elements of the structure were selected through sensitivity analysis, and the sensors placed on these elements monitored the construction process of the structure in real-time. The constraints of the structure will change during the unloading process, and the stress of the structural members will change simultaneously. Figure 7 shows the monitoring data from the sensors during the unloading stage of the structure, and the construction period is from September 14 to September 20, 2021. Stress 1 and stress 2 represent the stress on the two symmetrical surfaces, and the deviation of stress 1 and stress 2 indicates the bending moment of the member.

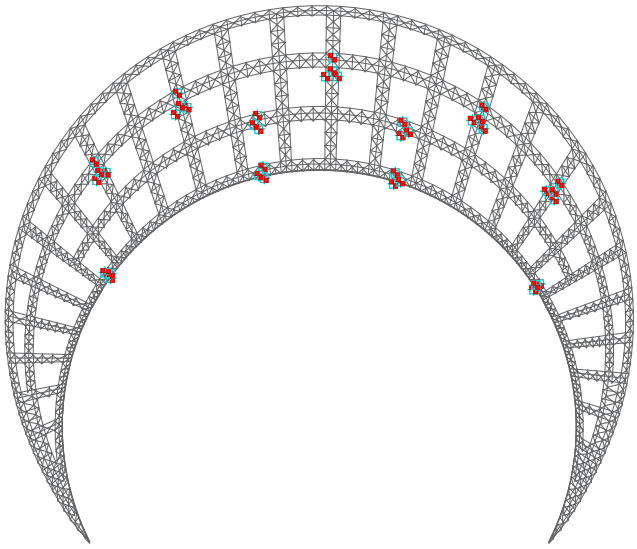

Figure 6. Sensor placement

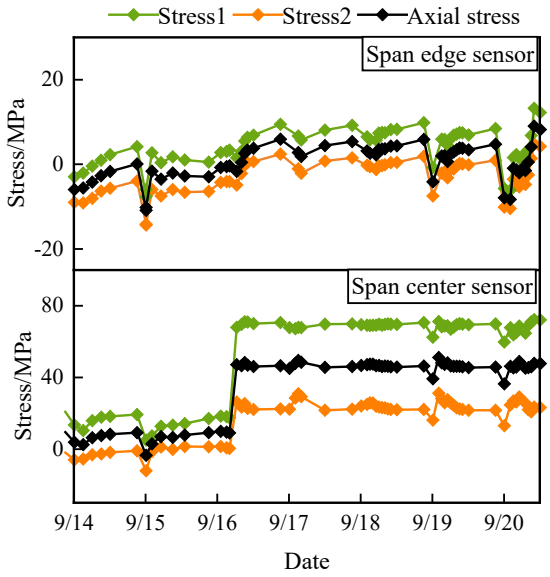

Figure 7. Monitoring data during the unloading stage

The monitoring data shows that the sensors in the span of the structure have a more obvious stress increase during the unloading stage, while the sensors at the edge of the structure have minor stress fluctuations. The stress values are within the allowable stress range of the steel. The monitoring data from the sensors successfully provided critical information during the unloading of the structure.

4. Conclusion

In this study, we propose a novel sensitivity analysis method based on structural static characteristics, which is used to guide the OSP. By calculating the sensitivity index, the method can identify the key members with significant stress change under load change and high influence on the structural mechanical property during their damage for sensor placement. The method is applied to place sensors in the Ouhai Olympic Sports Center stadium, the monitoring data shows that the sensors can reflect the stress of the whole structure and have a high sensitivity to changes in the structural state.

Abstract

The building industry is responsible for 38% of total global energy-related CO2 emissions. In the previous years, policies have focused on reducing operational energy, and embodied emissions have become most significant contributors to the total greenhouse gas (GHG) emissions of buildings. Structural systems almost always constitute the largest source of embodied carbon in buildings and largest emissions occur during the production stage. However, embodied CO2 values are strongly influenced by material provenance, and their magnitude varies greatly between countries [1]. Databases gathering information on GHG emissions are therefore essential to improve our understanding of current emissions (baseline), targeted emissions (budget) and to make recommendations from their analysis for the future (benchmarks). The digitalization of the building industry has facilitated the introduction of carbon footprint assessment tools in the structural engineering practice [2]. Choosing appropriate structures in a given project can greatly reduce material consumption and material waste. However, methods to efficiently assess GHG emissions of such structures are lacking. Moreover, they are rarely computed at early design stages, when changes with highest impact are made, but quantitative volumetric and material information – 'hard' features - are still unavailable [3]. This research uses machine learning models and investigates strategies to predict the GHG emissions of buildings with two structure typologies, massive structures and frame structures, using descriptive data available in competition briefs - "soft" features. It proposes a methodology to obtain accurate predictions, despite limited data available for the learning. The methodology is tested on the Embodied Carbon of European Buildings EUCB-D database, describing the embodied GHG emissions of buildings. Results prove the potential of the methodology, and motivate its further developments into a tool for data-driven low carbon structural design. Moreover, results identify the importance of soft-features and suggests ways of assembling efficient databases describing building structures, in order to improve the understanding of their environmental impact.

Keywords: structural design, greenhouse gas emissions, machine learning, structures, sustainable architecture, feature analysis, Hangai Prize

1. Introduction

The building sector accounts for 38% of total global energy-related CO2 emissions [4]. Greenhouse gas (GHG) emissions of buildings include Embodied Emissions (EE) and Operational Emissions (OE). EE correspond to GHGs emitted during the production of a material, including mining, manufacturing, transportation, installation, maintenance and disposal. OE correspond to GHGs emitted during the operational phase of a building, including energy consumption tasks such as heating, ventilation and lighting. To help reduce GHG emissions, tools, policies and certification bodies can be developed [5].

Copyright © 2023 by Sandie Kate FENTON, Klaas DE RYCKE and Lars DE LAET. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

In the previous years, policies have focused on reducing operational energy [6]. They have resulted in the regulation of energy consumption on new buildings and have motivated the renovation of old buildings for increased energetic performance. They have also led to the development of "green" building certificates such as LEED or BREEAM [7]. As a result, operational emissions have dropped in buildings and are expected to be reduced to near zero in the future. EE in buildings have become therefore become increasingly significant contributors to total GHG emissions [8].

Tools for computing building GHG emissions are numerous. Tables, such as the Structural Carbon tool, allow to estimate the amount of carbon at different design stages, based on materials and volumes used [2]. Parametric tools, such as the grasshopper plug-in One Click LCA [9], are directly linked to building geometries, and are updated as the design materials and volumetry change. The different tools help identify GHG emissions hotspots and help communicate about impacts of design on these emissions. Unfortunately, since using these tools is often highly time-intensive, they are run at late stages of the design, when data is fixed, and little effective changes can be made. Moreover, architects and engineers have a limited control and visibility on the emissions of their projects since GHG emissions assessments are often performed by environmental offices [10].

Many research projects have worked on developing new GHG emissions evaluation tools. Studies making use of data from existing buildings include the use of value engineering principles to integrate embodied carbon reduction strategies in building design [11], the use of linear regression to predict GHG emissions of buildings from main building materials and structural forms [12], the use of statistical and probabilistic principles to evaluate GHG emissions from main materials and quantities [13] and the use of analytical principles to evaluate the impact of structural forms on GHG emissions in high-rise buildings [14]. Studies making use of data from generated buildings include the use of data visualization techniques to explore thousands of parametrically generated architectural alternatives[15], or the use of visualization frameworks to explore multi-dimensional intuitive design spaces without requiring any underlying parameterization [16].

2. Problem statement

GHG emissions are usually computed from "hard" features, by summing all emissions associated to materials with given volumes. Since precise building materials and geometries are often unavailable at early design stages, GHG emission computation tools are used later in the design process. Unfortunately, this means less changes can be made to the design and costs of making changes are high.

This research aims to "sum" GHG emissions associated to building properties in order to evaluate building emissions. These properties, called "soft" features in the scope of this work, include quantitative features such as gross floor area, and qualitative features such as structure type [17]. They are already available in design briefs meaning emissions can be assessed early on. Rather than computed, EE are predicted by first gathering data describing many buildings, then building tools to model this data and learning to progressively predict the content, as displayed in Figure 1. To reach this goal, the underlying modelling and predictive methodology makes use of multiple machine learning techniques. To facilitate model interpretability and understand feature impacts, regressions models are preferred to black-box models.

GHG emission values vary strongly depending on the assessment boundaries and the hypothesis set. To be applicable to any country or context, the methodology developed in this research can be tailored to any database containing a list of buildings for which both soft features and associated EE emissions are provided. To allow working despite the little data available, data and features used for the training are made efficient. Redundant and uncorrelated elements are removed during data processing and feature processing steps. The resulting "soft-feature approach" aims to provide a real-time carbon assessment tool, available at early design stages and accessible to practitioners. The research builds on previous work from the authors, in which the methodology was introduced and developed [18]. In this paper, we

test and discuss its performance for the assessment of GHG emissions of building with two types of structures, massive structures and frame structures.

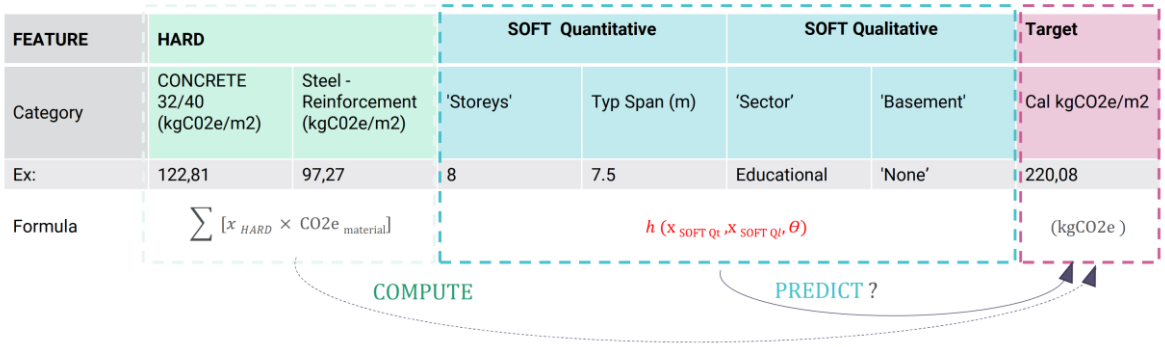

Figure 1: Soft Feature Approach – Rather than computed from ”hard” features, EEs are predicted by first gathering ”soft” features describing many buildings, then building tools to model this data and learning to predict the target values.

3. Data

The database used for the learning models lists 625 buildings, and provides 16 soft features (quantitative and qualitative) and their computed true GHG embodied emissions expressed in kgCO2e/m². Values, ranging between 100 and 1800 kgCO2e/m2 , include Ground, Structure, Envelope, and Internal Services and Appliances. Learning features are provided in Table 1. Data was extracted from the Embodied Carbon of European Buildings database, a public repository on Embodied and Whole Life Carbon. Data was assembled and verified as part of the ”Towards embodied carbon benchmarks for buildings in Europe” project [19] funded by the Laudes Foundation, and performed in collaboration between Ramboll, Aalborg University Build and KU Leuven [20].

Table 1: 16 Soft features are extracted from the Embodied Carbon of European Buildings database - The 625 buildings in the database are used to train and test prediction algorithms and evaluate the methodology.

FEATURE NAME	Range of values
Gross_Floor_Area [m2]	65 - 79000
Use type	Non residential / Residential
Use_Subtype	Hospital and health, Mixed Use, Office, Retail and restaurant , school and daycare, Technology and Science / Single Family, Multi family house, Row house, semi-detached , Hotel and resort
Site Country	Austria, Germany, United Kingdom, Finland, Belgium, Germany, France, Switzerland
Completion Year	2015-2019, 2020-Today
QTO Type	As-built measurement, Conceptual Design, Detailed design
Building area interval	0-5000, 5001-10000, 10001-15000, 15001-20000, 20001-25000, 25001-30000, 30001-35000, 35001-40000, 40001-45000, 45001-50000, 50001-55000, 55001-60000
Users_Total [-]	2-1800
Structure	Frame Concrete, Frame Concrete-Wood, Frame steel, Frame Wood/ Massive brick, Massive Concrete, Massive Wood
Roof	Flat roof / Gable or Saddle Roof / Single Pitched Roof / Other
Energy_Class_Country	1-2-3/A-A+-B/2015-2020
Energy_Class_General	New standard, existing standard, New advanced
Main_Material	Ceramics, Concrete reinforced, Concrete w/o reinforcement, Stone Timber / Metals, Earth, Other
Second_Material	Cement mortar plaster, Ceramics, Concrete reinforced, Concrete w/o reinforcement, Stone, Stone wool, Timber, Steel, Earth, Other, Gypsum
Lifespan	14, 25, 50, 60, 80,100
Life cycle scopes	ABCD, ABC,
Life cycle scope handling D	not in scope, separately considered, substracted,
GHG_sum_em_m2	100 - 1800

4. Method

The goal is to build a predictive algorithm that can accurately estimate a building's GHG emissions based on a set of features matching a training database. The methodology followed is divided into 4 training steps: data processing, feature processing, model processing and blender processing, described in Figure 2. *Data processing* consists in converting input data into a format that can be read by training algorithms. *Feature processing* consists in reducing the size of the training data to be more effective, by extracting impactful feature subsets with selectors. *Model processing* consists in using the data and training regression models to map feature subsets to the target values. In supervised learning, regression models are used to model data with continuous target values. Regression methods are composed of a hypothesis function, that maps input data to a function, and error functions, that evaluate how close the points predicted with this function are to the true points [21]. Many types of regression methods can be built by varying the mathematical formulation of the hypothesis and error. They are always a function of x, the value of input features, and theta, the weights associated to the features or transformations of the features. For each regression, the goal is to find the best weights (θ), that minimize the error and allow to best predict the target footprints with input soft features (x_i) [17] . *Blender processing* consists in using the best trained models and training "meta" regression models to map predictions from these individual models, to a blended prediction with higher robustness and accuracy.

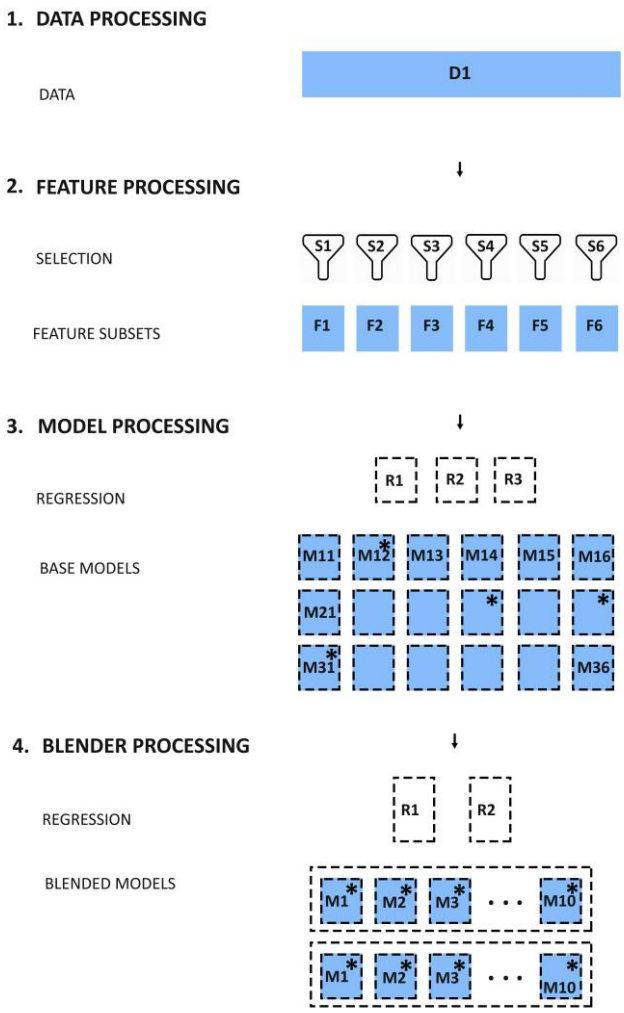

Figure 2 : The methodology followed is divided into 4 training steps: data processing, feature processing, model processing and blender processing.

Different metrics can be used to assess prediction results. This research uses four evaluation metrics : the coefficient of determination R^2 , the mean squared error MSE, the predictive accuracy PA and the residual plot. MSE evaluates the performance based on the squared distance between true and predicted values, it ranges between 0 and $+\infty$. R^2 evaluates the performance based on the variability of the predicted value around the mean. It penalizes models that always predict average values, regardless of input data, and ranges between 1 and $-\infty$. PA is the percentage of accurate predictions that fall within a 15% threshold of the true value, it ranges between 100 and 0 %. The difference between true and predicted values are called residuals. Residual plots should present a random distribution, be normally distributed and centered around zero.

In order to evaluate a model's performance, two conditions must be met : training and testing must be done on two separate data sets, and the training and testing steps must be repeated 10 times in order to retrieve mean and standard deviation of the scoring metrics after 10 runs. Results used in this research are retrieved from nested cross validation, a data partitioning scheme that meets these two conditions. All results described below are averaged over 10 training runs.

5. Results

A base model is composed of a set of features and a regression algorithm. Model processing consists in feeding feature subsets to regression algorithm, calibrating their weights and hyperparameters, and selecting the best predictive models amongst them. This research compares 18 models made from the combinations of 6 feature subsets (pearson filter, spearman filter, gradient boosting regressor, decision

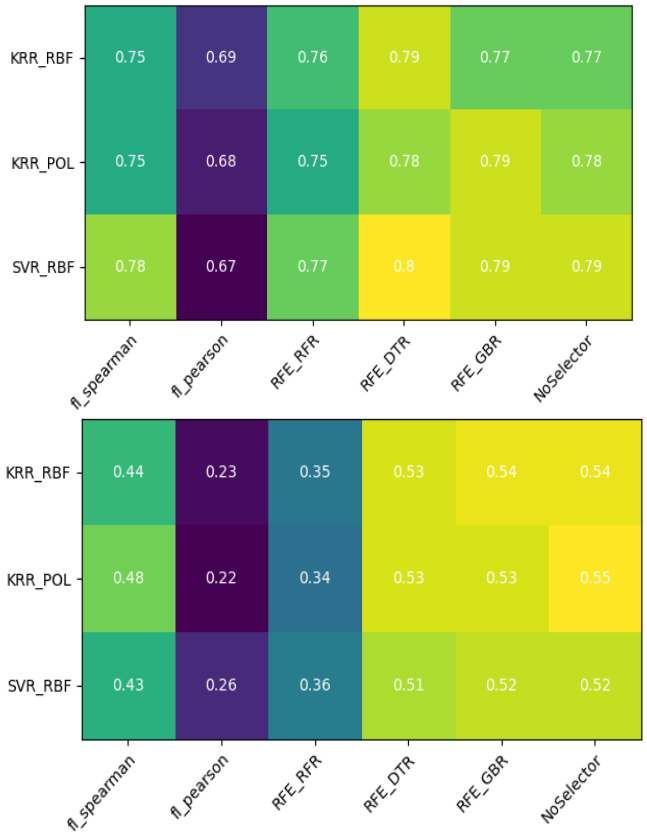

Figure 3: Prediction results for the 18 learning models, made from 3 regression algorithms trained on 6 feature subsets. Prediction accuracies (top) are similar, ranging between 67 and 80 %. R^2 values on testing (bottom) range between 0.22 and 0.55.

tree regressor, random forest regressor, no selector) and 3 regression algorithms (support vector regressions with radial basis function, kernel ridge regression with radial basis function, kernel ridge regression with polynomial kernel). The prediction accuracies and R^2 values for the 18 models are displayed in Figure 3. The 10 models with the highest R^2 values on testing are used as base models for the blender models.

A blender model is composed of a set of trained base models and a regression algorithm. Blender processing consists in feeding base models to regression algorithm and calibrating weights and hyperparameters accordingly. This research compares 2 blender models (linear ridge regression and support vector regression) made from the blending of 10 base models. The evaluation metrics of the 10 best base models and the 2 blender models are compared in Table 2. Evaluation metrics are similar amongst base models, with prediction accuracies PA ranging between 75 and 80 %. Blender models have higher evaluation metrics than base models, with a PA increase of 9 % for SVR RBF and 12 % for LR Ridge. Moreover, they have a higher R^2 score on testing, a lower MSE on testing, lower residual means and residual variance. The residual distributions for the two blender models are displayed in Figure 4. Both graphs present a Gaussian centered distribution with residual values comprised between -200 to +200 $kgCO2e/m^2$.

Table 2: Prediction results for 10 best base models and 2 blender models - an average PA of 78% is reached with base models, 87% with LR Ridge Blender and 91 % with SVR RBF Blender.

		Train R^2	Test R^2	Test MSE	Test PA	Residual Mean	Residual Variance
A	**KRR_RBF_RFE_DTR (Best model)**	0,81	0,53	7254,66	79%	59,01	7124,11

6. Application

With this methodology, trained models can be implemented into GHG emission prediction tools. One can simply input a building's soft features and receive the predicted emissions as output. In Table 3, the GHG emissions of a building are predicted with the trained KRR RBF base model.

Output values can be interpreted using explanation tools, such as SHAP, SHapley Additive exPlanations. SHAP quantifies the magnitude and direction of a feature's effect on a prediction. On Figure 5, the SHAP waterfall plot provides an explanation of the value predicted with the KRR RBF model. On the plot, features are ranked in descending order of importance. Each row shows the positive (red) or negative (blue) contribution of a feature. The sum of these contributions explains the difference between the predicted output ($f(x) = 491.92$ kg CO_2e/m^2), and the expected output ($E[f(x)] = 624.46$ kg CO_2e/m^2) corresponding to the average of the learning dataset. The QTO type, "Conceptual Design" (-81.01 kg CO_2e/m^2), the structure type, "frame wood" (-66.99 kg CO_2e/m^2), and the second material type, "Timber, wood" (-54.06 kg CO_2e/m^2), are the three main features that help reduce GHG emissions of the building, compared to an average project. Although these values are still very preliminary, and explanations must be further investigated, the potential of providing real-time detailed explanations to help reduce GHG emissions, and pointing out impactful features is great.

Table 3: GHG emissions of an example building, predicted with the trained KRR RBF base model, using the listed soft features

FEATURE	INPUT VALUES
Gross_Floor_Area [m2]	200
Use type	Residential
Use_Subtype	Single Family
Site Country	France
Completion Year	2015-2019
QTO Type	Conceptual Design
Building area innterval	0-5000
Users_Total [-]	4
Structure	Frame Wood
Roof	Gable or Saddle Roof
Energy_Class_Country	A

Life cycle scope handling D	not in scope
TARGET	OUTPUT VALUES
GHG_sum_em_m2 [kgCO2e/m²]	491.92

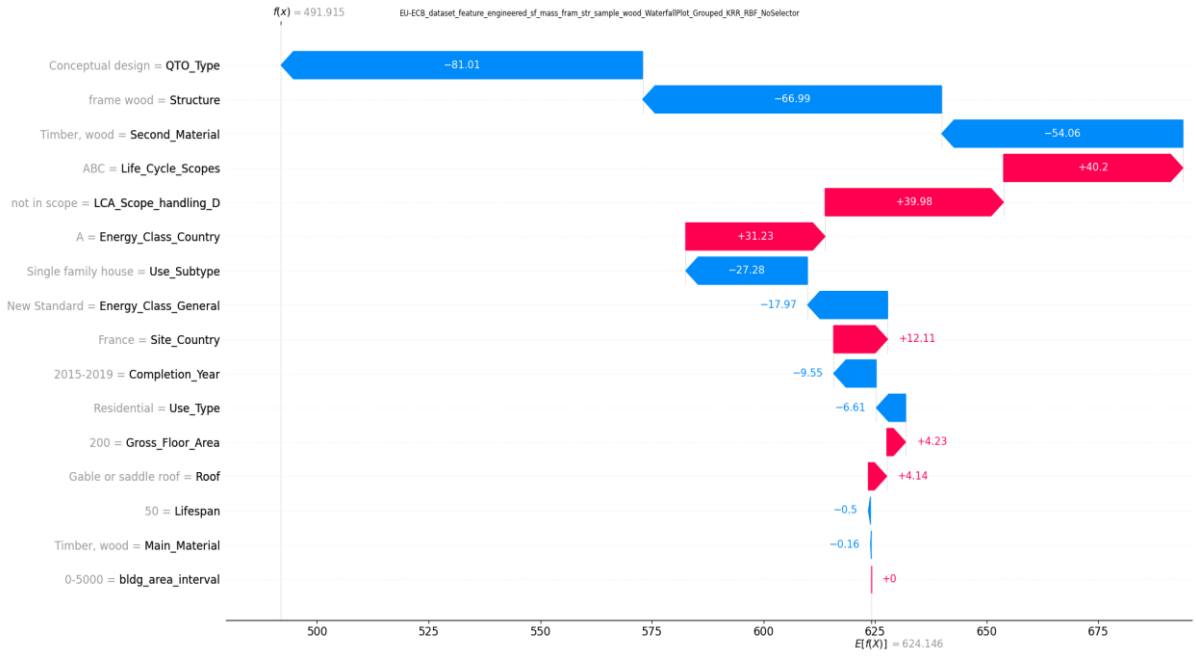

Figure 5 : SHAP explanation quantifies the magnitude and direction of a feature's effect on a prediction. This SHAP waterfall plot explains predictions made with the trained KRR RBF base model for the building studied in Table X.

7. Conclusion

In this research we further developed the "soft feature approach", a methodology for predicting embodied GHG emissions of buildings at early design stages, using building features rather than materials and volumes. With the heterogeneity of data available, and the high variability of GHG emission values, the methodology has been made adaptable to any database, containing a list of buildings features and associated GHG emissions. For the prediction, basic regression models are used in order to facilitate the explainability of results. Despite limited training data available, feature selection, nested cross-validation and model blending help ensure the robustness of the predictions.

18 base models were trained and compared. The 10 best base models were selected and fed into two blender models. The combined data processing, feature processing and model processing steps lead to a GHG emission prediction accuracy of 78 %, and blender processing rose the number to 91 %. All trained models presented a gaussian distribution of residuals centered around 0, indicating they were working and confirming the potential of the presented methodology. This motivated the investigation of the prediction values themselves. Although results are still preliminary, explanation models using SHAP values identified "QTO type", "structure type" and "second material type", as the three main levers to reduce GHG emissions on a given building. Next steps will focus on these explanation methods, aiming to enable the "soft feature approach" to provide real-time predictions as well as tailored recommendations and explanations about GHG emissions of buildings. Finally, and since learning models are only as good as the data they are trained on, a focus will also be set on acquiring more learning data, and motivating companies to archive and share their data in a systematic way.

Abstract

The construction industry takes up a significant part of global carbon emissions and other environmental impacts, and thus accurate calculation and evaluation of the life cycle carbon emissions of structures are important for low carbon-oriented structural design. Current studies often ignore the emission of repair and replacement in the use phase. The omission of in-service impacts increases the uncertainty of the results and might lead to wrong judgments. This paper proposes a probability-based method to calculate the structure carbon emissions generated by the repair and replacement during the life cycle. Based on probabilistic risk assessment, the proposed method is divided into four parts: load hazard analysis, structural response estimation, damage assessment, and loss analysis. An orthogonal pyramid space grid structure is used as a case study to evaluate its life cycle carbon emissions. The effects of different load distribution models on its life cycle carbon emissions are discussed. It is found that carbon emissions from repair and replacement due to loads with high variability should be considered in the design of low carbon-oriented structures. This study provides a useful reference for carbon emission assessment.

Keywords: life cycle assessment, probability, carbon emission, space grid structure

1. Introduction

Global warming caused by greenhouse gas (GHG) emissions has become the focus of attention around the world. Many governments aim to achieve the targets of the Paris Agreement [1] by limiting and reducing carbon emissions. The building sector is responsible for a significant proportion of carbon emissions across the world. For example, the building sector in China consumed the most energy and accounted for 51.3% of the total carbon emissions in 2018 [2]. As the largest contributor to building carbon emissions, the operational phase has received much attention. In recent years, there has been a great growth of energy saving and emission reduction measures in the building operation phase [3, 4]. In this context, the carbon emissions beyond the operational phase of buildings, known as embodied carbon emissions, account for an increasing proportion of the total [5]. As a result, the embodied carbon emissions of buildings are currently key to addressing emissions from the building sector.

The carbon emissions of building structures make up the majority of the embodied carbon emissions [6], and scientifically evaluating the life cycle carbon emissions of building structures is the key to the lower carbon-oriented design of structures. Life cycle assessment (LCA) is an approach that can be used to assess whole life environmental impact of products or processes. It analyzes the inflow of material and energy processes and the outflow of environmental impacts during the entire lifespan. For the carbon emission assessment, there are three conventional methods: the process-based method (P-LCA) [7], the input-output analysis-based method (I-O LCA) [8], and the hybrid LCA method [9].

P-LCA calculates carbon emissions from the top down using process activity data and emission factors based on the numerous production processes in the life cycle of a building. I-O LCA converts the

monetary value to carbon emissions, and based on the value-based economic input-output table, carbon emissions can be calculated by evaluating economic activities. Considering the strengths and weaknesses of the above methods, the hybrid LCA is regarded as a potential alternative. According to the ways of data combination, hybrid LCA can be divided into tiered hybrid (TH), IO-based hybrid (IOH) [10], and integrated hybrid (IH) methods. Case studies on the hybrid LCA of building carbon emissions mainly focused on the TH method, due to its clear concept and low computational effort [11].

By using the above LCA approach, many recent studies have focused on the carbon emissions assessment and lower carbon-oriented design of structures. Kumanayake et al. [12] assessed the embodied carbon of a commercial office building in Sri Lanka, confirming that reinforced concrete and clay bricks are the major carbon-emitting materials. Hart et al. [13] conducted a systematic comparison of the carbon emissions of steel, concrete, and wood structures. Gan et al. [14] investigated the carbon emissions of different structural forms of high-rise buildings. Su et al. [15] analyzed the energy consumption and carbon emissions of three steel structure residential cases.

It should be noted that most of the existing studies focus on the carbon emissions from the production and construction phases. The carbon emissions from repair and replacement are ignored by assuming that the service life is equal to the design life. However, Francart et al. [16] indicated that service life can significantly affect LCA results and maintenance and replacement processes may be important for some materials.

In recent years, studies of structural seismic damage have developed rapidly due to the huge human casualties and economic losses caused by seismic hazards[17]. The Performance-Based Earthquake Engineering (PBEE) methodology, takes into account the relationship between structural seismic damage and loss and various uncertainties [18]. The PBEE provided useful information regarding the importance of probabilistic seismic assessment, and there are studies [19-21] evaluating the economic losses and environmental impacts of seismic hazards. It should be noted that, when the loads are greater than the resistance, the structure or member will be damaged, and the seismic hazards are one of the 'loads' during the design life. Therefore, the probability of damage to a structure can be calculated by the probabilistic risk assessment method proposed by PBEE, and thus the carbon emissions can be assessed.

Based on the probabilistic risk assessment method, this paper proposes a method to calculate the structure carbon emissions generated by the repair and replacement during life cycle. An orthogonal pyramid space grid structure is used as a case study to evaluate its life cycle carbon emissions. The effects of different load distribution models on its life cycle carbon emissions are discussed. Instead of previous studies, the proposed method provides a new perspective and a useful reference for life cycle carbon emission assessment.

2. Methodology

2.1. System boundary

The first step in LCA is to determine the system boundary. The life cycle of a building involves a variety of processes, from the extraction of raw materials to recycling. According to EN 15978 [22], the life cycle of a building is divided into the product stage, construction process stage, use stage, and end-of-life stage. The recovery and reuse of building materials after demolition are not within the life cycle boundary, as shown in Figure 1. The life cycle carbon emissions of a structure are the main component of the life cycle embodied carbon emissions of the building, and the scope of its life cycle includes A1-C4, but not B6-B7. Normally, structure elements are not allowed to be replaced within the design life, therefore many studies ignored the carbon emissions in the B3 and B5 phases.

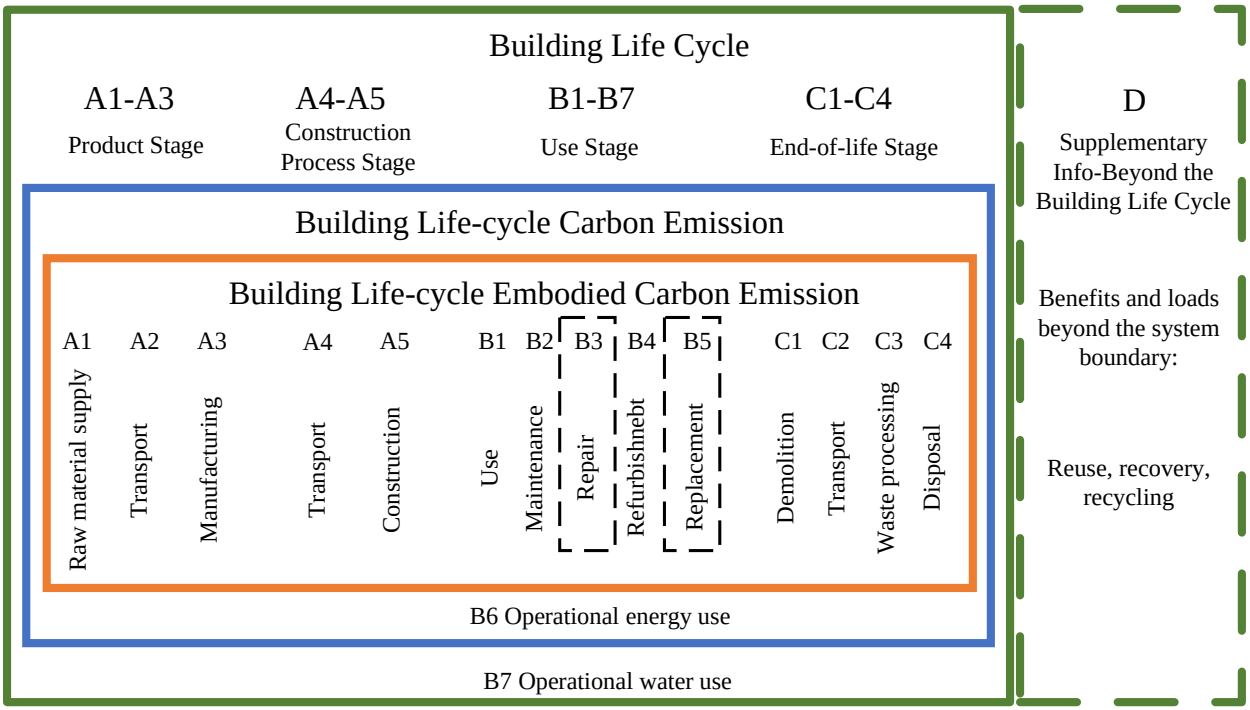

Figure 1. Building life cycle according to EN 15978

2.2. Method for carbon emission assessment

2.2.1. Process-based method

The basic concept of process-based method can be expressed as:

$$E_{pro} = \sum_{i=1}^{n} (EF_i \cdot Q_i) \tag{1}$$

where E_{pro} is the life-cycle carbon emissions, EF_i and Q_i are the carbon emission factor and activity data of production process i, respectively.

Because of the numerous production processes, a comprehensive database for emission factors is necessary for accurately calculating carbon emissions. Besides, the process-based method typically involves truncation of the system boundary, which introduces errors to the calculations.

2.2.2. Input-output analysis

The input-output analysis is commonly used to calculate the carbon emissions of sectors in an economic system. According to carbon emission input-output table [23], the carbon emissions of sector j can be calculated as:

$$E_{IO,j} = C_j \cdot \varsigma_j \tag{2}$$

where C_j and ς_j are the value of products and embodied carbon emission intensity of sector j.

When using input-output analysis to calculate structure carbon emissions, the result is inaccurate due to the use of average data instead of individual.

2.2.3. Tiered hybrid method

By combining the two methods described above, the basic concept of the TH method can be expressed as:

$$E_{TH} = E_{pro}^{m} + E_{IO}^{n} = \sum_{i=1}^{m}(EF_i \cdot Q_i) + \sum_{j=1}^{n}(C_j \cdot \varsigma_j) \tag{3}$$

Note that combining process and input-output data remains a highly manual and time-consuming process, Crawford et al. [24] proposed a path exchange method and established emission factors database of common building materials EPiC [25], thus the E_{TH} can be calculated as:

$$E_{TH} = \sum_{i=1}^{m+n}(EF_i^{EPiC} \cdot Q_i) \tag{4}$$

where EF_i^{EPiC} is the hybrid emission factor for process i in EPiC.

2.3. Probability-based assessment method

When calculating carbon emissions for phases B3 and B5 using above method, the Q_i or ς_i of repair and replacement is uncertain. Therefore, it is necessary to calculate the structure damage under load based on probability. Referring to the PBEE method, the damage calculation can be divided into four steps: load hazard analysis, structural response estimation, damage assessment, and loss analysis.

The purpose of load hazard analysis is to assess the probability of the load occurrence. The probability distribution functions of typical loads are assumed based on statistical analysis, for example, constant loads are assumed to be normally distributed, live loads to be extreme value I distributed, and seismic hazard to be Poisson distributed.

Structural response estimation is to calculate the response of a structure under different load magnitudes by elastoplastic analysis, select the response (displacement, stress, strain, etc.) of the structure or member as engineering demand parameters (EDPs), and determine the relationship between load and EDPs.

The damage assessment aims to calculate the conditional probability that the load demand S_d (generalized load) exceeds the structural resistance S_c (generalized resistance) under a given load. Considering the uncertainty of S_d and S_c, usually both are assumed to follow a logarithmic normal distribution, thus the fragility function of the structure can be expressed as:

$$P\left[\frac{S_d}{S_c} \geq 1\right] = 1 - \Phi\left(\frac{\ln(1) - \lambda}{\zeta}\right) = \Phi\left(\frac{\lambda}{\zeta}\right) \tag{5}$$

Where λ is the mean value of $\ln(S_d/S_c)$, ζ is the standard deviation of $\ln(S_d/S_c)$, $\Phi(\cdot)$ is the normal cumulative distribution function.

Based on the EDPs, structural damage is classified into different damage states (DS). After that, the probability that the structure exceeds the DS_i under a specific load can be expressed as:

$$P[DS > DS_i \,|\, Load] = \int_{EDP} P[DS_i \,|\, EDP] \cdot p[EDP \,|\, Load] \cdot dEDP \tag{6}$$

Where $P[DS_i \,|\, EDP]$ shows the probability of the DS_i on condition of the EDP, and $p\left[EDP \,|\, Load\right]$ denotes the probability density of the EDP for the load.

Based on the fragility analysis, the probability of DS_i under a given load can be obtained from Eq. (7):

$$P\left[DS = DS_i \middle| Load\right] = \begin{cases} 1 - P\left[DS > DS_1 \middle| Load\right], i = 0 \\ P\left[DS > DS_i \middle| Load\right] - P\left[DS > DS_{i+1} \middle| Load\right], 1 \le i \le n-1 \\ P\left[DS > DS_i \middle| Load\right], i = n \end{cases} \tag{7}$$

Loss analysis is to specify repair strategies for different damage states and calculate the carbon emissions of the m th repair strategy $E(DV_m|DS)$ using Eq. (1) to Eq. (4).

As a result, the carbon emissions from the B3 and B5 phases of the structure can be expressed as:

$$E_R = \sum_m \int_{Load} E(DV_m|DS) P(DS = DS_i|Load) \cdot dp(Load) \tag{8}$$

The life cycle carbon emission of the structure can be calculated by Eq. (9):

$$E_T = E_P + E_C + E_R + E_M + E_E \tag{9}$$

Where E_T is the life cycle carbon emission, E_P is the carbon emission from production stage, E_C is the carbon emission from construction process stage, E_M is the carbon emission from maintenance process, E_E is the carbon emission from end-of-life stage. However, this paper mainly focuses on the calculation of E_R, the E_C, E_M, and E_E are ignoring. Therefore the E_T can be expressed as:

$$E_T = E_P + E_R \tag{10}$$

3. Case study

3.1. Structure design

Consider an orthogonal pyramid space grid (OPSG) structure with a square plan of 30 m × 30 m, as shown in Figure 2. The size and height of the grid are 5 m and 3 m, and the supports are arranged at intervals around the top chord elements. The structure is made of Q235 steel and the design load is a uniform load of 1.3 kN/m^2, which is assumed to be loaded on the top chord joints. According to China Technical Specification for Space Frame Structures (JGJ7-2010) [26] and the Standard for Design of Steel Structures (GB50017-2017) [27], the elements are made of round steel pipe, and the cross-sections are designed according to the full stress principle. Figure 3 shows the design results of the OPSG, noting that the line widths represent the size of the element cross sections.

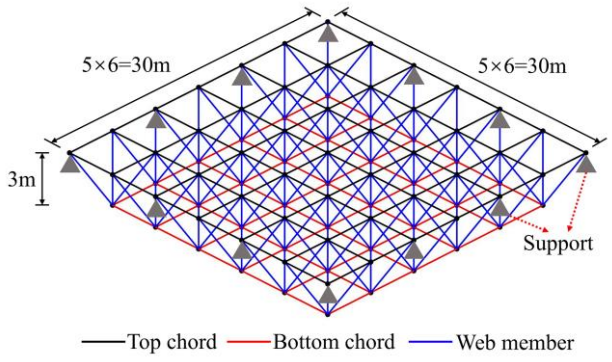

Figure 2. Schematic diagram of OPSG structure

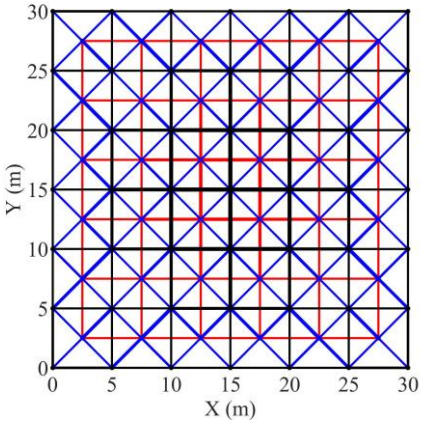

Figure 3. Section design result of the OPSG

3.2. Fragility analysis

Consider the load as a uniform load and perform elastic-plastic analysis on the structure. When the yield strength is 235 MPa and the elastic modulus is 206 Gpa, the curve of the maximum joint displacement versus load is shown in Figure 4. The ratio of tangential stiffness to initial stiffness (K_t/K_0) is taken to be EDP [28], and the variation of EDP with load is shown in Figure 5. The damage state of the OPSG structure can be divided into four stages [29], and the EDP corresponding to each damage stage is defined as shown in Table 1.

According to the uncertainty of yield strength and modulus of elasticity of the structural material (Table 2), multiple elastoplastic analyses were performed by Monte Carlo sampling. After that, the λ and ζ of Eq.(4) for each damage state were obtained statistically, as shown in Table 3.

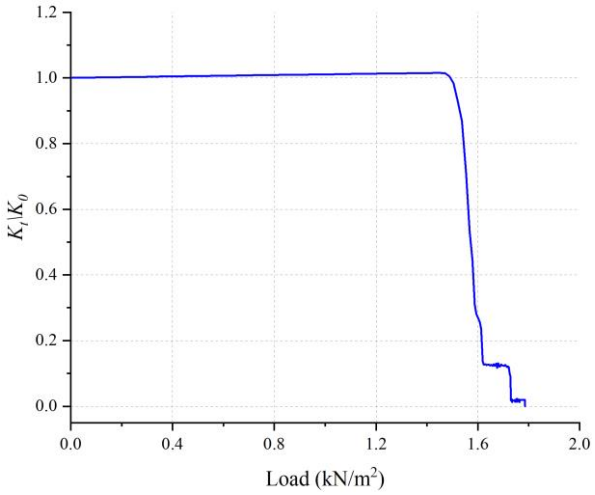

Figure 5. EDP (K_t/K_0)-load curve

Table 1. Damage state classification of OPSG structure

Damage state	Discriminatory boundaries	EPD (K_t/K_0)
DS0 Undamage	Before structure enters plasticity	≥ 1
DS1 Slight damage	Structure enter plasticity and before the stiffness decreases significantly	≤ 0.5
DS2 Moderate damage	Stiffness significantly reduced and before stabilization	≤ 0.25
DS3 Extensive damage	After structural stiffness stabilization and before structural failure	≤ 0.1
DS4 Complete damage	After structural failure	> 0.1

Table 2. Probabilistic models of structural parameters

Structure parameters	Distribution Model	Standard value	μ	CV
Yield strength f_y /Mpa	Normal	235	270	0.08
Elastic modulus E /10^5Mpa	Normal	2.06	2.06	0.03

Table 3. Statistical parameters of $\ln(S_d/S_c)$ in fragility analysis

Statistical parameters	DS1	DS2	DS3	DS4
λ	0.503	0.557	0.579	0.640
ζ	0.0928	0.0929	0.0916	0.0936

Based on Eq. (4) to Eq. (6), the fragility curves and damage probability curves of the OPSG structure are shown in Figure 5 and Figure 6.

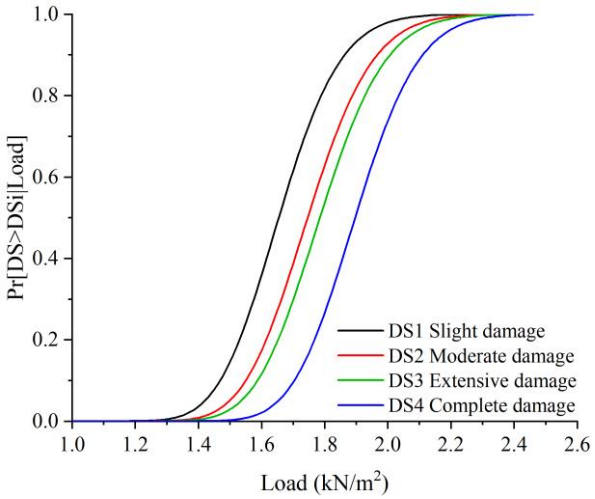

Figure 5. Fragility curves of the OPSG

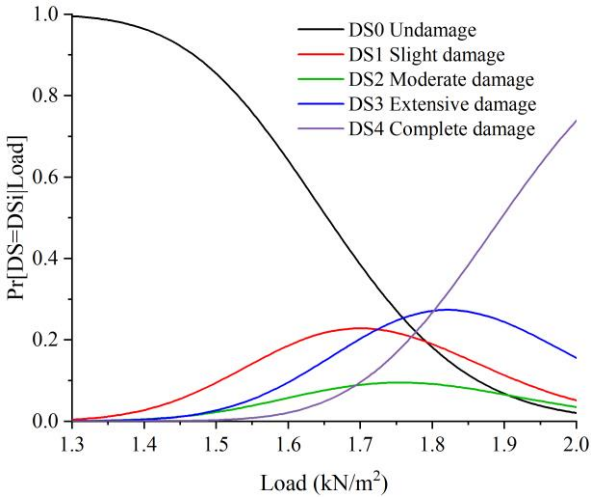

Figure 6. Damage probability curves of the OPSG

3.3. Carbon emission assessment

According to the design result, the self-weight of the OPSG structure is 6081.04 kg, and the EF^{EPiC} of the steel pipe is 3.5kg/kgCO_2e. Using Eq. (4), the carbon emissions of product stage E_P are 21283.6 kgCO_2e. Note the E_P calculated above do not include the emissions of joints, as these are not the focus of this paper. Since the same EF^{EPiC} is used for different sizes of steel pipes in EPiC, the carbon emissions of the structure are linearly related to the steel consumption, thus the carbon emission variation in the processing of different sizes of steel pipes is ignored.

Based on the damage probability curves, repair and replacement strategies for different damage states need to be determined and then the E_R can be calculated. However, there are no comprehensive repair and replacement strategies for space grid structures. In this paper, the carbon emissions from repairing and replacing slight damage are assumed to be 30% of E_P, 60% for moderate damage, 80% for extensive damage, and 100% for complete damage.

When the load follows normal distribution $N(1,0.2)$, the E_R of the structure are 36.23 kgCO_2e and the E_R of each damage stage are shown in Table 4. It should be emphasized that fragility is an inherent property of the structure once the design is completed. Hence the distribution of loads has a greater effect on E_R.

Assuming the uniform load is normal and extreme value I distribution, the mean value is 1.0 to 1.3, and the coefficient of variation is 0.05 to 0.3. The carbon emissions under different load distributions are calculated. Figure 7 shows the ratio of E_R to E_P with different load distributions. As can be seen, the carbon emissions from repair and replacement increase rapidly as the coefficient of variation increases. While E_R also increase with the mean value of the load, existing design methods (e.g. the partial factor

method) have ensured that the probability of failure of the structure is within acceptable limits and the corresponding E_R are small. However, the E_R caused by loads with large coefficients of variation are not ignorable. Although the probability of failure of the structure has been verified, the E_R are large once the damage occurs under such loads.

Table 4. Carbon emissions of repair and replacement for each damage state

Damage state	DS1	DS2	DS3	DS4
E_R (kg/CO_2e)	15.14	6.72	11.46	2.91

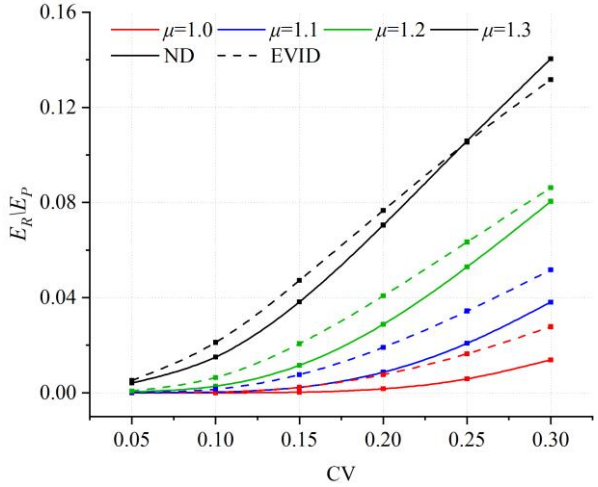

Figure 7. E_R/E_P for different load distributions

4. Conclusion

This paper proposes a probability-based method to calculate the structure carbon emissions generated by the repair and replacement during life cycle, which are always neglected in previous studies. Based on probabilistic risk assessment, the proposed method is divided into four parts: load hazard analysis, structural response estimation, damage assessment, and loss analysis. An orthogonal pyramid space grid structure is designed as a case study to evaluate its life cycle carbon emissions. By assuming that the loads are normally and log-normally distributed with varying coefficients of variation, the effects of different load distribution models on its life cycle carbon emissions are discussed. The results show that the carbon emissions from structural repair and replacement is proportional to the coefficient of variation of the load distribution. The carbon emissions from repair and replacement due to loads with high variability should be considered in the design of low-carbon structures. Overall, this study provides insight into the carbon emission assessment of structures and provides a systematic repair and replacement carbon emission calculation method.

Abstract

Canberra centre is an existing commercial development in Canberra, comprising retail spaces, restaurants and cinema. The development is divided into several buildings, each of the buildings being separated by street crossings accessible by cars. In order to bring back a sense of unity in the shopping centre, make the restaurants attractive again and improve the customers experience, it was decided to close to traffic one of the streets separating the buildings. The newly pedestrian Scott's crossing street has been covered by two new steel and ETFE canopies, providing an elegant space protected from the rain for the pedestrians. Although complex, the geometry of the canopies was generated to fully take into account buildability – all the steel members were translated in a language of single radii, comprehensible for the steel fabricator. As the shopping centre would remain in use during the steelworks installation, bolted connections have been designed to simplify installation without impacting the sizes of the members, which were designed to be as small as possible. The resulting structure is an elegant lightweight structure providing protection from the rain, reviving an underused part of the shopping centre and bringing pride to the adjacent shop owners.

has been covered by two new steel and ETFE canopies, providing an elegant space protected from the rain for the pedestrians.

The Scott's crossing canopies are steel canopies supporting ETFE cushions and surrounded by buildings on 3 sides each. The canopies are supported by 4 tree columns each. The structure is composed of 9 curved main arches spaced at about 2.8m and spanning diagonally between the edge beam and straight transversal beams spanning between the arches and providing restraints to the arches. The east canopy is about 19mx19m in plan and 12m high, the west canopy is about 24mx15m in plan and 15m high. Plan view and section of each canopy is shown in Figures 2 and 3.

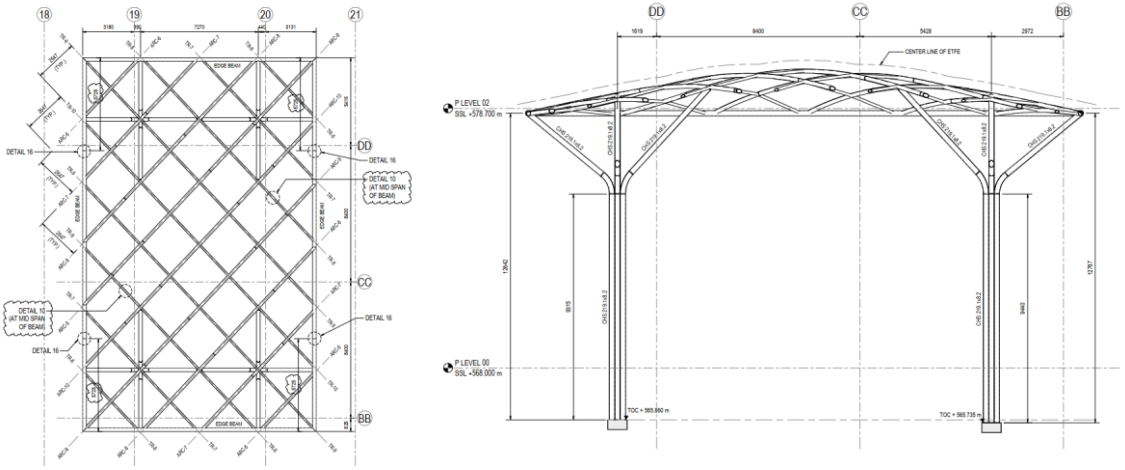

Figure 2. West Canopy plan view and section [Passage Projects]

The fabrication and installation of the steel occurred between July 2022 to October 2022 while the installation of the ETFE occurred between October 2022 to December 2022.

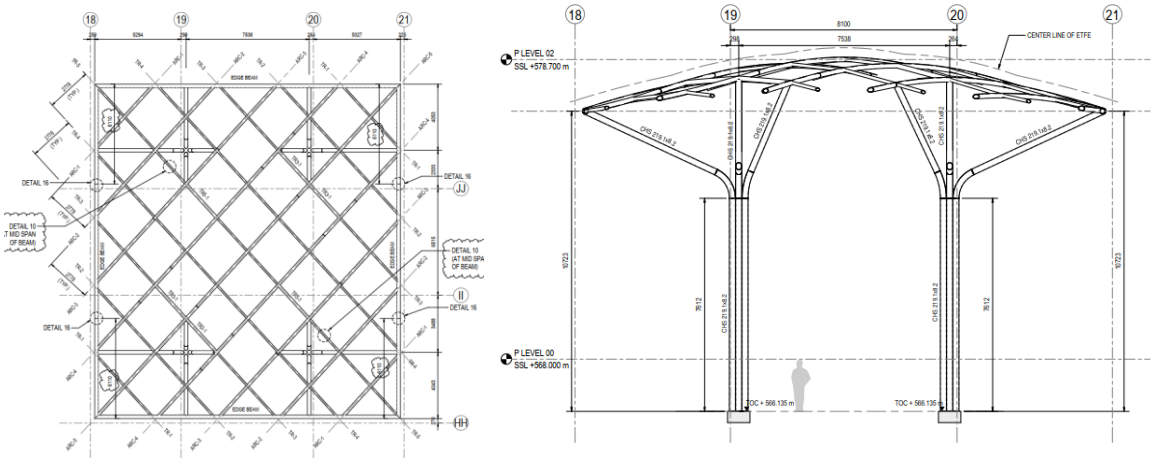

Figure 3. East Canopy plan view and section [Passage Projects]

2. Basis of design

The steel structure has been designed following Australian code AS1170-0 [1], AS1170-1 [2], AS1170-2 [3] and AS4100:2020 [4]. The next sections present the loadings applied to the structure.

2.1. General Loadings

2.1.1. Dead Loads and Live Loads

The roof should be able to withstand the self-weight of the steel, the weight of the ETFE and aluminium, about 10 kg/m2 and the weight of services running on the structure, estimated to 25 kg/m^2. The Live Loads correspond to maintenance loadings. The Live Loads applied are 25kg/m^2 on the whole roof surface.

2.1.2. Wind Loads

A wind tunnel test has been carried out for the roof. The pressures obtained for the roof steel structure design vary between 0.75 kPa to -0.73 kPa.

2.1.3. Temperature Loads

The variations of temperature of the steel structure are mainly caused by the heat from the sun during the day and the colder temperatures of the night. The construction temperature is assumed to be 20ºC, so the temperature differentials considered for the design are +42ºC/-30ºC.

2.1.3. Seismic Loads

Following Australian code AS1170-4 [5], the canopies structures fall in Earthquake category 2. A simplified design approach of equivalent lateral force can be used. The lateral force to be applied on the structure is equivalent to 0.14Wi where Wi is the seismic weight of the structure, including the dead loads of the structure. The seismic loads were not governing the design.

2.1.4. Load combinations

The load combinations considered for the design are shown in Table 1:

Table 1: ULS Load Combinations

LC1	1.2(SW+DL)+1.5LL+0.9T
LC2	1.2(SW+DL)+1.5WL+0.9T
LC3	0.9(SW+DL)+1.5WL+0.9T
LC4	1.0(SW+DL)+1.0E

3. Geometry Rationalization and setting out

3.1. Structure setting out

To avoid the need to use costly nodes for the ETFE aluminium extrusions and costly ETFE cushions, the ETFE cushions are not diamond shaped cushions but are long strips spanning between arches, as shown in Figure 4. The setting out between the main arches supporting the cushions and the transversal beams providing restraints to the arches was carefully studied in order to avoid any clash between the transversal beams and the cushion belly.

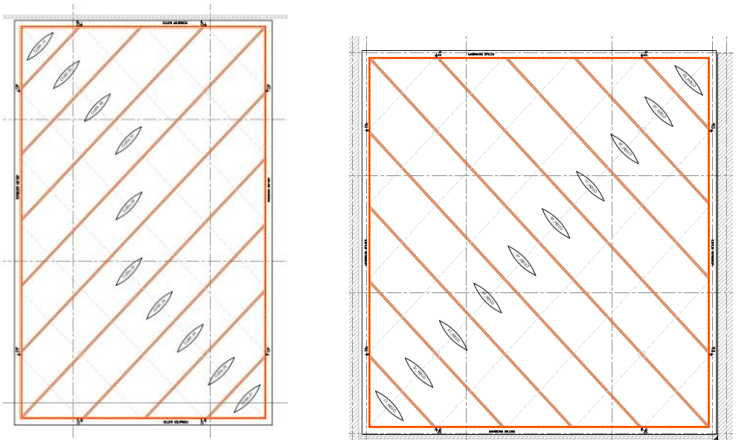

Figure 4. Canopies ETFE cushions layout [Vector Foiltec]

Several options have been considered in the design, as shown in Figure 5. The first option consists in keeping the arches and the transversal beams at the same level and using high Tee brackets to elevate the ETFE cushions from the structure to avoid any clash. The second option consists in offsetting the transversal beams down compared to the arches, giving 3 layers in the structure, a first layer for the ETFE, a second layer for the arches and a third layer for the transversal beams. The third option consists in offsetting the transversal beams up and supporting the ETFE cushions from the transversal beams.

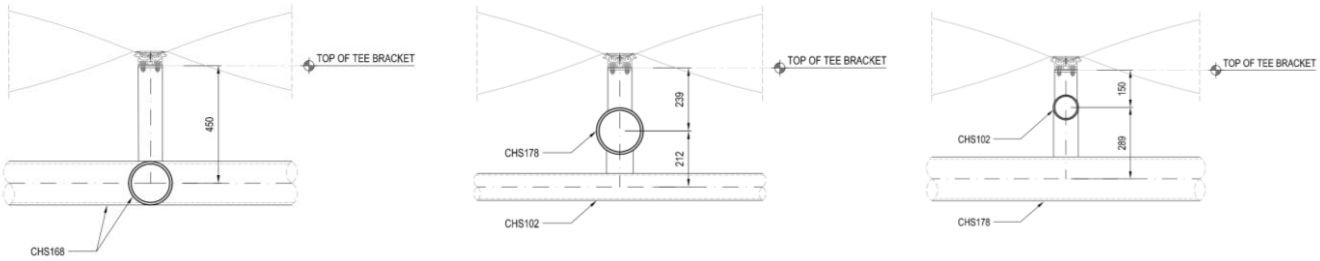

Figure 5. Beams setting out options considered in the design [Passage Projects]

The option adopted in the design was option 1, as it enabled to run services above the arches through the Tee brackets, effectively hiding the services from the public view. Tee brackets height and shape have been optimised to achieve an elegant look of the canopy, as shown in Figure 6.

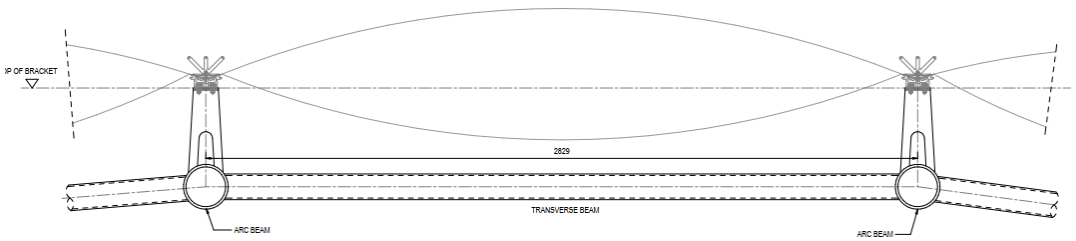

Figure 6. Section through arches and ETFE cushions [Passage Projects]

3.2. Geometry rationalisation

The initial geometry generated by the architects consisted in freeform curved arches and transversal beams. Without further rationalisation, the structure would have been difficult to fabricate.

The arches geometry has been translated in a language of single radii, ie arcs, comprehensible for the steel fabricator. The canopies are mirrored diagonally so there are only 5 different arches on each canopy. Each arch is decomposed into a maximum of 1 radii each of minimum 5m long, except for one arch which has been decomposed into 4 radii, which simplified the fabrication.

As seen in Figure 7, the deviation from the architect original design is maximum 100mm, which was acceptable from an aesthetic point of view.

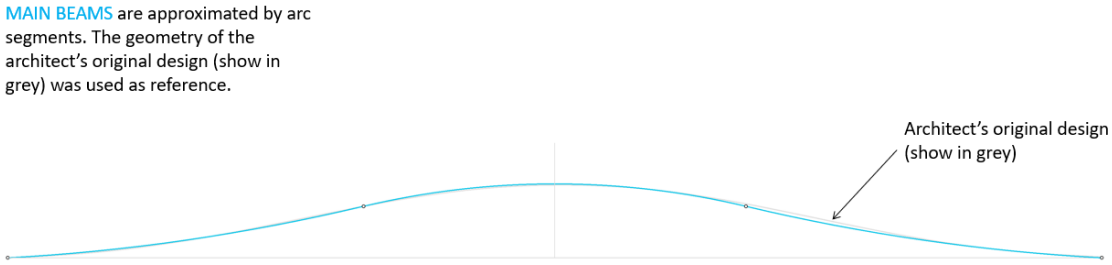

Figure 7. Approximation of arches into arcs with slight deviation from the architect's geometry [Passage Projects]

The transversal beams were proposed to be straight between arches to simplify the fabrication. Straightening the transversal beams also enabled to reduce the tee bracket height.

4. Structural analysis

4.1. Stability and supporting conditions

The Scott's crossing canopies are supported by 4 tree columns each. The tree columns are fixed to the concrete. Surrounded by existing buildings, the canopies could not rely on horizontal restraints to the existing façade. As a result, lateral and torsional sway buckling had to be accounted for in the structural design in addition to the arches buckling.

The stability of the roof is checked in two steps: the global stability of the structure and the local stability of the members.

The global stability of the structure is checked following AS4100 Annex E [4]. A Linear buckling analysis, also called Eigenvalue analysis is carried out.

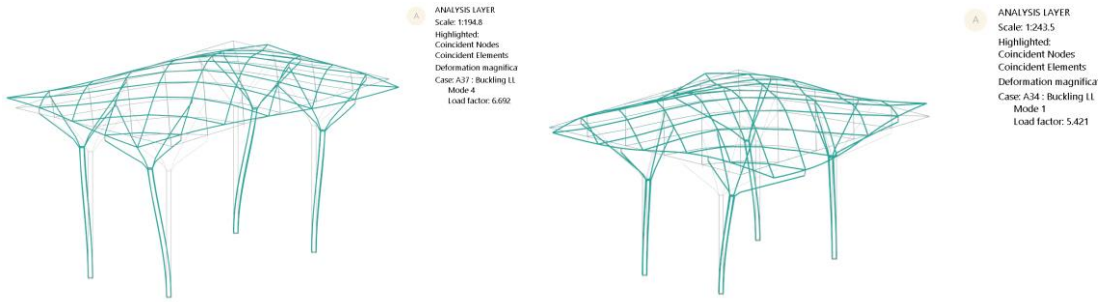

Figure 8: Structure first buckling mode – Critical Load Factor = 5.4 [Passage Projects]

The first buckling mode can be seen in Figure 8. The structures are highly sensitive to lateral and torsional sway buckling, with the first buckling modes having a critical load factor of around 5.4.

As per AS4100 [4], a structure of buckling factor smaller than 10 will be highly sensitive to second-order effects. As a result, if any global buckling mode is found with a buckling factor lower than 10, a Geometrically non-linear elastic analysis with imperfections included is performed. Global imperfections are included in the model using the deformed shape of the global buckling modes with a buckling factor lower than 10 one at a time. A non-linear buckling analysis was also performed to confirm the buckling modes from the Eigenvalue analysis.

The local imperfections and local stability of the members are taken into account in the checks for buckling resistance of members following AS4100 [4] – as an addition to the imperfections taken into account in the GNIA, for conservative design.

4.2. Bolted connections

As the shopping centre would remain in use during the steelworks installation, no welding was allowed on site. Bolted connections have been carefully placed to facilitate transport and installation without impacting the sizes of the members.

The connections of the arches to the edge beams consist in a stump welded to the edge beam and connected to the arch through and end plate connection, as seen in Figure 9.

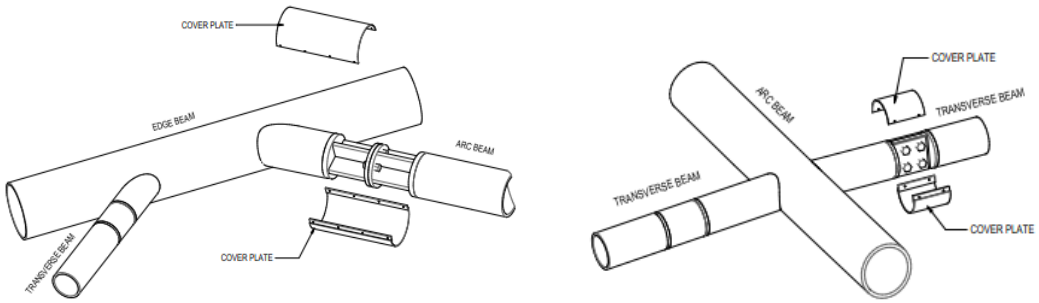

Figure 9: Bolted connections [Passage Projects]

Figure 10: Canopy view during construction with various bolted connections [Passage Projects]

The connections of the transversal beams to the arches consist in a stump welded to the arch and connected to the transversal beam through a 4-bolts fin plate connection, as shown in Figure 9. The connection can transfer moment in the major axis direction of the transverse beam to provide stiffness to the canopy. The connection is considered as a pin or semi-rigid connection with low stiffness in the minor axis direction of the transversal beam. This release condition has been considered in the analysis model to ensure that the adequate stiffness of the arch-transversal beam system has been taken into account in the buckling analysis. Figure 10 shows the various bolted connections in the structure during installation.

All bolted connections have been covered by cover plates once installation has been completed, almost invisibles to the visitors.

4.3. Final design summary

The main arches support the ETFE cushions. They are circular hollow sections of diameter 168mm. The arches transfer the forces to the edge beams through compression and bending. The edge beams are circular hollow sections of diameter 219mm. The transversal beams beams provide a restraint against out-of-plane and lateral-torsional buckling to the arches. They are circular hollow sections of diameter 114mm. The columns transfer all forces to the ground, they are formed of 4 branches of circular hollow sections of diameter 219mm joining into a 4-column trunk to the baseplate.

Figure 11. Overall view of the two Scott's crossing canopies during construction [Passage Projects]

5. Conclusion

As a conclusion, the resulting structure is an elegant lightweight structure providing protection from the rain, reviving an underused part of the shopping centre and bringing pride to the adjacent shop owners. Careful consideration in the design enabled to avoid connecting to the adjacent buildings with complex existing facades. Bolted connections enabled to allow construction without welding on site accommodating the intricate site conditions of a building under use.

Abstract

The new expansion of Hamad Airport in Doha includes a very big atrium covered by a glazed grid shell of 14052 m² surface. The intention was to create a very big organic space with the perception of being in an openair garden. The scope of Lanik in this project included geometrical design, calculation, fabrication, and installation of the metallic grid shell structure. One of the main challenges during the design process was to define the boundary connections to the buildings providing enough bracing to avoid too low natural frequencies, but at the same time, allowing enough relative displacement and elasticity between the structure and the buildings to avoid excessive efforts due to thermal and deformational effects. The design and fabrication were integrated by means of Lanik's GOOSE software. This paper explains the design, engineering, parametric fabrication, and assembly of the structure. In January, 2023, the airport is operative and the atrium ready for being used by the travelers.

Keywords: realization, airport, funnel, grid shell, parametric fabrication, parametric design

1. Introduction

This paper describes the envelope from a structural point of view, since this is the scope of Lanik in the project. Lanik was awarded for the redesign, reengineering, fabrication and assembly supervision of the structure. The client of Lanik in this project was Glassline, who contracted the whole envelope package and installed the glass.

This project has been challenging for Lanik, first because of its size, 14.000 m² of free form surface to be covered by glass. The original triangular mesh was optimizable in terms of size and mainly angulations between members. The dynamic analysis was critical to define the right way to connect the upper side of the structure to the surrounding buildings, and finally, GOOSE software was use for the first time for the CSL single layer System meaning a huge advantage in terms of fabrication engineering performance and efficiency, integrating design and fabrication in the same software. These aspects of the project are developed along the paper.

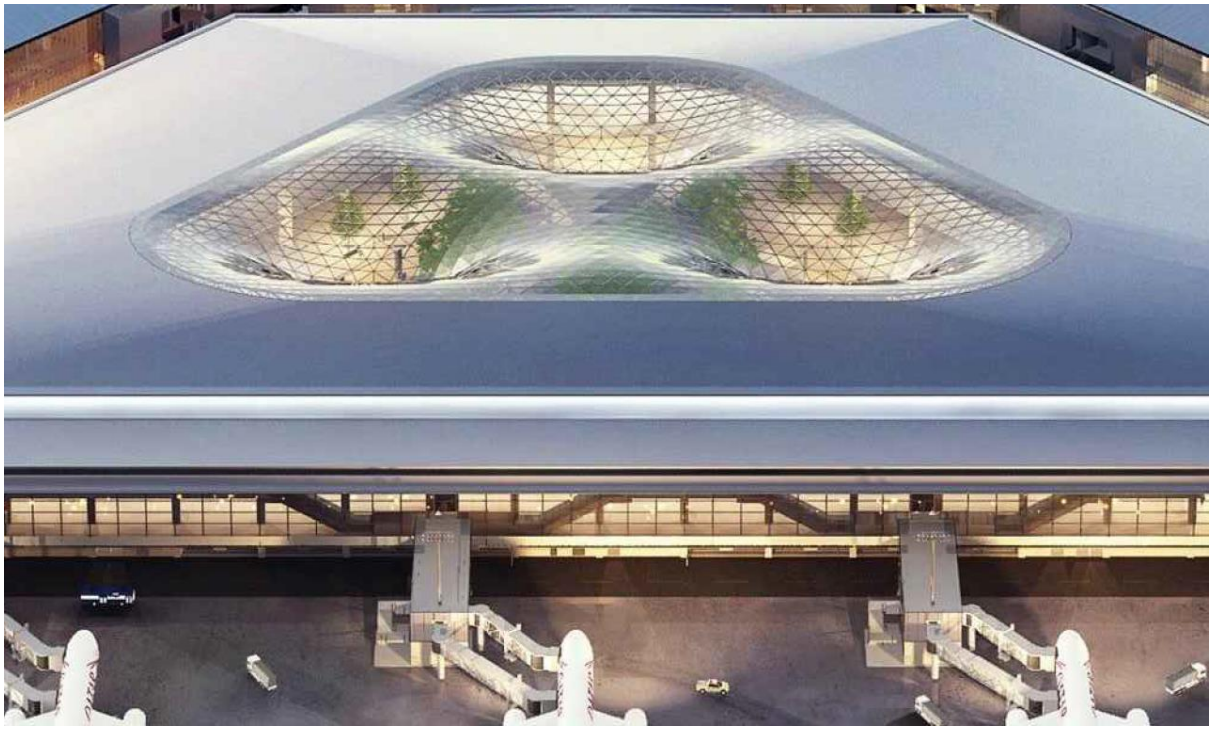

Figure 1: Render of the general aspect of the project

2. Project description

2.1. Geometry

The global dimensions of the structure are 175m long, 94m width and 29m high. The main characteristic is the structural configuration based on a double curvature surface with three funnels with structural purposes that introduce stiffness out of the plane because of the double curvature, drain the water, and work as supporting columns in collaboration with the perimetral supports.

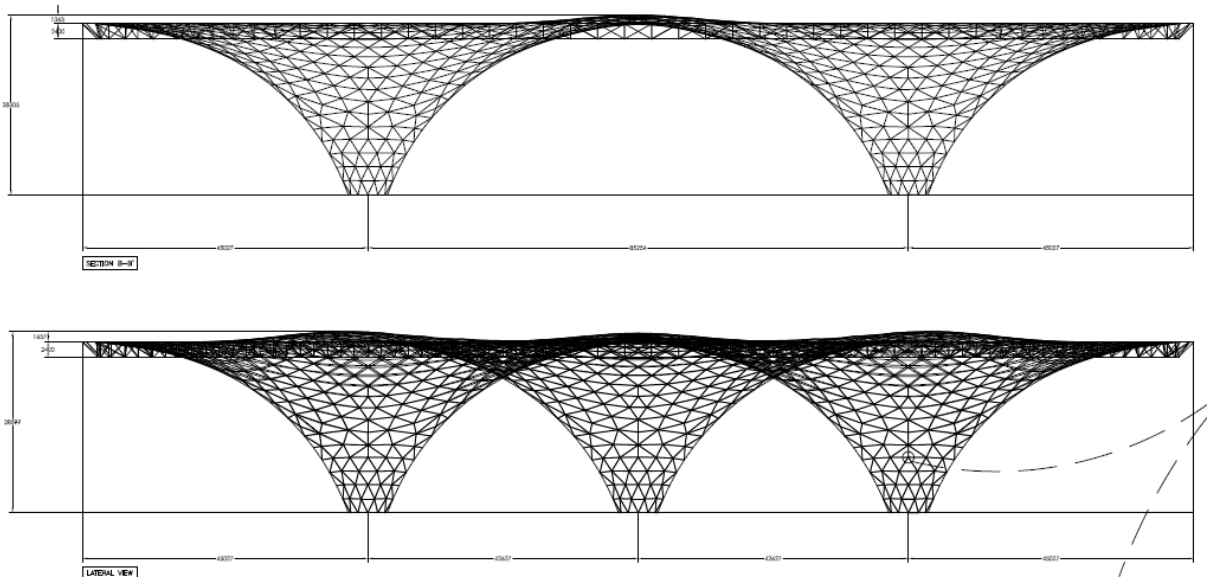

Figure 2: Front and lateral views

2.2. Mesh optimization

The generatrix surface was an input coming from the architectural design. In a previous phase, before Lanik being involved in the project, there was a triangular grid design for the envelope. The polygonal discretization of the funnels was based on local partitions producing the geometry shown in Figure 3.

(a) (b)

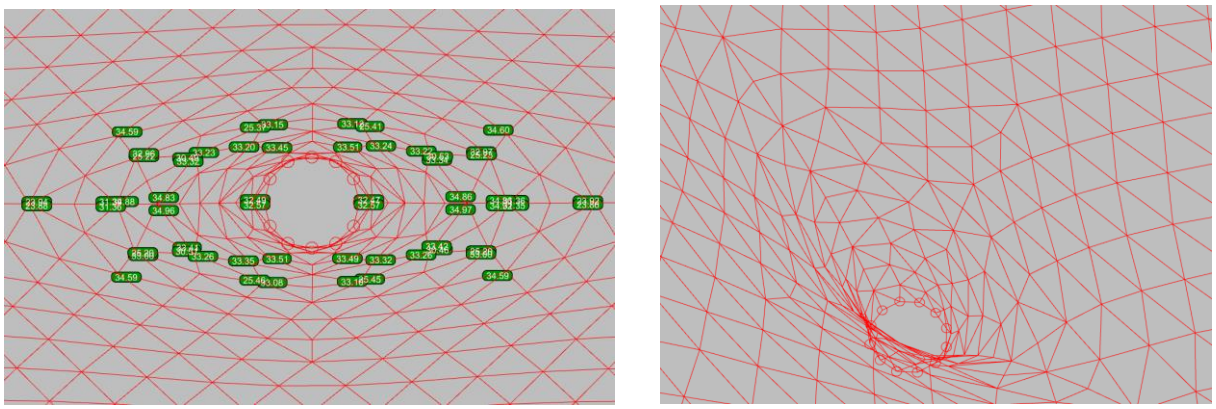

Figure 3: original mesh of funnel with many singularities and bad angles: (a) Angles under 35º, (b) Perspective

This triangular mesh had many discontinuities and very bad angles creating interferences and need for big nodes. After many redesign phases using Rhino and grasshopper tools, the mesh was smoothed, rationalized and as a result, size of elements, angulations and aesthetic was significantly improved.

(a) (b)

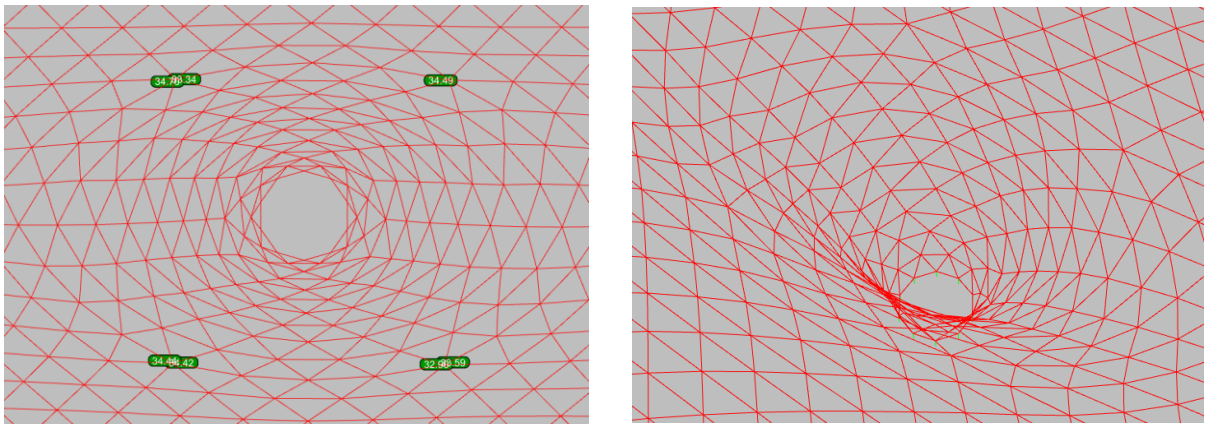

Figure 4: optimized mesh with smoother angles and les singularities: (a) Angles under 35º, (b) Perspective

In figure 4 it can be checked that the amount of angles under 35º (used as reference for reasonable limit to avboid too big nodes) decreases very significantly with the new mesh. This change was approved by the architect and the property, and became the basis for the design and calculation of the structure.

2.3. Constructive system

The single layer structure is composed by RHS (Rectangular Hollow Section) profiles connected to each other by CSL structural system. This system is based on some truncated hollow nodes to which the bar are fixed by means of bolts

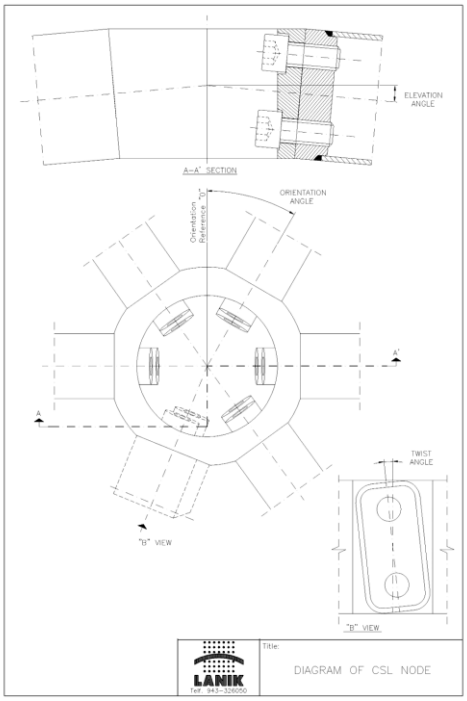

Figure 5: CSL system sketch

Figure 6: CSL System general aspect

All angulations can be solved by the system and the connection allows for bending moment transmission in the main axis.

3. Boundary conditions and dynamic analysis

The first calculations of the structure before Lanik was involved in the project were based on the assumption that the boundary upper perimeter was supported only vertically by means of sliding supports. This way, all the horizontal loads where transmited to the basement trough the funnels and no horizontal reaction needed to be transmited to the upper side of the surroundin buldings.

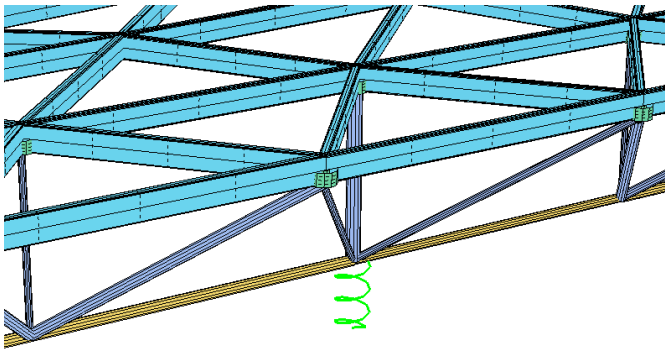

Figure 7: Top horizontally sliding supports

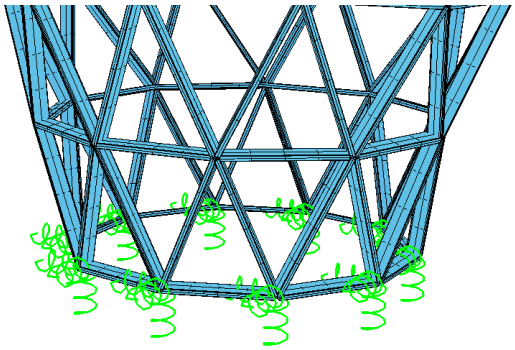

Figure 8: bottom fixed pin supports

This support configuration promotes a big horizontal elasticity of the whole system since the embedding connection of the funnels and the funnels themselves are responsible to retain horizontally the upper part of the structure.

This lack of horizontal stiffness combined with an enormous amount of mass in the upper side (structure + glass) lead on very low frequency of the first vibration modes. In fact, the first vibration modes for this configuration are translational activating mass in X and Y directions as can be shown in table 1.

Table 1. Natural vibration frequencies and activate masses without horizontal retention in upper supports

Modal masses - activated mass

No.	LC	frequency [Hertz]	effective modal Mass X[t]	Y[t]	Z[t]	factor X[%]	Y[%]	Z[%]	activated mass [%]*

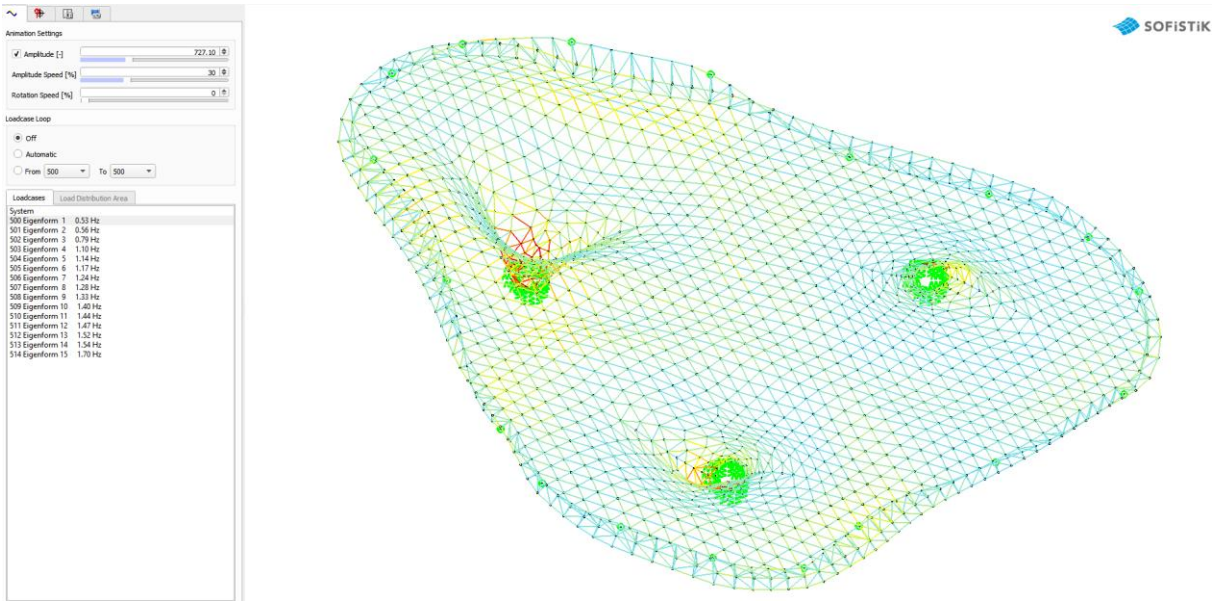

Figure 9: Deformation of the structure with the first natural vibration mode of 0.53 Hz (translational)

This very low frequencies supposed a big risk of resonance response under alternate wind loads and because of this reason the supporting configuration needed to be changed. In the other hand, the surrounding buildings where already designed and executed without taking into consideration reactions of the grid shell.

It took more than 65 attempts of supporting configurations with different combinations of sliding, retained in only one or two directions, elastic, and friction simulations etc. to achieve to a final configuration of top support which allowed to enough stiffness to avoid low frequency vibration modes, but at the same time did not transmit too big and undesirable reactions to the surrounding buildings.

4. Integration of design and fabrication

This project has been developed using LANIK's automatic tool for grid shell design, calculation and fabrication engineering. This tool is called GOOSE and is a complete self-made software environment which allows for geometrical design with Rhino-grasshopper, calculation pre-processing inside Rhino, direct use of Sofistik non-linear engine from goose Rhino plugin (automatic resizing), automatic 3D solid and parametrical fabrication engineering inside Rhino, and assembly phases definition in Rhino for its simulation in Sofistik. Databases are directly edited via goose web application.

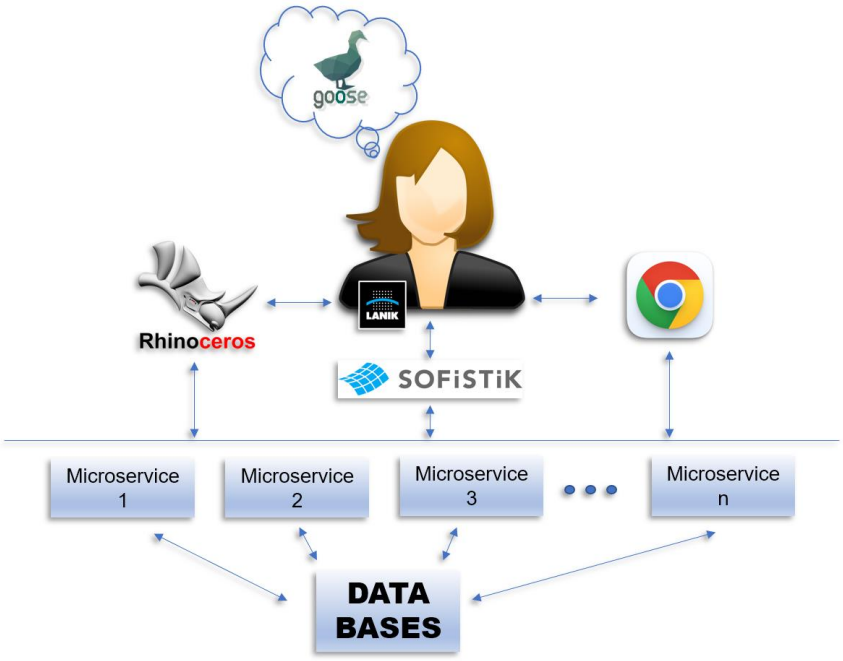

Figure 11: GOOSE environment graphic description

As some examples of the tools that includes GOOSE, the next image shows Calculation model preprocessing inside Rhino by means of GOOSE:

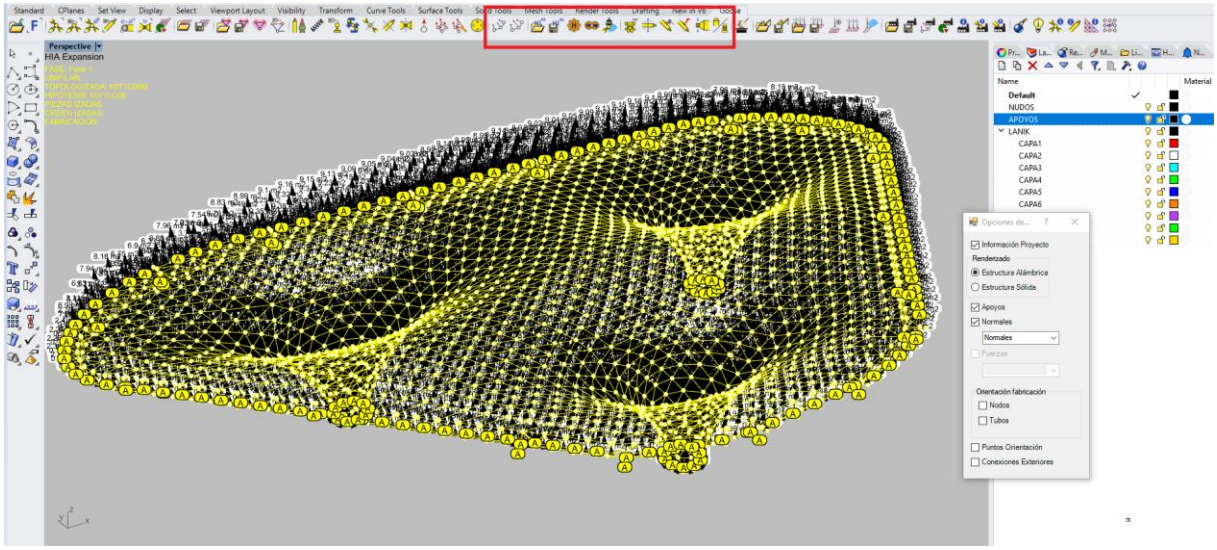

Figure 12: GOOSE Rhino plugin calculation model pre-processing

The calculation model can be launched automatically in Sofistik and GOOSE is able to interact directly with the database of Sofistik and extract from the calculation model all information needed for structural sizing of beams and connection bolts.

Regarding fabrication engineering, the next images show fabrication parametric design where nodes are automatically generated to solve interferences using standard node sizes:

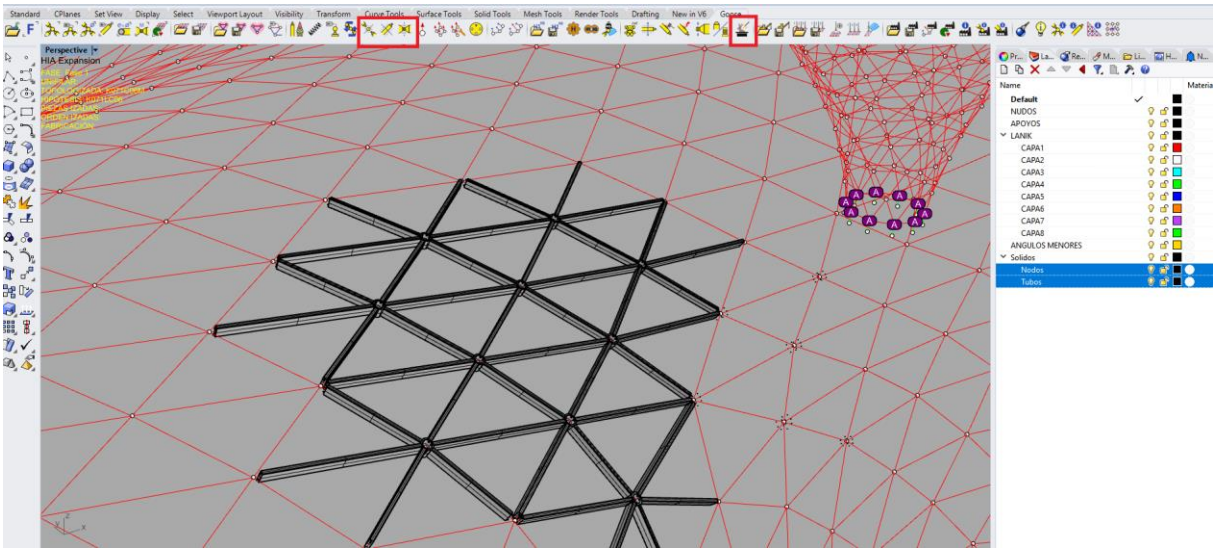

Figure 13: GOOSE Rhino plugin node automatic generation

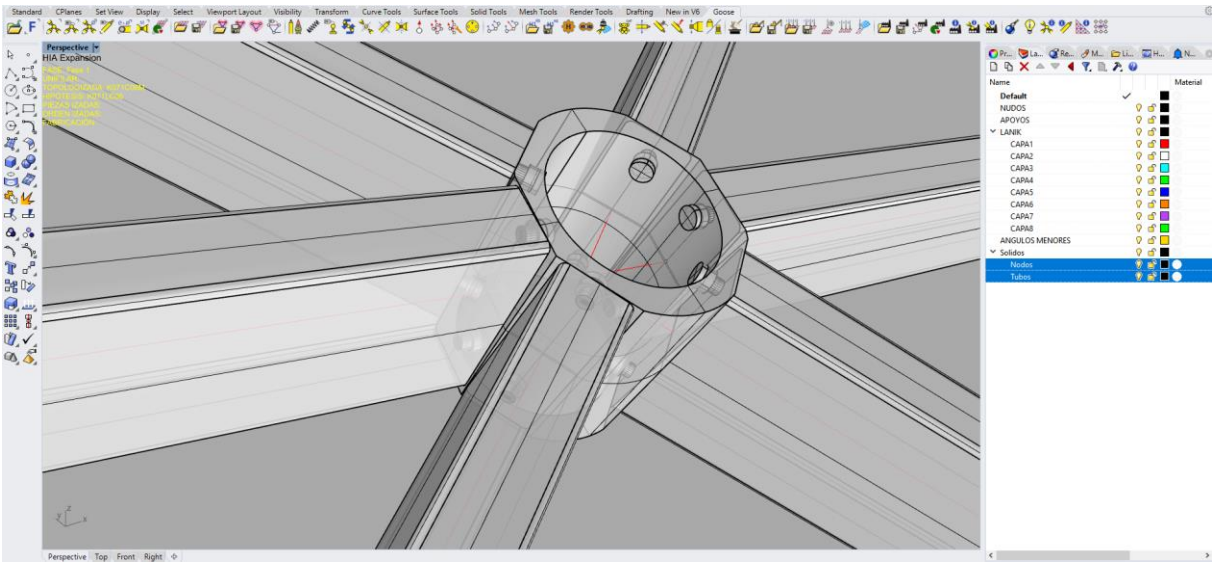

Figure 14: GOOSE Rhino plugin node automatic generation

5. Final aspect

The aesthetic result can be seen in the following pictures:

Abstract

Tubelike latticed cylindrical shells have come to be used as building column or tower. For the use as building columns, not only buckling strength but also post-buckling deformation capacity is sometimes required especially in earthquake-prone region. An experimental study was conducted to observe buckling and post-buckling behaviour of axially compressed latticed cylinder made of aluminium alloy. Two test bodies were fabricated using 3D-printer. Axially symmetric (elephant leg) buckling occurred in the test. However, the shell geometry had some considerable deviation from the anticipated flawless cylinder. 3D-scaned data of the test bodies were measured and analysed in the Grasshopper to specify the deviation and an FE models including the specified imperfection were constructed. The newly devised method to specify the initially distorted geometry is highlighted in the paper. The buckling behavior was traced using the FE models. The plastic buckling load is also evaluated by comparing to calculation based on the column-bucking concept using the generalized slenderness.

Keywords: latticed cylindrical shell, buckling, aluminium, 3D-printer, elephant leg buckling, experiment, 3D-scan

1. Introduction

Latticed cylindrical shells have been used to form airplane bodies because of good efficiency [1]. So far, buckling of latticed cylinders have been studied especially in the aircraft field and several experimental studies using various materials have been conducted. Chen et al calculated energy absorption on aluminium latticed cylinders for impact load using FE, and conducted axially loading test of 3D-printed ABS latticed cylinders for the validation of numerical analysis [2]. Kim[3] and Fan[4] also conducted axial compression test of latticed cylinders made of composite material. Graciano formed metal latticed cylinder with expanded metal sheet and conducted axial compression test focusing deformability [5]. However, though the load-deformation curves are shown in these papers, information on the test bodies such as geometric imperfection, dimension or nonlinear properties of material is not sufficiently described and the buckling strength is not evaluated at all.

On the other hand, in the architectural field, the use as building column or tower is becoming popular today (Figure 1). As such building structure, not only sufficient strength but also deformable capacity in the post-buckling path is sometimes required especially in earthquake-prone region. For understanding strong nonlinear phenomenon like buckling of metal shells, both experimental and analytical studies are required. However, experiments on large-scaled metal latticed shells consisting of members and joints, which have been carried out in the field of building construction [6,7], require a large amount of money and large-scaled facilities. Easier and cheaper experimental method is needed.

To propose an easier and cheaper method on buckling test of metal latticed structures, the authors carried out buckling test of 3D-printed aluminium latticed cylinders that were axially loaded to buckle. This paper :

1) describes a buckling test carried out on two latticed cylinders, composed of hexagonal and triangular grid. The diameter, height and thickness were approximately 160mm, 100mm and 2mm, respectively.

2) demonstrates a method to build an FE model of the test bodies composed of beam elements, where the actual nodal coordinates were specified from the 3D-scanned data using functions of grasshopper. The FE models contained actual geometric imperfection and variation of member section.

3) reports the follow-up FE analysis. The maximum strength is also evaluated in accordance with a method proposed by the AIJ recommendation in which the generalized slenderness is used [8].

2. 3D-printed latticed cylinders

2.1. Anticipated geometry

Figure 1 illustrates the designed dimensions for the input of 3D-printer and the definition of the layer. Two latticed cylinders, composed of regular hexagon (called hereafter “Cylinder 1”) and equilateral triangle (“Cylinder 2”), were fabricated. The thickness and width of the anticipated member section in the two latticed cylinders were 2mm x 3mm and 2mm x 2mm, respectively. 16 and 20 were the number of circumferential division. To fix the upper and lower boundary, continuous 8mm bands were installed.

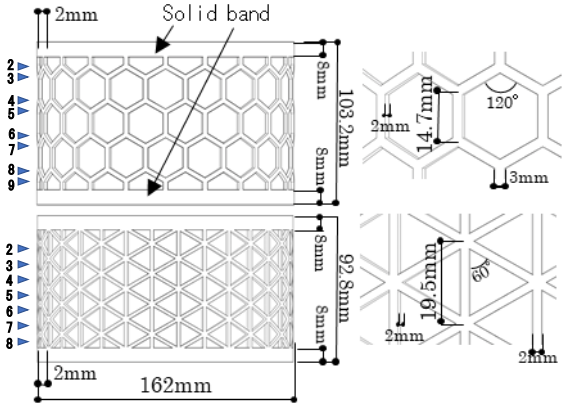

Figure 1. Designed geometry

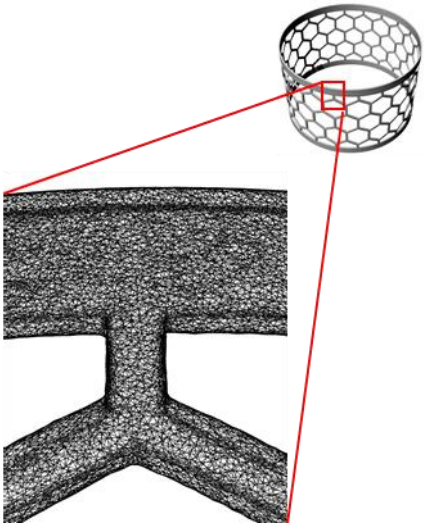
2.2. Material

Aluminum alloy (AlSi10Mg) powder was used for the additive manufacturing. After completion of the 3D-printing, annealing was provided to improve ductility. Figure 2 illustrates the stress-strain diagrams. The tensile specimens were manufactured simultaneously to the latticed cylinders, where the direction of additive manufacturing was the same as the cylindrical axis. Despite annealing, the fracture strain was only up to 6%, approx. Table 1 contains approximated function of the s-s curves for the FE nonlinear analysis, in which the n-th power hardening law was assumed. In the S-S curve of the aluminium alloy, clear yield point cannot be not specified so that 0.2%-offset strength is used to determine the yield point.

Figure 2. Stress-strain diagram



2.3 3D-scan of test bodies

The 3D-printed two-test bodies are shown in Figure 3(a). These were 3D-scanned to specify the actual geometry. The 3D-scanner can measure with the resolution of 85 μ m. The scanned geometry was output as a meshed surface data (Figure 3(b)). The meshed surface was not smoothed.

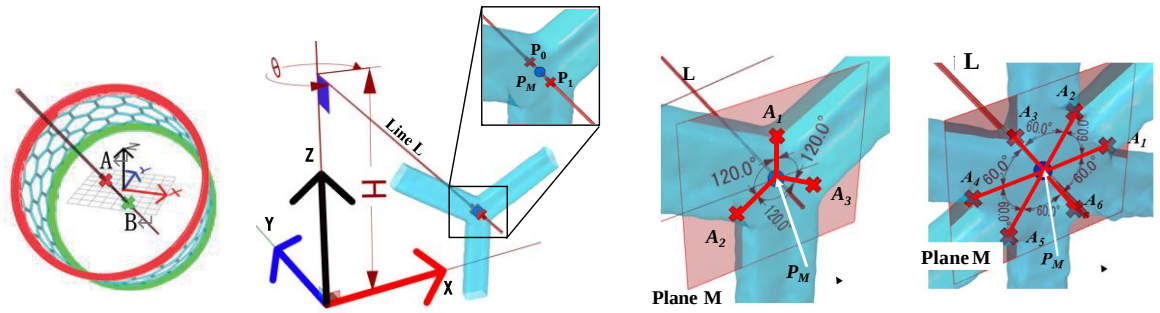
Figure 3. 3Dprinted cylinderical shells

2.4 Finding nodal points and geometry of latticed cylinders



To construct a FE model composed of linear beam elements, the nodal points, connecting the elements, had to be specified from the scanned surface. To specify the nodal coordinates, the cylindrical axis, corresponding to the Z-axis of the Cartesian coordinate, had to be established.

Several previous researches [9 for example] demonstrates how to determine the cylindrical axis from many 3D points (dots) distributing to a cylindrical shape. However, these methods are not applicable so that a method using Galapagos, a component of Rhino+Grasshopper, was developed to specify the axis. The procedure on the Grasshopper is described as follows:

1) A temporary cylindrical axis is set as the line AB, between the centers of the top (A) and bottom (B) rigid belts (Figure 4(a)). Coordinate of A or B is determined as the average of the coordinates of vertices of the mesh within the belt. The Z axis corresponds to the cylindrical axis.

2) A line (*L*) perpendicular to the Z axis (=the cylindrical axis) is drawn which penetrates the nodal joints. The penetrating points on the inner and outer surfaces, and the midpoints between them are denoted as P_0, P_1 and P_M (Figure 4(b)) . The Z coordinate of the starting point of line L on the Z axis and the angle between the X axis and line L are denoted as H and θ.

3) Let *M* be the plane that contains P_M and is perpendicular to line *L*. For Cylinder 1, set a straight line parallel to the Z-axis on plane *M*, and let *A1* be the nearest intersection with the scanned surface. Next, set two straight lines forming an angle of 120° with this straight line on *M*, and set the intersection points with the scanned surface as *A2* and *A3*(Figure 4(c)). For Cylinder 2, set 6 straight lines starting from P_M on the plane *M* at 60° intervals, and set the intersection points with the scanned surface as *A1* to *A6*(Figure 4(d)).

(a) Temporary axis

(b) Penetration of L to scanned surface

(c) Intersection of radiating lines to scanned surface

(d)

Figure 4. Extract nodal points from 3D-scanned surface

4) Next, determine the coordinates of the nodal point P_M. Let J be the variance of the distance between P_M and A_i ($P_M A_i$).

$$J = \sum_{i=1}^{n} \left(P_M A_i - \overline{P_M A} \right)^2 \rightarrow \min \tag{1}$$

in which n is 3 for Cylinder 1 and 6 for Cylinder 2. $\overline{P_M A}$ is the average of $P_M A_i$. Using Galapagos (a Grasshopper plug-in, for optimization by GA), H and θ minimizing J are determined together with the coordinates of P_M. In the optimization, the points of A_i move depending on the location of P_M. This sequence of operations is performed for all nodes.

5) Determine the center of all the nodal points, specified by the step 4). Let the distance between the center O (x_o,y_o,z_o) and the i-th nodal points P_{Mi} be d_i. By minimizing the variance of d_i L, the coordinates of the center O are determined as step 4).

$$L = \sum_{i=1}^{N} \left(d_i - \overline{d_i} \right)^2 \rightarrow \min \tag{2}$$

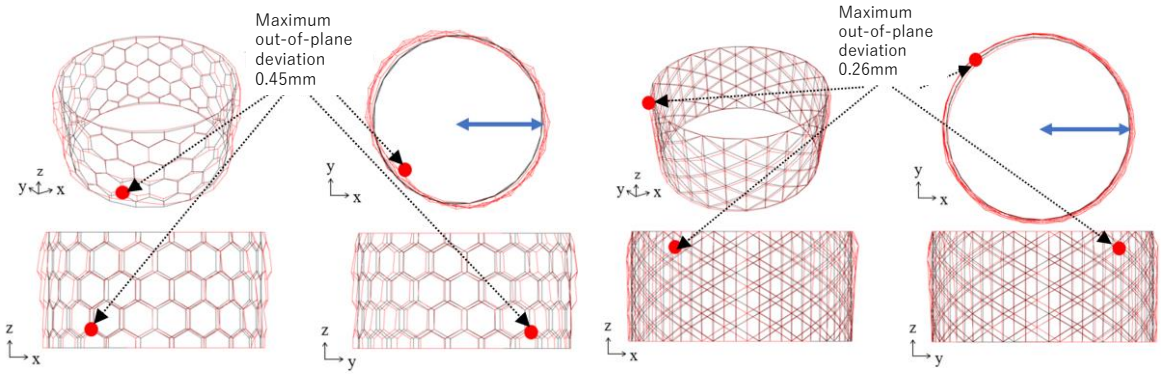
in which N is the number of nodes. $\overline{d_i}$ is the average of d_i.

6) The latticed cylinder is subjected to further small rotation around the determined center O, to find more appropriate cylinderical axis for the initially distorted cylinder. Let α and β be the rotation about the X and Y axes, respectively. The rotated nodal coordinates are calculated by Eq.(3).

$$\left\{ \overline{x_i} \right\} = \left[R_y(\beta) \right] \left[R_x(\alpha) \right] \left\{ x_i \right\} \tag{3}$$

where $\left\{ \overline{x_i} \right\}$ and $\{x_i\}$ are the rotated and original i-th nodal coordinates. $[R_y(\beta)]$ and $[R_x(\alpha)]$ are the linear rotation matrix about Y and X axes, respectively. Then, a circle that approximates the projected nodal points to XY plane is determined by least square method.

$$\left(\overline{x_i} - a \right)^2 + \left(\overline{y_i} - b \right)^2 = {r_m}^2 \tag{4}$$



where a,b and r_m are the center and radius of the circle. Then the approximation error Q is defined by Eq.(5).

$$Q = \sum_{i=1}^{N} \left(\sqrt{(x_i - a)^2 + (y_i - b)^2} - r_m \right) \rightarrow \min \tag{5}$$

All the variables in Eq.(5) depend on α and β. Q is minimized changing α and β using Galapagos and then the Z axis is the most appropriate cylindrical axis. The origin have to be moved to $\{a,b,0\}$.

2.5 Out-of-plane imperfection

In Figure 5, the initially distorted geometry, specified applying the aforementioned procedure, is drawn by the red lines where the deviation is 20 times enlarged.

(Cylinder 1) (Cylinder 2)

Figure 5. Specified geometry including initial imperfection

The out-of-plane imperfection of the latticed cylinders was finally specified based on the optimized coordinate system for α and β. The out-of-plane deviation at the i-th node from the perfect cylinder is calculated using Eq.(6).

$$\delta_i = \sqrt{x_i^2 + y_i^2} - r_m \tag{6}$$

In Cylinder 1, the specified maximum out-of-plane deviation δ_{max} and radius r_m were 0.45mm and 80.15mm. δ_{max} was 0.56% of r_m. In Cylinder 2, these were 0.26mm and 79.22mm. δ_{max} was 0.33% of r_m.

2.6 Member section

The width and thickness of the member section (Figure 6) were also measured in the 3D-scanned data. Table 1 contains the dimensions. With respect to Cylinder 1, the fabrication dimensions were generally 10% less than the anticipated, while the width of the diagonal member in Cylinder 2 was 17% larger. The fabrication error on thickness was larger than that on width.

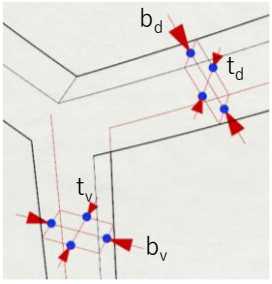


Figure 6. Width(b) and thickness(t) of diagonal(d) and vertical (v) member

Table 1 Section dimensions

				Designed dimension (mm)	Average (mm)	Fabricated/ Design	Maximum (mm)	Minimum (mm)	C.O.V

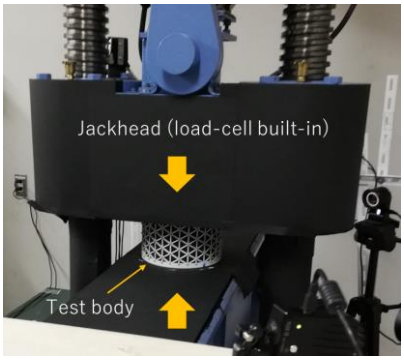
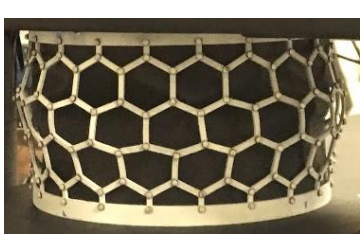
3. Bucking test

3.1 Setup

Figure 7 overviews the axial compression test setup. Mechanical displacement gauge was used to measure axial shrinkage, while nodal 3D displacement was measured using a non-contact 3D measurement system (VENUS3D Nobby-Tech. Ltd.). The applied load was monitored by the load-cell installed at the jackhead. Axial load was statically given by forced axial deformation (1.3mm/min).

Spherical washer was not installed between the jackhead and the test body to avoid instability in largely deformed state.





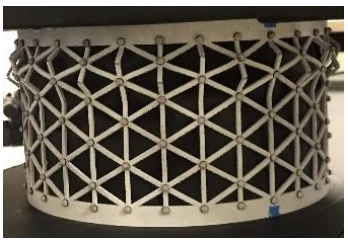


Figure 7 Test setup

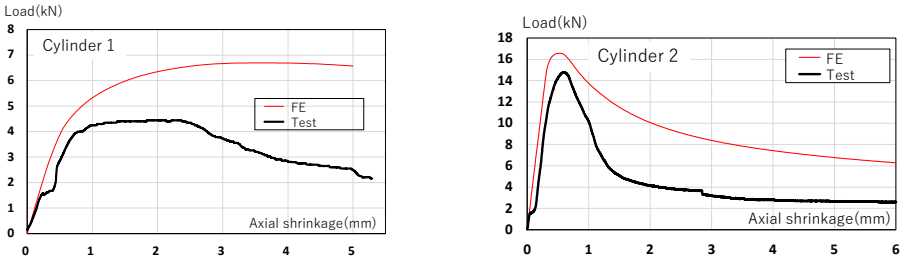
3.2 Cylinder 1

Figure 8(a) shows the deformed test bodies. In Cylinder 1, axially symmetric deformation was observed where the out-of-plane deformation was maximum at the 5-6th layers. The load-deformation curve is illustrated in Figure 9(a), in which the axial shrinkage of the latticed portion is for the horizontal axis. The shrinkage was measured by the aforementioned 3D system.



(a) Cylinder 1

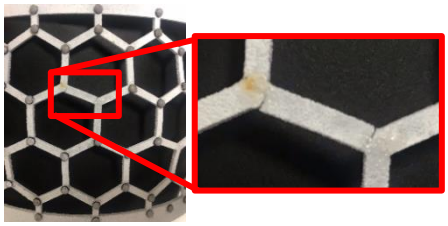
(b) Cylinder 2

Figure 8 Observed buckling

(a) Cylinder 1 (b) Cylinder 2

Figure 9 Load-deformation curve (Test vs. FE)

As shown in the graph, the buckling behaviour was extremely nonlinear. Since hexagonal grid structures are bending-dominated, crack due to in-plane bending was observed at the shrinkage of about 1mm as illustrated in Figure 10. The load-deformation curve becomes flat during the shrinkage of 0.8～2.3mm.



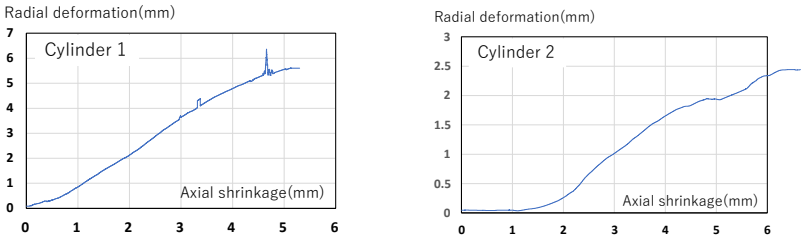


Figure 10 Crack due to in-plane bending

In spite of the strong nonlinearity, compatibility between axial and out-of-plane radial deformations was almost linear. The radial deformation gradually increased from the early stage (Figure 11(a)).

(a) Cylinder 1 (b) Cylinder 2

Figure 11 Axial vs radial deformation

3.3 Cylinder 2

As shown in Figure 8(b), the upper portion locally and extremely deformed, so-called “elephant-leg” buckling. The load-deflection curve is greatly different from that of Cylinder 1, where rapid degradation after the peak is observed in Figure 9(b).

Out-of-plane radial deformation was very small until the peak of axial strength, but it was remarkably developed in the post-buckling behavior after the peak (Figure 11(b)). The buckling wavelength was about 1.5 times of the member length. Severe crack on the buckled member was also observed in the post-buckling behavior.

4. Follow-up FE analysis

4.1 FE model

MSC-Marc[10] was used for geometrically and materially nonlinear FE analysis. Two kinds of FE model for a test body were constructed. These models are composed of linear beam-column elements. One (called Model_0, hereafter) is a latticed cylinder without geometric imperfection and scattering of section dimension. The radius was r_m, determined from the 3D-scanned data. Single member section of which the dimension was the average of the measured dimension indicated in Table 1. Another model (called Model_1) was a digital-twin of the test body, the FE model that imitated the actual geometry including imperfection and variable member section, which has been described in the previous section.

The top boundary of the latticed cylinders was completely fixed. For the bottom boundary, only displacement along the cylindrical generatrix was free and other D.O.F.s were fixed. Displacement control to the bottom boundary, similarly to the experiment, was given.

The stress and strain curves already shown in Figure 2 were used. One member was divided into 20 beam-column elements where shear deformation was considered.

4.2 Test and FE results

Figure 9 superposes two load-deformation curves, the test and FE results. The FE results is higher especially on Cylinder 1, where the maximum load is 1.6 times that of the test. This discrepancy of strength was guessed to be caused by the aforementioned crack observed in the test, which was out of consideration in the FE analysis. Figure 12 illustrates the increase of bending strain of a cracked vertical member, calculated in the FE analysis. The bending strain exceeds the failure strain when the axial shrinkage reaches 1.2mm. It can be related to that the load-deformation curve becomes flat after the shrinkage of about 1mm.

A better agreement is found for Cylinder 2. This is because the fracture occurs at the very large deformed state in the post-buckling path, and not near the maximum strength.

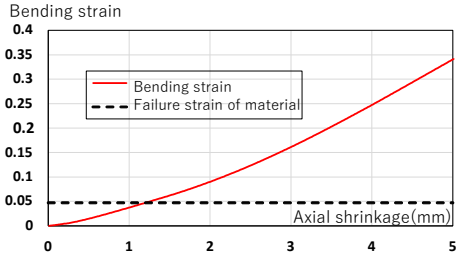

Figure 12 Strain due to in-plane bending

4.3 Eigenvalue analysis

Figure 13 illustrates the buckling modes and loads of Model 0 and 1 for each cylinder, obtained using the linear eigenvalue buckling analysis.

For Cylinder 1, the 1st linear buckling load of Model 1 (with geometric imperfection and variation of section properties) is 20.01kN, larger than 17.16kN of Model 0 (without imperfection). For Cylinder 2, 44.8kN of Model 1 is less than 50.0kN of Model 2. Generally, these buckling loads up to 5th are close.

The observed collapse deformation in the test was axially symmetric “elephant-leg-like” shape. However, except Model 0 of Cylinder 2, the buckling modes have circumferential buckling waves. In plastic buckling affected by material nonlinearity, a mode similar to the first-order linear buckling mode does not necessarily occur.

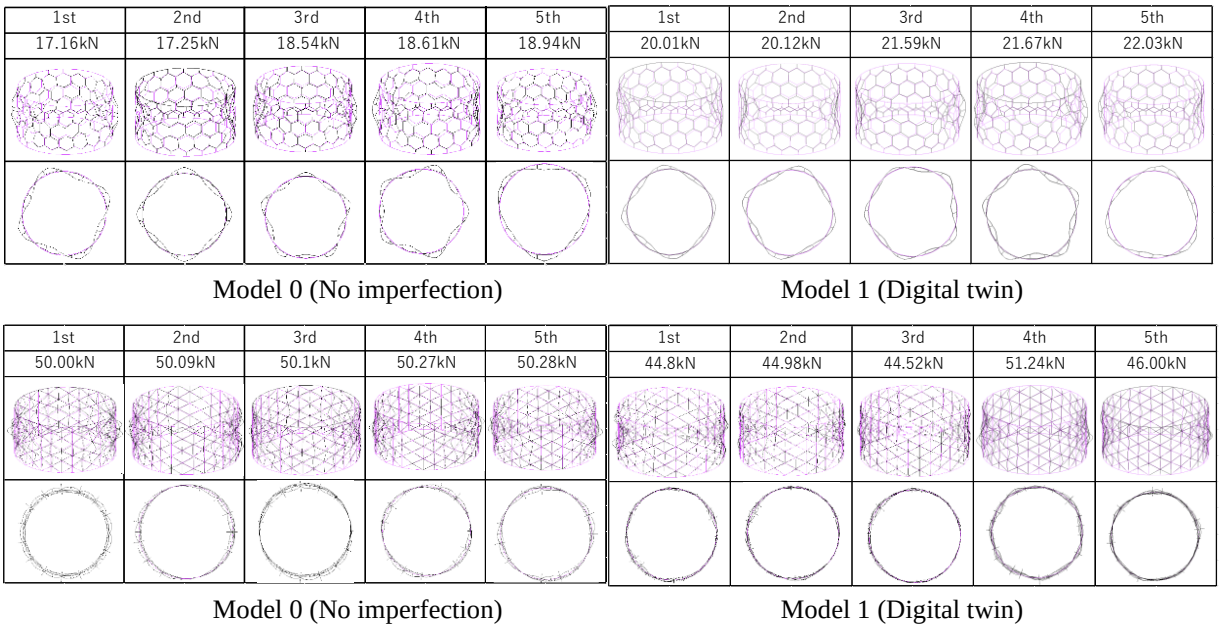

Figure 13 Linear buckling eigenmodes

4.4 Ultimate strength evaluation using generalized slenderness

The AIJ recommendation [8] provides a general concept to evaluate ultimate buckling strength of metal latticed shells. A formula to estimate ultimate buckling strength (P_{cr}) is given by Eq.(7).

$$\frac{P_{cr}}{P^{pl}} = \begin{cases} \dfrac{1-0.24\Lambda_s^2}{1+\dfrac{4}{15}\Lambda_s^2} & \left(\Lambda_s \le \dfrac{1}{\sqrt{0.6}}\right) \\ \dfrac{9}{13\Lambda_s^2} & \left(\Lambda_s > \dfrac{1}{\sqrt{0.6}}\right) \end{cases} \tag{7}$$

where P_{pl} is the yield strength obtained using so-called "pushover" analysis in which only material nonlinearity is taken into account in calculation. Λ_s is the generalized slenderness, defined by Eq.(8)

$$\Lambda_s = \sqrt{\frac{P_{pl}}{P_{cr}^{el}}} \tag{8}$$

$P_{cr}{}^{el}$ is the elastic nonlinear buckling load obtained geometric nonlinear incremental analysis, where yield is out of consideration. However, in the case of cylinderical shells subjected to axial compression, static nonlinear analysis applying Rik's arc-length method often becomes unstable especially in the post-buckling path. Thus a quasi-dynamic transient analysis [11] was employed to obtain $P_{cr}{}^{el}$, in which mass-proportional damping was used and the damping factor h_1=0.5. Figure 14 illustrates two kinds of load-deformation curves drawn by elastic nonlinear and "pushover" analysis.

The ultimate strength in the two tests fall in the vicinity of the estimation curve (Figure 15). However, the strength of Cylinder 1 might be much higher if bending crack did not occur.

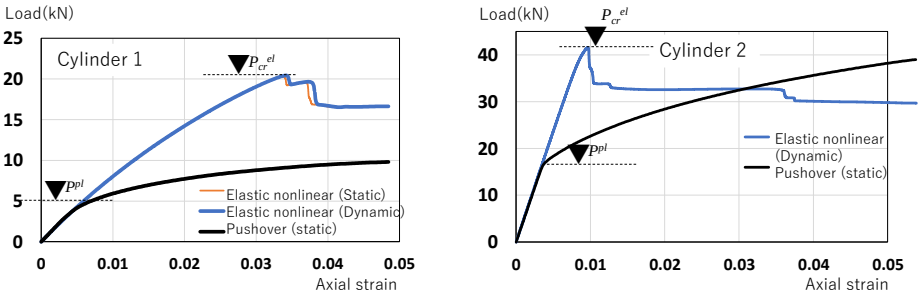

Figure 14 Elastic nonlinear and "pushover" analysis

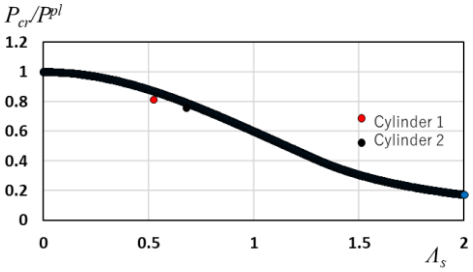

Figure 15 Ultimate strength evaluation using column-bucking concept

5. Conclusion

Two aluminium latticed cylinders were fabricated by 3D-printer with annealing to increasing ductility. One was composed of hexagonal and another was triangular grid. The cylinders were 3D-scaned and a methodology to specify the actual geometry, using Grasshopper, has been proposed in this paper.

The out-of-plane radial deviation in the 3D-printed geometry were 0.56 and 0.33 % of the specified radius for Cylinders 1 and 2, respectively. The variation in the section dimension was about 10% less than the anticipated.

Axially symmetric buckling was observed in both tests. The buckling wavelength of Cylinder 1 was longer than that of Cylinder 2 where localized "elephant-leg-like" protruding was observed. This is different from the 1st linear buckling eigenmode. Due to low ductility of the material, severe crack occurred, which reduced the strength especially in Cylinder 1.

The maximum load obtained in the follow-up FE analysis was larger than the test results, especially on Cylinder 1. This is guessed to be due to crack caused by in-plane bending in hexagonal lattice. The maximum strength was also evaluated by comparing to the calculation by the AIJ method using the generalized slenderness. The plotted strength is quite near the estimation curve.

Abstract

The safety of single-layer reticulated shells depends largely on their buckling capacity, on which the initial geometric imperfections of joint deviations generated during the installation of the structure have a significant impact. By reviewing existing simulation methods on the initial geometric imperfection field of single-layer gridshells, it is concluded that existing stochastic, deterministic, and semi-stochastic simulation methods are all with deficiencies, and it is impossible to determine the real probability model of the buckling capacity of single-layer gridshells. This study proposes an initial imperfection field simulation method considering fabrication constraints, with reasonable basic assumptions and controllable computational costs, providing a scientific basis for improving the stability analysis method for single-layer gridshells and a theoretical foundation for the analysis of stability reliability.

Keywords: single-layer reticulated shells, initial geometric imperfection, simulation methods, buckling capacity

1. Introduction

Due to the advantages of small self-weight, excellent load-bearing performance, and strong individuality, single-layer gridshells (SLGs) have been widely used in China since the 1950s [1]. With the development of social economy and modern aesthetics, SLGs with larger spans and made of different materials have also become landmark buildings in various regions in recent years.

SLGs and continuous thin-shell structures share similarities in that they both resist external loads through internal forces within the shell plane, with the axial forces in the members being predominant [2]. To meet the requirements for clear height and drainage in the lower space, the shape of the shell is often designed as an arch to induce axial compression in the members. The load-bearing capacity of thin, flexible or long, slender compression structures is generally controlled by stability, and the global stability of the SLGs must be considered during its design. When the global stability of an SLG is lost, most joints will significantly deviate from their initial equilibrium positions, resulting in large-scale depressions or bulges on the shell surface and a loss of load-bearing capacity, ultimately leading to collapse and failure [3]. Thus, it is evident that the analysis of the global stability of an SLG exhibits strong non-linear characteristics.

All structural systems inevitably have initial imperfections, such as material, geometric, and physical imperfections, which can alter the stability of the perfect structure at its critical equilibrium point and significantly affect its load-bearing capacity [3]. In practical engineering, these initial imperfections are further classified according to their location and impact range as member imperfections, joint imperfections, and global structural imperfections [4].

Member imperfections mainly include geometric imperfections and residual stress imperfections. Geometric imperfections refer to the global or local deformation of components, such as initial bending [5−7], initial eccentricity [8], irreversible deformation, and section deformation. However, the component factory and site acceptance can easily eliminate these imperfections. Moreover, previous studies [7] have shown that the weakening effect of initial bending on the global stability and load-bearing capacity of a shell structure is less than 5% when meeting the acceptance standards.

Joint imperfections vary depending on the type of joint. For welded joints, common imperfections include weld cracks, incomplete penetration, and slag inclusion [9], while for bolted connections, common problems include looseness, fracture, and insufficient tightening. Similarly, these joint imperfections can be avoided by improving construction quality and increasing inspection frequency.

Global structural imperfections include random installation deviations of the designed surface shape, non-uniform structural settlement, and global tilting. Among these, the random installation deviation of the surface shape, which refers to the random initial deviation between the actual and design joint positions, is a significant factor that cannot be effectively avoided. Besides, this issue also has a major impact on the buckling capacity of SLGs [10−12]. Additionally, the evolution of the buckling capacity of SLGs under random initial geometric imperfections exhibits highly non-linear characteristics [13].

Currently, the modeling methods for the initial imperfection field of SLGs can be classified into four categories: field measurement, stochastic simulation, deterministic simulation, and semi-stochastic search. Field measurement primarily utilizes modern techniques (such as 3D scanning and optical measurement) to measure the precise values of the initial imperfections of the structure, but this method cannot be applied in the structural design phase. In this paper, we investigate the research status and development trends of three modeling methods for initial imperfection fields that can be used in the structural design phase and summarize the existing problems.

2. Stochastic simulation method

Since construction errors in SLGs are often random, their initial imperfections should also follow a stochastic distribution [2]. Therefore, a probabilistic simulation approach based on random search and probability theory is more suitable for evaluating the non-linear buckling capacity of imperfect gridshells [14]. Existing stochastic simulation methods mainly include the random imperfection method and the random field method.

2.1. Random imperfection method

The random imperfection method [2] (also known as the random imperfection modal method) assumes that the joint deviation amount $\Delta\mathbf{P}$ of an SLG, caused by random construction errors, follows a truncated normal distribution in the x, y, and z directions [15], and is mutually independent, can be expressed as

$$\begin{cases} \Delta\mathbf{P}_i = \left(\mathrm{d}x_i, \mathrm{d}y_i, \mathrm{d}z_i\right)^{\mathrm{T}} \\ \mathrm{d}x_i \sim N_{\mathrm{t}}\left(0, \sigma^2\right) \\ \mathrm{d}y_i \sim N_{\mathrm{t}}\left(0, \sigma^2\right) \\ \mathrm{d}z_i \sim N_{\mathrm{t}}\left(0, \sigma^2\right) \end{cases} \tag{1}$$

in which $\mathrm{d}x_i$, $\mathrm{d}y_i$, and $\mathrm{d}z_i$ represent the initial deviation of the ith joint (i = 1, 2, ..., n) in the x, y, and z directions, respectively. $N_{\mathrm{t}}(0, \sigma^2)$ denotes a truncated normal distribution with a mean of 0 and a variable range of $[-2\sigma, 2\sigma]$. Figure 1(a) shows the results of 10,000 samplings according to Eq. (1), which indicates that the generated joint deviations fall within a cube with a side length of 4σ. In Ref. [2], this method was applied to introduce 50 random initial imperfections in the gridshell experiment conducted

by Hu *et al*. [16]. The obtained average non-linear buckling capacity matched well with the experimental results.

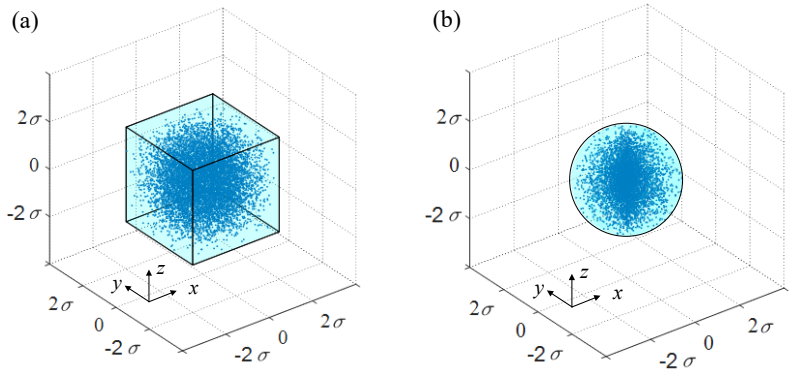

Figure 1. Sampling results of joint deviation of random imperfection method: (a) The method in reference [2], (b) The method in reference [18].

However, existing codes [17] often specify limits for the resultant deviation amplitude of joints $\|\Delta\mathbf{P}_i\|$:

$$\|\Delta\mathbf{P}_i\| = \sqrt{\mathrm{d}x_i^2 + \mathrm{d}y_i^2 + \mathrm{d}z_i^2} \le R_{\max} \tag{2}$$

where $R_{\max}$ is the limit value of the combined deviation of the joint. Thus, Sun [18] pointed out that the actual feasible domain of the initial deviation of each joint should be a sphere, and each directional component is calculated based on spherical coordinates:

$$\begin{cases} \mathrm{d}x_i = K_i \sin\gamma_i \cos\alpha_i \\ \mathrm{d}y_i = K_i \sin\gamma_i \sin\alpha_i \\ \mathrm{d}z_i = K_i \cos\gamma_i \end{cases} \tag{3}$$

in which K_i represents the amplitude of the resultant deviation amplitude of the ith joint, while γ_i (α_i) represents the angle between the bias direction (projection direction) and the positive direction of the local coordinate axis, as defined in Figure 2. According to reference [18], K_i should follow a truncated normal distribution, while γ_i and α_i should follow a uniform distribution U:

$$\begin{cases} K_i \sim N_{\mathrm{t}}\left(0, \sigma^2\right) \\ \gamma_i \sim U\left(0, 2\pi\right) \\ \alpha_i \sim U\left(0, 2\pi\right) \end{cases} \tag{4}$$

Unfortunately, this method is also unable to simulate actual joint deviation accurately. Figure 1(b) shows the 10,000 samples generated using Eqs. (3) and (4), indicating that although the feasible domain has been changed from a cube to a sphere, the generated joint deviations are significantly concentrated along the z-axis. This is because the spherical coordinate sampling method employed in Eqs. (3) and (4) cannot consider the non-uniform distribution of the spherical volume along the z-axis direction. Furthermore, from Eq. (3), it can be seen that although the maximum amplitude of each directional component is K_i, theoretically, the necessary condition for $\mathrm{d}x_i$ ($\mathrm{d}y_i$) to take the maximum amplitude is for $\sin\gamma_i$ and $\cos\alpha_i$ (or $\sin\gamma_i$ and $\sin\alpha_i$) to simultaneously take their amplitudes, while the necessary condition for $\mathrm{d}z_i$ is for $\cos\gamma_i$ to take the amplitude only.

On the other hand, Chen *et al*. [19] pointed out that the initial deviations between joints should be coupled due to the presence of members. Specifically, the fabrication errors in member length are generally on the order of millimeters [17, 20]. Considering the joint initial deviations independently will

lead to a significant deviation between the member length of the imperfect structure and its design length. If such deviations occur during the construction process, significant initial stress will appear in the member, and some members may enter the plastic state. Therefore, the initial deviations of the joints in the actual initial imperfection distribution are not independent random variables [21]. In order to consider the influence of member length on the coupling relationship between the initial deviations of joints, Du *et al*. [20] and Li *et al*. [22] proposed a stochastic imperfection method to simulate the initial deviations of joints under different member length deviations by heating and cooling the members. The methods proposed in Refs. [20, 22] also introduced the initial stress caused by member length deviation but did not discuss the specific magnitude of this initial stress or the reasonableness of the generated initial deviation amplitudes.

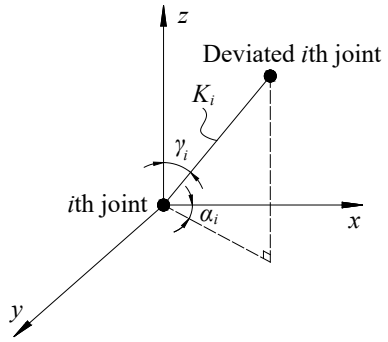

Figure 2. Spherical coordinate system parameters.

2.2. Random field method

To address the shortcomings of the random imperfection method, Chen *et al*. [19] and Liu *et al*. [23] proposed that the initial imperfections of SLGs can be regarded as a weakly homogeneous random field $B(\mathbf{P})$ with mean μ and variance σ^2, where $\mathbf{P} = (\mathbf{P}_1, \mathbf{P}_2, \ldots, \mathbf{P}_n)$ is the three-dimensional coordinate matrix of the gridshell joints, and $\mathbf{P}_i = (x_i, y_i, z_i)^{\mathrm{T}}$ is the three-dimensional coordinate vector of the ith joint. Assuming that the lengths of the grid shell members are equal, Ref. [19], based on experimental data, proposed that the correlation coefficient ρ_{ij} at the positions of the ith and jth joints in the random field $B(\mathbf{P})$ can be further assumed to exponentially decay with the minimum number of members S_{ij} between two joints, i.e.,

$$\rho_{ij} = \sqrt{\mathrm{e}^{-S_{ij}}} \tag{5}$$

Therefore, the correlation of initial deviations between joints caused by the topology of the gridshell can be considered through the covariance matrix $\mathbf{C}$:

$$\mathbf{C} = \left(c_{ij}\right)_{n\times n} \tag{6}$$

where c_{ij} is the covariance between the positions of joint i and j, calculated according to the following formula:

$$c_{ij} = \rho_{ij}\sigma^2 \tag{7}$$

Cholesky decomposition of $\mathbf{C}$:

$$\mathbf{C} = \mathbf{L}\mathbf{L}^{\mathrm{T}} \tag{8}$$

where $\mathbf{L}$ is the lower triangular matrix obtained by Cholesky decomposition. To determine the actual initial displacements of the joints, Chen *et al*. [19] assumed that the directions of the initial displacements were all in the outward direction of the shell plane. That is, each joint had an initial

displacement along the straight line of its normal vector. The vector of the magnitude of the initial displacement **r** is calculated as follows:

$$\mathbf{r} = \left(\left\|\Delta\mathbf{P}_1\right\|, \left\|\Delta\mathbf{P}_2\right\|, \ldots, \left\|\Delta\mathbf{P}_n\right\|\right)^{\mathrm{T}} = \mathbf{L}\boldsymbol{\kappa} + \boldsymbol{\mu} \tag{9}$$

where $\boldsymbol{\kappa} = (K_1, K_2, \ldots, K_n)^{\mathrm{T}}$ T is the magnitude vector of the resultant deviation of the joints subject to the standard normal distribution, $\boldsymbol{\mu} = (\mu)_{n\times 1}$ is the mean vector of random field $B(\mathbf{P})$.

Based on numerical examples of Kiewitt-type single-layer spherical gridshells, Ref. [19] compared the stochastic field method with the stochastic imperfection method and pointed out that the imperfect structure obtained by the former has significantly smaller non-linear buckling capacity variability.

3. Deterministic simulation method

The computational cost of stochastic simulation methods is generally high. Deterministic simulation methods rely on physical concepts and introduce displacement trends during structural buckling as the *most unfavorable initial imperfection distribution pattern*. These displacement trends include both non-linear and linear buckling modes. For clarity, Figure 3 presents an example of the load-displacement curve for a typical SLG under vertical loading, where Λ is the load coefficient, δ is the resultant displacement of the critical joint at buckling, and point *A* represents the first critical point of the structure.

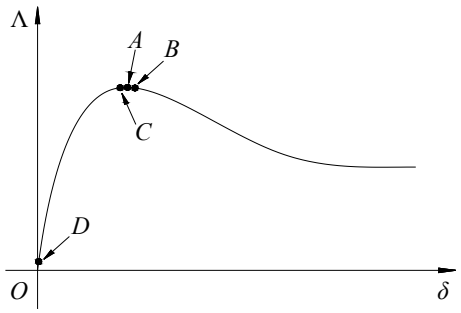

Figure 3. Example of the load-displacement curve of a typical perfect SLG.

3.1. Consistent imperfection modal method

In 1992, Chen and Shen [24] proposed that the displacement trend at the first critical point of the load-displacement curve of SLGs (i.e., the non-linear buckling mode) could be a possible *most unfavorable initial imperfection distribution pattern*. The non-linear buckling mode can be calculated based on the displacement difference before and after structural buckling (points *A* and *B* in Figure 3) or through linear buckling analysis approximation before the critical point (point *C* in Figure 3). Based on the computational results of a single-layer spherical gridshell example, Ref. [24] indicated that the non-linear buckling capacity of the imperfect structure introduced by this method was consistent with the lowest value obtained by the random imperfection method under the same amplitude. However, the authors did not provide specific methods for determining the imperfection amplitude in the paper, nor did they discuss the practicality of the imperfection distribution.

Cao [25] pointed out the high cost of solving non-linear buckling modes. Therefore, the lowest-order linear buckling mode of the structure near its initial state (point *D* in Figure 3) can be used as the initial imperfection distribution pattern. Ref. [25] termed this method the *eigenmode imperfection method* and indicated that it also falls within the category of the *consistent imperfection modal method*. Numerical results show that the consistent imperfection modal method can provide a non-linear buckling capacity of imperfect structures extremely close to those obtained by the traditional eigenmode imperfection method under the same amplitude.

Fan *et al*. [26] and Xiong *et al*. [27], based on the eigenmode imperfection method, conducted numerical analyses on the non-linear buckling capacity of Kiewitt-type single-layer steel and aluminum alloy

gridshells with different imperfection amplitudes. They pointed out that when the imperfection amplitude is greater than $L/300$ (where L is the span), the non-linear buckling capacity of the structure will not be further reduced. Therefore, it is suggested in Refs. [26, 27] that when analyzing the non-linear buckling capacity of imperfect SLGs using the lowest-order linear buckling mode, the imperfection amplitude should be conservatively taken as $L/300$.

3.2. *N*-order eigenmode imperfection method

Based on numerical analysis, Cai *et al*. [28] pointed out that the lowest-order linear buckling mode is not necessarily the *most unfavorable initial imperfection distribution pattern* for Kiewitt-type grid shells with relatively large height-to-span ratios, and the corresponding imperfect structure has lower stability reliability. Considering that the eigenvalues (i.e., linear buckling coefficients) corresponding to the linear buckling modes of SLGs are quite dense, Ref. [28] suggests that the first N linear buckling modes of an SLG should be used to simulate the initial imperfection distribution patterns to obtain N non-linear buckling capacities of the imperfect structures. The minimum value among them should be taken to evaluate the non-linear buckling capacity of the structure. By comparing the results obtained by the N-order eigenmode imperfection method and the random imperfection method, Ref. [28] believes that the stability reliability of the imperfect structure obtained by the N-order eigenmode imperfection method can meet the requirements of actual engineering under the same imperfection amplitude when N is 20.

However, many scholars have questioned the rationality and effectiveness of deterministic simulation methods. Liu *et al*. [29] and Cai *et al*. [30] pointed out that the imperfection amplitude $L/300$ determined in Ref. [26] is significantly larger than the limit value $L/1500$ specified in the code [17] for local surface depressions of gridshells. It is worth mentioning that since this amplitude is significantly larger, the length of the structural members of the imperfect structure will also differ significantly from their design length, and the simulated initial imperfection is non-realistic, i.e., the initial imperfection cannot occur in actual engineering. Bruno *et al*. [31] used the eigenmode imperfection method to conduct numerical analysis on a meridian gridshell. The results showed that different linear buckling modes of different orders (as initial imperfection patterns) would induce lower non-linear buckling capacities of the structure under different amplitudes, indicating that a single linear buckling mode cannot represent the most unfavorable initial imperfection distribution pattern. This conclusion is consistent with the analysis results of Huang and Zhao [32] on small gridshells. In addition, when a specific-order linear buckling mode is used as the initial imperfection pattern, the non-linear buckling capacity of the imperfect structure does not monotonically decrease with the increase of the imperfection amplitude. Zhu *et al*. [13] pointed out that the mathematical essence of the linear buckling mode is the eigenvector, so the positive and negative linear buckling modes can be separately applied as initial imperfections to the perfect structure, and numerical analysis results show that there can be significant differences in the non-linear buckling mode and buckling capacity of the two imperfect structures. Therefore, Ref. [13] pointed out that the imperfection pattern has a significant impact on the non-linear buckling performance and explored the impact of different-order positive and negative linear buckling modes on the imperfection pattern and non-linear buckling capacity based on supervised learning methods.

4. Semi-random search method

4.1. Heuristic search method

From a theoretical perspective, there exists a highly non-linear relationship between the design parameters of a structure and its non-linear buckling capacity. Although various meta-models or surrogate models (such as response surface approximation and Kriging interpolation [33]) can approximate the structural response as a function of the design parameters, their ability to handle highly non-linear problems is limited. Therefore, some scholars regard *finding the most unfavorable initial imperfection* as an optimization problem to directly establish the relationship between the initial imperfection parameters (unknown variables) and the non-linear buckling capacity (objective function):

$$\begin{cases} \text{find} & \Delta\mathbf{P} \\ \text{min.} & \Lambda \\ \text{s.t.} & g\left(\Delta\mathbf{P}\right) \le 0 \end{cases} \tag{10}$$

where $\Delta\mathbf{P} = (\Delta\mathbf{P}_1, \Delta\mathbf{P}_2, \ldots, \Delta\mathbf{P}_n)^{\mathrm{T}}$ denotes the initial deviation matrix of three-dimensional coordinates at each joint of an SLG; n is the total number of joints; $g(\Delta\mathbf{P}) \le 0$ represents the constraint that the initial deviation of three-dimensional coordinates at each joint must satisfy.

Luo *et al*. [34], Karmi and Kani [35] utilized particle swarm optimization and genetic algorithm, respectively, to solve the optimization problem, and the results showed that these heuristic algorithms could provide lower non-linear buckling capacity than deterministic simulation methods and random imperfection method under a certain amount of computation.

However, it should be noted that the numerical examples used to verify the proposed algorithms in Ref. [34] are SLGs with few joints. Although heuristic algorithms have global search capabilities, their computational cost will significantly increase with the problem size, and there is a problem of premature convergence to local optimums [36]. Moreover, heuristic algorithms are generally based on intuitive experience and lack mathematical foundations such as convergence theory and complexity evaluation systems [37]. Therefore, heuristic algorithms are generally used to provide feasible solutions for complex problems at an acceptable computational cost but cannot guarantee that the obtained solution is the global optimum.

4.2. Stochastic imperfection modal superposition method

Liu *et al*. [38] considered the influence of higher-order linear buckling modes on the non-linear buckling capacity of structures. They indicated that the actual imperfection distribution pattern of the structure: $\Delta\mathbf{P}' = \left(\Delta\mathbf{P}_1', \Delta\mathbf{P}_2', \ldots, \Delta\mathbf{P}_n'\right)^{\mathrm{T}}$ can be represented as a random linear combination of linear buckling modes:

$$\begin{cases} \Delta\mathbf{P}' = \sum_{j=1}^{m} r_j \boldsymbol{\varphi}_j \\ r_j \sim U\left(-1,1\right) \end{cases} \tag{11}$$

where m is the order of linear buckling modes involved in the combination, r_j is the participation coefficient of the jth (j = 1, 2, ..., m) linear buckling mode, $\boldsymbol{\varphi}_j = (\mathbf{u}_{j,1}, \mathbf{u}_{j,2}, \ldots, \mathbf{u}_{j,n})^{\mathrm{T}}$ is the jth linear buckling mode of the perfect SLG, $\mathbf{u}_{j,i} = (\Delta x_{j,i}, \Delta y_{j,i}, \Delta z_{j,i})$ is the three-dimensional displacement vector of the ith joint under the jth mode, and $U(-1, 1)$ is a uniform distribution on the interval [−1, 1]. The actual imperfection distribution $\Delta\mathbf{P}$ can be calculated by adjusting the amplitude of $\Delta\mathbf{P}'$, i.e.,

$$\Delta\mathbf{P} = \frac{R_{\max}\Delta\mathbf{P}'}{\max\limits_{i}\left\|\Delta\mathbf{P}_i'\right\|} \tag{12}$$

Based on numerical examples of hexagonal single-layer flat gridshells, it has been verified that the stochastic imperfection modal superposition method can achieve a lower non-linear buckling capacity compared to the random imperfection method and the eigenmode imperfection method. Therefore, the reference [38] argued that the stochastic imperfection modal superposition method could provide the *worst initial imperfection* of the structure.

Similarly, Zhao *et al*. [39] combined the consistent imperfection modal method and the random imperfection method, decomposed the random initial imperfections of the structure based on the theory of random fields, and projected them onto the standard orthogonal basis of the structural linear buckling modes. Lu and Zhang [40] proposed a method for determining the worst initial imperfection of single-layer spherical gridshells based on the convex model, where the initial imperfection is also expressed as

a linear combination of the first *N*-order linear buckling modes. Through the analysis of a Kiewitt SLG example, Refs. [39] and [40] indicated that the proposed methods could give the *worst initial imperfection* at a lower computational cost.

However, the probability distribution of the non-linear buckling capacity of the imperfect structures obtained by the above methods has not been provided, and the basic assumptions of the random imperfection method used for verification are problematic (see section 2.1), making it difficult to determine the true probability characteristics of the analysis results and to ensure that the obtained imperfection is the *worst initial imperfection*. At the same time, the number of linear buckling modes *m* involved in the combination, and the specific modes combined will significantly affect the calculation results, and artificially adjusting these parameters will lead to a significant increase in workload and computational cost.

5. Initial imperfection field simulation method considering fabrication constraints

To solve the problems existing in the above methods, we propose a simple and efficient method to generate stochastic initial geometric imperfections for SLGs considering fabrication constraints by abstracting the gridshell into an equivalent particle-spring-particle system, and introducing non-linear heuristically perturbed virtual interaction forces, as shown in Figure 4.

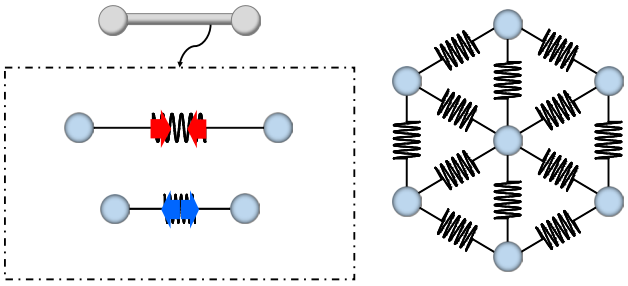

Figure 4. Illustration of the proposed method. (a) Virtual interaction forces. (b) Equivalent system.

To address the unrealistic distribution of random joints, the method assumes that the magnitude of the resultant joint deviation obeys $N_t(\mu, \sigma^2)$, while its components obey the uniform distribution. Specifically, the following procedures are used for generating the independent stochastic 3D joint deviations:

S1 Generate a unit uniformly-distributed direction vector for the *i*th joint $\mathbf{n}_i$ as

$$\begin{cases} \mathrm{d}x_i \sim U(-1,1) \\ \mathrm{d}y_i \sim U(-1,1) \\ \mathrm{d}z_i \sim U(-1,1) \\ \mathbf{n}_i = \dfrac{1}{\sqrt{\mathrm{d}x_i^2 + \mathrm{d}y_i^2 + \mathrm{d}z_i^2}} (\mathrm{d}x_i, \mathrm{d}y_i, \mathrm{d}z_i) \end{cases} \tag{13}$$

where $U(-1, 1)$ is the uniform distribution with an interval of $[-1, 1]$;

S2 Sample the amplitude of the resultant joint deviation of the *i*th joint m_i according to the truncated normal distribution as

$$m_i \sim N_t(\mu, \sigma^2) \tag{14}$$

S3 Calculate the actual joint deviation of the *i*th joint $\Delta\mathbf{P}_i$ as

$$\Delta \mathbf{P}_i = m_i \mathbf{n}_i \tag{15}$$

Considering the fabrication constraints of SLGs, we introduce virtual intercation forces (VIFs) to modify the unrealistic initial geometric imperfections pattern. The stiffness of the *j*th virtual non-linear spring K_j, corresponding to the *j*th member in the structure, can be expressed as

$$K_j = \frac{k_c}{l_{j,0} - \left| l_{j,0} - l_j \right|} \tag{16}$$

where $l_{j,0}$ and l_j are the design and actual lengths of the *j*th member, respectively; k_c is the dimensionless constant stiffness factor. This way, the VIF of the spring at the *j*th member F_j can be calculated as

$$F_j = K_j \left(l_j - l_{j,0} \right) \tag{17}$$

The complex topological relationship in SLGs can be implicitly considered by calculating the resultant virtual force at each joint as

$$\mathbf{T}_i = \sum_{j \in \Pi_i} \mathbf{F}_j \tag{18}$$

where $\mathbf{T}_i$ is the resultant virtual force vector at the *i*th joint; Π_i is the set of members connected to the *i*th joint; $\mathbf{F}_j$ is the virtual force vector of the spring at the *j*th member. Note that the magnitude of $\mathbf{F}_j$ is F_j, and its direction is along with the *j*th member.

In the proposed method, the joint coordinates in the equilibrium state are updated using the forward Euler method [41]. The joint coordinates **P** are assumed to be dependent on an artificial concept of time *t*. Furthermore, the proposed method introduced a perturbation VIF based on the firefly algorithm [42] in iterative equation expressed as

$$\mathbf{P}_i^{(k'+1)} = \mathbf{P}_i^{(k')} + \beta_i^{(k')} \Delta t \mathbf{T}\left[\mathbf{P}_i^{(k')} \right] + \alpha_i \Delta \mathbf{P}_i' \tag{19}$$

Denote $t_k = k\Delta t$ as the artificial time at the equilibrium state, in which Δt is the artificial time step and k is the iteration step. $\mathbf{P}^{(k)}$ is the joint coordinate matrix at the kth iteration step, $k' = 0, 1, 2, \ldots, k-1$. $\mathbf{P}_i^{(k'+1)}$ is the coordinates of the *i*th joint at the (k'+1)th step. Furthermore, the random time step factor of the *i*th joint at the k'th iteration step is expressed as $\beta_i^{(k')}$, which obeys $U(0, 1)$; α_i is the perturbation factor of the *i*th joint; $\Delta \mathbf{P}_i'$ is a random joint deviation vector.

To illustrate the effectiveness of the above method, 1,000 stochastic IGIs are generated for a Kiewitt-6 (K6) steel SLG using the initial imperfection field simulation method considering fabrication constraints. Its parameters are described as follows:

1) Span: L = 40 m;
2) Height-to-span ratio: f/L =1/4;
3) Number of rings: m = 8;
4) Joint system: welded spherical joints;
5) Support condition: pinned supports located at the joints along the periphery, i.e., the stochastic joint deviations are only introduced to the 169 internal joints.

The histograms of the resultant joint deviations $\|\Delta \mathbf{P}_i\|$ and the length deviations of the members Δl_j in the 1,000 stochastic IGIs generated by the above methods are shown in Figure 5.

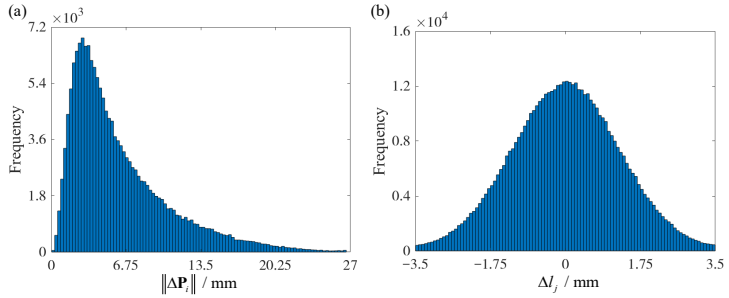

Figure 5. Distributions of 1,000 stochastic IGIs. (a) distributions of $||\Delta\mathbf{P}_i||$. (b) distributions of Δl_j.

As depicted in Figure 5, the distribution of $||\Delta\mathbf{P}_i||$ generated by the initial imperfection field simulation method considering fabrication constraints exhibits a high degree of concentration. It is also notable that the distribution of $||\Delta\mathbf{P}_i||$ generated by this method is the densest, around 2.800 mm. The amplitude of the joint deviation is taken as L/1,500 (i.e., 26.6 mm). Meanwhile, the distribution of Δl_j generated by this method is approximate to normal distribution. Manufacturing error is taken as 3.5 mm; obviously, $|\Delta l_j|$ of all members in the IGIs generated by the above method can strictly satisfy the manufacturing error constraint.

6. Conclusion

1) The random imperfection method suffers from an inherent lack of rationality in sampling the initial deviations of single joints and ignores the influence of the topology of the shell structure on the coupling relationship of the initial deviations of each joint. As this method may generate non-actual initial imperfections, although previous studies have shown good agreement between the non-linear buckling capacity values obtained and experimental results, it cannot be directly used statistically to determine the probability model of the actual buckling capacity or stability reliability;

2) The random field method considers the influence of the topology of the shell structure on the coupling relationship of the initial deviations of joints by making fundamental assumptions, thereby reducing the search range of the random imperfection method and lowering the discreteness of the obtained non-linear buckling capacity. However, this method does not directly consider the constraint effect of the topology of the shell structure. It completely ignores the initial deviation component of the joints in the plane of the shell structure while also including many simplified calculation assumptions. Therefore, although the random field method has certain theoretical significance, the probability model of the non-linear buckling capacity of the shell structure determined using this method is still not accurate;

3) The deterministic simulation method can provide a relatively conservative estimation of the non-linear buckling capacity of a structure based on physical background with lower computational costs. However, the simulated initial imperfections are not actual, and the introduced imperfection amplitude is significantly larger than the construction acceptance limit. Thus, this method cannot determine the probability characteristics of the obtained buckling capacity in the real probability distribution and cannot accurately determine the stability reliability of the structure;

4) The semi-stochastic search method can obtain the initial imperfections corresponding to relatively low non-linear buckling capacity at a certain computational cost but cannot determine the probability characteristics of the obtained non-linear buckling capacity.

5) A stochastic geometric initial imperfection simulation method that takes into account the coupling relationship between the initial geometric deviation of joints and the fabrication constraints of the structure (i.e., the influence of member lengths) is proposed. Theoretically, it has an acceptable computational cost for practical engineering applications. This method will provide a scientific

basis for improving the global stability analysis method for SLGs and a theoretical foundation for analyzing their stability reliability.

Abstract

This research investigates the possibility of fabricating shell-based cellular structures using knitting techniques. Shellular Funicular Structures are two-manifold single-layer structures that can be designed in the context of graphic statics. These are efficient compression/tension-only structures that have been designed for a certain boundary condition. Although the shellular funicular structures are efficient geometries in transferring the forces, the fabrication process is challenging due to the geometric complexity of the structure. Since Shellular structures comprise a single surface, they are suitable candidates to be fabricated using knitting technique, a method by which yarn is manipulated to create a textile or fabric. Using knitting approach, one can fabricate shellular structures with minimum production waste in which the knit can work as a formwork for actual structure or act as a composite structure combined with bio-based resin. This research proposes a workflow to fabricate shellular structures using knitting that can be scaled up for industrial purposes. In this process, the designed shellular structures are divided into multiple sections that can be unrolled into planar geometries. These geometries are optimized based on the elastic forces in the knitted network and knitted and sewn to make a topologically complex geometry of the shellular systems. After assembling the knitted parts and applying external forces at the boundaries, the final configuration of the structural form in tension is achieved. Then this form is impregnated with custom bio-resin blends from chitosan, sodium alginate, and silk fibroin to stiffen the soft knit structures into a compressed system. Although this method is an efficient fabrication technique for constructing shellular structures, it needs to be translated into an optimized method of cutting, knitting, and sewing with respect to the complexity of the shellular geometry. As a proof of concept of the proposed workflow, a mesoscale shellular structure is fabricated.

Keywords: shellular funicular structures, graphic statics, knitting, biocomposite structures

1. Introduction

The following section is divided into three primary sections. The initial section introduces a collection of spatial shell geometries known as shellular funicular structures, designed within the framework of graphic statics. The subsequent section discusses knitting structures and the historical progression of knitting techniques used in the development of shell structures. Lastly, the third section delves into

composite structures of fabric or knitting, which are subsequently solidified using synthetic or biological compunds.

1.1. Shellular funicular structures

Shell structures are thin, curved plate structures that transfer forces through compression, tension, and shear stresses that act within the surface plane. These structures have numerous applications in science, design, and construction [1–3]. As a category of cellular structures, shell cellular (shellular) structures consist of continuous, smooth-curved shells. The geometry of these structures involves a surface with minimal material, known as a minimal surface [4]. The geometry of these surfaces, found in nature such as soap films, has inspired architects and engineers to design lightweight structures [5]. At each point on the minimal surface geometry, the mean curvature ($H = k_1 \quad k_2$) is zero, and the Gaussian curvature ($G = k_1 \quad k_2 < 0$, considering k_1 and k_2 as the principal curvatures of the surface) is negative [6]. Due to their high surface-to-volume ratio and unique morphology, shells with these surfaces' geometry exhibit superior mechanical performance compared to other cellular structures, such as strut-based cellular structures [7–9].

Utilizing graphic statics as a method for structural design, designers can create structures using reciprocal diagrams while controlling the flow of force within the structure and the external loading scenario [10–14]. Polyhedral graphic statics (PGS), an extension of two-dimensional graphic statics (2DGS), enables the user to design axially-loaded structures in 3D, in which no bending occurs [15–17]. The form and force diagrams provide a clear relation between the geometry and the equilibrium of a 3-dimensional node (Figure 2a). In this technique, the form diagram (denoted by Γ) represents the reaction forces combined with the geometry of the structure while each force diagram (denoted by $\Gamma^{\dagger}$) explains the equilibrium of forces. Each strut member e_i in the form diagram is perpendicular to its corresponding face $f_i^{\dagger}$ in the force diagram. In this technique, each vertex$v_i^{\dagger}$, edge $e_i^{\dagger}$, face $f_i^{\dagger}$, and cell $c_i^{\dagger}$ in the force diagram corresponds to a cell c_i, face f_i, edge e_i, and vertex v_i in the form diagram [15]. In this technique, the magnitude of the force in each strut member is proportional to the area of the corresponding face in the force diagram. By applying different subdivisions to a force diagram, various cellular strut-based structures in equilibrium can be designed (Figure 2a-d). Adding thickness to each edge of the form diagram proportional to the area of its corresponding face results in a strut-based cellular funicular structure.

The process of increasing the number of subdivisions in the force diagram leads to a form diagram with

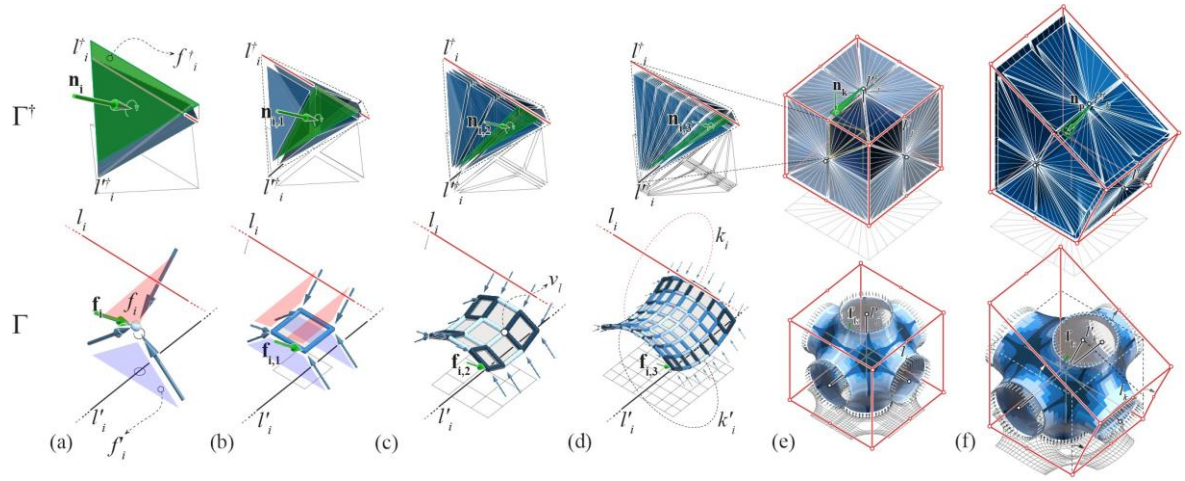

Figure 2. Iterative subdivision of a tetrahedron as a force diagram approximates a discrete surface with anticlastic curvature (a-d) as the form diagram. Using this subdivision between specific labyrinth graphs, one can design a shellular funicular structure (e) and use the labyrinths as control handles to manipulate the structure (f).

smaller edges and distributed forces in the members (Figure 2a-d). This procedure can eventually result in edges with near-zero length, approximating a surface as a form diagram. Polyhedral Graphic Statics (PGS) employs specific subdivision techniques to approximate surfaces with anticlastic or synclastic curvatures as form diagrams [9]. Figure 2a depicts a tetrahedron as a force diagram corresponding to a node in equilibrium with two upward and two downward forces as a form diagram (a node with an anticlastic curvature). This tetrahedron is produced by connecting the endpoints of the two skew lines $l_i^{\dagger}$ and $l_i'^{\dagger}$. Dividing these lines into equal segments and establishing a tetrahedron between every two skew segments from each line subdivides the force diagram into multiple tetrahedrons, resulting in a discrete anticlastic surface as a form diagram (Figure 2a-d) [9, 18]. This subdivision method is referred to as the *anticlastic subdivision*. These lines ($l_i^{\dagger}$ and $l_i'^{\dagger}$) serve as subdivision axes in the force diagram and curvature axes in the form diagram (Figure **??**d). These lines constitute two connectivity graphs known as *labyrinths*, which connect two segregated regions divided by the anticlastic surface in between [19]. By employing the *anticlastic subdivision* technique, one can design an anticlastic polyhedral surface, called a Shellular Funicular Structure (SFS) [20]. The labyrinths serve as subdivision axes in the form diagram and control handles in the force diagram, simplifying the design process and manipulation of the SFSs form-finding technique [18].

1.2. Knitting Structures

Historically, textiles have been a primary material used to develop fully tensioned structural systems. Knitted textiles, one of the many types of textiles, are created by producing loops with a continuous yarn and pulling that yarn through previously formed loops to create new ones. The resulting loops, or stitches, can be manipulated to form different stitch structures depending on the movement of the yarn. The structure of a knitted fabric is determined by the shaping of stitches, the manipulation of yarns, and the type of knitting machine used to create it. Knitted textiles have unique properties that make them suitable for developing complex and 3D shapes due to their multi-directional, heterogeneous and anisotropic characteristic [21]. Knitted textiles have been used in developing tension structures [22–25],

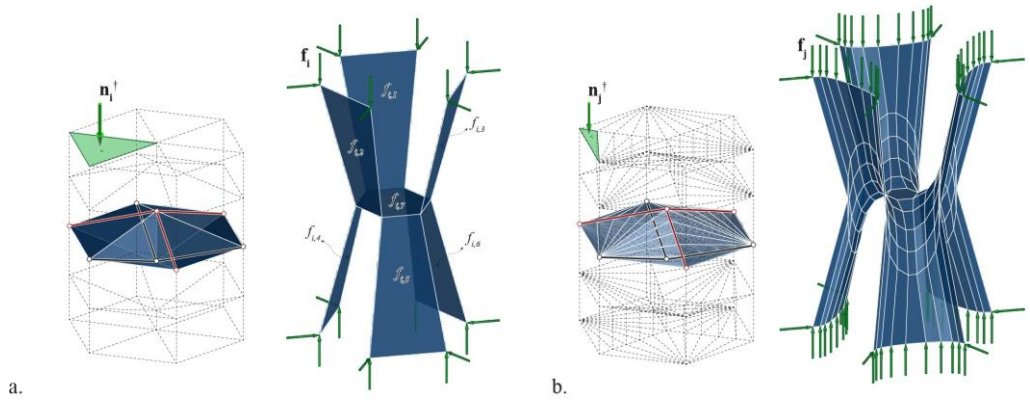

Figure 3. Designing a low-resolution (a) and high-resolution (b) of the force and form diagram of a shellular structure.

as well as in connection with concrete as a formwork system [26–28].

1.3. Biocomposite structures

Materials such as silk, shell, chitin, cellulose, or bone present internal hierarchical configurations that confer stiffness, flexibility, and buckling resistance unmatched by man-made materials [29, 30]. Recent research in chemical and biomedical engineering has derived new synthesis methods to extract these materials from the natural structures they produce such as insect cocoons or shrimp shells [31, 32], and reverse-engineer them as water-based raw biopolymers to make new structures such as drug delivery micro-devices, tissue scaffolds, resolvable electronics, small object casts, and natural adhesives [33, 34] that are not only biocompatible to the human body but also able to be naturally decomposed. As in nature some of these materials perform as bio-resins binding together minerals and proteins into organism structures, we explore here if they could substitute toxic man-made synthetic resin compounds that are widely used as stiffeners of woven fiber structures (i.e epoxy, vinylester, or polyester resins used on carbon fiber, fiberglass, and aramid fiber). In this work we used simple polysaccharides and proteins extracted from shrimp shells, algae cell walls, and silk cocoons, because of their biodegradability, strength, and flexibility properties, their compatibility with natural fibers of wool, cotton, and linen that compose our knits, and their proven ability to be precisely distributed in large additive manufacturing platforms as developed in our previous work [35, 36].

1.4. Problem statement and objectives

Shellular funicular structures are highly efficient structures designed for a specific boundary condition. However, their fabrication process can be challenging due to their geometric complexity. Shellular structures, consisting of a single surface, are suitable for fabrication using the knitting technique, a process used to manipulate yarn to create fabric. Knitting can minimize production waste while serving as a formwork or composite structure, when combined with bio-based resin. This study proposes a workflow to fabricate shellular structures using knitting and scale them up for industrial purposes. The process involves dividing the designed shellular structures into sections that can be unrolled into planar geometries. These geometries are optimized based on the elastic forces in the knitted network and stitched together to form a topologically complex shellular system. After assembling the knitted parts, external forces are applied to achieve the final configuration of the structural form in tension. The form is then impregnated

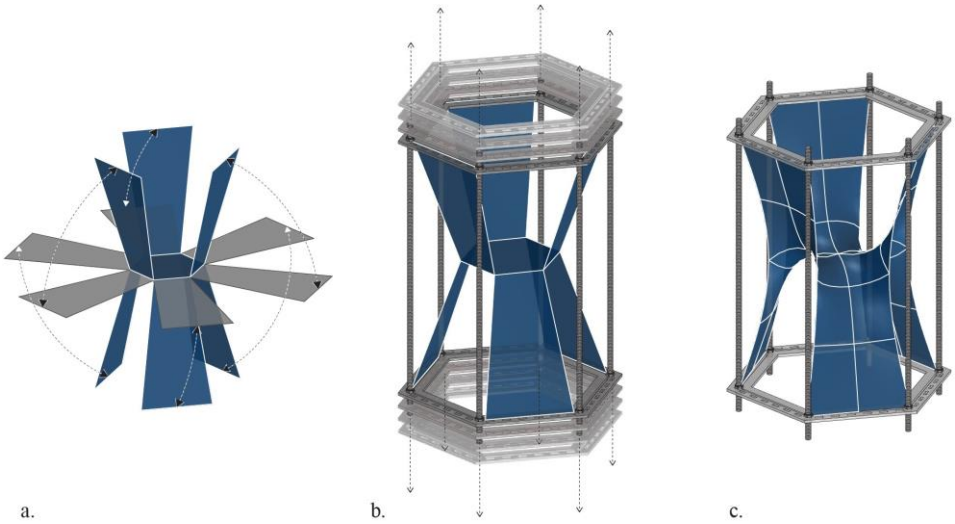

Figure 4. Unrolling the low-resolution shellular structure (a), and holding it using a jig (b). Turning the screws in the jig controls the height of the knit structure, assuring that the structure is in tension (c).

with custom bio-resin blends made from chitosan, sodium alginate, and silk fibroin to stiffen the soft knit structures into a compressed system. Although this method is efficient, an optimized method for cutting, knitting, and sewing must be developed to match the complexity of the shellular geometry. To demonstrate the proposed workflow's viability, a mesoscale shellular structure has been fabricated as a proof of concept.

2. Methodology

In this section, first, the process of designing a shallular structure for specific boundary conditions has been explained. In the next sections, this structure will be knitted and impregnated using bio-based materials. In the next section the knitting process will be explained through three different trials. In the last section, the biomaterial-based stiffening through different impregnation technique will be explained.

2.1. Shellular structural design

In order to develop a form for the structure in tension, shellular method in the context of graphic statics have been used [20, 37]. A rectangular prism (h:25 cm, w,l:20 cm) has been considered. Figure 3a displays the force diagram (left) corresponding to a structure comprising 30 edges, 7 faces, and 24 reaction forces. It is worth mentioning that the labyrinths graphs have been marked with black and red in the force diagram. Faces in the form diagram corresponding to these graphs have been removed in order to result in a 2-manifold structure [9]. To generate the form diagram, after designing the labyrinth graphs, a tetrahedron has been constructed for each pair of labyrinths (red and black labyrinths that are in a skew position together). This force diagram results in a low-resolution shellular funicular structure. The shellular structure with the higher resolution has a smoother surface along with a higher number of faces. In order to increase the smoothness of the structure, each labyrinth edge is subdivided into smaller segments, and a tetrahedron has been constructed between smaller edges in the force diagram (Figure 3b). In fact, each tetrahedron in Figure 3a is subdivided into 25 tetrahedrons in order to result in the force diagram in Figure 3b. This force diagram corresponds to a smooth form diagram, representing a shellular funicular structure.

In order to construct the geometry out of knitting, one needs to unroll the shellular structure to the *XY plane*. Due to the ease of unrolling the first form diagram prior to smoothing, the authors made the de-

cision to unroll the form diagram consisting of seven faces. In this process, faces $f_{i,1}$, $f_{i,2}$, $f_{i,3}$, $f_{i,4}$, $f_{i,5}$, $f_{i,6}$ (Figure 3a), have been rotated along one of their edges in order to unroll the whole structure (Figure 4a). Using an elastic material for constructing this structure and tensioning it would result in a smooth structure, approximating the form diagram in Figure 3b. To apply tension to the structure, a jig comprising two flat panels and 6 screws have been constructed (Figure 4a). The screws will give the user the possibility to control the height of the structure, assuring that the whole knitting structure is in tension (Figure 4b).

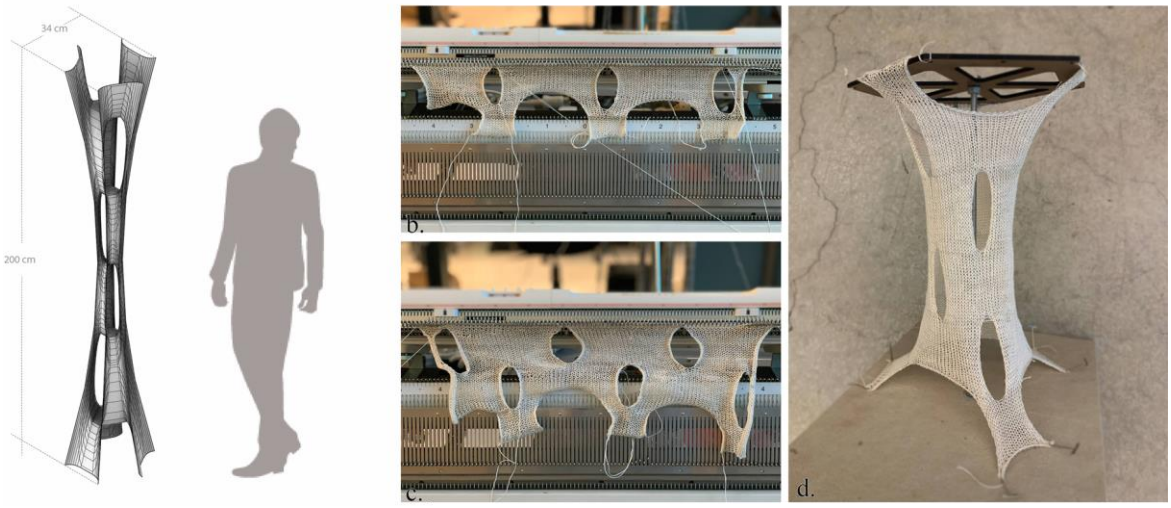

Figure 5. Trial1, The geometry of a shellular funicular structure (a), the knitting fabrication of a shell (b,c), and the tensioned model of it (d).

2.2. Knitting technology

The knitting process design for the shellular knit structure involves a series of trials aimed at achieving a seamless surface. The initial trial involved making a planar surface with holes, with the goal of making the entire surface seamless. However, the first attempt did not result in a shellular structure. For the second trial, a rough representation of the overall form was used, which was then unrolled as a seamless flat shape. The stitches were then generated over this flat shape and knitted. The knitted unrolled seamless flat shape was then sewn together to give an overall shape to the knitted textile. The rough 3D knitted structure was then tensioned to obtain a smooth tensioned structure. However, the model did not precisely replicate the digital model. Therefore, in the next step, efforts were made to increase the accuracy of the initial shape that should be knitted to achieve the final shape. At this stage, the focus was on only a portion of the overall form.

2.2.1. Trial 1

In the initial attempt, the focus was on creating a planar surface with holes (Figure 5). The aim of this trial was to knit the exterior skin first, and then add the interior planar surfaces. However, in this method, the exterior and interior surfaces were not connected and required more sewing to achieve the desired 3D shellular shape. This approach proved to be less efficient and required more effort and time to achieve the desired result. Therefore, further trials were conducted to explore alternative methods to create the shellular structure more efficiently and with fewer seams.

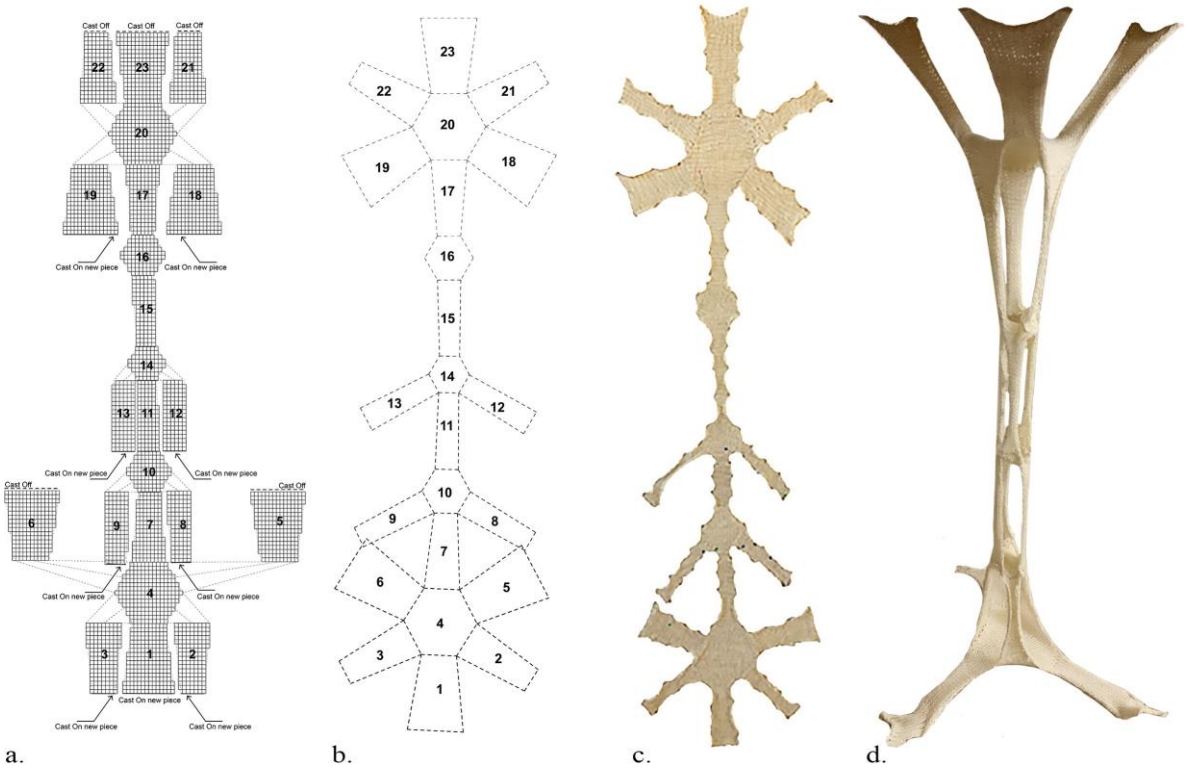

Figure 6. Trial 2, Sequence of knitting (a), distribution of stitches (b), knitted form pattern (c), and the knitted structure in tension.

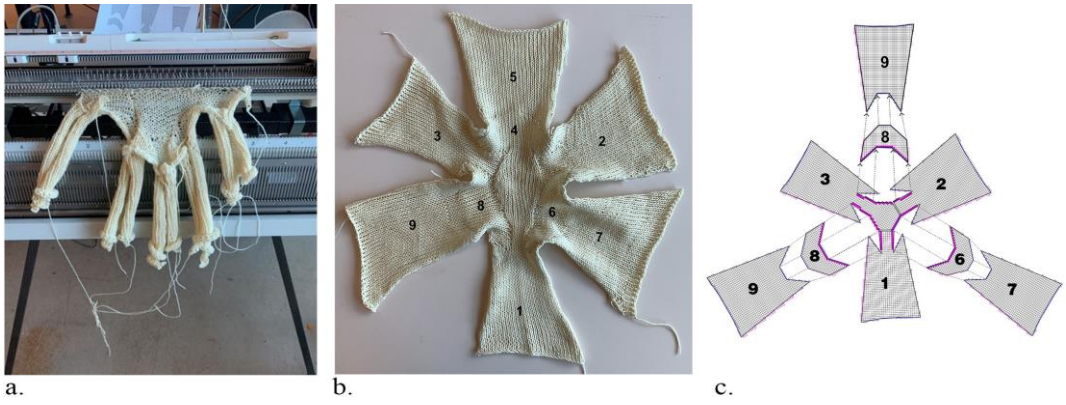

Figure 7. Trial3, sequence of knitting for the main alternative.

2.2.2. Trial 2

In the second trial, the authors aimed to improve the seamless feature of the shellular knit structure. To achieve this, the whole structure (Figure 5left) was unrolled and a single connection between the hexagons in the middle of the structure was ensured. The process involved creating a seamless flat shape and generating the stitches over this flat shape. The objective was to create pieces with the knitting direction pointing towards the center of the hexagon. This was considered crucial as the direction of knitting plays a significant role in determining the behavior and performance of the textile. It was important to achieve a consistent behavior throughout the entire structure. Therefore, special attention was given to the direction of knitting during the fabrication process to ensure a more uniform and reliable behavior of the knitted textile. In addition, by ensuring a consistent knitting direction, the

overall aesthetics of the structure were also improved, resulting in a more visually appealing end product. Figure 6 show the pro- cess of the knitting and after knitting the whole structure, in which the legs were sewn to the hexagon to obtain a rough 3D shape. This figure includes the unrolled diagram, distribution of the stitches, sequence of the knitting of different parts of the model, and the knit model in tension. By following this sequence, the authors were able to create a knitted shape that was more closely aligned with the digital model.

2.2.3. Trial 3

In order to achieve a higher degree of accuracy, the structure that is explained in section 2.1 is knitted. This structure is a portion of the structure displayed in Figure 5left, which is magnified in order to result in a more accurate model. The boundary shapes of this piece were then generated using a more precise digital model, and the stitches were generated accordingly. This approach aimed to improve the accuracy and consistency of the knitted structure, resulting in a more reliable and efficient end product.

2.3. Biomaterial-based stiffening

Biomaterials used as bio-resins here are chitosan from shrimp shells, sodium alginate from algae cell walls, and Fibroin protein from silk cocoons. Silk Fibroin solution was produced by Canon Virginia Inc. Chitosan (medium molecular weight at 85% deacetylation) was purchased from TidalVision Inc. Acetic acid, glycerol, and sodium alginate were purchased from Sigma-Aldrich (USA). Fibroin aqueous solutions at 7%w/v combined with sodium alginate at $4.5\%w/v$ as well as Chitosan at 4%w/v in 3%w/v acetic acid in gel solution are both blends used as homogeneous stiffeners throughout all knit samples (Figure 9). A blend of silk Fibroin at 7%w/v combined with sodium alginate at $4.5\%w/v$, natural coloring, and glycerol is used to additively manufacture targeted stiffening. To impregnate these blends onto knitted forms, casting and printing methods are used. Casting is based on spatula distribution of pre-measured biomaterial quantities according to surface area and knit thickness. Printing is performed with our exiting custom platform [35, 38]: a 3-axis computer numerically controlled (CNC) system with a 1x1m print bed that positions a pneumatic extrusion system in space. Toolpaths are designed in Rhinoceros3D® computer-aided design software and machine instructions are translated into custom Gcode via *C#* scripts. Positioning instructions are interpreted and sent via Serial Port JSON Server to the 3-axis CNC system. Extrusion machine instructions are sent via Serial Port to a dispense valve controller and precision valve using a $1.5mm$ inner diameter nozzle at 10PSI and receiving materials from 100PSI pressured reservoirs.

3. Results

The authors commenced their study by conducting experiments on stiffened knitted pieces composed of linen, wool, or cotton, as illustrated in Figure 9. Each of these materials was knitted in sparse and dense versions. The linen pieces were impregnated with Chitosan or Chitosan + Fibroin (Figure 9 S.01 - S.03). The wool pieces were impregnated with Fibroin + Alginate or Chitosan + Fibroin (Figure 9 S.04 - S.06). Lastly, the cotton pieces were impregnated with chitosan (Figure 9 S.07 - S.08). All specimens were subjected to loading after impregnation, and their loading capacity is presented in Figure 9. Based on the experimental results, the primary knitted structure shown in Figure 7 was homogeneously stiffened

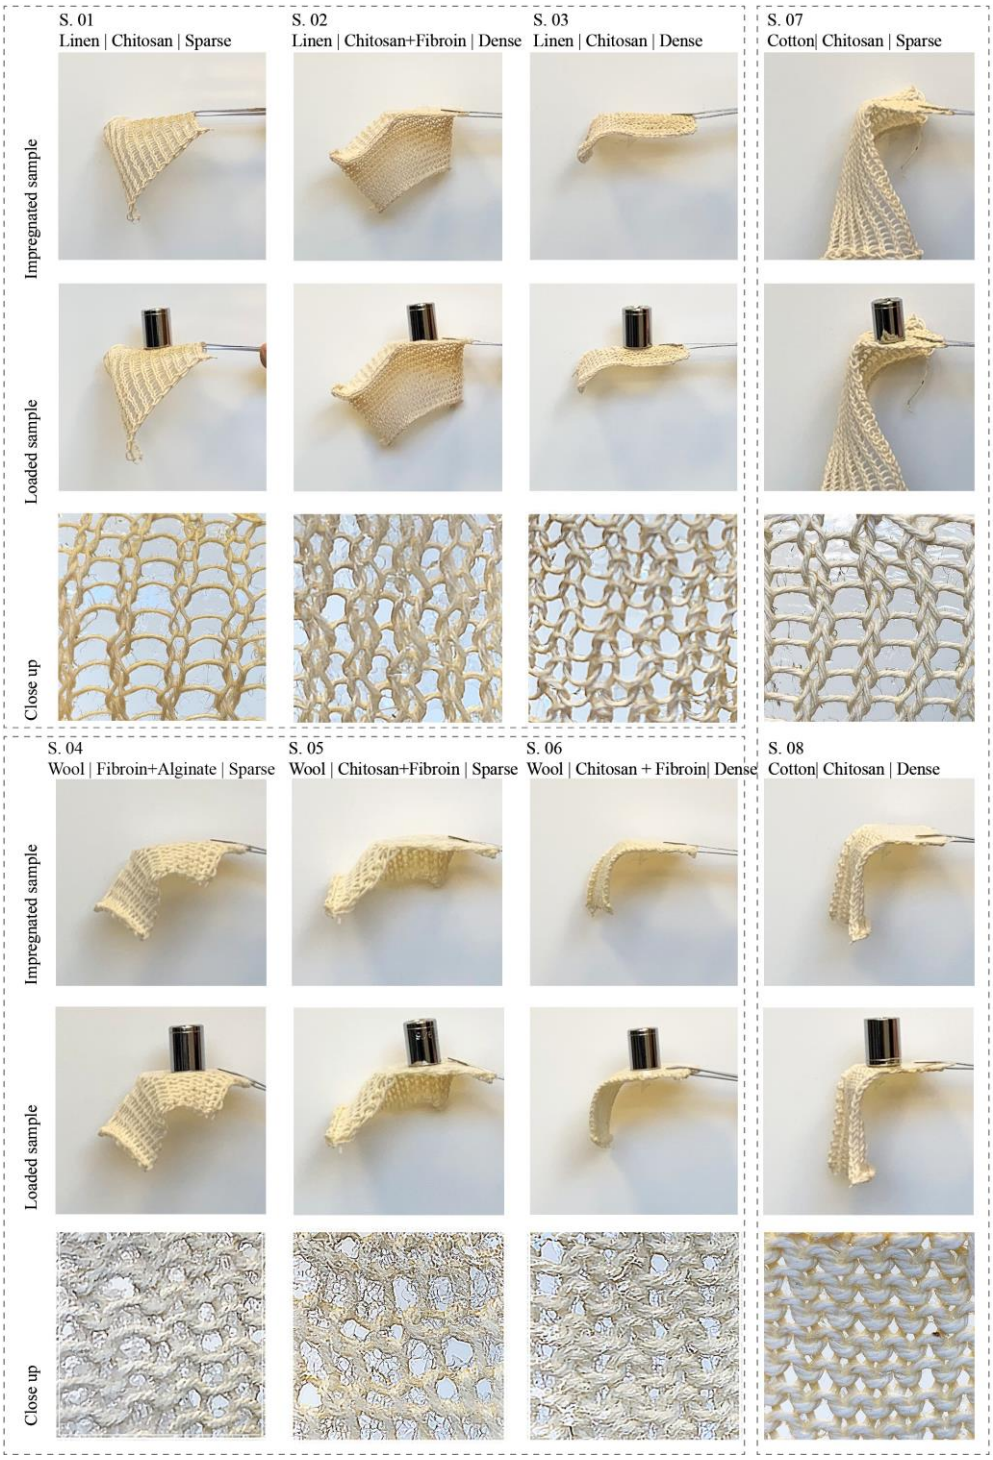

Figure 8. Biomaterial-based Stiffening of the knitting samples, in this experiments only half of the knit is impregnated in order to compare the stiffness of the rigid part with the part that is draped.

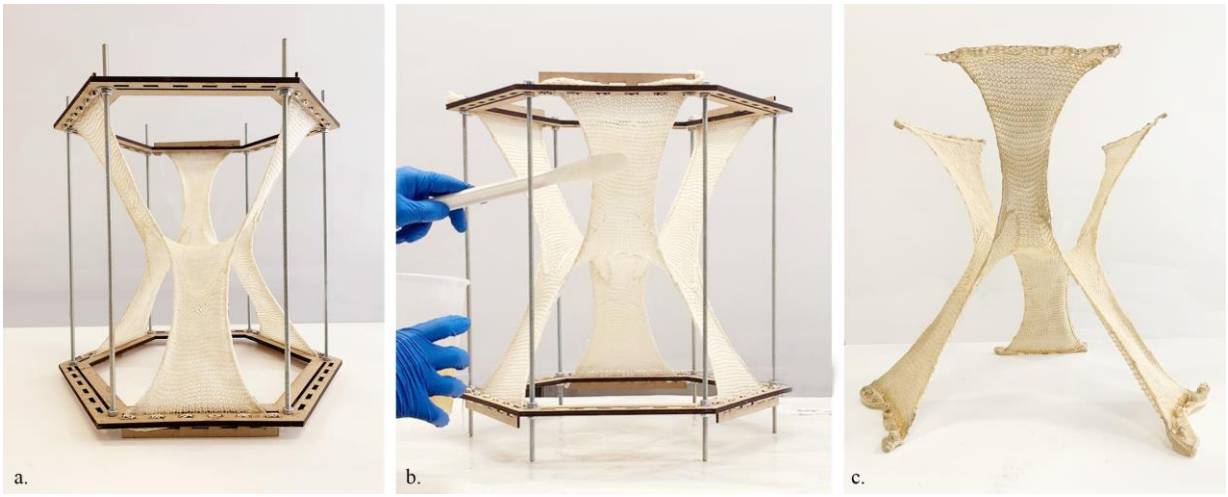

Figure 9. Biomaterial-based homogeneous stiffening of a knit structure: applying tension to the sample on the jig (a), impregnating the sample (b), and final structure after drying (c).

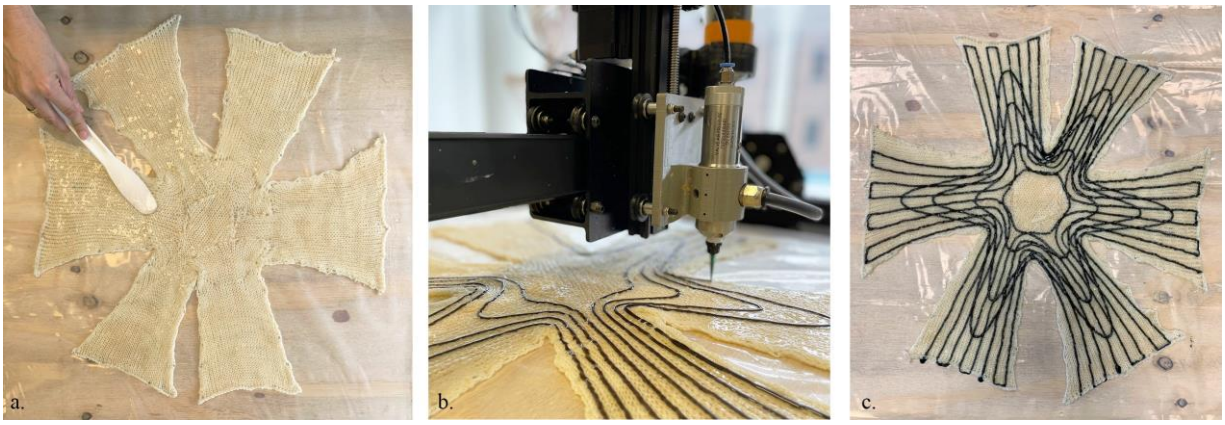

Figure 10. Biomaterial-based targeted stiffening; by impregnating the whole structure with a homogeneous Chitosan base layer (a), then printing a Fibroin-based stiffening toolpath on top (b), resulting in fully impregnated piece with expected differential behaviour (c).

by impregnating sparse wool knit with a blend of Chitosan + Fibroin (silk fibroin at 7%*w/v* combined with chitosan at 4%*w/v*) in the subsequent stage, and the model was held under tension in the jig. After one day, the dried model was loaded and its structural capacity was evaluated. In the final stage, targeted heterogeneous stiffening was performed the same knitted model in Figure 7, a base impregnation of Chitosan (at 4%*w/v*) was followed by an additively manufactured layer of Fibroin + Alginate blend (using in this case silk fibroin at 7%*w/v* combined with sodium alginate at 4.5%*w/v*, natural coloring, and glycerol to optimize the blend for our printing technology). Given that the smooth version of the model in Figure 3a is depicted in Figure 3b, the pattern of the smooth model has been applied and projected onto the model prior to smoothing. In fact the pattern that is printed on the model displays the force flow of the smooth version of the model. This pattern would increase the material in places that we need, improving the structural capacity of the system. Figure 11 displays the process of global stiffening (with a clear Chitosan gel) and local targeted stiffening of this specimen (with black silk fibroin blend). In this process a 3-axis computer numerically controlled (CNC) system with a 1x1m print bed has been

used to print the pattern on top of the knitted piece. Final experimental results display that both global and local impregnation of the knitted structures results in a stiff structure with specific structural capacity. It is noteworthy that the structure depicted in Figures 7 requires an identical boundary condition to the one it has been designed for, to attain adequate structural capacity. Consequently, several tension ties are necessary at the top and bottom of the structure to reinforce it.

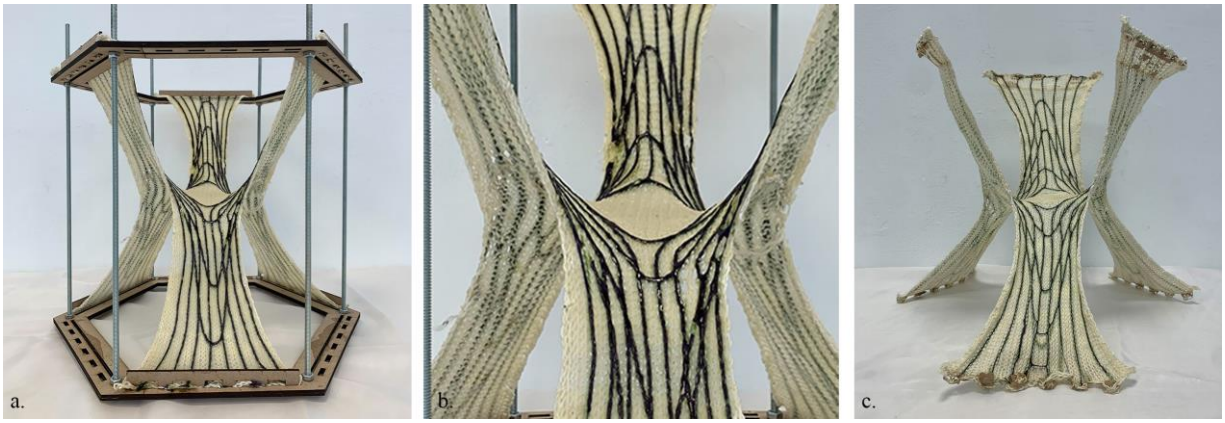

Figure 11. Biomaterial-based targeted stiffening.

4. Conclusion and future work

This research investigated the possibility of fabricating shell-based cellular structures using knitting techniques. The research proposed a workflow to fabricate shellular structures using knitting that can be scaled up for industrial purposes. In this process, the designed shellular structures are divided into multiple sections that can be unrolled into planar geometries. These geometries are optimized based on the elastic forces in the knitted network and knitted and sewn to make a topologically complex geometry of the shellular systems. After assembling the knitted parts and applying external forces at the boundaries, the final configuration of the structural form in tension is achieved. Then this form is impregnated with custom bio-resin blends from chitosan, sodium alginate, and silk fibroin to stiffen the soft-knit structures into a compressed system. In forthcoming research, it is crucial to concentrate on numerically assessing the structural efficacy of each structural specimen and contrasting it with experimental testing. Furthermore, it is imperative to concentrate on structures with greater dimensions, whose structural efficacy must be examined under actual loads.

Sheng223@mit.edu

Abstract

Compared with metal, glass, wood and most other building materials, carbon composite materials offer a new paradigm by enabling the production of building components with complex shapes. As a construction material for shells, composite materials have outstanding structural and mechanical properties, such as light weight, high strength, high stiffness, fatigue resistance, strong durability, and corrosion resistance. They provide architects and engineers with new possibilities for design and construction modes. This paper reviews previous literature on composite fabrication and discusses its application in shells and structures. The structural properties and fabrication methods of composite materials are studied, and digital design technologies are discussed. An evaluation index system is offered for sustainability of composite projects from the perspectives of ecology, society, and economy. This paper offers a material perspective into shell and structural design and proposes the wider use of composite materials in urban environments.

Keywords: carbon composites, mechanical property, structural design, building industry, overview

1. Introduction

For more than 160 years, industrialized production and construction have reshaped the human living mode [1]. With urban expansion and population growth, the challenges brought by the climate crisis are becoming increasingly obvious. We need to rethink construction materials and technologies to improve the resilience and climate adaptability of human settlements. Many landscape architects and urban planners have attempted to mitigate climate change through the allocation of green space and vegetation, which absorbs CO_2 (carbon dioxide) from the atmosphere. However, the CO_2 emitted using various hard construction materials may exceed the CO_2 absorbed by green plants, so that the ecological benefits brought by greening cannot offset the energy cost of these traditional materials [2]. In addition, the buildings contribute to almost one third of the global greenhouse gas emissions annually, making it one of the primary sources of the greenhouse effect [3].

"Carbon footprint" refers to the total greenhouse gas emissions directly or indirectly caused by buildings from the material production, building construction, and use until the end of the life cycle of the materials [4]. The annual CO_2 emissions from the manufacturing of building materials are 18629 tons, of which the manufacturing of concrete and cement is the main cause of CO_2 emissions, accounting for 46% of the total CO_2 emissions of building materials [5]. Figure 1 shows the CO_2 emissions per functional unit of timber, aggregate, asphalt, steel, and concrete [2]. To mitigate the impact of greenhouse gas emissions and global warming, it is necessary to minimize energy consumption and CO_2 emissions at all stages of human settlements planning, to reduce the negative effects of the construction industry [6,7]. Thus, sustainability has been the key issue in architectural design, and "nature positive development" can help mitigate climate change and foster energy-saving effects [8, 9]. In 2014, the Intergovernmental Panel on Climate Change (IPCC) proposed measures to reduce building energy consumption and greenhouse gas emissions. Low-energy and low-carbon building materials are used to

improve the durability of building components and the efficiency of water supply, cooking, lighting, electrical equipment and heating and cooling systems [10].

In the process of architecture and landscape construction, the use of building materials is the main factor that determines its impact on the environment [2]. Nanotechnologies and novel forms of materials including carbon composites, new alloys, ceramics, and metal assist in the innovative architectonics in modern architecture [11]. Considering the possible environmental impact caused by the doubling of the buildings and infrastructure in 2050, Goulthorpe (2019) put forward a new carbon material approach, which suggests using carbon-based building materials derived from methane pyrolysis for civilizational scale construction [12]. New forms of carbon materials are applied to the facade and structure of buildings to replace concrete, cement, steel, copper, aluminium, and other traditional building materials with high energy consumption. Goulthorpe (2019) advocates that this kind of material can be applied not only in residential houses, but also in other buildings and landscape infrastructure in urban environments, including bridges, parks, and irrigation systems. As a lightweight material, carbon composite has outstanding structural and mechanical properties, which can be used to build lightweight structures with beautiful shapes to achieve sustainable design goals. Just like the revolutionary impact of the steel structures on modern buildings in the 19th century [13], carbon materials have great application potential, which can promote innovation in architectural design concepts.

This paper gives an overview of the application of carbon composite materials in architectural design, and the framework of this review can be divided into three sections: 1) analysing the energy-saving characteristics of carbon composite materials compared to other construction materials; 2) discussing the properties and forms of carbon composite materials; and 3) investigating the fabrication and design methods of carbon composite materials. The objective of this paper is to summarize the main advantages of carbon composite materials in buildings and illustrate their potential for wider applications as a new paradigm for construction.

2. Research methods

A search for previous literature on the use of composite materials in the building industry was conducted on Web of Science, with four criteria: 1) the crossing keywords of "carbon composites" and "building design"; 2) publication year: 2013 to 2023; 3) language: English; 4) document type: article or book chapter. As the search result, 612 papers were found on Web of Science and VosViewer was used to analyse the co-occurrence of keywords from 2013 to 2023, with the minimum number of keywords co-occurrence as five. Figure 2 shows hot spots of "composites", "performance", "design", "carbon", "graphene" and "nanocomposites", and judging from the colours of keywords and their linking lines, most keywords fell in the time range from 2016 to 2020. The citation sources of the papers under this topic were also analysed (Figure 3). Then, we selected papers that are most relevant to our work and categorized them into the three sections defined in the introduction.

3. Properties and forms

3.1. *Energy-saving characteristics of carbon composite materials*

3.1.1. Reducing the overall mass of the construction materials

Embodied energy refers to the energy of all materials used in buildings and technical installations, as well as the energy generated during the construction and renovation of buildings [14]. The magnitude of the embodied energy of materials is affected by factors such as the difficulty of developing natural resources, the properties of raw materials, material preparation and processing technology, and the distance between materials and building sites [15]. In the process of preparing and using carbon composite materials, the energy in hydrocarbons (oil/natural gas /coal) stored in nature is converted into the embodied energy of the materials [16]. Although carbon composite materials have higher embodied energy compared with concrete, steel, metal, wood, ceramics, and other building materials, they have a lower specific weight and require less energy to achieve the same tensile strength, so they are more material-saving. How to offset the high embodied energy through the energy-saving effect of carbon composite materials poses a challenge in material manufacturing and deserves further inquiry [17].

3.1.2. Recyclability

There are two ways of recycling carbon composites: physical recycling and chemical recycling [17]. In physical recycling, after the construction is completed, the materials are removed and recycled, and the fiber-reinforced polymer is cut and ground into small elements for use in new composite materials. The other is the chemical method, which decomposes the composite materials and dissolves the matrix through heating or chemical treatment [17]. The fibers and resins obtained by pyrolysis, fluidized bed combustion, chemical and enzyme circulation have little mechanical damage, and these materials can be used to form new composites [18].

3.1.3. Life cycle assessment

Life cycle assessment uses quantitative indicators to measure the impact of materials on the environment throughout their life cycle [14]. For buildings, the system shown in Figure 4 describes the energy required to maintain the structural and functional integrity of the building throughout its life cycle, including the extraction of raw materials, the manufacture of building components, the transportation and placement of building materials, the installation of building components, the operation of building equipment, and the energy consumed by disassembly, disposal, and recycling after the end of functional use. Building materials are a very important factor, and various elements should be integrated to consider the energy input and output at all stages of the life cycle [19].

The initial embodied energy of building materials can account for a considerable proportion of the energy cost of a building, ranging from as low as 13% to as high as 50% [16]. The specific proportion is related to the scale, purpose, material type, operation efficiency and service life of the building, as well as the local climate and resources [14]. Compared with traditional building materials with high energy consumption, the embodied energy of high-performance building materials accounts for a larger proportion of the total energy cost of buildings. These materials can improve the use efficiency of buildings, to reduce the energy consumed by buildings in the operation and maintenance stage and control the total energy cost over the whole life cycle [17].

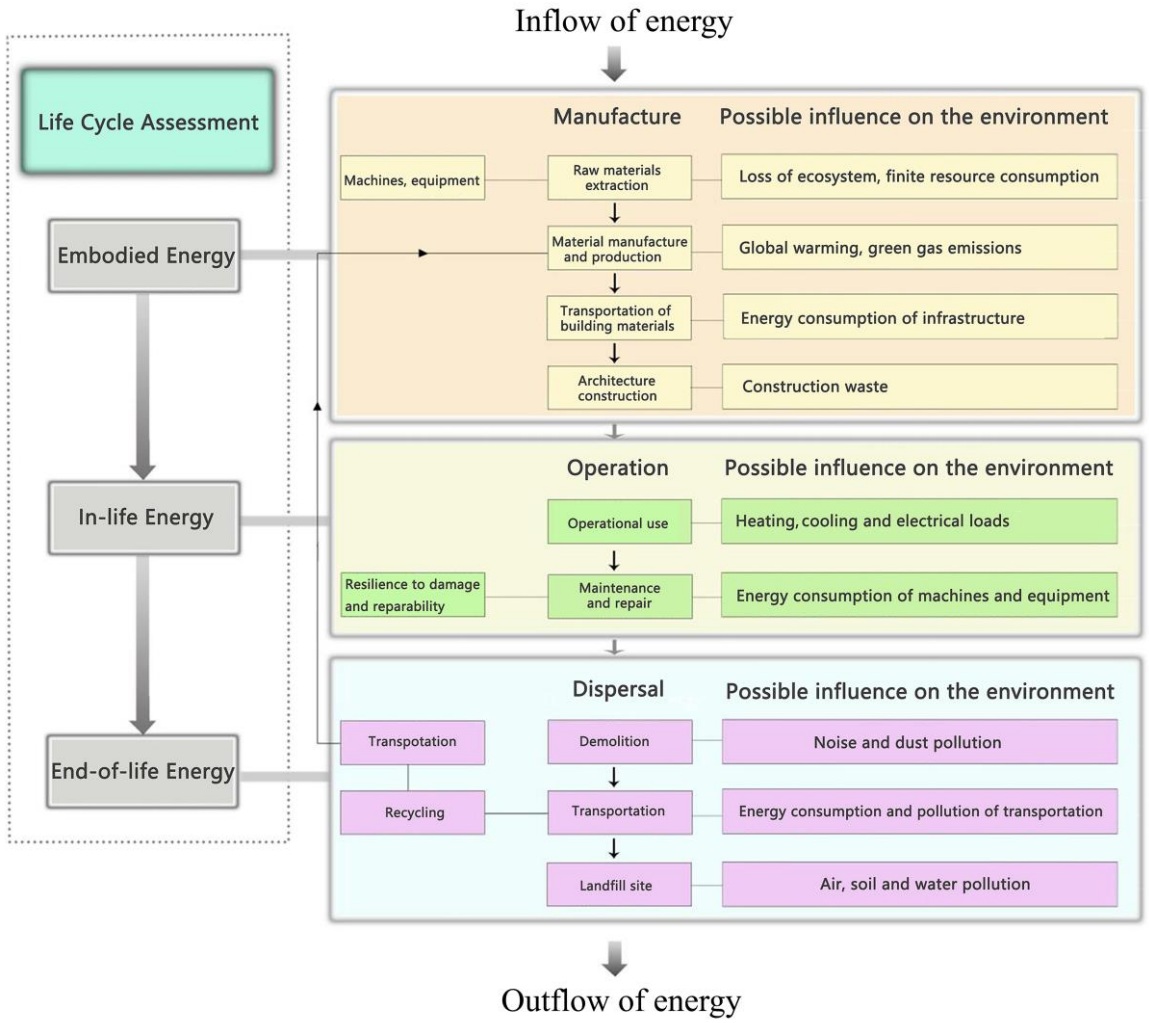

Figure 4. Life Cycle Assessment.

Source: Q. Truong (2020).

3.2. *Mechanical and structural properties*

3.2.1. High specific strength

The specific strength, also known as the strength/weight ratio, is the ratio of the tensile strength of materials to the apparent density of materials and is also an important index affecting the use efficiency of materials [17]. The specific strength of carbon fiber is 2457 NM/ kg [20]. Due to the special composition and connection between carbon fiber and resin matrix, the specific strength of carbon fiber composites is much greater than that of wood, concrete, steel bars and aluminium alloys. Generally, when comparing the strength of materials with the same thickness and size, the weight of fiber reinforced polymers (FRP) composites is one-seventh of that of steel and one half of that of aluminium [17]. In the appropriate interface, structure, and equipment of the building, replacing concrete, cement, metal, and other materials with lightweight, low-energy, high-strength carbon fiber composites will effectively reduce the total use of building materials and the energy contained therein, and make the building lighter and stronger [21]. When carbon fiber composites are used in long-span structures, the self-weight of the structure can be greatly reduced. For example, the self-weight of the whole carbon fiber roof of Jobs Theater is only 80t, which can be constructed by integral hoisting [22].

3.2.2. High durability

Carbon composites are corrosion-resistant and easy to maintain and clean [23]. This material has a variety of connection methods including bolting, and the light weight makes it easier to disassemble and assemble [24]. Due to the exceptional durability of the materials, the service life of the building is long, and the purpose of saving materials is achieved [17]. Considering the multitude, redundancy, and open-ended control of fiber reinforced polymers (FRP), the structures show higher resilience to geometrical errors at the local site and could return to stable state [25].

3.3. *Different forms*

The carbon composite forms discussed in the literature can be classified into several types: fibers, matrices, foams, sheets, fabrics, tapes, and carbon nanotubes, etc. FRP composite materials have three main characteristics: textile parametric variability, self-organization, and resilience, and can be built into linear elements and surface elements, enabling elegant architectural expression [25]. The CFRP sheets and fabrics are structural applications and manufacturing composite parts for aerospace, automotive, marine and sports industries. The CFRP bars, tapes, and strips are commonly used for reinforcement, repairs or strengthening applications [17].

4. Fabrication methods and design possibilities

4.1. *Carbon composites and related digital design and manufacturing tools*

Burry and Burry (2010) review 46 exemplary projects in computational design and delineate the interconnection between mathematical principles and parametric language in architectural forms [26]. Compared with metal, glass, wood and most other building materials, carbon composites can form and produce building components with complex shapes and improve the overall structural efficiency by increasing the structural spans. Through parametric design, intelligent construction and robotic manufacturing, new morphological logic can be obtained, and nonlinear components can be manufactured. Thus, architects will have wider design possibilities.

At present, carbon fiber weaving and 3D printing have created new manufacturing processes. For example, the technology of manufacturing continuous fiber composites with three-dimensional lithography 3D printing technology [27] can achieve high technical efficiency. The biomimetic design research conducted by Menges and Knippers (2015) has investigated the fiber tectonics in biological structures and transferred the fibrous morphology into architectural components, forming tectonic articulation in structural design [28]. The shape of the ITKE Research Pavilion has been compared to that of spider webs, and its fabrication process entails the assemblage of glass fiber shell and carbon fiber rovings. Supported by the Institute for Computational Design (ICD) and the Institute of Building Structures and Structural Design (ITKE) at the University of Stuttgart, the biomimetic shape forming research based on fiber composites integrates the computation, simulation and fabrication skills and exploits the structural and morphological potential in the inner shapes of nature. The tectonic philosophy behind this series of projects renders the fibrous composites as active and adaptive agents of shape formation rather than passive substances. Lee and Xie (2021) helped define the curve design parameters in the architectural forms and classified the elastic-ruled surfaces into five types: planar form, tabular or closed strip form, open surface, self-intersected and connected surface [25].

4.2. *Building components for energy conservation and environmental protection*

Carbon composites have outstanding mechanical structural properties and can be used to manufacture building components. In addition, they also have heat insulation, waterproofing and other properties. They can be used to build the envelope and equipment of residential or other light building structures, including wallboards, shells, roofs, doors and windows, structural systems and so on [17]. New material

manufacturing forms have been developed based on carbon fiber composites, including board structure, window frame, carbon solar skin, carbon nanotube structure, LED lamps and carbon nanotube lighting, carbon foam materials, etc. These materials show the application potential of carbon fiber composites, offering a variety of material characteristics for the construction of multi-functional "all carbon housing" [12]. For example, the roof of the penthouse called "Bankside Paramorph" next to the tower of Tate Modern apartments in London is composed of 16 light carbon fiber sheets, and the glass is assembled on the structural components [29]. The low thermal conductivity, opacity and vivid structural aesthetics of these plates make the shell of the attic roof innovative in structure and function. Similarly, Startink systems is also developing a modular composite system for building low-cost, energy-saving houses. The system connects a series of composite plates by bolts to realize rapid assembly. This design concept can provide more economical and environmentally friendly housing in developing countries and provide permanent or temporary housing [30].

4.3. *Reinforcement of ancient wooden buildings*

Carbon fiber composites can not only be used to build lightweight structures, but also to strengthen the main structure of bridges and historical buildings [31]. The Chinese ancient architectural heritage is a valuable resource that needs to be developed. Carbon fiber composites can be used for the restoration of ancient buildings in characteristic cultural sites, strengthening beams, columns, purlins, arches, and other wooden components [32]. Compared with wood, carbon fiber composites have the advantages of fire prevention, water resistance, chemical corrosion resistance, light weight, and good flexibility [33]. Properly combined with the wooden structures, they can help express cultural themes in regional landscape design. Meanwhile, this choice of material can greatly save natural wood and reduce damage to the environment.

5. Discussion

5.1. *Challenges*

Admittedly, carbon composites are not perfect choices for all construction applications, and as a result, the architects should take the following limitations of composite materials into consideration: 1) low thermal mass [34]; 2) high rigidity and stiffness [35]; 3) in-plane and through-thickness properties [36]; 4) structured randomness [25]; 5) complicated failure mechanism [34]; 6) influence of human factors [37]; 7) fire performance limitations [38]; 8) high cost [35]. For example, during the design and manufacturing process, despite the organized design principles, complexity still arises from the structured randomness and the internal configuration [25].

5.2. *Index framework for sustainability*

According to Truong (2020), architecture design is closely related to social, humanistic, ecological, and economic aspects of urban life. Therefore, the evaluation system for the sustainability of architecture and landscape should be composed of ecological, social, and economic considerations, among which the ecological benefits outweigh the others. Table 1 shows the index system for the sustainability of carbon composites, which embodies three aspects of sustainability, six levels of values, and 19 design goals for the projects [17]. The advantages and disadvantages of building projects can be assessed within the parameters in this table, and the related concerns can also be addressed.

Table 1. Sustainability evaluation index framework.

Sustainability	Evaluation	Design goals
Ecological	Basic properties of materials	Carbon footprint Life cycle Embodied energy Durability
	Energy consumption	Recycling and reuse of resources and materials Electric and thermal energy consumption Energy performance
Social	Climatic adaptability	Carbon dioxide emissions reduction Rainwater recycling Efficient use of solar energy
	Cultural impacts	Modern and regional expression Technical and aesthetic values Environmental behavior and psychology
Economic	Production	Promote workforce and skills development Support economic activities
	Mutual benefit	Efficient use of land and space Convenience of services and goods Fair financing environment Promoting physical and mental health of the general public

Source: Q. Truong (2020).

6. Conclusions

In the context of "all carbon", designers should not only pay attention to the forms, structures, and technologies of buildings, but also endow them with characteristics such as stability, toughness, sustainability, and eco-friendliness. Within the overall goal of consuming less energy and spending less on materials, carbon composites exemplify more sustainable construction materials. Carbon composite materials provide architects and engineers with new choices, open new design and construction pathways, and offer great potential for urban progress. The carbon material paradigm requires interdisciplinary collaboration and bridges the technical gaps between material production, fabrication, and design. The carbon composites will create new tectonics and expressions in architectural design and with its noticeable potential in forms, structures, and sustainable properties, could be developed and applied to larger-scale urban residential environments.

Abstract

Global steel production amounts to around 2 billion tons per year [1]. Half of the world's annual production of steel is used in the construction of buildings and infrastructure [2]. Steel is a material that can be recycled without loss of properties, a huge potential for urban mining and the circular economy, yet, the demand for new steel is higher than the offer of secondary raw material. Lightweight structures are saving material and can therefore help to reduce the extraction of materials through the primary route and optimise the use of secondary raw material, which can be extracted through urban mining [3].At the intersection of research and teaching, the paper examines the formation of concepts, starting from an understanding of materials and fabrication technologies and going forward to questioning and rethinking existing methods with strong focuses on computational design and digital fabrication processes that enable novel concepts for circular economy in construction. By applying fabrication concepts from textile technology, a series of steel structures were re-conceptualized, redesigned and prototyped. The material distribution was locally tailored, based on the interplay between geometry and structural behaviour. Several prototypes were built to validate the overall approach, and in a next step, recycled secondary building materials could be used.

Keywords: optimization, digital fabrication, form finding, steel, textile, metal, membrane structures, weaving, structural membrane

1. Introduction

Steel is a material that can be recycled without loss of properties, a huge potential for urban mining and the circular economy. Yet, the demand for new steel is higher than the offer of secondary raw material. The construction industry accounts for 50% of global steel production and consumes more than 3 billion tonnes of raw materials [3]. Steel is therefore a perfect case study for the implementation of circular material cycles in construction. Based on the principles of the technical cycle as described in the concept of circular economy by the Ellen MacArthur Foundation, the aim should be to avoid the extraction of materials through the primary route and focus instead on the use of secondary raw material, which can be extracted through urban mining. However, the recycled products must use the material more efficiently: recycling a conventional steel component into a multitude of components with locally tailored material distribution, while delivering the same function and strength as those created by traditional methods, could enable the industry to meet growing global demand. While steel is traditionally thought of as a heavy and rigid material, the availability of thin sections, wires and yarns allows a level of flexibility and adaptability which bigger profiles do not offer. The use of these materials enables it to be processed in a textile way, but still allows for the combination with established steel working processes such as cutting and welding. In this scenario, digital design and fabrication processes

could enable the shift from the serial production of identical parts to the custom production of material-optimised components.

At the intersection of research and teaching, the combination of fabrication concepts from textile technology and concepts of resource-efficient steel components were investigated. Experimental prototypes made of steel wire and yarn, focusing on hands-on explorations and concept models were created.

2. Research and teaching method

The course explored a variety of concepts through a design-through-making approach. Starting from an understanding of materiality and existing technology, students then developed initial concepts through exploratory prototypes and realised three final proof of concept models through full-scale prototyping. Guided through three development phases, the course investigated processes, techniques and material properties in an initial phase to provide students with the technical foundations for the seminar. The second phase entailed the development of exploratory small scale prototypes to iteratively refine a novel digital design and fabrication concept for material-efficient steel components. The third phase of the seminar focused on validation of the developed concepts through physical prototypes on a 1:1 scale, while showcasing its architectural implications.

3. Phase 01 - initial investigations

Students investigated a varied range of textile processes and digital fabrication techniques, in search for manufacturing and processing techniques that enable resource-efficient, functional arrangements, utilizing material properties and mechanical techniques for steel. This created a reliable repertoire of knowledge on which the following development phases could base upon. This phase was complemented by skill-building tutorials for digital design tools to aid the concept specific design tool development. In all examined textile fabrication techniques variations in weaving, braiding or knitting patterns can be used to create 3-dimensional spatial structures.

3.1 Textile steel fabrication techniques

Weaving is the process of interlacing two sets of thread, yarn or sometimes other materials to create textile sheets. There are different variations of weaving techniques, but the basic principle is the same: There are threads that are pre-tensioned parallel to each other, the "wefts", and threads that run orthogonally to them, the "warps". By passing the warp threads, which are contained by the "loom", alternately over and under the weft threads, a textile can be created. Special warp knitting machines can produce "spacer fabrics" that create connections between two or more layers of flat fabric, or even create a honeycomb structure in cross section (as implemented by the Belgian company "3D Weaving"). Braiding is the process of intertwining three or more strands of flexible material in a specific pattern to form a three dimensional structure. Unlike weaving, braiding in its purest form requires no equipment other than the material itself, on an industrial scale automated braiding machines are widely established (e.g. braiding machines by HERZOG GmbH) [4]. Knitting is the process of making interlocking loops of yarn or thread using two or more knitting needles. The loops are created by pulling a loop of yarn through an existing loop, then pulling a new loop through the previous loop, and so on, creating a series of interlocking loops. On an industrial scale there are two main types of knitting: flat bed and circular knitting. By varying the knitting pattern locally, the textile can be brought into a three dimensional shape later (as implemented by Zaha Hadid Architects and ETH Zurich) [5].

3.2 Steel joining techniques

During the seminar, the students have explored various fastening techniques with a focus on interlocking techniques that do not require fasteners and are suitable for thin sections rather than sheet material.

Therefore, techniques such as riveting, nailing and screwing were not considered. Instead methods that do not need any additional heat or adhesives such as clinching and interlocking, as well as methods that uses heat like welding, brazing and soldering, were explored. For the development of digital fabrication concepts it was important to focus on steel joining methods which can be implemented using industrial robots. This allows complex 3d structures to be produced with millimetre precision. As such, traditional methods like welding and bending can be used and incorporated in form of robotic WAAM(Wire Arc Additive Manufacturing) or robotic wire bending [6][7][8].

3.3 Material behaviour

Keeping the different properties of steel in mind, several options had been considered. Each has different characteristics to suit specific applications. In most cases, iron is either combined with other materials such as carbon, chromium and nickel to form an alloy, or coated with zinc or oxidised to form a protective layer against corrosion. Typically, the dead weight of the structure is a small fraction of the applied load or generated forces. Lightweight structures often use light and high strength materials as well as advanced technologies for their design and construction. Many shapes are pre-stressed, resulting in double-curved shapes that require special cutting patterns and care during erection. Typical lightweight structures include cable, membrane, shell and folded structures as well as space grids, braced vaults and domes, arched, stayed and trussed systems. For the purpose of the seminar such structural principles and typologies were investigated regarding their potential as textile steel structures and building components.

4. Phase 02 - development of initial concepts

Exploratory prototypes were manufactured as small experiments to gain insights into materials, systems and structures as well as test key assumptions, strengths and weaknesses of the concepts. Produced in rapid iteration, this helped to formulate further research questions and address them in the next evolution, but also narrowed the investigations through research-based decision making.

4.1 Knitted steel

Aiming to produce building elements utilising steel and knitting techniques, required the conceptualization of a process starting with form finding, extraction of 2d knitting information which has the three dimensional shape inscribed, a forming phase in which the knitted structure is tensioned and a solidification step in which the tensile structure assumes bending stiff properties. Different options for the solidification of the structure were explored. Using the custom knitted steel membrane as integrated concrete rebar and formwork provides a stiffening effect that allows the structure to resist bending forces as commonly used in construction. Through experimentation, it was determined that spaced layers of fabric were beneficial to build thickness on the structure, allowing concrete poured onto the mesh to adhere more effectively. Another method of transforming a tensile network into a bending stiff shell structure is to use local spot welding or brazing to join the steel wires together at specific points or along the entire curve network length to create a stiff structure. Such a knitted steel membrane could therefore be conceptualized as a precursor for a subsequent robotic WAAM process. To fabricate the building elements, a form-giving strategy was devised, and an external frame was employed to put the knitted meshes of steel under tension, enabling tension-based doubly curved membrane geometries to be created(Fig.1).

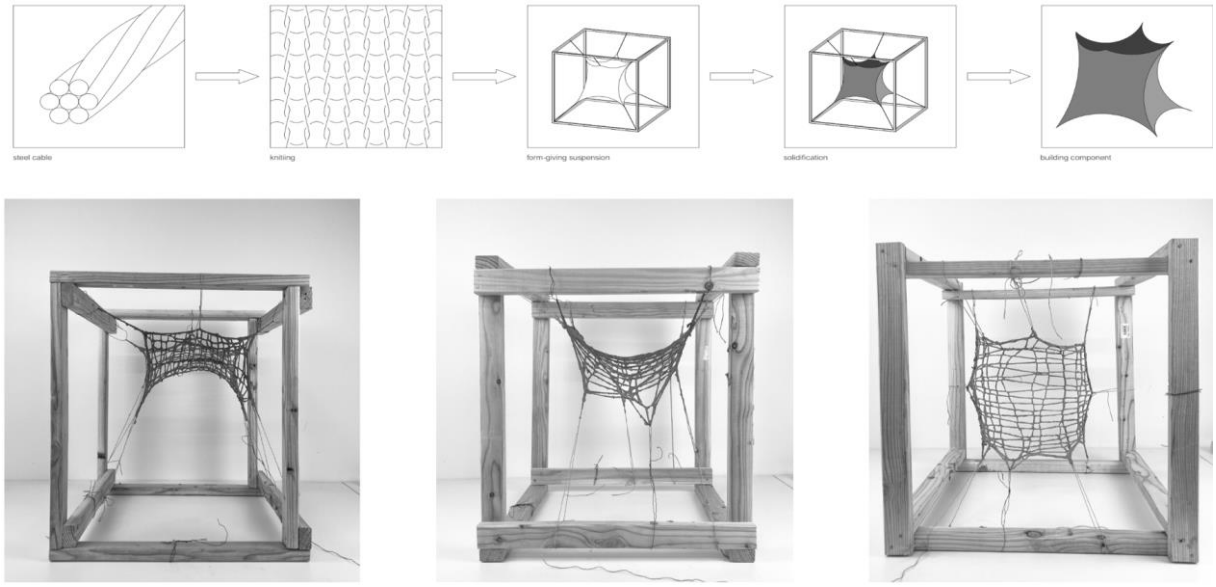

Figure 1. Production concept of steel knitting and first prototypes [Graphics and photo by authors].

4.2 Woven wall

The envisioned spatial weaving concept allows for a three dimensional interconnected network of steel cables to be spanned between a set of initial steel pipes. For building elements like floor slabs or wall segments, several hexagon patterns were subsequently merged into each other. These could either be lined up in a flat manner to develop slab like ceiling or wall components, or be spatially arranged into more complex geometrical configurations. The basic wire layout could be reinforced by subsequent locally differentiated reinforcement layers to provide differentiated structural capacity. Sleeves around the threaded rods separate the levels from each other and reduce the density of the structure as well as reduce the buckling length of the threaded rod. Vertical braces are woven in to provide additional stability (Fig.2).

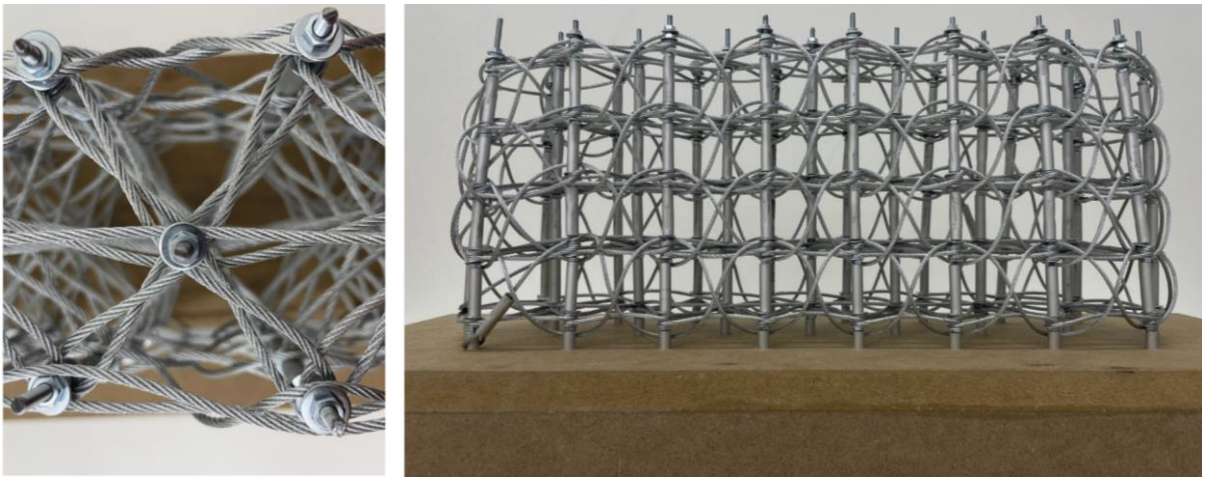

Figure 2. First prototype of steelweaving [Photos by authors].

4.3 Braided column

This fabrication concept utilises threaded rods which are intertwined by steel wire or cables through a braiding process. The steel cable is wound around rods to form connecting points, forming very fine mini-members of a spatial truss which is bracing the main parallel aligned members. The diagonally connected inner webbing supports the column and reduces the buckling length. Through the centre of the structure more cables tie the individual rods together to cope with the pressure forces resulting from vertical loads. These continuous wires represent the stiffening of the structure. The intertwined rods and wires are subsequently soldered and could conceptually be robotically spot welded to form load transferring nodes (Fig.3). Although locally consisting of weak members and connections the high resolution and redundancy of the structure could form a robust load bearing component.

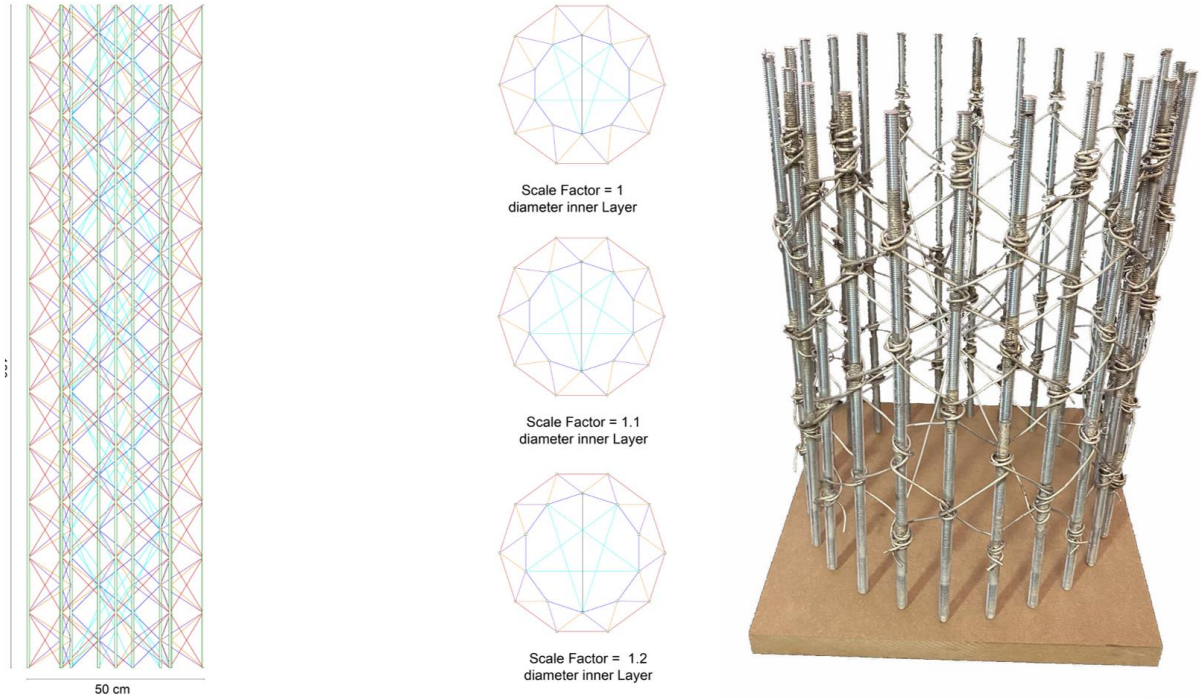

Figure 3. Production concept of steel braiding and first prototype [Graphics and photo by authors].

4.4 Metal distance weaving

Distance weaving is a fairly novel concept which is able to form multiple interconnected layers of fabric at once. Metal screen weaving on the other hand is practised for many decades and well understood. The concept aims to alter the manufacturing process of metal screen weaving in such a way that a rigid metal distance weave can be produced on an industrial scale. In a first prototype weaving pattern, the weaving process itself as well as the appropriate metal gauges were explored (Fig.4). The development of a process specific parametric design tool allowed to explore several different variations in thickness, patterns, as well as shapes of the structure. Through specific bending of the metal wefts of the 2nd prototype it was possible to prove the concept of inscribing curvature into the piece. This opened up the potential to inscribe information about the components global geometry into local machine bending instructions. Being able to form curved shapes opens up a wide range of possibilities from thin free standing walls to quick industrial production of mesh moulds for construction. Through the inscription of local deviation of material distribution, it is possible to tailor the structure to the specific application and load while using as little material as possible.

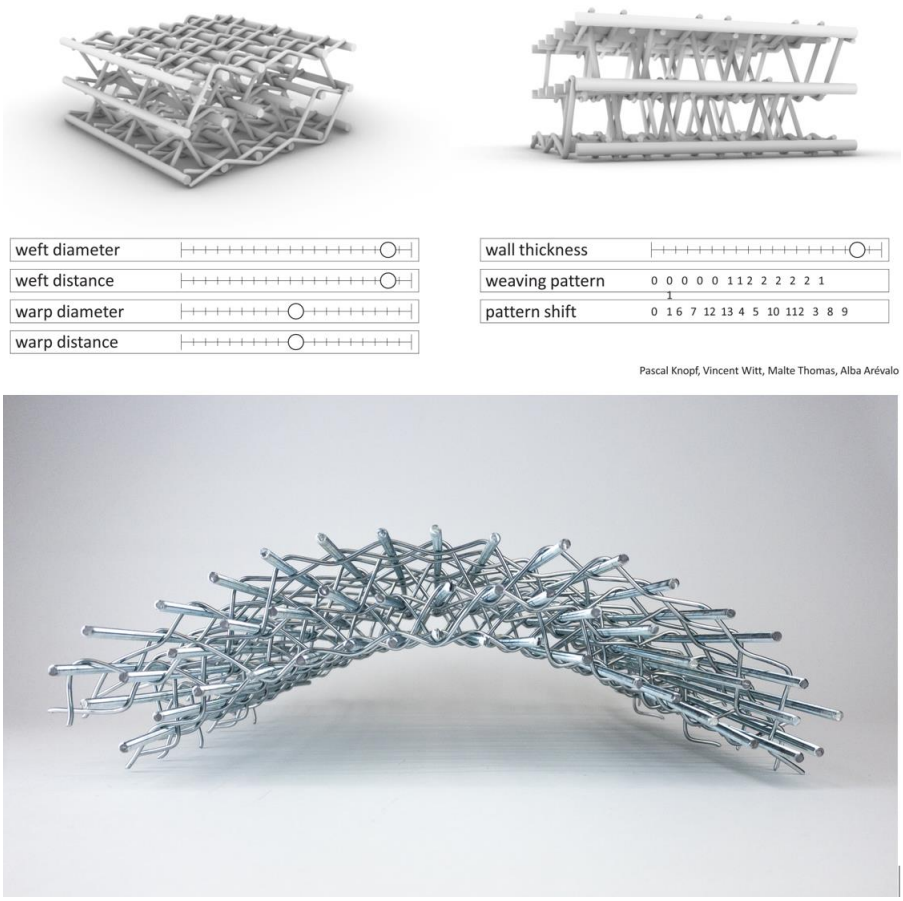

Figure 4. Production concept of steel distance weaving and first prototype [Graphics and photo by authors].

5. Phase 03 -1:1 scale explorative prototyping

The research of the third phase was driven by the bottom-up concept developments of the second phase process focused explorations and aimed at their translation into material-efficient building components based on simple structural models. Within the limited scope of a selected building element (e.g. column, façade panel etc.), each group carried out early qualitative design explorations for loading conditions to inform the material layout in high resolution and cross reference them for potential differentiation with the textile techniques investigated thus far. This resulted in three physical 1:1 scale, handcrafted prototypes, made of steel wire in varying gauges and yarn utilizing and scaling the techniques explored in the previous phases. Furthermore, the models were soldered, welded and galvanized(Fig.5) to provide structurally stable components. The final prototypes serve as a proof of concept at the intersection of research and teaching and validate the architectural potential.

Figure 5. Hot dip bath galvanisation of the final 1:1 prototypes [Photo by Daniel Fischer].

5.1 Braiding steel

Braiding techniques emerged as a concept from phase two to be explored further to interconnect paired rigid, straight, load-bearing braid strands with flexible strands to reduce the buckling distance of the load-bearing strands. The concept aims to explore an idea for lightweight, high-efficiency column structures using digital fabrication. The structure consists of vertical steel rods, which create its main skeleton; steel cables were braided between the rods to form the lattice structure. The diagonals, created by winding the cables around the rods, are digitally designed in continuous paths from the bottom to the top, an important aspect considering later potential for its implementation in a fully digitally controlled textile braiding process. The structural concept of the column has been extended through a double layered rod structure with local buckling bracing and a second layer was introduced within the inner core where cables create a secondary web to further strengthen the column. The entire structure was galvanised by immersion in a zinc bath to fix the braided structure in place and to provide a layer of adhesion and slip resistance at the interface between the rigid rods and the flexible steel cables. In a next step, the concept could be adapted to slab applications such as roof trusses or ceiling structures by modifying the manufacturing setup, which is currently conceptualized for circular linear construction members.

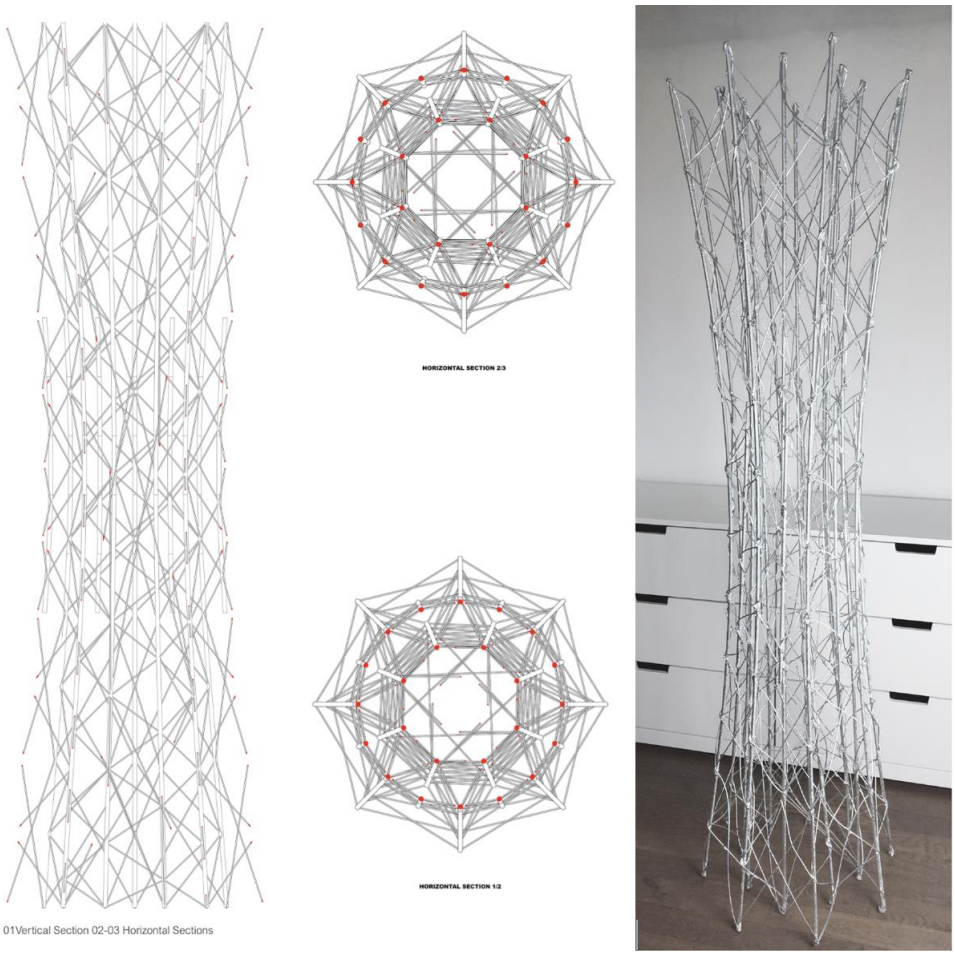

Figure 6. Production concept of steel braiding and second prototype [Graphics and photo by authors].

5.2 Weaving steel

The second 1:1 prototype resulting from phase three continued the exploration of industrial weaving techniques and applied them to steel components to create structures that are based on mechanical interlocking, thus enabling the structure to be fully dismantled after use and creating a closed material cycle. The process is derived from the looms used in the industrial manufacturing of woven textiles (Fig.7).

By adjusting parameters of the structure through the parametric design tool according to the differentiated requirements, such as structural load, the desired shape was found. The adaptable parameters are: weft and warp diameter, distance between wefts and warps, bending patterns as well as bending pattern shift. These parameters are derived from the global design of the geometry. Conversely, the specific sequence of wire bending instructions to the machine inscribes the global geometry and especially curvature into the produced part. Through varying these parameters, a high degree of local differentiation of the resulting properties of the structure is achieved resulting in a variety of possible geometries (Fig.2). The wefts and warps only form a connection through mechanical interlocking, thus enabling the structure to be reused or remanufactured. Other than as rebar the structure can serve as installation walls, facade elements, partitioning walls as well as plant racks or lattices. The manufacturing technique that was developed for the concept could become an industrial alternative for rebar installation, which usually requires great amounts of manual labour.

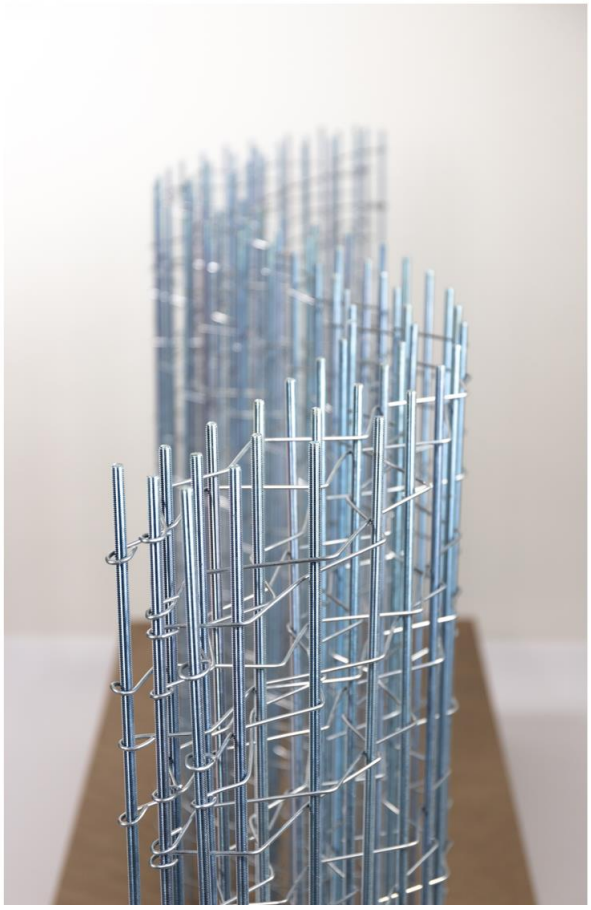

Figure 7. Final 1:1 prototype of weaved steel wall [Photo by the authors].

5.3 Knitting steel

The third 1:1 prototype resulting from phase three built on knitting techniques in combination with thin steel cables to create facade elements that are locally differentiated for shading and aesthetics, as well as material distribution. The concept is based on knitting a 2D mesh and using an external framework to suspend it. In this way, it is possible to navigate the textile repertoire of form found membranes as doubly curved lightweight structures. The form found membrane geometry enables the forming process during fabrication and provides structural performance as shell action in its final bending stiff configuration.

Different knitting technique patterns were investigated through the initial exploratory prototypes. By reducing the knitting patterns to three basic principles it was possible to create a pattern that offers great variation in terms of density and resolution but also enables ease of production. Different options for the solidification of the structure were explored in phase two. The 1:1 mock up realized in phase three utilized zinc dip bath galvanization to locally stiffen and bind the steel cables together. As an outlook this process could be replaced with a robotic WAAM process to locally thicken and stiffen the spatial metal network.

Digital tools were utilised as form-finding workflow for the concept. In particular, a physics simulation was used to adapt the behaviour and the final shape of the membrane according to potential positions of integrated building component connection details and tailored density of the knit. This also allowed to gain an understanding of the required fabrication bed size for potential future automated flat knit fabrication and varied density distribution to form the membrane.

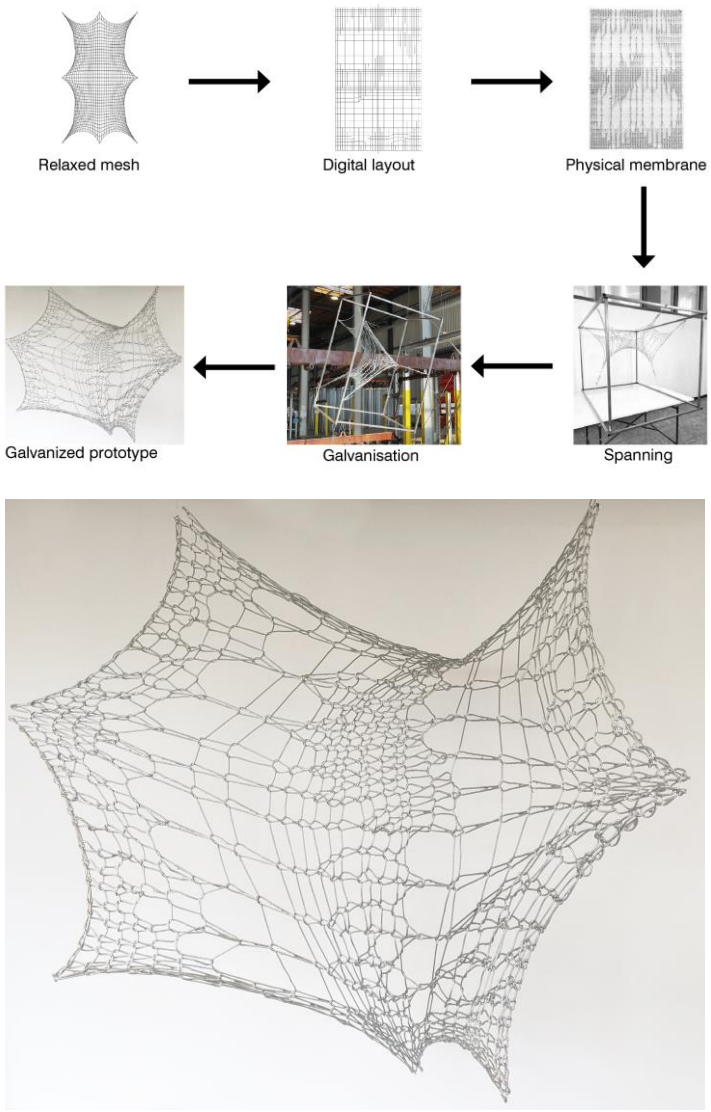

Figure 8. Production process of steel knitting and final prototype [Graphics and Photo by the authors].

5. Conclusion and outlook

We were able to show that through digital design workflows, a critical review of textile manufacturing techniques as well as a gained understanding of the interplay of steel and textile processes it is possible to generate new concepts for building technologies out of steel which offer the ability of local differentiation while reducing the amount of material used. Two of the three explored concepts make use of zinc galvanisation to stiffen the structure, through this process the recyclability of the resulting structures is impaired. Further development of the concepts should include processes to replace the zinc galvanization in order to keep the products mono-material structures. The seminar project revealed several design and fabrication related research questions as starting points for future research endeavours into digital circular construction concepts for steel structures.

Multi-modal transportation hub: 'Fill-material-free' technology for a marine-air-land terminal

Abstract

'Multi-Modal Transportation Hub' terminals are a growing stark necessity, especially in mega port-cities. Transportation infrastructures, within port-city Metropolitan areas are in rising conflict, mostly concerning eco-environmental and economic (real-estate) values, while robbing the cities of their sea-frontage. A conceptual approach with supporting technologies are suggested: Development (in deep waters) of a combined marine-air-land terminal, as a 'Multi-Modal Transportation Hub'. It has to be compact, multi-layered, with shared work-service-storage infrastructures, with flight decks above the dock piers below, and connected by bridge avenues to the city and its hinterland beyond. A marine development 'fill material free' technology is suggested, with 'Permeable Sponge Breakwaters', 'Modular Tub Platforms' and 'Infinite Polyhedra Lattice' space frames. All the technology constituents were widely researched and analyzed, all with positive results and economically attractive.

Keywords: marine environment, transportation hub, multi-modal, compact, fill material free, space frames

1. Introduction

The human habitat is continuing to expand and devour greater space and land area resources, and that for multiple self-evident reasons:

- Worldwide population growth and the resulting evolution of mega-metropolitan urban areas, some with tens of millions of residents, mostly sprawling along the coastal lake-sea-ocean expanses of the globe.
- A continuously growing area-space consumption per-capita, as a manifestation of the basic human desire to raise its standard of living.
- A growing area-space consumption for public community services of education-culture-recreation-work and commercial conglomerates.
- A growing demand for mobility and the resulting explosive growth of land, air, marine transportation infrastructures, with the growing volumes-tonnage of shipped materials and merchandise, and their storage and trans-shipment.

All these happen in alarmingly growing proximity to the urban clientele, with a dramatic rise in the level of eco-environmental conflicts and costs, sky-rocketing real-estate land values, and perpetual rise of pressure on our free time, cost of living and well-being at large. Sometimes, as in the case of urban marine port terminals, the infrastructures are robbing the city of its sea-frontage and clogging the downtown land transportation to a state of paralysis. It turns out that all expertly statistic forecasting

Copyright © 2023 by Michael BURT and Yehiel ROSENFELD. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

are promising ever-continuing (doubling-tripling) growth within the foreseeable future, of land-space consumption and the resulting deterioration.
Eventually, we come to realize that land-space resources, especially those in close proximity to our urban environments, are most critically limited and expendable. We have to re-evaluate and re-think the way we manipulate space employment-usage within the context of our evolving future habitat.

Some development design paradigms were considered, and none of them appears to be as promising as the 'expansion into the marine environment' option.

2. Conceptual principles of the evolving design paradigm

Most of the attention in this paper is focused on the infrastructures, and in particular – transportation infrastructures. At the core of the issue, it is not just the land–space scarcity and its manipulation, but also the growing global public sensitivity and concern over the eco-environmental sustainability prospects, and whenever the marine development option is raised, the emergent 'Fill Material Based' design paradigm comes under ever-growing criticism, even to a point of its total rejection.

This double feature of land–space manipulation for effective economization of its exploitation, and the drastic reduction of dredged-excavated-mined fill-materials, to a point of 'Fill Material Free' conception, have to be the main-stay of the evolving design paradigm of expansion into the marine environment.

The conceptual principles of the evolving design paradigm of the Transportation Infrastructures in the Marine Environment are suggested to be the following:

a. Infrastructures have to be relocated-developed in deeper waters, leaving the coastal areas and the urban frontage for (mostly) social and recreational activities.
b. Infrastructures have to strive for much more compact development and employment of land and space, thus promoting multi-level (below and above the water level) design and sprawl.
c. Functionally interrelating and complementary transportation infrastructures have to be spatially combined-intertwined synergetically together, as much as possible and viable.
d. Every possible ingenuity and design orchestration has to strive and enable 'Fill Material Free' development, with no dredged, excavated or mined materials from nature, involved.
e. All production-assembly-construction processes must be realized in highly industrialized coastal (on the water line) plants and sea-transported to their sites of function.

The suggested comprehensive design paradigm should be termed as the 'Multi-Modal Transportation Hub'. It is a compact, multi-level combined Marine-Air-Land transportation terminal, utilizing for its realization a 'Fill Material Free' Technology.

2.1. "Fill Material Free" technology

The constituents of the "Fill Material Free" technology (Fig.1) may be summarized as follows:

2.1.1. Permeable sponge breakwaters (P.S.B.)

Of a highly periodic-modular continuous hyperbolic geometry, realized-executed as thin reinforced concrete (and/or metal, and/or composite, and/or other) Shell structure (Fig.2). A range of geometries was considered with a preference of the cubic sponge surface (hyperbolic continuous space partition between two dual cubic networks) [1]; [6]. Small scale experiments showed that 80% of the wave energy was absorbed, just 10% was reflected and 10%, infiltrating through. The dimensions will be dictated by a thorough analysis of the wave conditions, bathymetry and foundation considerations of the site and the demands on the standard of the water protection behind.

2.1.2. "Modular tub platforms" (M.T.P.)

From reinforced concrete or steel (volumetric) structure, to perform as reclaimed buildable land infrastructure, capable of carrying-supporting high-rise building structures, piers, interior (below water-level) storage volumes (Fig.4), all depending on the platforms interior depth characteristics [8]. The dimensional design of the platform, the size and depth of its modules and the structural design of its walls, floor space frames and piers, will be determined by its specific functional utilization mode.

The P.S.B. structures may reach to a hundred meters in width (in Mediterranean Conditions), up to 20 meters below sea level, and overall cross section of up to 2500 sqm, and still, the overall volume of the P.S.B. Shell structure amounts to just 3÷5% of the conventional breakwater's only. The M.T.P. structures may reach to 2500 sqm per each module's area and assembled into 15÷30 modular units mega-platforms, of 35.000÷75.000 sqm each (Fig.5). The P.S.B. and the M.T.P. modular structures will be fabricated and assembled in a coastal industrial plant, as floatable structures, sea-transported-dragged to their location sites (Fig.3) and founded on a worked out sea-bed, or pile supported, or moored-anchored, as may be required by the local bathymetric-geological conditions and functional characteristics.

2.1.3. Infinite polyhedral lattice (I.P.L.) space frames

From steel tubes-profiles, to construct large span upper mega-platforms (Fig.6). The I.P.L.'s six-layered space truss geometry conforms with the uniform hexavalent vertex configuration of the $3^3.4.3.4$ infinite polyhedrons [2]. It is 'just stable' and, with an edge length of a, with a very low projected density of 9,9593 a/a^2, slightly less than that of the double-layered octatruss (with 10,3923 a/a^2) and structural depth which is five times greater (!). [3]; [4]; [5]. Comparatively, it is a 'light weight' structure, with high-bearing capacity and rigidity, reaching to spans of hundreds of meters and being highly cost-effective. These I.P.L space trusses can support flight and plane parking decks, large span 'bridge avenues' and large functional work and storage platforms. It's six (or more) layered low-strut-density interior spaces may be utilized for a large variety of functions and (vehicular) transportation modes.

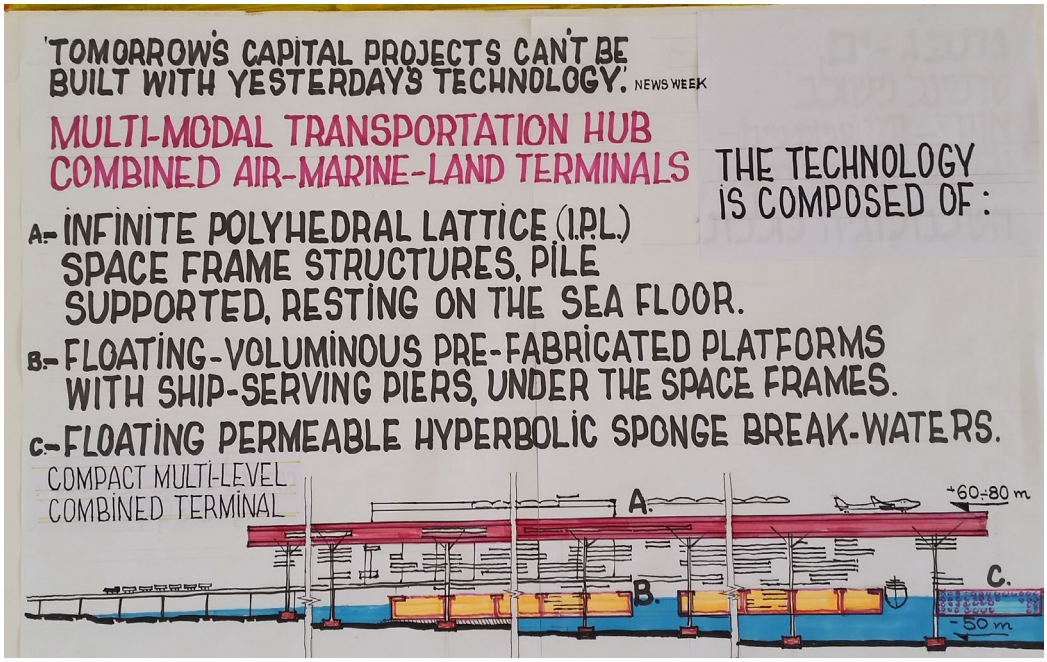

Figure 1. The technology constituents of the combined marine-air-land transportation terminal

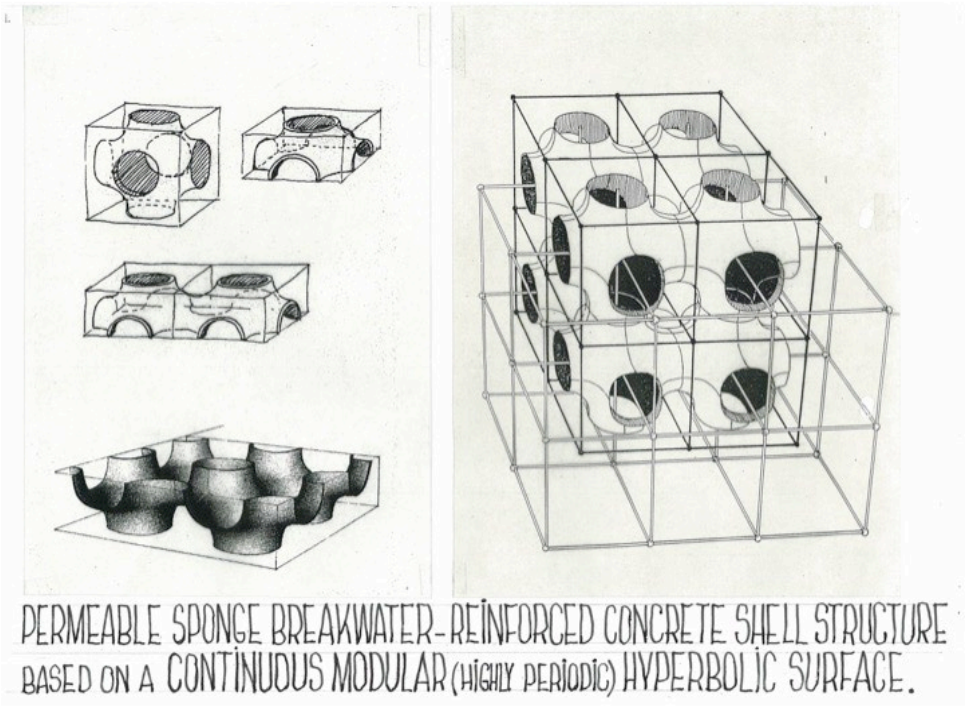

Figure 2 (left). Modular hyperbolic (cubic) shell structure, to be employed as 'Permeable Sponge Breakwater'.

Figure 3 (right). Modular floating mega-block, sea transported to its site of function.

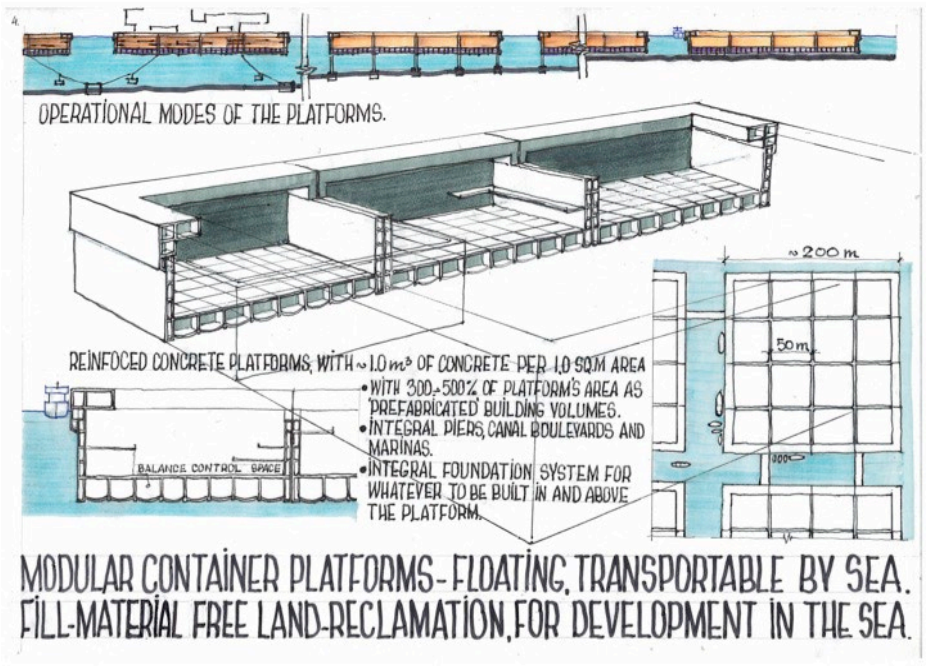

Figure 4. 'Modular Tub Platform' reinforced concrete structure.

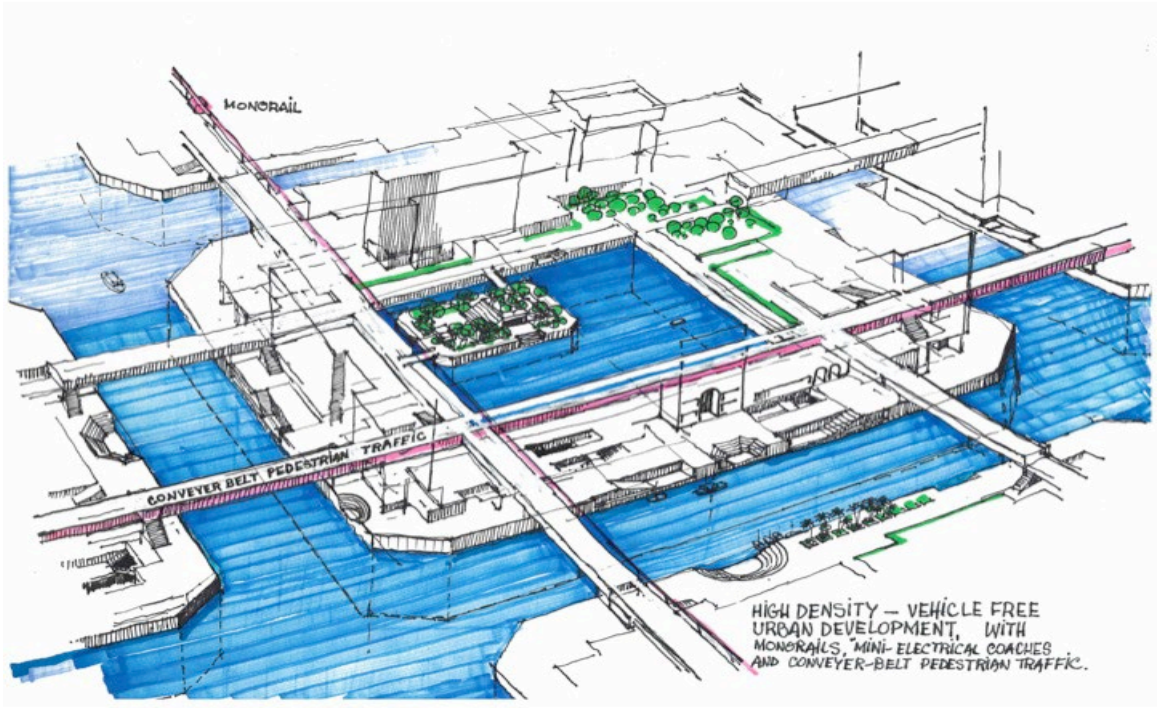

Figure 5. 'Modular Tub Platforms', assembled into mega-platforms, and the generated channel system.

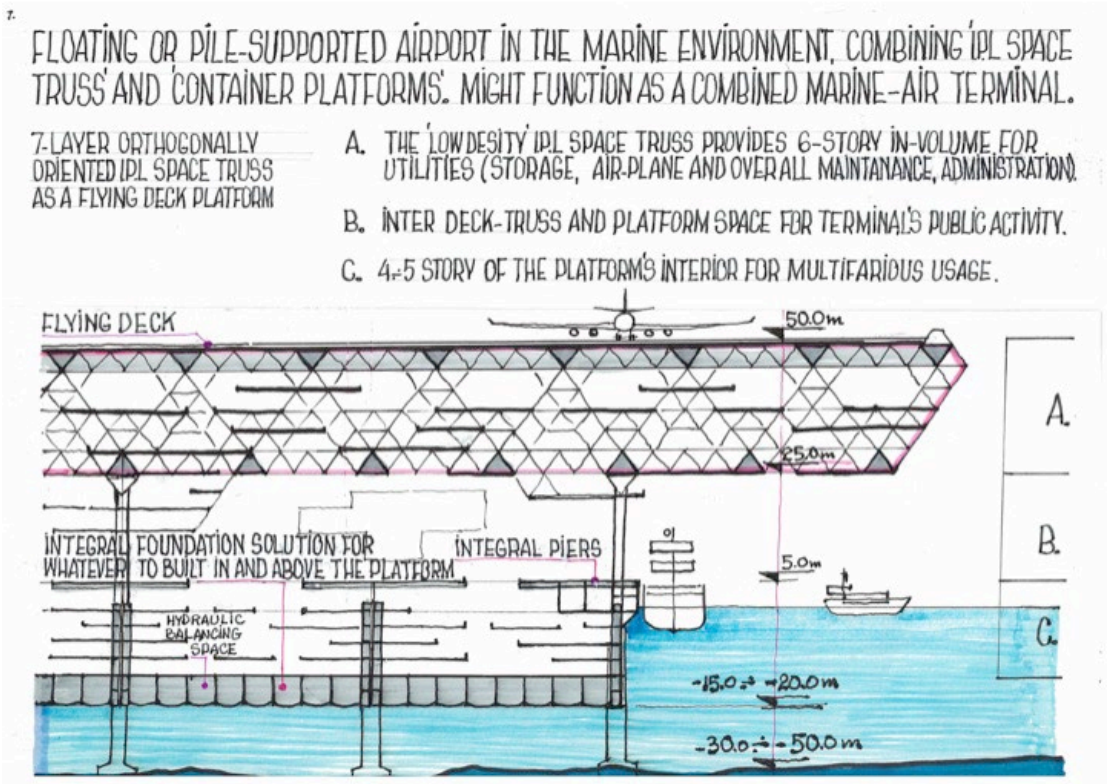

Figure 6. I.P.L Space Frame as an elevated mega-platform, supported on a Tub-platform, to perform as a combined working space.

The I.P.L. space truss concept (Burt-1969) was analyzed by many (P. Kneen, Y.Tene, H. Sanchez of 'Mero' in Wŭrzburg and M. Frances), all with converging positive results., [9] Within the protected water zone, the tub-platforms arrangement allows for a generation-realization of docking piers for large sea vessels and integrated interior multi-functional channel system for interior transportation, ferries-boat-yacht marinas, 'blue boulevards' of public recreation, when in an urban context utilization.
The channel system's area may amount to more than 50% of the reclaimed artificial island's area, thus contributing dramatically to it's cost-effectiveness and speed of its realization [8].

3. The multi-modal transportation hub

The combined Marine-Air-Land Terminal, with a marine deep-water port for mega-carriers, and the required piers and storage volumes within the platform's interior, with the elevated flight decks of 80÷100m above sea level, on I.P.L. (large span space truss) mega-platforms, starts to take shape (Fig.7).

The sea port infrastructures and the flight deck runway I.P.L. platforms, carried by the M.T.P.'s and protected by the P.S.B.'s, with all servicing and storage and the multi-layered working spaces, are connected with the coastal urban fabric and beyond by 'bridge avenues', carrying the vehicular-rail-conveyer transportation infra structures, mostly above the urban fabric. These 'bridge avenues', while 'above and through' the city, may assume the role and appearance of high-grade living-working spaces with green sky promenades (Fig.8).

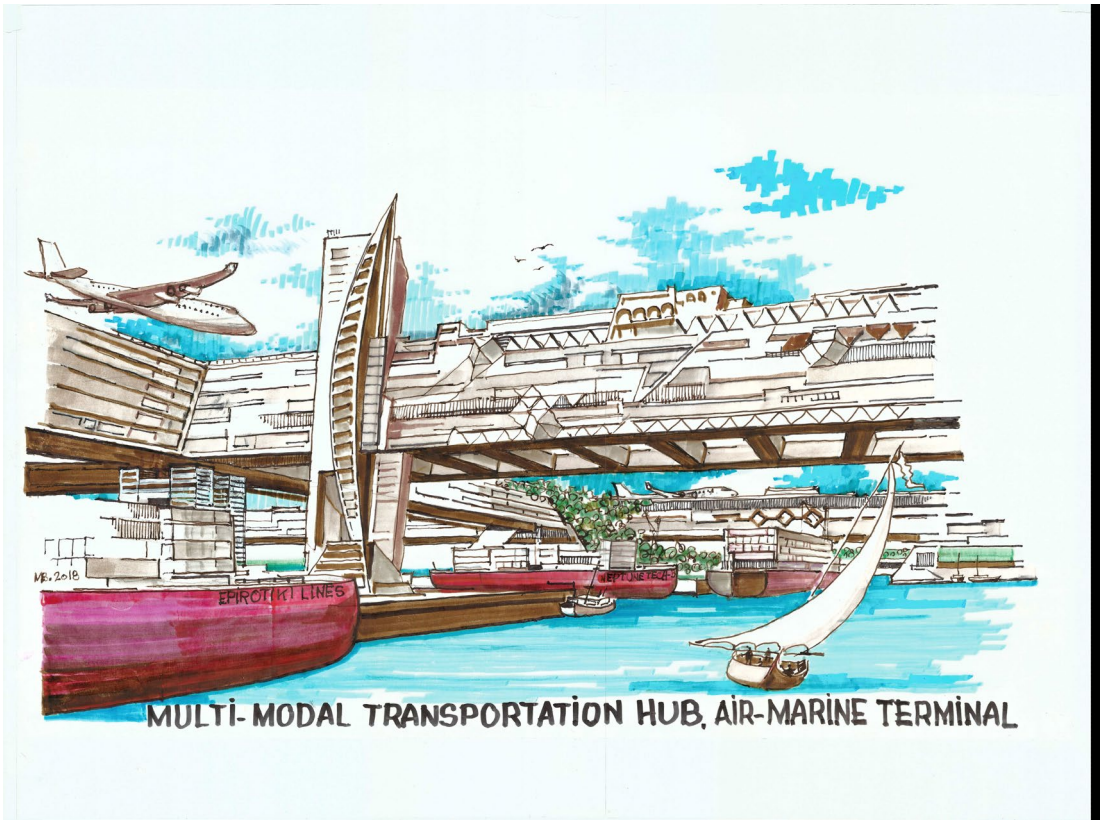

Figure 7. 'Multi Modal Transportation Hub', a combined marine-air-land terminal.

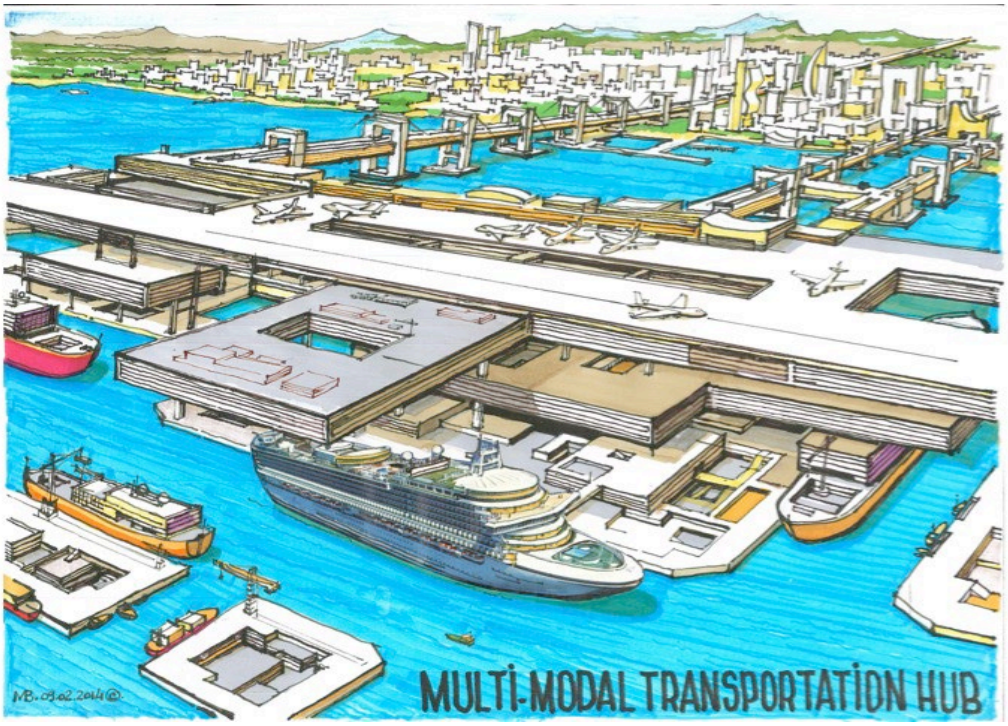

Figure 8. 'Multi Modal Transportation Hub', vis-a-vis the costal urban environment

The whole complex agglomeration of the combined 'multi-modal transportation hub' is very economical in terms of consumed area-volume-space and its realization time, that are just a fraction of the 'conventional approach' figures. The construction process is solved for stage-completion, expansion (with the time), rearrangement and relocation, if and when desired, into deeper waters or even to alternative sites, which is practically unimaginable with the conventional 'Fill Material Based' methods.

4. Conclusion

In view of the expected dramatic growth of transportation infrastructures, their spread, volume and cost, and the growing friction (environmental pollution and damage) with the land locked urban habitat, an alternative design paradigm is required, that is considerably more compact in terms of consumed space, employed servicing interaction, communication energy and time.

All that might be promoted and achieved by turning the various transportation terminals into one intertwined synergetic functioning conglomerate: the 'Multi-Modal Transportation Hub', with the Marine-Air-Land terminals sharing space, manpower, servicing and managerial infrastructures. This functional conglomerate, served by 'bridge avenues' for contacting the coastal city and beyond, enables a development venture into deeper waters (with 'fill material free' design approach and technology) thus relieving the pressure on the city sea-frontage, real-estate costs and the eco-environmental conditions.

All that may be achieved basically with the employment of existing fabrication-construction

- realization technology.

What is basically required is a critical state of mind that is receptive to a novel planning-design paradigm.

"Lets be the architects of the future and not its victims" (R. Buckminster Fuller)

Abstract

Computational design is now ubiquitous in building practice having led to integrative, yet robust digital workflows [1]. In a culture of highly interdisciplinary collaboration, information transfer, data management and communication are critical for the successful completion of a built project. Architects, engineers, and contractors are now able to communicate in a more common language, however contrary to industry demand, software does not often natively communicate to the same degree. To deliver optimal results a multi-faceted tool environment [2] often ad-hoc solutions coupled with open-source tools provide much needed link to connect communication, processes, and people [3].This paper presents a one such case study of a design and construction of a landmark urban artwork located in Sydney, Australia. A sprawling steel structure populated with modulated zinc panelling and biophilic green wall elements is fluently wrapped around three concrete ventilation towers each 40m tall. With a total tonnage of approximately 170t of steel a close coordination with all parties involved is paramount. The project represents a challenging yet effective design workflow for this large-scale structure. The paper concludes with assessing emerging interoperability platforms and the presented workflow that allow for fruitful collaboration in design environments in a data driven setup.

Keywords: parametric framework, Grasshopper, geometric form finding, structural optimization, artist-engineer collaboration, BIM, Karamba3D, Dlubal RFEM

1. Introduction

A landmark urban structure emerges from a new parkland in the inner west suburbs of Sydney, Australia. This integrated landscaped artwork envelopes three concrete monoliths which reflect the history of the site: transformed from once vibrant ecosystems with mudflats and mangrove forests to industrial maritime and rail yards [4]. These concrete structures function as ventilation stacks for the Rozelle Interchange, a new underground motorway as part of Sydney's WestConnex major urban infrastructure project. The aim of the artwork is to help transform the vast infrastructure project into a habitat for urban biodiversity, whilst integrating into the surrounding parklands. Additionally, it allows for maintenance of the concrete outlet, and the air monitoring and sampling ports that are located at the elevated sampling platforms.

The artwork has been designed by Studio Chris Fox in close collaboration with structural engineers Bollinger+Grohmann. The cylindrical towers each have their various dimensions, providing challenges and opportunities for the new artwork design, having been previously designed, engineered and already undergoing construction. The three ventilation towers stand at 40-42m high with a diameter of 9.8-13.8m and were all constructed in in-situ reinforced concrete.

The artwork encompasses a main steel framework of columns and beams that follow a radial spacing around each outlet. The columns are fixed onto the top slab of the cut and cover structure with mechanical anchors. The framing is laterally pinned back to the outlets with beams and the platform structure. Platforms at a height of 33m surround each outlet with stairs integrated in the interstitial space between the concrete and the framing. Bridging elements connect the three tower frames to form one coherent structure. A series of rope-like elements twist and weave around the entire structure. Figure 1 depicts the main structural elements of the artwork. Finally, modulated zinc panelling and biophilic green wall modules are distributed across the framework to create a porous and dynamic façade treatment (Fig.2).

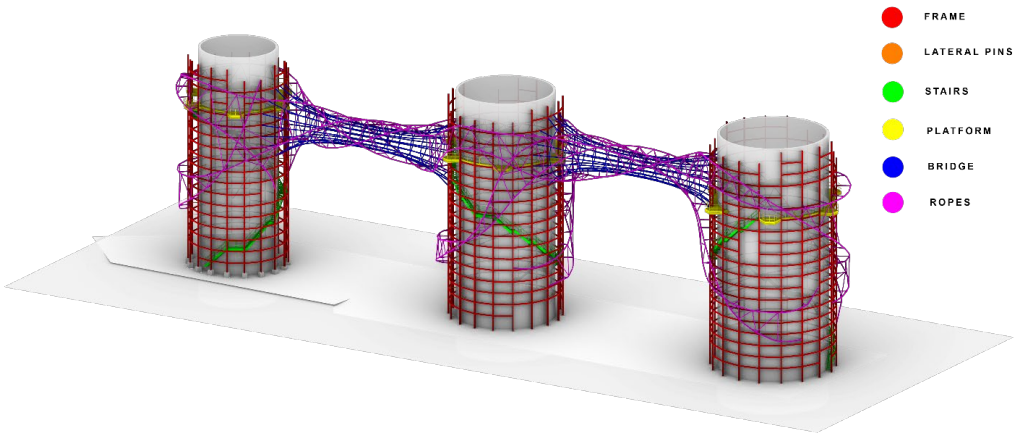

Figure 1. Main structural elements of the artwork

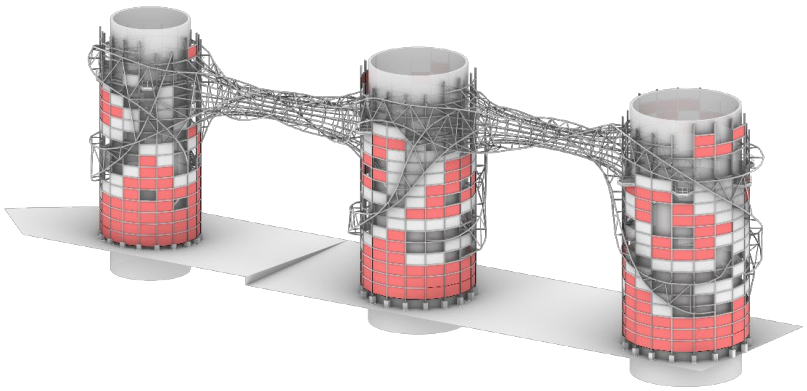

Figure 2. Zinc cladding (red) and green wall components.

This paper will present in three main sections the integrated design procedure of this artwork. We will look at how workflows were established to provide effective collaboration between artist and engineers. Optimisation techniques were explored to not only create more efficient structures but implemented to streamline fabrication and construction methods. Finally structural processes and challenges will be presented.

2. Integrated workflows

2.1. Teams and tools

In order to tackle such complex art/architectural design projects at large scales, there are many different actors involved at multiple stages of the project. Numerous consultants additional to the core artist and structural engineering team were engaged such as the lead contractor, the workshop planners, the steel fabricators and those responsible for vertical landscape design. It was also essential to consider a 'Design for Manufacture and Assembly' (DfMA) approach, where fabrication and assembly were seriously taken into account in the early design phases to avoid unexpected delays and costs later on [5].

When working in the field of Design Technology, a multi-faceted tool environment delivers optimal results [2]. An open and adaptive yet robust digital workflow needs to be established from the beginning to ensure clear communication between all stakeholders [6]. Such workflows and tools provided a much-needed link to connect communication, processes, and people [3].

2.2. Central data hub

A "Common Data Environment" follows the principle of interoperability where common data is shared using information management and transferable file formats [6]. All changes from the architectural model, structural analysis, façade engineering, MEP and other consultants are held centrally in this shared environment for coordination. Each discipline operates within their own individual software environment and typically additional work is required to translate this data to other specialists who work with different software platforms. A central data hub should allow for the exchange of data seamless throughout the various software packages as well as an interface to manage this geometry and data [7]. The implementation of a central data hub platform ensures a fully integrated digital workflow (Fig. 3).

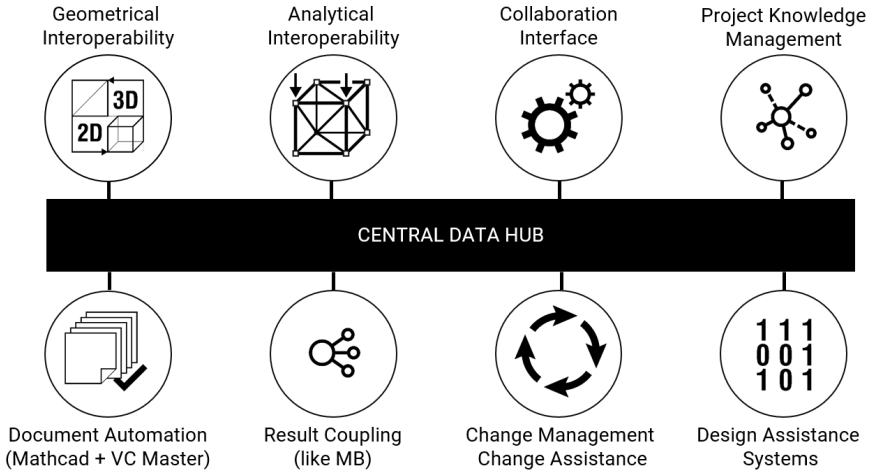

Figure 3. An example of an integrated central data hub.

Demand from the AEC industry has resulted in the emergence of several interoperability and CDE platforms such as Speckle [8], BHOM [9], 3D Repo [10], Konstru [11] and Conveyor [12]. Such platforms enable users to seamlessly communicate within different software environments. Speckle and BHOM offer a broader spectrum of support in an open-source framework; Konstru is especially tailored for engineering workflows and 3D Repo and Conveyor are directed towards the BIM environment.

2.3. Rhino as a central data hub

After assessing the multiple tools available in the aforementioned section, the team decided to opt for a more ad hoc approach by using Rhino as the main coordination model to feed into multiple software platforms, in essence a central data hub. The implementation of Grasshopper, Rhino.Inside [13] and an accessible Rhino3D/Grasshopper API has extended the interoperability functions of Rhino3D, allowing for translation of data at ease. The design and engineering team have had a long-time collaboration where model data was transferred in the interface of Rhino3D on smaller projects, it also seemed appropriate to implement it on this context. However careful control and management of the data was important for a successful workflow in such a large-scale project.

The implementation of Rhino3D as a central data hub platform was used in multiple phases of the project, for communication and exchange within the design/engineering team, as well as in the construction/documentation team. Often consultants work in a very manual process where models are created from scratch in each individual software environment [14]. This can potentially lead to data being lost on the way, as well as lost resources. All data in Rhino3D can be easily accessible, is easy to interrogate and check, making the entire process much easier. Typically used for its geometrical prowess, Rhino3D also offers the ability to assign attributes to all its objects. Attributes were critical to communicate with the entire team specific information about all objects in the model (Fig. 4). They also enabled for information from the model data to be easily transferred from the central Rhino3D model into multiple software platforms and vice versa.

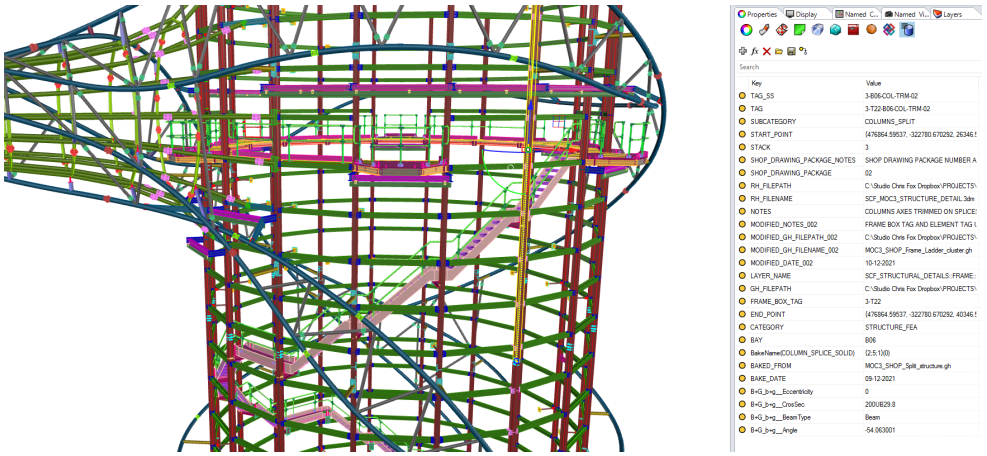

Figure 4. Rhino attributes.

The design team worked primarily in Rhino3D and Grasshopper to develop the complex geometry. Engineers worked with Karamba3d and RFEM to perform analyses of the structural model. Detailed analyses for the development of the steel connections were performed with IDEA Statica. Communication with the client and contract or was through a centralised Revit and Navisworks model taken from Rhino3D. GeometryGym and Rhino.Inside Revit were implemented to translate this data. Tekla Structures was finally used by the fabrication and construction team for detailed workshop planning of all the steel framing. Coordination of the models was managed by the core design/engineering team to ensure all parties involved received the most accurate and relevant data (Fig. 5).

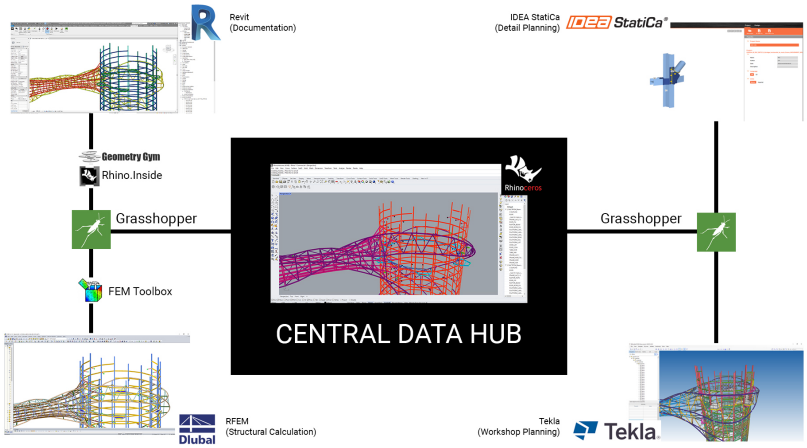

Figure 5. Coordination through a central data hub.

3. Geometry – optimisation & development

3.1. Steel vine elements

The rope geometry formed a crucial component of the overall design of the project. Wrapping the repetitive steel framing are twisted rope elements that weave and connect all components of the structure together. The freeform geometry was optimized (Fig.6) to potentially reduce the number of unique elements: their lengths and bending radii as well as its deviation to the original starting geometry (Fig. 7 & 8). Rigid beams were used to tie back the rope geometry to the main frame, whose position were also governed by optimisation algorithm. The computational logic was designed to be flexible to be adaptable for future design changes or external design parameters such as lateral connection positions and constructability. Overall, the geometry could be optimised and rebuilt into arc modules that can be easily rolled and fabricated.

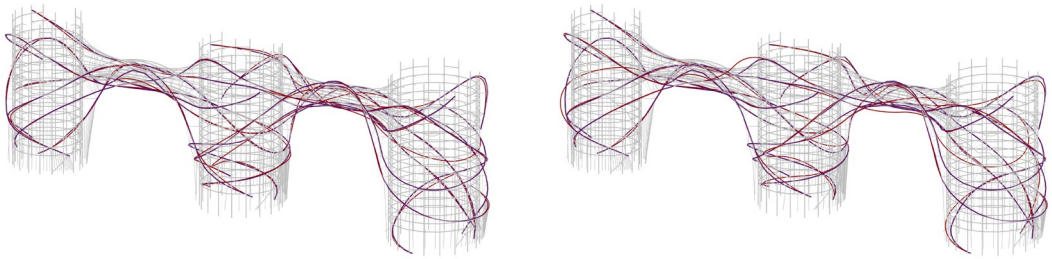

Figure 6. Iterations during the optimisation procedure showing the original (purple) and new (red).

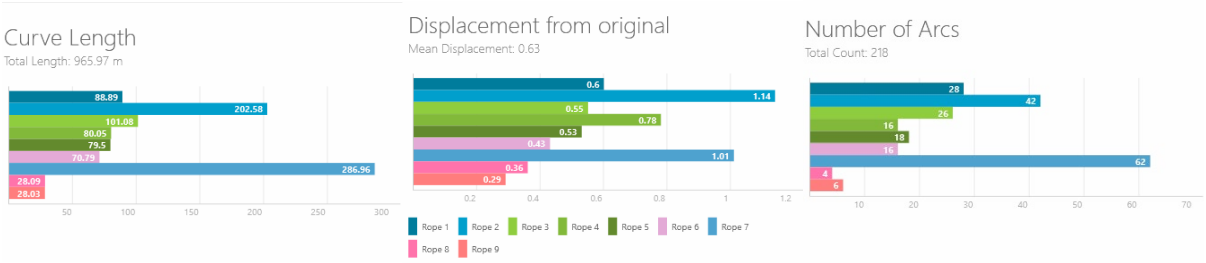

Figure 7. Parameters for the evaluation of the optimisation process.

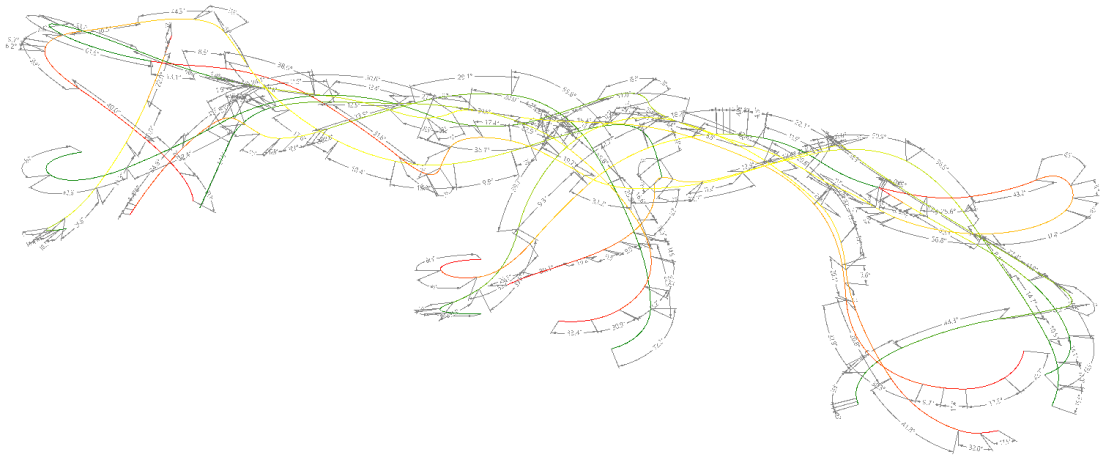

Figure 8. Overview of the steel vines showing the arc segment lengths and radii.

3.2. Stitching elements

To stabilise the rope geometry, prevent them from buckling and to maintain minimal cross section profiles, it was necessary to introduce stitching truss elements. Due to the complexity of the geometry and the multitude on options that are available to the stitching elements, an optimization algorithm was introduced to define the best positions, the number of elements at one single node and to limit the angles regarding constructability (Fig. 9). The stitching elements with the least performance were also then postprocessed and culled to achieve an optimised structural performance.

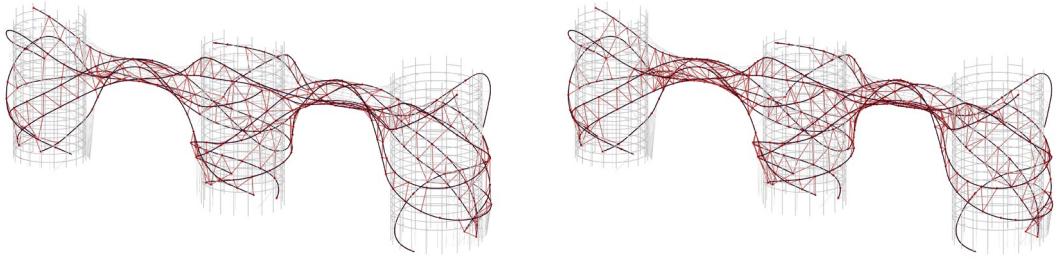

Figure 9. Overview of the steel vines showing the arc segment lengths and radii.

4. Structural model

4.1. Steel vines

The rope geometry was an integral component in the wholistic performance of the structure. They were not only a major architectural design feature, but also provided required global stability for the bridging elements. Figure 10 shows the impact on the overall structure should the steel vines and all there incorporated adjacent elements such as diagonals and pin locations be removed. Elements would start to become over-utilised and thus require much larger cross sections in order to resist all loading scenarios.

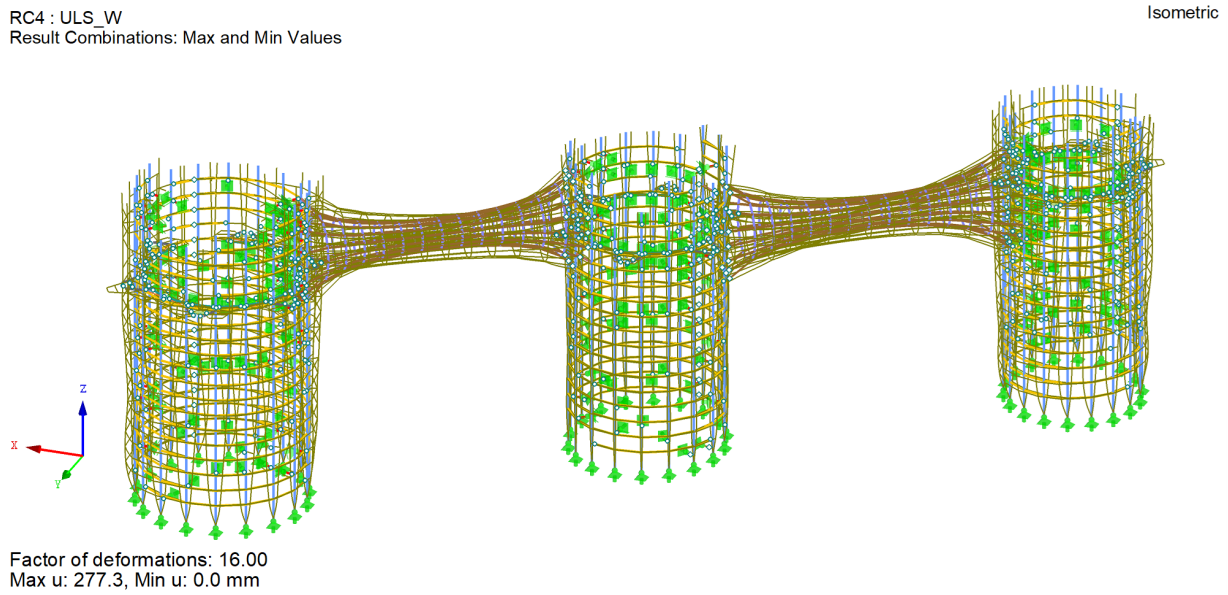

Figure 10. Impact of removing the freeform rope elements in the structure.

4.2. Joints

To allow for movement due to temperature changes (a temperature difference "ΔT" of maximum 50 was determined) and lateral deformations, it was critical to introduce movement joints in the connection between the bridging elements and the main frame, similar to bridge supports. In a similar manner, joints were also used in the rope geometry (Fig. 11). A mixture of pinned connections and physical gaps were applied for the steel vines. This was not only crucial to mitigate effects of deformations but aid in the fabrication and assembly process. Collaboration with the steel fabricators ensured that a balance between welded connections, pin connections and physical gaps were met.

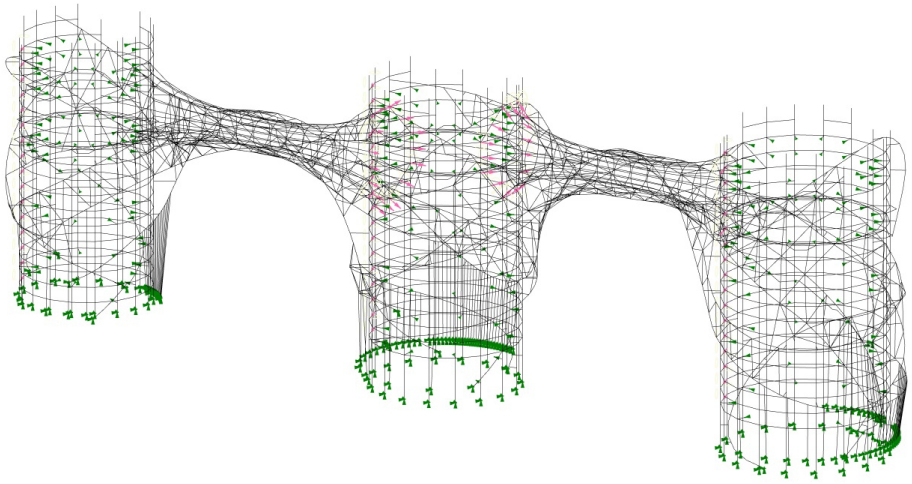

Figure 11. Positions of the movement joints in the overall structure.

4.3. Lateral pins

The vertical loads from the steel framing structure including the façade cladding and green wall elements are supported by the roof slab of the exhaust vent building below. To provide lateral support to resist wind loads and dynamic effects due to seismic loading for the steel framing, beams span from the frame and are pinned to the concrete stack. Beams in the platform and stair framing also contribute to the global lateral stability of the steel framing structure. The concrete structure had been designed with a specific load capacity and it was critical to evaluate the impact each anchoring element had on it. The developed workflow allowed for quick implementation of geometric updates and to extract the reaction forces at all the supports (Fig.12).

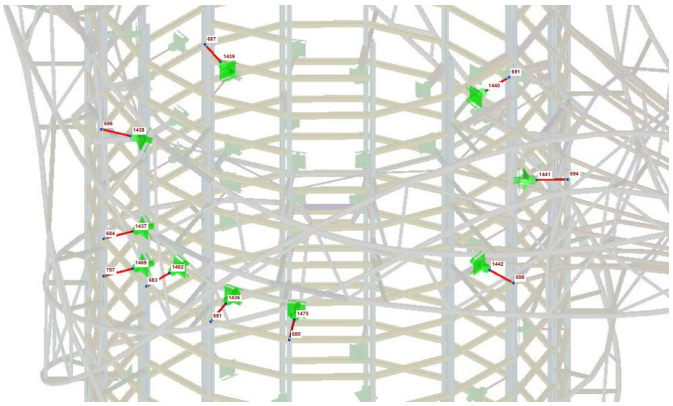

Figure 12. 3d structural model showing reaction forces at the supports on the concrete stack.

Optimisation algorithms (Fig. 13) were introduced to reduce the overall number of lateral pins and internal bracing elements to reduce dead load of the structure and the reaction forces onto the concrete outlet. Coordination with engineers of the ventilation structure were critical to ensure the maximum allowances of anchor forces that can be induced into the concrete stacks and the concrete roof.

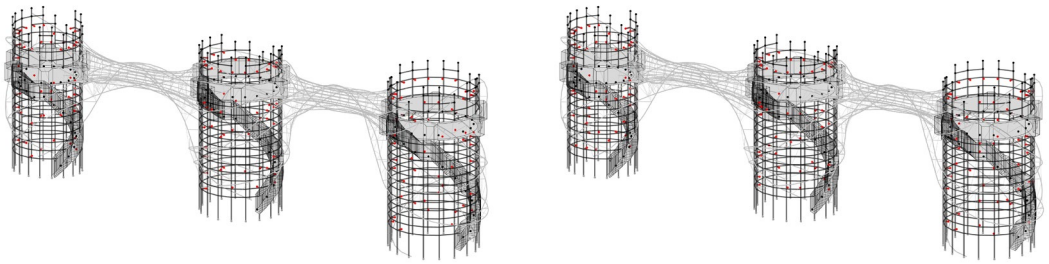

Figure 13. Iterations of the lateral pins.

5. Conclusion & reflection

The digital workflow from the early engagement in the concept phase was kept and improved thoroughly throughout the project until the implementation of the shop drawing process. The established central data hub platform was a crucial tool for communicating design decisions among the involved consultants and designers. The central data hub model was the 'master' template and served also as a control mechanism to check the 3D Tekla model, Revit models, the FEA models and the Rhino3D design files.

The project is currently under construction and is expected to be finished by the end of April / early May. Overall, the team had a little over one year of planning and one and a half years for shop drawing preparation and installation. During the shop drawing phase, the coordination and optimisation in regards of the buildability of the structures was intensified. Due to the early implementation of the DfMA process, many details could easily be adopted. Further to that, the high level of detail that was implemented in the design phase resulted in a very precise fabrication of the elements that did not need any mayor adjustment on site.

This paper discussed the utilisation of Rhino3D as a centralised "master" environment. The integration of open source and third-party plug-ins made it possible to design, exchange, control and coordinate the project over a multitude of software platforms. The presented work outlines the possibilities to effectively work on large scale projects in a "Common Data Environment".

Abstract

This paper presents a form finding method for free-form shells that specifies the distribution of stresses projected onto the horizontal plane. The vertical coordinate of the shell surface is defined as a graph surface with respect to the horizontal coordinates. The shape of the shell is given as a solution to the vertical equilibrium equations of the surface heights at the grid points discretized by the finite difference method. The equilibrium shape is found by sequentially solving the linear system of equations. We specify the shear stress distribution that satisfies horizontal equilibrium to generate various shell shapes with a region of negative Gaussian curvature and a free boundary. Finite element analysis is carried out to investigate the effect of elastic deformation on the stress distribution due to material properties such as out-of-plane bending deformation and transverse strain that are dependent on Poisson's ratio. We compare the ratio of the membrane strain energy and the bending strain energy of the shell to demonstrate that the proposed method generates shell shapes that resist external loads through membrane action.

Keywords: free-form shell, form finding, horizontal projected stress, concrete shell, finite element analysis

1. Introduction

Shell structure is described by three-dimensional curved surface in which one dimension is significantly smaller compared to the other two [1], and its mechanical performance is highly correlated with geometry of the surface. It resists external loads primarily through membrane stresses. Recently, there has been renewed interest in form finding of spatial structures based on graphic statics. Thrust network analysis (TNA) is one of the methods based on graphic statics. Block and Ochsendorf [2] demonstrated that TNA can express the relationship between in-plane forces and funicular shell geometry as discrete reciprocal diagrams.

Free-form shells are complex-shaped shell structures compared to classical geometrical shells such as cylinders and spheres. The geometry of free-form shells is often described by non-uniform rational B-spline (NURBS) surfaces. When the vertical coordinate of the shell surface is defined as a graph surface with respect to the horizontal coordinates, Pucher's formulation [3] describes the equilibrium of membrane stresses on the shell with horizontal projected stresses, which can be expressed using Airy stress function. Various methods have been proposed for shape design of shells modelled as NURBS surfaces by utilizing the framework of Airy stress function. Miki *et al.* [4] developed a method to generate shell surface geometry modelled with NURBS surfaces using Airy stress function for the horizontal projected stress under gravity load. Xia *et al.* [5] suggested a method to design funicular shells by using NURBS and isogeometric analysis. Miki and Mitchell [6] extended the method by Miki *et al.* [4] to design tension-compression mixed shells by interactively searching for pairs of shell geometry and stress function that satisfy the equilibrium equations. Chiang and Borgart [7] proposed an approximation method employing radial basis functions to represent shapes and stress functions of shells

Copyright © 2023 by Taku NAKAJIMA and Makoto OHSAKI. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

and solve the equilibrium equations converted into a least-squares problem. The stress function is a powerful tool that automatically gives stress distribution that satisfies the horizontal equilibrium equations and obtains the shell shape in a reciprocal relationship with the stress function. However, higher-order derivatives are required for the NURBS basis functions, making it difficult to solve the differential equations analytically. In addition, parametric representation limits the class of possible shapes.

In contrast, non-parametric design methods that do not use parametric surfaces have been proposed. Sakai and Ohsaki [8] proposed a non-parametric design method for funicular shells under gravity load. The method enables designers to control the horizontal reaction forces on the boundaries, and accordingly, the influence on the substructure. Takeoka *et al*. [9] extended the method of Ref. [8] to shells with curved boundaries. Olivieri *et al*. [10] proposed a non-parametric method to design purely compressed shells by constraining the Airy stress function to be concave.

This paper extends the method in Ref. [9] and presents a non-parametric form finding method for continuous shell structures with specified horizontal projected stress distribution. The vertical coordinate of the shell surface is defined as a graph surface with respect to the horizontal coordinates and discretized by the finite difference method. The horizontal projected stresses are assigned to satisfy the horizontal equilibrium equations. The shell shape is given as a solution to the vertical equilibrium equations with respect to the surface heights at grid points. To generate various shell shapes, the shear stress distribution is described as a function of horizontal coordinates. Numerical examples show that the proposed method obtains various shapes with a region of negative Gaussian curvature and free boundaries where no reaction forces exist. Furthermore, finite element (FE) analysis is carried out to investigate the effect of elastic deformation on the stress distribution due to material properties such as out-of-plane bending deformation and transverse strain depending on Poisson's ratio. We compare the ratio of the membrane strain energy and the bending strain energy of the shell to show that the proposed method generates shell shapes that resist external loads through membrane action. Furthermore, the effect of the edge beams at the free boundary on the mechanical performance is discussed through FE analysis.

2. Equilibrium equations and discretization

Consider a shell structure described as a graph surface on the *xy* horizontal plane. The vertical *z*-coordinate of the surface *h* is defined as a function $h(x,y)$ of *x* and *y*.

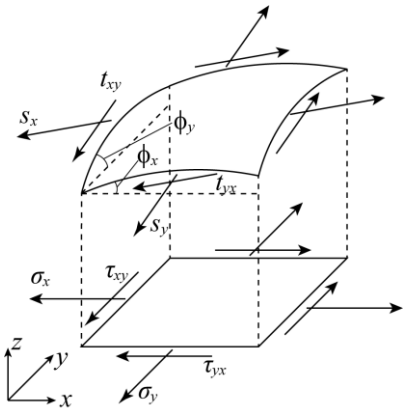

Figure 1. Definition of stresses and angles

A curved surface element is defined with respect to the planes parallel to *xz*- and *yz*-planes, respectively. The stress components on the element are shown in Fig. 1. Based on Pucher's formulation, the equilibrium between the membrane stresses and external loads is expressed using their projected components on the horizontal plane. Note that in-plane forces per unit length of the shell section are

referred to as *stresses* for simplicity. The membrane theory of shells is applied and bending moment and out-of-plane shear forces are not considered.

Let s_x and s_y be the in-plane normal stresses along the sections on the planes parallel to the *yz*- and *xz*-planes, respectively. They are the stresses in the tangent plane of the shell. t_{xy} and t_{yx} denote the in-plane shear stresses along the sections on the planes parallel to the *yz*- and *xz*- planes, respectively. The vectors corresponding to s_x, s_y and t_{xy} (= t_{yx}) are projected onto the *xy*-plane to generate the vectors of σ_x, σ_y, τ_{xy} and τ_{yx}, respectively. Horizontal projected stresses σ_x, σ_y, τ_{xy} and τ_{yx} are stresses per unit length of the horizontal plane. ϕ_x and ϕ_y denote the angles between the horizontal *xy*-plane and the curves obtained by cutting the surface with planes parallel to the *xz*- and *yz*-plane, respectively. s_x, s_y, t_{xy} (= t_{yx}), σ_x, σ_y and τ_{xy} (=τ_{yx}) satisfy the following equations.

$$\sigma_x = s_x \frac{\cos\phi_x}{\cos\phi_y}, \quad \sigma_y = s_y \frac{\cos\phi_y}{\cos\phi_x}, \quad \tau_{xy} = t_{xy} \tag{1}$$

The relationship between *h* and *x*, *y* can be written as

$$\frac{\partial h}{\partial x} = \tan\phi_x, \qquad \frac{\partial h}{\partial y} = \tan\phi_y \tag{2}$$

The horizontal equilibrium equation can be expressed as

$$\frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} = 0, \qquad \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \sigma_y}{\partial y} = 0 \tag{3}$$

Integrating Eq. (3) with respect to *x* and *y*, respectively, σ_x and σ_y can be defined using τ_{xy} as

$$\sigma_x = -\int\left(\frac{\partial \tau_{xy}}{\partial y}\right)dx + C_x(y), \quad \sigma_y = -\int\left(\frac{\partial \tau_{xy}}{\partial x}\right)dy + C_y(x) \tag{4}$$

where $C_x(y)$ and $C_y(x)$ are arbitrary functions of *y* and *x*, respectively. If the shear stress τ_{xy} is given as a function of horizontal coordinates (*x*,*y*), the normal stresses σ_x and σ_y are defined as the sum of the functions of the shear stress and the arbitrary functions $C_x(y)$ and $C_y(x)$, respectively, according to Eq. (4). To satisfy the horizontal equilibrium equations, the functions $C_x(y)$ and $C_y(x)$ must be constant in the *x* and *y* directions, respectively. On the other hand, they can be defined independently and uncorrelated with the other horizontal projected stresses. The normal stresses σ_x and σ_y are correlated with the magnitude of the shell curvature and the shear stress τ_{xy} is correlated with the direction of the principal curvature of the shell, respectively. Therefore, the shell shape can be controlled by varying these stresses.

The vertical equilibrium equation is expressed as a second-order partial differential equation as

$$\sigma_x \frac{\partial^2 h}{\partial x^2} + 2\tau_{xy} \frac{\partial^2 h}{\partial x \partial y} + \sigma_y \frac{\partial^2 h}{\partial y^2} = f \tag{5}$$

where *f* is self-weight per unit horizontal projected area of the shell that is expressed by the following equation using the mass density ρ, the acceleration of gravity *g* and the uniform shell thickness *t*:

$$f = -\rho g t \sqrt{1 + \left(\frac{\partial h}{\partial x}\right)^2 + \left(\frac{\partial h}{\partial y}\right)^2} \tag{6}$$

In this paper, the *x* and *y* coordinates of the graph surface are defined by the mapping from parameter space $(u,v) \in [0,1]^2$, respectively, as $x(u,v)$ and $y(u,v)$ to generate surfaces with curved boundaries. The differential coefficients of *u* and *v* with respect to *x* and *y* are denoted by *a*, *b*, *c*, and *d* for simplicity.

The finite difference method discretises the vertical equilibrium equation. Consider an $N \times N$ uniformly spaced grid in the (u,v) parameter space. The grid point is indicated by (i, j) $(i, j = 1, \cdots, N+1)$ and the sizes of grid in u- and v- directions are δu and δv, respectively. Eq. (5) is discretized with the z-coordinate of the grid point $h_{i,j}$ using the central finite difference method :

$$\begin{aligned}
&\left(a^2\sigma_x + 2ac\tau_{xy} + c^2\sigma_y\right)\frac{h_{i+1,j} - 2h_{i,j} + h_{i-1,j}}{(\delta u)^2} \\
&+2\left[ab\sigma_x + (ad+bc)\tau_{xy} + cd\sigma_y\right]\frac{h_{i+1,j+1} - h_{i+1,j-1} - h_{i-1,j+1} + h_{i-1,j-1}}{4\delta u\delta v}z \\
&+\left(b^2\sigma_x + 2bd\tau_{xy} + d^2\sigma_y\right)\frac{h_{i,j+1} - 2h_{i,j} + h_{i,j-1}}{(\delta v)^2} \\
&+\left[\left(a\frac{\partial a}{\partial u} + b\frac{\partial a}{\partial v}\right)\sigma_x + 2\left(a\frac{\partial c}{\partial u} + b\frac{\partial c}{\partial v}\right)\tau_{xy} + \left(c\frac{\partial c}{\partial u} + d\frac{\partial c}{\partial v}\right)\sigma_y\right]\frac{h_{i+1,j} - h_{i-1,j}}{2\delta u} \\
&+\left[\left(a\frac{\partial b}{\partial u} + b\frac{\partial b}{\partial v}\right)\sigma_x + 2\left(a\frac{\partial d}{\partial u} + b\frac{\partial d}{\partial v}\right)\tau_{xy} + \left(c\frac{\partial d}{\partial u} + d\frac{\partial d}{\partial v}\right)\sigma_y\right]\frac{h_{i,j+1} - h_{i,j-1}}{2\delta v} = f_{i,j}
\end{aligned} \tag{7}$$

The right-hand side of Eq. (7) $f_{i,j}$ is computed as

$$f_{i,j} = -\rho g t\sqrt{1+\left(a^2+c^2\right)\left(\frac{h_{i+1,j} - h_{i-1,j}}{2\delta u}\right)^2 + 2(ab+cd)\frac{\left(h_{i+1,j} - h_{i-1,j}\right)\left(h_{i,j+1} - h_{i,j-1}\right)}{4\delta u\delta v} + \left(b^2+d^2\right)\left(\frac{h_{i,j+1} - h_{i,j-1}}{2\delta v}\right)^2} \tag{8}$$

See Ref. [9] for details. Takeoka *et al.* [9] solved Eq. (7) using the successive over-relaxation (SOR) method to derive the shell shape. In this study, the solution of Eq. (7) is found by sequentially solving linear system of equations [11]. If the right sides $f_{i,j}$ are constants, Eq. (7) can be regarded as a linear system with respect to the z-coordinates $h_{i,j}$ of the grid points. The shell shape is obtained by deriving Eq. (7) at all free grid points, fixing the right-hand sides $f_{i,j}$ to the current shape, and solving them as a linear system of equations. We have verified that the method converges with lower computational cost than the SOR method [11]. The procedure is summarized as follows.

1. Define horizontal projected geometries and horizontal projected stresses of a shell.
2. Solve the linear system of the equilibrium equation (7) to obtain the z-coordinates $h_{i,j}$ assuming that the right-hand side $f_{i,j}$ of the equation is a constant value $-\rho g t$.
3. Calculate $f_{i,j}$ from Eq. (8) based on the shell shape obtained in the previous iteration step.
4. Substitute the obtained $f_{i,j}$ into the right-hand side of Eq. (7) and solve it as a linear system of equations for $h_{i,j}$ to update the shell shape.
5. Calculate e, the sum of the changes in $h_{i,j}$ at each grid point, by the following equation. The superscript (l) indicates the iteration counter.

$$e = \sum_{i=1}^{N+1}\sum_{j=1}^{N+1}\left|h_{i,j}{}^{(l+1)} - h_{i,j}{}^{(l)}\right| \tag{9}$$

6. Return to Step 3 if e is greater than or equal to the specified positive small value ξ.
7. Output the solution $h_{i,j}$ for the shell shape and terminate the iteration.

The relationship between the specified horizontal projected stress distribution and the shell shape is discussed using Mohr's stress circle. The principal stress σ_1, σ_2 ($\sigma_1 \geq \sigma_2$) of the horizontal projected stress can be written as follows.

$$\sigma_1, \sigma_2 = \frac{\sigma_x + \sigma_y}{2} \pm \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + {\tau_{xy}}^2} \tag{10}$$

The angle θ between the direction of the principal stress σ_1 and the *x*-axis is expressed as

$$\theta = \tan^{-1}\left(\frac{\sigma_1 - \sigma_x}{\tau_{xy}}\right) \tag{11}$$

The relationship between the larger principal stress, which is simply called *principal stress* below, and the stress σ_x, σ_y and τ_{xy} is shown in Fig. 2 using Mohr's stress circle. The vertical equilibrium Eq. (5) is a second-order partial differential equation. For the coefficients σ_x, σ_y and τ_{xy} of the equation, the partial differential equation is elliptic when $\sigma_x\sigma_y - {\tau_{xy}}^2 > 0$ and hyperbolic when $\sigma_x\sigma_y - {\tau_{xy}}^2 < 0$. It is known to be difficult to obtain a solution when the equilibrium equation is hyperbolic [6].

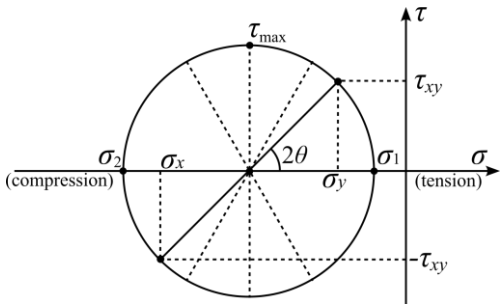

Figure 2. Mohr's Circle

3. Numerical examples

In this section, various shell shapes with different horizontal projected stress distributions are generated using the proposed method and their mechanical performances are investigated utilizing FE analysis. Note that the equilibrium surface shape depends only on the ratio of the projected stresses to the self-weight ρgt per unit projected area. Therefore, for simplicity, the units are omitted in the process of form finding and ρgt is set to 1. The Bernstein basis polynomials are used for defining the (*x*,*y*)-coordinates by the parameters $(u,v) \in [0,1]^2$. The number of grids in the parameter space is $N = 30$. The value of ξ for convergence of e is 1×10^{-10}. The form finding program is created using Python, and the linear system of the vertical equilibrium equations is solved using the Python library Numpy. OpenSeesPy [12], a Python interpreter of the FE-analysis software OpenSees, is used for linear static analysis. The shell surface is modelled utilizing the quadrilateral isoparametric shell element (ShellMITC4), which considers out-of-plane bending and shear deformations.

First, the relationship between the specified shear stress distribution and the shell shape is discussed using Models 1a–1f with rectangular boundaries and Models 2a–2f with curved boundaries. Next, the method is also applied to Model 3 with free boundary where vertical reaction forces do not exist. Finally, FE analyses are carried out for Models 1a, 1f, 2f and 3 to confirm their mechanical performance.

3.1. Form finding

We consider the following models with parameterized (*x*,*y*)-coordinates using the Bernstein polynomials:

Model 1a–1f, 3 : $x = 2u - 1, \quad y = 2v - 1$

Model 2a–2f : $x = -(2u-1)(2v^2 - 2v - 1), \quad y = (2u^2 - 2u + 1)(2v - 1)$

Models 1a–1f and 3 have square plans and Models 2a–2f have curved boundaries. The specified horizontal projected stresses are shown in Table 1. The forms found for Models 1 and 2 are investigated to reveal the influence of the shear stress distribution on the shell shape. The shell shapes and the directions of the principal curvature line of Models 1a–1e and 2a–2e are shown in Fig. 3. The red circles in the figures of shell shapes indicate the fixed boundaries. Only the *z*-coordinates of the diagonal view

Table 1. Specified horizontal projected stress

Model	σ_x	σ_y	τ_{xy} $(=\tau_{yx})$
1a–1e, 2a–2e	Defined by Mohr's stress circle. (σ_1=–0.2, σ_2 =–1.8, $\tau_{\max}$ =0.9 and θ={0, π/6, π/4, π/3,π/2})		
1f, 2f	$-\frac{1}{2}\left\{\frac{1}{2}(x+1)^2+1\right\}$	$-\frac{1}{2}\left\{\frac{1}{2}(y-1)^2+1\right\}$	$\frac{1}{2}\{(x+1)(y-1)+1\}$
3	$0.5(-x-1)$	–1	$0.5y$

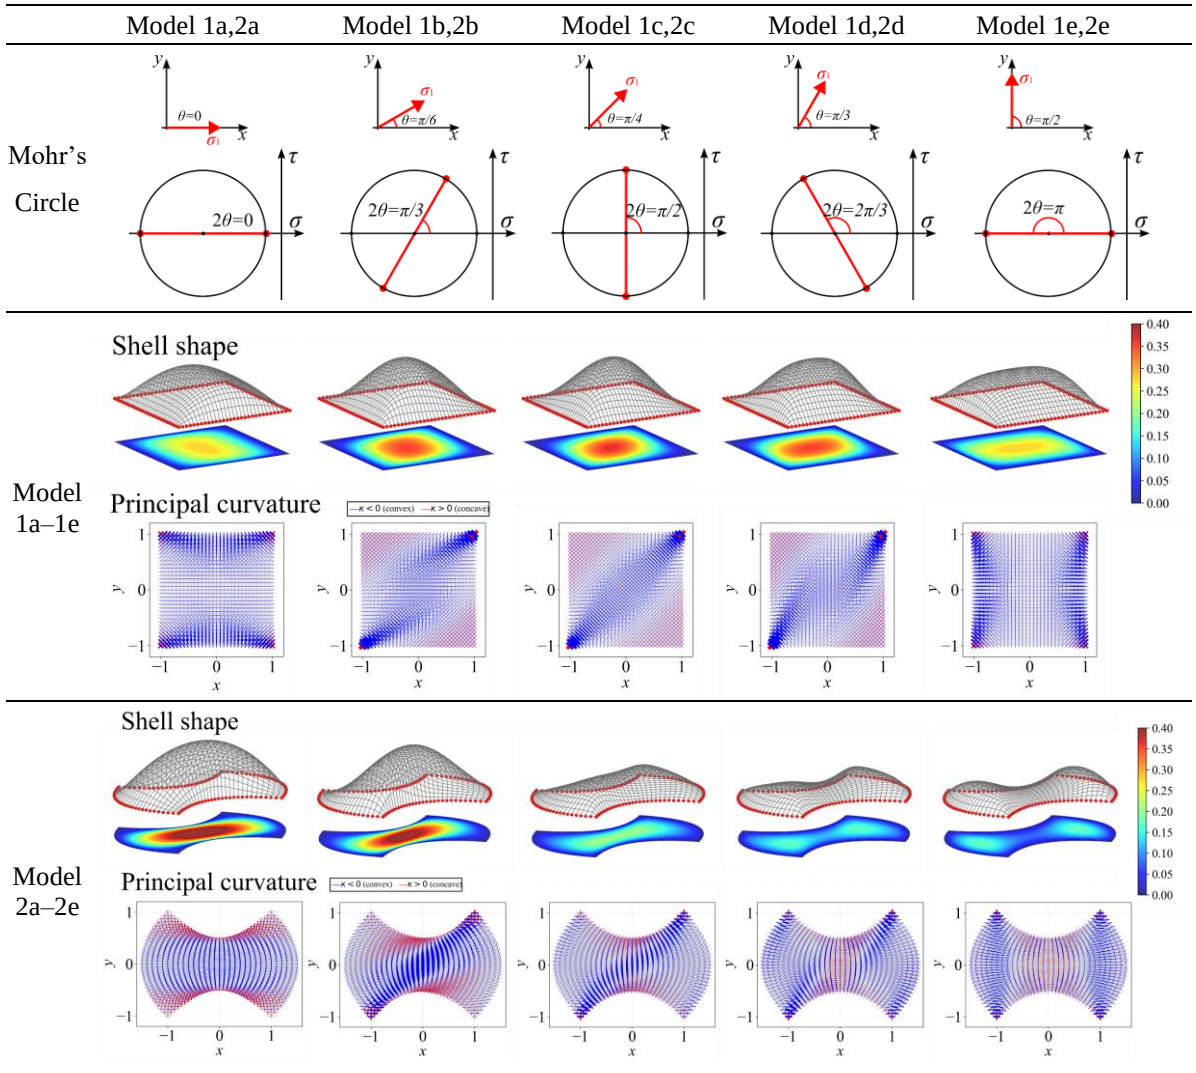

Figure 3. Shell shape and distribution of principal curvature of Model 1a–1e and 2a–2e

are scaled to 2.0 times the *x*- and *y*-coordinates. The directions of the principal curvature κ of the surface are shown as blue lines when the surface is convex ($\kappa < 0$) and red lines when it is concave ($\kappa > 0$). The thickness of the principal curvature line is proportional to the magnitude of the curvature, and the legends in the figure indicate the thickness of the line for curvature $\kappa = \pm 1$. The thick blue lines indicating the direction of smaller principal curvature are oriented orthogonally to the direction of the principal stresses. Model 2 has the highest rise when the principal stress direction is $\theta = 0$ (model 2a) due to the large span in the *x*-direction. It can also be seen that some shells contain regions of negative Gaussian curvature, where the product of the two principal curvatures is negative. These figures show that there is a correlation between the principal stress direction of the specified horizontal projected stress and the principal curvature direction characterising the shell shapes. The designer can control the curvature of the surface by specifying the principal stress direction of the horizontal projected stress.

Figure 4 shows the shell shapes and distributions of principal curvatures of Models 1f and 2f. The shear stress is defined as a function of (*x*,*y*)-coordinates. Asymmetric shell shapes are obtained by specifying asymmetric horizontal projected stress distribution.

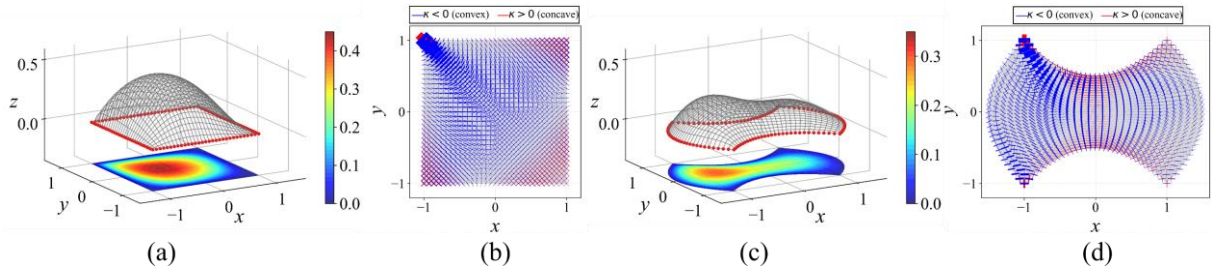

Figure 4. Shell shapes and distributions of principal curvature: (a) Model 1f, (b) Model 2f

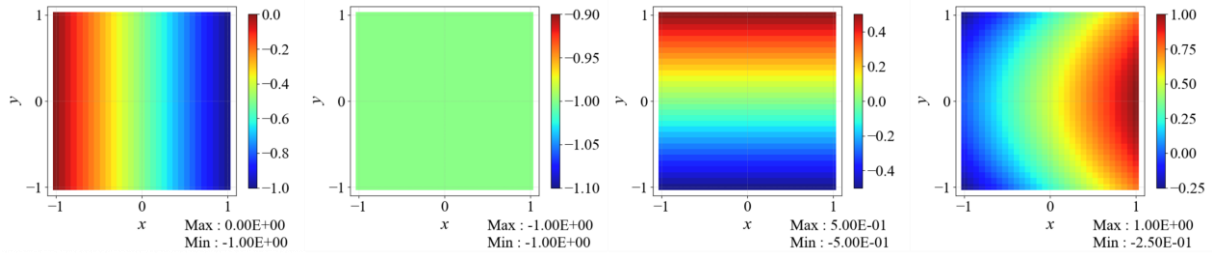

Figure 5. Horizontal projected stress distribution of Model 3: (a) σ_x, (b) σ_y, (c) τ_{xy}, (d) $\left(\sigma_x \sigma_y - {\tau_{xy}}^2\right)$

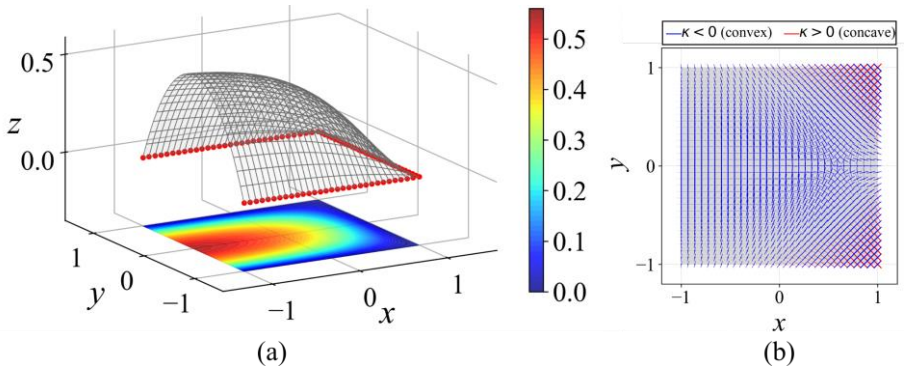

Figure 6. Model 3: (a) shell shape, (b) distribution of principal curvature

Model 3 has free boundary at $x = -1$, and the *z*-coordinates of along the free boundary are considered as variables in the shape design. The normal stresses σ_x at $x = -1$ are specified to be 0. The horizontal projected stress distribution and the corresponding shell shape are shown in Figs. 5 and 6, respectively. Note that s_y and t_{xy} are not 0 at the free boundary. These stresses can be transferred to the supports by the axial forces of beams if edge beams are arranged. Model 3 has areas where the equilibrium equations are hyperbolic as shown in Fig. 5(d). The results indicate that shell shape with hyperbolic region can be successfully obtained for this specific model, which has a free boundary and a small hyperbolic region.

3.2. Finite element analysis

FE analyses are performed for Models 1a, 1f, 2f and 3 to account for elastic deformation, including out-of-plane bending deformation and transverse strain due to Poisson's ratio; thus, units are considered for length and force. For the coordinates (*x*, *y*, *h*) of a graph surface in the form finding method, the respective coordinate values are scaled as (αx, αy, αh) (m) using the coefficient α in FE analysis. In the following examples, α is set to 10 and the scaling gives, for example, the span is 20 (m) and the rise is 2.80 (m) for Model 1a. The shell thickness and vertical distributed load are t = 0.1 (m) and $\rho g t$ = 2.4 (kN/m^2), respectively. The shells are assumed to be composed of concrete material with Young's modulus E = 20.0 (GPa) and Poisson's ratio $\nu = 0.2$. The horizontal projected stress $\sigma_x = -1.8$ in the form finding method for Model 1a corresponds to the horizontal projected stress $\sigma_x = -43.2$ (kN/m) in the FE analysis. To study the differences in shell properties with and without edge beams placed at the free boundary, FE analyses are carried out for Model 3a without edge beams at the free boundary and Model 3b with edge beams. The edge beam is assumed to have a rectangular section with the width 0.3 (m) and the height 0.6 (m).

Figure 7 shows the horizontal projected stress distribution of Model 1a obtained from the FE analysis. Focusing on the stresses at the boundary that correspond to the horizontal reaction forces, the result for Model 1a demonstrates that the stresses at the middle of the boundary closely approach the specified horizontal projected stress σ_x of 43.2 (kN/m). However, the stress falls below the specified value at the boundary near the corner. The maximum vertical displacement and the strain energy of each model are listed in Table 2, and Fig. 8 shows the distribution of the vertical displacement. The maximum displacement of Models 1a, 1f and 2f are less than 0.05% of the shell span length. More than 90% of the strain energy is due to membrane action (in-plane stress). For Model 3b, the effect of the edge beams transferring the load by axial forces reduces the vertical deformation to approximately 25% of that of Model 3a. The results of these FE analyses confirm that the shell shapes that resist external loads through membrane action have been successfully found.

Table 2. Summary of FE analysis

Model	Max. displacement (mm)	Strain energy (Nm) (Ratio (%))		
		Membrane	Bending	Total
1a	0.57	121.5 (95.4)	5.8 (0.8)	127.3 (100.0)
1f	0.43	77.3 (97.4)	2.1 (2.6)	79.4 (100.0)
2f	0.96	79.8 (93.9)	5.2 (6.1)	85.0 (100.0)
3a	1.93	101.9 (96.0)	4.3 (4.0)	106.2 (100.0)
3b	0.46	91.8 (98.6)	1.3 (1.4)	93.1 (100.0)

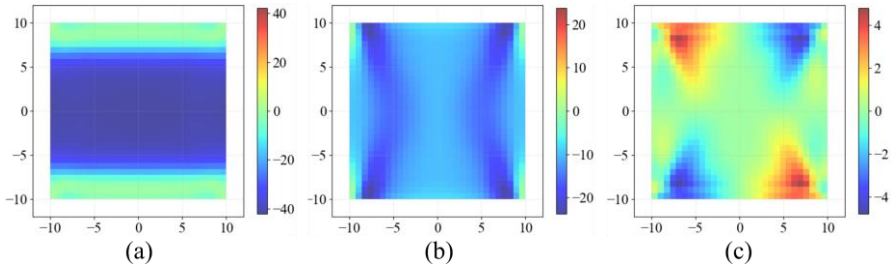

Figure 7. The projected stress distribution of model 1 obtained by FE analysis (kN/m): (a) σ_x, (b) σ_y, (c) τ_{xy}

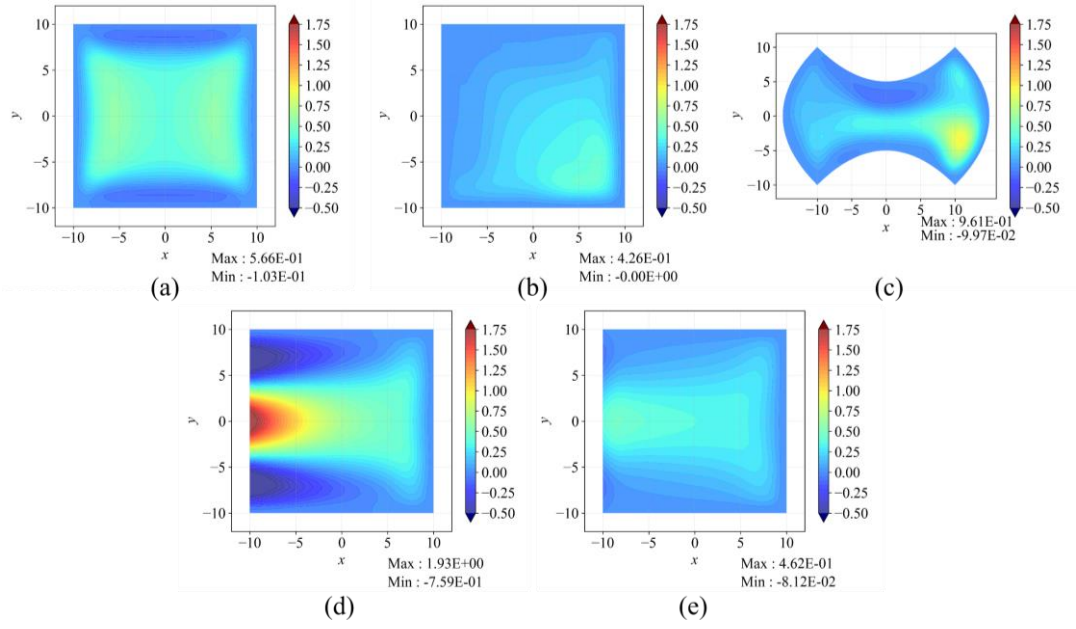

Figure 8. Distribution of vertical displacement (mm): (a) Model 1a, (b) Model 1f, (c) Model 2f, (d) Model 3a, (e) Model 3b

4. Conclusions

This study has shown a form finding method for free-form shells specifying the distribution of stresses projected onto the horizontal plane. The shell shape is obtained as a solution to the vertical equilibrium equations of the surface heights at the grid points discretized by the finite difference method. Our research has shown that various shell shapes can be generated by varying the shear stress and a shell shape with free boundaries. We conducted FE analyses to investigate the effect of elastic deformation

due to material properties on the mechanical performance of shells. These analyses confirmed that the obtained shell shapes by the proposed method resist external loads through membrane action. Conditions for obtaining solutions for shells with hyperbolic regions have not yet been clearly obtained, which is a subject of future study.

Abstract

To capture complex structural properties of free-form surfaces, geometric deep learning approaches, which can encode geometric properties of data, have been proposed regarding mesh models as graphs: a specific type of data consisting of nodes and edges. However, the connectivity of graphs becomes complex as the resolution of finite elements increases, which causes a huge computational load in training the geometric deep learning model. Recently, as an alternative to the finite element method (FEM), an increasing number of studies have focused on isogeometric analysis, which maintains the smoothness of the surface by utilizing parametric representation. In this research, by combining isogeometric analysis and geometric deep learning, a new machine learning method is developed for free-form structures that consistently perform surface representation, structural analysis, and machine learning to capture the latent information of free-form structures. This study utilizes hierarchical graphs to represent the structural model; the connectivity of patches is represented by a graph, where its nodes is associated with another subgraph representing the shape and connectivity of the control polygon. The proposed workflow will be applied to predict the maximum displacement of free-form shell structures, which requires a large computational load when using the conventional FEM. Since the proposed method uses only the control points of the surface and does not require surface discretization, more precise structural properties and behavior can be captured at a lower computational cost.

Keywords: shells, free-form structures, machine learning, geometric deep learning, isogeometric analysis, hierarchical graph neural networks, discrete representation

1. Introduction

As computer-aided design spreads to architects and engineers, free-form surfaces have become a popular choice to create dynamic, organic, and visually attractive shapes. Although it is possible to intuitively manipulate the shape of a free-form surface by manipulating control polygons, the shape needs to be converted into a polyhedron with finite small elements to analyze its structural performance using a finite element method (FEM). Moreover, a well-known dilemma in FEM is that the finer the element resolution, the higher the accuracy of structural analysis results, but the greater the computational load.

In recent years, many attempts have been made to introduce machine learning to reduce the computational load of numerical analyses. One of the most famous applications is physics-informed neural networks (PINNs) [1], where neural networks approximate solutions to partial differential equations governing the laws of physics over the predetermined domain. However, the performance of regular PINNs can be ensured only on a single geometry, and they need to be re-trained when the domain or the boundary conditions are changed; this suggests that regular PINNs cannot fully take into account the geometrical information of the various regions.

Geometric deep learning is a field that explicitly considers the geometric property of data in the machine learning model [2]. It has become increasingly popular, as it enables the analysis and manipulation of complex geometric data, such as meshes, graphs, and point clouds, in a more efficient and accurate way. Geometric deep learning represents the input geometry as a graph, where nodes represent individual elements and edges represent the connections between them. By analyzing the data using geometric deep learning techniques, it is possible to accurately predict stress distribution [3,4], displacements [5], and dynamic particle behavior [6].

In addition to geometric deep learning, hierarchical deep learning is a method that explicitly considers the hierarchical structure of data and machine learning models, and has the strong potential to enhance the prediction performance of the machine learning model. The work by Marvouniotis and Chang [7] is one of the earliest examples of introducing hierarchy into machine learning models. Saha et al. [8] utilized a hierarchical neural network architecture to capture stress concentration and solve multiscale problems.

Considering both geometric and hierarchical aspects in deep learning may improve the prediction accuracy of the machine learning models. Fortunato et al. [9] introduced a hierarchical approach to process mesh data with two different resolutions, and the trained machine learning model successfully predicted a Kármán vortex street, one of the typical fluid behaviors, on a very coarse mesh at high accuracy.

Regular FEM, geometric deep learning, and hierarchical deep learning methods are developed on a discrete basis. On the other hand, isogeometric analysis (IGA) [10] is based on the concept of isogeometric modeling of smooth shapes, which uses the same mathematical expressions, e.g., Bézier, B-spline, and NURBS, to describe both the structural geometry and the shape functions used for numerical analysis. This approach allows for more seamless integration between the design and analysis phases, as the same mathematical functions can be used for both tasks without the need for re-meshing. IGA also offers several advantages over traditional finite element analysis, including improved accuracy, smoother results, and more efficient computation. IGA is expected to be applicable to new parametric forms of surfaces consisting of limited favorable classes of surface patches such as piecewise constant Gaussian/mean curvature surfaces [11].

This study attempts to seamlessly perform free-form shape modeling, structural analysis, and machine learning to capture the structural performance by combining geometric deep learning, hierarchical deep learning, and IGA techniques. We use Bézier surfaces and Bézier curves to represent the shape of concrete shells and their ribs, respectively. The control net is not only a discrete representation of the surface shape, but can also be regarded as graph-structured data, making it posible to use existing machine learning methods for graphs. In the numerical examples, the machine learning model trained by the proposed framework predicts the displacement distribution of the structure with 93.3% accuracy in a logarithmic scale.

2. Hierarchical graph representation of ribbed shell structures

2.1. Hierarchical graph representation of a Bézier surface with multiple patches

In this research, we use Bézier surfaces, which are a relatively simple free-form surface representation uniquely defined by the position information of the control net. For a Bézier surface with order $n_\mathrm{u} \times n_\mathrm{v}$, the position of the point on the surface is calculated by the following formula by specifying the parameters $u, v \in [0,1]$ on the surface

$$\mathbf{p}(u,v) = \sum_{i=0}^{n_\mathrm{u}} \sum_{j=0}^{n_\mathrm{v}} B_i^{n_\mathrm{u}}(u) B_j^{n_\mathrm{v}}(v)\, \mathbf{R}_{ij} \tag{1}$$

where $B_i^{n_\mathrm{u}}(u)$ and $B_j^{n_\mathrm{v}}(v)$ are the Bernstein basis polynomials, and $\mathbf{R}_{ij}$ is a position vector of the control point indexed by (i,j).

In almost all practical cases, it is necessary to design the shell shapes with multiple patches, because the tensor product expression of parameters of a single patch is not suitable for representing complex shapes. Multiple-patch representation is also beneficial when considering constructability; the surface shape can be simply reinforced with ribs along the patch connection to stiffen the shell structure.

One of the highlights of this research lies in representing multiple-patch surfaces using hierarchical graphs. Figure 1 shows an example of the hierarchical graph representation. Here, the parent graph represents the connectivity of patches. Each node in the parent graph corresponds to a patch, and each edge represents G0 continuity between the patches. A child graph branches from a parent node, and the nodes and edges of the child graph represent the control nets of the patch surface.

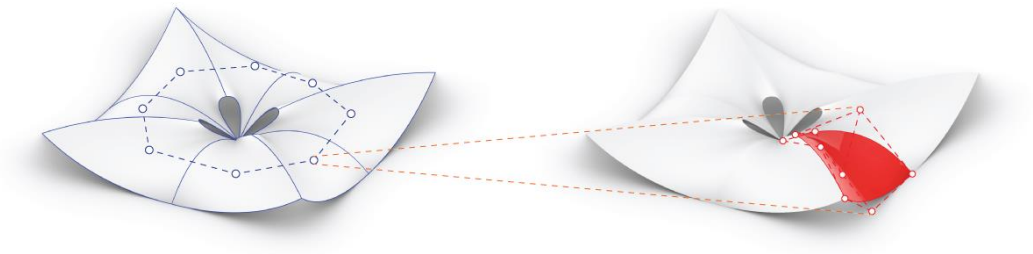

Figure 1. Hierarchical graph representation of a multiple-patch Bézier surface.

2.2. Extraction of node and global features over a single graph

To handle graph data with arbitrary connectivity in geometric deep learning, graph neural networks are the most popular machine learning model. Among various graph neural network models, Edge-Conditioned Convolution (ECC) [12] is introduced to extract node features, because it is one of the representative methods to handle both node and edge inputs.

This paragraph briefly summarizes the ECC method. Suppose there are n_n nodes and n_m edges in a graph. Let $\mathbf{X}_0(i) \in \mathbb{R}^{n_\mathrm{v}}$ denote the input of node i and $\mathbf{L}(j,i) \in \mathbb{R}^{n_\mathrm{w}}$ denote the input of edge (i,j). If node i is connected to a set of nodes $N(i)$, the node feature $\mathbf{X}_l(i)$ $(l \geq 0) \in \mathbb{R}^{d_l}$ is updated to $\mathbf{X}_{l+1}(i) \in \mathbb{R}^{d_{l+1}}$ as follows:

$$\mathbf{X}_{l+1}(i) = \frac{1}{|N(i)|} \sum_{j \in N(i)} F_l(\mathbf{L}(j,i); \mathbf{w}_l)\mathbf{X}_l(j) + \mathbf{b}_l \tag{2}$$

where $\mathbf{w}_l \in \mathbb{R}^{(d_{l+1} \times d_l) \times s}$ and $\mathbf{b}_l \in \mathbb{R}^{d_l}$ are the trainable parameters, and $F^l \colon \mathbb{R}^s \mapsto \mathbb{R}^{d_{l+1} \times d_l}$ is a filter generating network parametrized by $\mathbf{w}_l$. Except that $d_0 = n_\mathrm{v}$, the feature dimension d_l $(l \geq 1)$ can take an arbitrary positive integer. By repeating this convolution, the node features can capture the property of neighborhood nodes and edges.

This study modifies the ECC method to further consider self-node and global features. In addition to the node and edge input matrices, the proposed method requires another input vector $\mathbf{G}_l \in \mathbb{R}^{n_\mathrm{g}}$, which inform the machine learning model of the global information about the entire graph. The modified convolution operation is formulated as

$$\mathbf{X}_{l+1}(i) = \mathbf{H}_{l+1}^1(i) + \mathbf{H}_{l+1}^2(i) + \mathbf{H}_{l+1}^3(i) \tag{3a}$$

$$\mathbf{H}_{l+1}^1(i) = \varphi\left(F_{l,1}\left(\mathbf{X}_l(i); \mathbf{w}_{l,1}, \mathbf{b}_{l,1}\right)\right) \tag{3b}$$

$$\mathbf{H}_{l+1}^{2}(i) = \frac{1}{|N(i)|} \sum_{j \in N(i)} \varphi\left(F_{l,2}\left(\mathbf{L}(j,i); \mathbf{w}_{l,2}, \mathbf{b}_{l,2}\right)\right) \mathbf{X}_l(j) \tag{3c}$$

$$\mathbf{H}_{l+1}^{3}(i) = \varphi\left(F_{l,3}\left(\mathbf{G}_l; \mathbf{w}_{l,3}, \mathbf{b}_{l,3}\right)\right) \tag{3d}$$

where φ is the Leaky ReLU activation function, and $F_{l,1}$, $F_{l,2}$, and $F_{l,3}$ are filter generating networks parametrized by $(\mathbf{w}_{l,1}, \mathbf{b}_{l,1})$, $(\mathbf{w}_{l,2}, \mathbf{b}_{l,2})$, and $(\mathbf{w}_{l,3}, \mathbf{b}_{l,3})$, respectively. From each operation, $\mathbf{H}_l^1$, $\mathbf{H}_l^2$, and $\mathbf{H}_l^3$ are regarded as features encapsulated into a node considering the self-node, neighbor nodes and edges, and whole graph, respecrively.

The node feature matrix can be expressed in a matrix form $\widetilde{\mathbf{X}}_l \in \mathbb{R}^{n_\mathrm{n} \times n_\mathrm{v}}$, whose rows contains the feature of each node. Once the updated node feature matrix $\widetilde{\mathbf{X}}_{l+1} \in \mathbb{R}^{n_\mathrm{n} \times n_\mathrm{v}}$ are obtained, the global feature vector $\mathbf{G}_l$ can also be updated to $\mathbf{G}_{l+1}$ using a variant of the soft attention mechanism [13] modified by the PyTorch geometric library [14] as

$$\mathbf{G}_{l+1} = \sum_{i=1}^{n_\mathrm{n}} \mathrm{softmax}\left(F_{l,4}\left(\widetilde{\mathbf{X}}_{l+1}; \mathbf{w}_{l,4}, \mathbf{b}_{l,4}\right)\right) \odot F_{l,5}\left(\widetilde{\mathbf{X}}_{l+1}; \mathbf{w}_{l,5}, \mathbf{b}_{l,5}\right) \tag{4}$$

where $\Sigma_{i=1}^{n_\mathrm{n}}$ indicates column-wise summation, "softmax" is a softmax function over the matrix rows, and $\odot$ indicates element-wise multiplication. Similar to Eq. (3), Eq. (4) introduces neural networks $F_{l,4}$ and $F_{l,5}$.

2.3. Extraction of node and global features over a single graph

This study further augments the graph embedding method in Sec. 2.2 to handle hierarchical graph data. Figure 2 illustrates the two types of graphs on the surface; one is a parent graph representing the patch connectivity; the other is a child graph representing the control net connectivity of each patch. Tables 1 and 2 describe the node and edge inputs of the parent graph, and Tables 3 and 4 describe the inputs of the child graphs. Although any number of inputs can be given with any definition for $\mathbf{X}_0$ and $\mathbf{L}$ we carefully defined these inputs such that the machine learning model can accurately capture the geometrical and struructural information on the surface.

Table 1. Node input definition $\mathbf{X}_0(i)$ of the parent graph.

index	description
1	Maximum difference of *x*-coordinate in the control net
2	Maximum difference of *y*-coordinate in the control net
3	Maximum difference of *z*-coordinate in the control net

Table 2. Edge input definition $\mathbf{L}(j,i)$ of the parent graph.

index	description
1	1 (constant)

Table 3. Node input definition $\mathbf{X}_0(i)$ of the child graph.

index	description
1	*u*-coordinate of the closest point on the patch
2	*v*-coordinate of the closest point on the patch
3	1 if supported, 0 otherwise
4	Normalized *x*-coordinate in the control net
5	Normalized *y*-coordinate in the control net
6	Normalized *z*-coordinate in the control net

Table 4. Edge input definition $\mathbf{L}(j,i)$ of the child graph.

index	description
1	1 if beam, 0 otherwise

In the proposed method, the graph embedding operations Eqs. (3) and (4) are alternately repeated for the child graphs and the parent graph. That is, the global feature of the child graph becomes the node feature of the parent graph, and vice versa. This way, the node feature of child graph can capture not only the local-scale information about the control net but also global-scale information about the patch after several iterations. In this study, the number of repetitions is two.

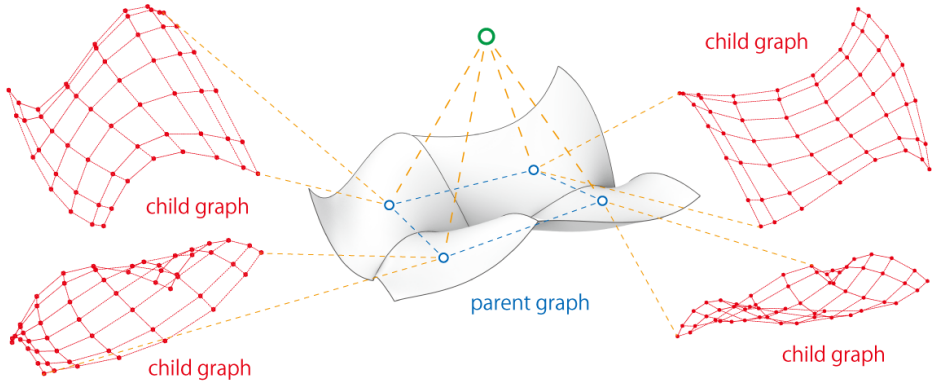

Figure 2. Classification of two types of graphs in the multiple-patch Bézier surface: parent and child graphs.

2.4. Prediction of responses at the nodes

Let d_{r} denote the intermediate feature dimension in predicting the nodal responses. After obtaining the node features $\widetilde{\mathbf{X}}_2 \in \mathbb{R}^{n_{\mathrm{n}} \times d_2}$ in the child graphs, the prediction of response value $\mathbf{r}_{\mathrm{pred}} \in \mathbb{R}^{n_{\mathrm{n}}}$ is computed as follows:

$$\mathbf{r}_{\mathrm{pred}} = \mathrm{Sigmoid}\left(F_{\mathrm{r},1}\left(\varphi\left(F_{\mathrm{r},2}\left(\widetilde{\mathbf{X}}_2; \mathbf{w}_{\mathrm{r},2}, \mathbf{b}_{\mathrm{r},2}\right)\right); \mathbf{w}_{\mathrm{r},1}, \mathbf{b}_{\mathrm{r},1}\right)\right) \tag{5}$$

where $F_{\mathrm{r},1}: \mathbb{R}^{d_{\mathrm{r}}} \mapsto \mathbb{R}$ and $F_{\mathrm{r},2}: \mathbb{R}^{d_2} \mapsto \mathbb{R}^{d_{\mathrm{r}}}$ are the neural network layer parametrized by $(\mathbf{w}_{\mathrm{r},1}, \mathbf{b}_{\mathrm{r},1})$ and $(\mathbf{w}_{\mathrm{r},2}, \mathbf{b}_{\mathrm{r},2})$, respectively. Equation (5) can be interpreted as the process of converting the node feature of size d_2 into another feature vector with size d_{r} and then into a scalar value. Note that the output is scaled by the Sigmoid function into (0,1) to facilitate the training.

3. Numerical example

3.1. Surface modeling

In this study, the shell shape is composed of $n_{\mathrm{u}} \times n_{\mathrm{v}}$ grid Bézier patches, where n_{u} and n_{v} take 2 or 3 randomly; i.e., the orders of the patch can be either quadratic or cubic in its two directions. For example, if the order of the patch is determined as quadratic in one direction and cubic in the other direction, the patch shape is defined by a control net composed of $3 \times 4 = 12$ control points. Once the patch topology is determined this way, the overall surface shape is determined by the order of the patch surfaces and the location of control points. In order to generate various shapes, the positions of control points are randomly generated as follows. The *x* and *y* coordinates are determined by a uniform distribution so that there is a space within 5 to 7.5 meters between adjacent control points. The *z* coordinate is determined by a uniform distribution of between 0 to 5.0 meters.

The shell material is assumed to be the default concrete property of Kiwi!3D [15], which is an isogeometric analysis plug-in for the numerical modeling tool Grasshopper: Young's modulus 35000 N/mm^2, zero Poisson's ratio, and the strength 25 N/mm^2. The shell thickness shall be 200 mm. The rib material is assumed to be Kiwi!3D's default steel property: Young's modulus 210000 N/mm^2, zero Poisson's ratio, and the strength 235 N/mm^2.

The four corners in each Bézier patch are fixed in translation, while their rotation is unconstrained. The surface is subject to a downward surface load of 10 kN/m^2. For simplicity, the self-weight of concrete and steel is not included in the loading condition.

To accurately compute the displacement distributions, the surface orders are increased by increasing the control points while maintaining the original shape. In the following, the refined control nets are utilized to express the child graphs. In order for the machine learning model to learn on various surfaces, surface generation is performed 5000 times based on the rules explained above.

3.2. Structural analysis

For the surfaces randomly generated in the previous section, The displacement distribution is computed using Kiwi!3D. In Kiwi!3D, we implemented geometric nonlinear analysis to obtain the displacements closer to the actual behavior.

Structural analysis results by Kiwi!3D are generated in a text format summarizing displacements and stresses at Gauss integration points. After reading the text data, the displacement values of the closest Gauss point are assigned to each control point. This way, all the control points are associated with unique displacement values, which become the target value to be predicted. This process is repeated for all the 5000 surface shapes, and the target values are stocked and used for machine learning in the next section.

3.3. Machine learning

The displacements have a large variance among 5000 configurations and even within a single configuration. In order to normalize the displacement to be predicted, the response value r_{true} is normalized to $\tilde{r}_{\mathrm{true}}$ by the following equation:

$$\tilde{r}_{\mathrm{true}} = \frac{\log(r_{\mathrm{true}}) - \min(\log(r_{\mathrm{true}}))}{\max(\log(r_{\mathrm{true}})) - \min(\log(r_{\mathrm{true}}))} \tag{6}$$

Figure 3 shows the distributions of displacements sorted in the increasing order in the training data before and after the normalization. As seen in Fig. 3, the target values are distributed relatively evenly in the range [0, 1] by normalization described in Eq. (6).

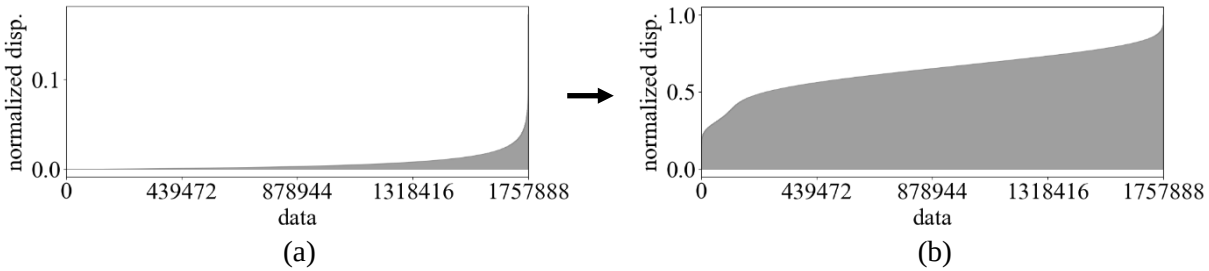

Figure 3. Distribution of displacements in the training data. (a): original displacements. (b): normalized displacements.

Structural analysis results corresponding to randomly-sampled 4500 configurations, which are 90% of the total training data, are used for training, and the remaining 500 configurations are used as test data for performance verification of the machine learning model. Suppose a unit learning process using all the training data is regarded as one epoch. This process repeats for 500 epochs in this example.

The following is the settings to train the machine learning model. The trainable parameters are initialized with a normal distribution with zero mean and 0.05 variance. The mean squared error (MSE) is adopted as the loss function to be minimized. Adam [16] is used as the tuning method of trainable parameters, and the initial learning rate is set to 0.001. The batch size is fixed to 32.

It took 55 minutes to finish the 500-epoch training with the 12th Gen Intel(R) Core(TM) i9-12900K@3.19 GHz CPU and the NVIDIA GeForce RTX 3090 GPU. Figure 4 describes the history of average MSE losses for training data and test data. Both train and test losses have deceased almost monotonically; however, the train and test losses are slightly separated as learning progresses in the second half of learning. This suggests that increasing the training epochs may merely result in overfitting, and the machine learning model will no longer be able to improve its generalization performance.

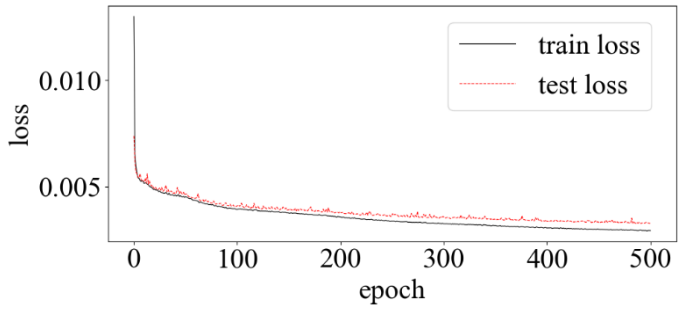

Figure 4. History of average MSE losses for training data (train loss) and test data (test loss).

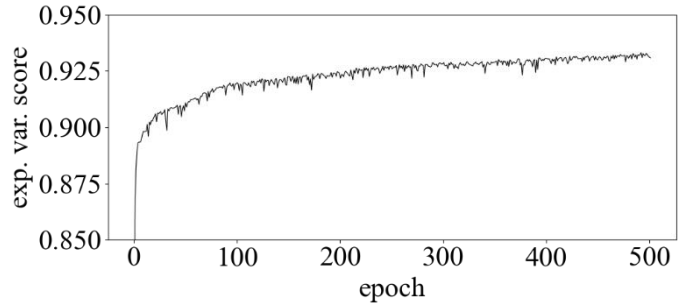
Figure 5 shows the history of explained variance score, which is a prediction accuracy metric. Although the prediction accuracy improves as the learning process progresses, the score peaks at 93.3% after 491 epochs. Considering that the best possible score is 1.0 and the target value $\tilde{r}_{\mathrm{true}}$ is logarithmically scaled, this prediction accuracy is insufficient to be used as a practical predictor bypassing the structural analysis.



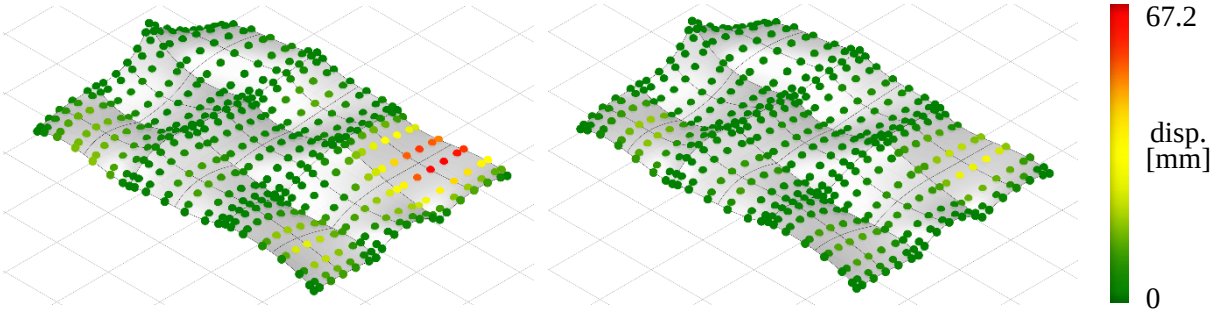


Figure 5. Explained variance score for the set of test data.

Figure 6 illustrates the difference between the true and predicted displacement distributions for a 3 × 3-patch structure. Note that this structural model has not been included in the training material. The maximum true displacement is 67.2 mm, while the maximum predicted displacement is 29.5 mm. Although the trained machine learning model cannot accurately estimate the magnitude of the displacement, it succeeds in simulating the true deformation mode in Fig. 6.

(a) (b)

Figure 6. Difference between the true displacement distribution (a) and the predicted distribution (b).

4. Conclusion

We proposed an isogeometric deep learning framework that combines geometric deep learning, hierarchical deep learning, and IGA techniques. This framework is specially designed to predict the displacements of free-form surfaces with piecewise smooth properties. To represent the structural shape composed of concrete shells ribbed by steel beams at the edges, two-level hierarchical graphs are introduced, in which the upper-level graph represents the connectivity of patch surfaces, and the lower-level graph represents the connectivity of control nets. By consistently using this representation for shape modeling, structural analysis, and machine learning, the proposed framework succeeded in completely avoiding re-meshing, which has been the cause of numerical errors and workload.

The development of isogeometric deep learning framework is still in the preliminary phase, and there are several limitations in the proposed method. The first limitation is the dilemma regarding surface order; higher order surfaces are necessary to accurately interpolate the displacement distribution; meanwhile, increasing the surface order makes the machine learning problem more difficult and computationally intensive. Second, this research dealt with only Bézier curves and surfaces. In order for the proposed method to handle NURBS, which are more general free-form surface representations, it is necessary to improve the data representation to include knot vectors. Third, the prediction accuracy of the current model has peaked at 93.3% in a logarithmic scale. In order to use the trained model as a surrogate model that does not require structural analysis, further improvement of the prediction accuracy is required.

Abstract

The detailing of structural steel connections in routine building design has a high reliance on the use of standardised connection arrangements. These arrangements, specified by national industry organisations or in-house as typical details, are formulated to incorporate structural, cost, and sustainability efficiency as well as constructability best practice. This integration of multiple knowledge bases, as well as the sophisticated design checks and detailing rules required for connection design, can make the underlying rationale for component selection difficult to intuit for junior structural engineers. This paper explores the use of Augmented Reality (AR) tools for the interactive design exploration and value engineering of structural steel connections. Connection component descriptions and structural design data is stored and accessed from a 'component-set' connection database. The database is connected to a parametric model of the connection in Rhino/Grasshopper, with model visualisation and interactivity then enabled via the Fologram mixed reality plug-in. Using a HoloLens 2 or mobile device, users are able to intuitively explore the real-time design variations of connection component alternatives. This tool is thus able to improve collaboration and understanding between designers and fabricators, toward the co-design of more efficient steel connections and structures.

Keywords: augmented reality, set-based parametric design, design automation, structural engineering, steel connection detailing

1. Introduction

The detailed design and documentation of structural steel connections is seen as a specialised and time-consuming task. Initial connection descriptions are normally specified by the structural engineer, based on connected member sizing and transmitted design load requirements. During coordination with fabricators and site erectors, connections will then be iteratively redesigned to improve the economy and efficiency of building manufacture and construction [1]. To reduce the level of required redesign, engineers often utilise standardised connection arrangements, which are specified by national industry bodies or from project precedent, to describe connection arrangements which are known to already achieve structural, cost, and sustainability efficiency, as well as constructability best practice [2].

Standardised connection design information is available to engineers through a range of physical or computational design support tools, including for example design look-up tables, parametric structural design tools (e.g. spreadsheet or code), and integrated structural design and analysis software (e.g. commercial software which may support BIM integration) [3]. These tools encapsulate sophisticated design checks, detailing rules, and permissible component arrangements, allowing users to quickly specify or compare connection options. However, for junior or inexperienced structural engineers, the

underlying rationale for component selection can be difficult to intuit, particularly as related to material vs labour cost efficiency and offsite vs onsite productivity differentials.

The aim of this paper is to provide users with an intuitive perception on the variation of connection designs, via 3D visualisation and real-time interaction with a mixed-reality connection model. This is proposed to enable improved designer evaluation and selection of valid and efficient connection component arrangements. A 'component-set' connection database is proposed to store connection component descriptions and structural design data. The database data is then accessed and connected to a Rhino/Grasshopper parametric model, enabling visualisation and interactivity of the connection models. With a HoloLens headset or smart devices, users can have an immersive 3D experience and intuitive exploration of real-time design variations of connection component alternatives.

2. Background

2.1. Component-set connection representation

A wide range of steel connection types are physically constructed from a relatively small range of constituent components. For example, a common simple connection typically consists of steel sections, bolts, welds, or plates as shown in Fig.1.

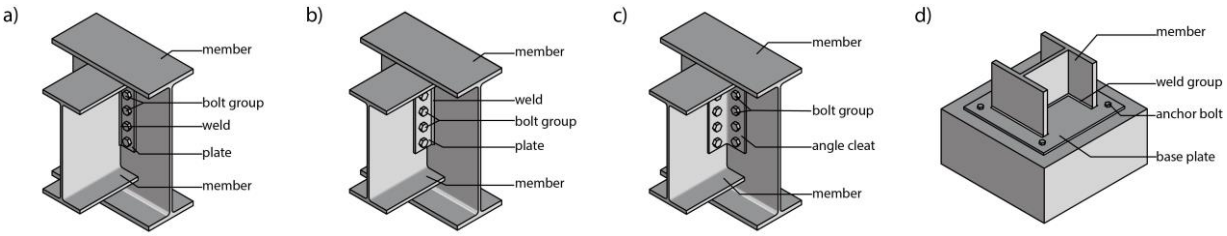

Figure 1. Simple steel connections with assembled components. Connection types: (a) flexible end plate, (b) web side plate, (c) angle cleat and (d) pinned base plate connection.

This component-based connection representation is commonly standardised in Building Information Model (BIM). It utilises Industry Foundation Class (IFC) data schema following an object-oriented modelling approach to store building information into entities with inheritance hierarchy [4]. This allows for a steel connection to be represented as an aggregation from individual component objects [5]. The geometric and non-geometric attributes and properties associated with the connections are all organised and integrated on a component object basis [6]. Relationships between the connection object with its component objects and other objects remains hierarchical. The component-based connection model has also been applied in simulation and analysis of structural behaviour. For example, the analytical connection modelling methods originally defined in the Eurocode 3 'Component Method' [7] and in component-based finite element modelling (CBFEM) for numerical analysis [8]. These procedures consider a connection as a set of discrete components, modelled as springs or rigid links to determine connection stiffness or rigidity [9, 10].

Some precedent research has formulated feasible component-based design process for steel connections [11-13]. In these frameworks, a connection is modelled from a hierarchical sub-component definition. The relevant design methods and parameters are encapsulated within each component object. Although the component-based representation is well established in BIM-enabled structural design tools, this design process is rarely utilised in the contemporary structural design tools. Rather, these usually require sequential input of discrete parameters for design capacity evaluation, without managing the relationships and hierarchy between components and connection structures.

2.2. Set-based parametric method in structural design

Due to the characteristics of internal design models within prevailing structural design tools, engineers predominately follow a point-based design (PBD) method. This involves progressive modification of the design variables of a single design option through consecutive deign steps, until a solution is satisfied [14]. Premature convergence in this design methods restricts the design space, resulting in a feasible but suboptimal design [15]. Low information availability during the early design phase may also cause high uncertainty and require repetitive rework, reducing time and cost efficiency [16].

As an alternative approach, set-based design (SBD) is based on concurrent and delayed decision-making. Its initial concept has been attributed to Toyota, known as 'second Toyota paradox', for improving car product development [17]. Design space exploration starts with sets of designs with feasible range; set size is progressively narrowed down based on input design constraints and criteria, until finally converging on a single solution [18]. This design approach is beneficial in solving contemporary and complex design and optimisation problems, especially in lean product development [19]. Its application in structural design problem is found primarily in reinforced-concrete design [20-22]. The SBD method has been used to assess and optimise the safety, cost or material efficiency, and environmental impact of sets of reinforced-concrete structures with varying design parameters (e.g. structural geometry, member sizes, rebar details, et cetera). However, its application to aspects of steel structure design is limited.

2.3 AR support tools for structural design and construction

The growing maturity and development of AR technology and devices have resulted in their widespread adoption in Architecture, Engineering, and Construction (AEC) industries, particularly in the areas of education, design, planning, manufacturing, and construction [23, 24]. AR is an advanced visualisation technique that seamlessly integrates virtual content, such as 3D models, video, and text, into the real world [25]. By superimposing the virtual object onto the physical environment, users can perceive an enhanced reality with coexisting virtual and physical objects [24]. AR is also noted as a vital technology for Industry 4.0, which for the steel industry aims to achieve the automation and digitisation of the entire production process to improve energy efficiency, productivity, quality, and flexibility of production customisation [26]. AR is suggested to apply steel manufacture and construction for workplace operator training and virtual assistance with assembly, maintenance, and inspection tasks [27].

AR has also been shown to be highly valuable and versatile when integrated with structural design and analysis processes. Researchers have developed interactive AR tools for educational purposes, to support students or junior engineers in understating intuitive design features and real-time simulation of structural behaviour [23, 28]. Wen et al. utilised cloud-based AR to superimpose virtual 3D BIM model of steel connection sculptures onto paper-based drawings, to assess the effectiveness of AR in helping student understand complex 2D drawing [25]. Dib and Adamo proposed an interactive learning environment to assist student to visualise stress, deformation, and failure on a virtual connection model, overlaid on a physical model by applying force [29]. Luo and Mojica Cabico developed an AR-based learning tool for bridge construction, that can superimpose a bridge model with load transfer path and highlighted elements on images [30]. Ilgu developed an AR application that allows users to adjust input load to observe structural behaviour of a physical building under certain loading condition [31]. Quinn et al. proposed an AR prototype which users can interact with visually augmented physical structure model and observe a real-time variation of internal load and deflection caused by applied forces [32, 33]. Abdullah, Kassim and Sanusi conducted an experiment to evaluate the effectiveness of AR application in enhancing students' understanding of steel architectural constructions [34]

3. Methodology

The aim of this study is to present an AR model for interactive design exploration and value engineering of structural steel connections. The proposed model is illustrated in Fig. 2 and comprises four processes, detailed further in the following subsections:

1) *Steel Connection Database:* Precalculated detailed design information of many connection alternatives and their assembled components.
2) *User Connection/Component Selection*: Interactive interface for user selection of connection and/or component arrangements, for indexing and deserialisation of database record.
3) *Geometric and Semantic Modelling*: A 3D parametric model of connection geometry, with accompanying textual and diagrammatic annotations of connection failure mechanisms.
4) *AR Visualisation and Interactivity*: a life-sized virtual connection model in mixed reality environment, with clickable buttons for failure mode observation and component selection.

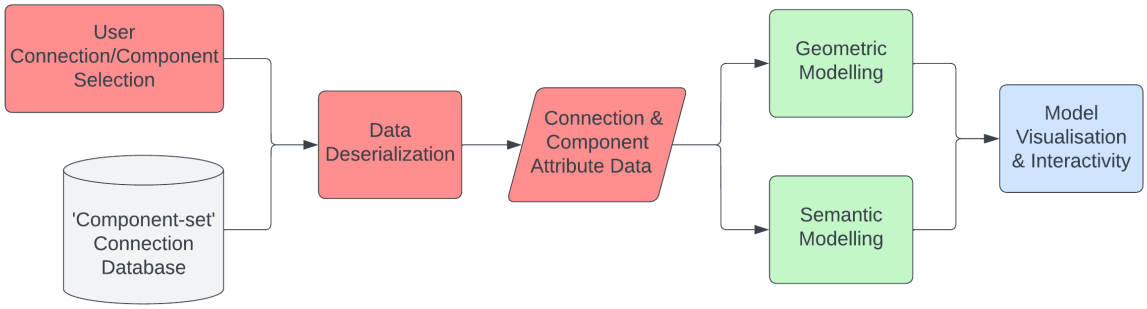

Figure 2. Modelling process of interactive AR steel connection in Rhino/Grasshopper.

3.1 Steel connection database

In prior research, the authors developed a ‘component-set’ steel connection design database for concise description and reusability of connection design data. Database information is generated from the integration of a component-based connection design model and a set-based parametric design method.

The component-based connection design model allows a connection to be represented as hierarchical aggregation of different class types, including component classes, component group classes, and connection classes as illustrated in Fig. 3. Component classes (e.g. bolts, welds, plates) encapsule the defined attributes and design methods for single component types, including designation, sizes, material properties, and capacities. Component group classes (e.g. bolt groups) aggregate component objects with additional attributes and methods to specify component groupings that are frequently used. Connection classes are constructed by aggregating component and component group objects. Connection objects can then invoke attributes and methods of their constituent components to perform detailed checks and component capacity calculations.

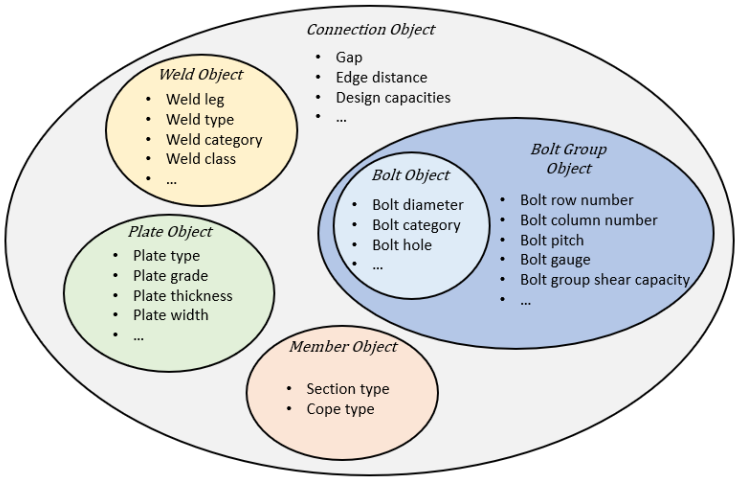

Figure 3. Data structure of a connection object and its constituent component objects.

Extending from the component-based connection design model, a set-based parametric design method is integrated to allow the highly flexible and concise generation of component, component group, and connection objects from set operations. Component and component group object sets are first generated from design parameters corresponding to standard Australian component sizes, types, and construction practice. Connection design parameter sets are then generated as the Cartesian Product of component objects with additional component arrangement parameters, that is as any potential combination of standard components. A set of connection design objects that contain full design data can be generated from their defined connection class accordingly.

In generating connections from the mass-combination of any potential component, a large number of invalid and/or inefficient connection designs are created. Here, validity of connection objects is self-evaluated based on the detailing checks implemented in the connection class, and efficiency is evaluated based on material consumption. For the present purpose of interactive design exploration, we preserved these invalid options in the generated data collection such that they can be 'discovered' by users and interrogated to understand the invalid or limiting conditions. The final collection of component and connection objects forms the steel connection database, containing all geometric, material, and structural capacity data in a structured JSON data format.

3.2 User component/connection selection

Interactive user engagement with the steel connection design database is facilitated via two input methods: 1) users select a connection record directly; or 2) users select connection sub-components, which are then aggregated to find a corresponding unique connection record. The first method allows a user to iterate directly over standardised (valid and efficient) design options, whereas the second method allows a user to explore the influence of component selection on connection validity/invalidity and efficiency/inefficiency.

From provided user input, a unique name-key index is used to retrieve the specified objects (connection and/or components) from the connection database. The returned data is in a serialised JSON format; this is deserialised to expose object attribute data for subsequent modelling steps. For the first input method, connection attribute data includes containing components, which can be used to retrieve and deserialise related component objects from the database, Fig. 4.

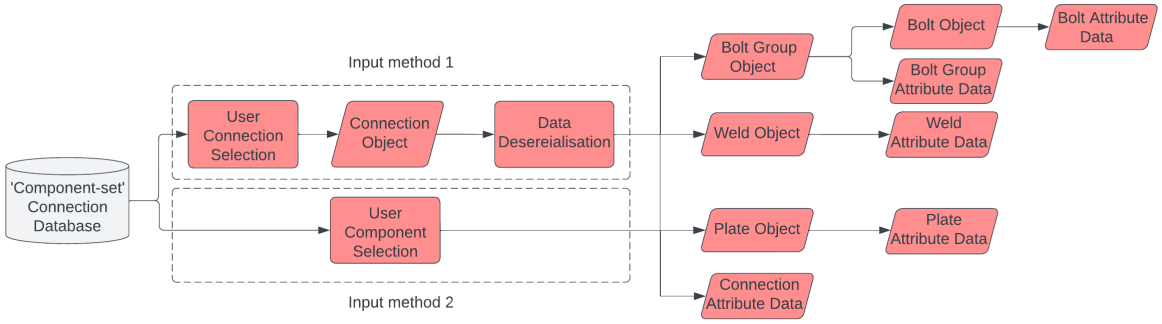

Figure 4. Deserialisation process of connection database data.

3.3 Geometric and semantic modelling

Parametric models for connection geometry were constructed for detailed connection visualisation, also adopting a component-based approach. For bolt components, detailed geometries containing thread and nut features were created first as static CAD meshes and parametrically referenced via bolt attribute data. Remaining components, including bolt group, weld, plate, and section were modelled as separate parametric geometries (closed Breps), instanced by geometric attribute data extracted from the component objects. Connection attribute data was then used to spatially arrange components, which were finally joined to create a 3D connection geometry.

Alongside the geometric model, we developed a semantic model to support user visualisation and interrogation of structural design features of a specified connection. Semantic design information includes the display of component design capacities, component failure modes, and governing design capacity. Capacity information is presented as floating text and input from the connection and component attribute data. Failure mode information is presented as geometric annotations (arrows and coloured surfaces) in the corresponding failure region.

3.4 Visualization and interactivity of virtual connection model

Final supporting processes were implemented to support the visualisation and interactivity of the virtual connection model in a mixed reality. For model visualisation, three ArUco marker trackers [35], detectable via AR device from their actual positions in physical three-dimensional space, were provided as virtual model inputs. The orientation and position of markers was evaluated in a virtual model to determine a central location point, orientation direction, and length scale for the virtual model to be displayed as actual size when viewed in the mixed environment. Two methods of model interactivity were implemented to support user interrogation of i) structural performance calculations and ii) connection design exploration. For structural performance interrogation, spherical buttons were placed next to each design capacity description in the semantic model. This were established as clickable triggers in the AR interface, such that selection of a particular capacity would display the corresponding failure region annotation. For connection design exploration, buttons were created to allow users interacting with component sizes. Simplified annotations would then state whether a connection was valid/invalid and efficient/inefficient, relative to the standardised connections. Users can inspect the connection geometry to find the source of invalid detailing condition and review the semantic information to find the source of design inefficiencies (for example, oversized components).

4. Implementation and result

4.1 Model implementation

The steel connection database was implemented in Python 3.10.4 for a ‘Flexible End Plate’ (FEP) beam-to-column or beam-to-beam connection type, Fig. 1a. The connection design space $\mathbb{C}^{FEP}$ was generated from the Cartesian Product of the component object sets specified in Table 1, with the expression defined

in Equation 1. The connection object set thus contains 8832 connection designs, of which 117 are the standardised connection details recommended by the Australia Steel Institute [36]

$$\mathbb{C}^{FEP} = \mathbb{B} \times \mathbb{W} \times \mathbb{P} \times \mathbb{M} \times \mathbb{A}_1 \times \mathbb{A}_2 \quad (1)$$

Remaining processes were implemented in Rhino/Grasshopper. Three Grasshopper plug-ins, jSwan, GeomGym, and Fologram, were used for database deserialisation, geometric modelling, and AR interactivity, respectively [37-39]. The integrated Grasshopper model is illustrated in Fig 5. The connection database collections are provided as input files and red, green, and blue regions correspond to the user component/connection selection, geometric/semantic modelling, and AR visualisation/interactivity processes as described previously.

Table 1. Component object sets for FEP connection CPs.

Component	Design Parameters		Design Parameters/Object Sets	
	Name	Unit	Values	#
Bolt Group $\mathbb{B}$	bolt	N/A	{M20 8.8/S TI}	(1)
	rows	mm	{2, 3, 4, 5, 6, 7, 8, 9}	(8)
	columns	mm	{2}	(1)
	pitch	mm	{70}	(1)
	gauge	mm	{90, 140}	(2)
Weld $\mathbb{W}$	leg thickness	mm	{6, 8}	(2)
	type	N/A	{CFW}	(1)
	category	N/A	{SP}	(1)
	class	N/A	{E49XX}	(1)
Plate $\mathbb{P}$	type	N/A	{Plate GR250}	(1)
	width	mm	{150, 200}	(2)
	thickness	mm	{10}	(1)
Member $\mathbb{M}$	type	N/A	{200UB→610UB}	(23)
	cope	N/A	{O, SWC, DWC}	(3)
Spacing 1 $\mathbb{A}_1$	gap	N/A	{70, 100}	(2)
Spacing 2 $\mathbb{A}_2$	edge distance	N/A	{35}	(1)

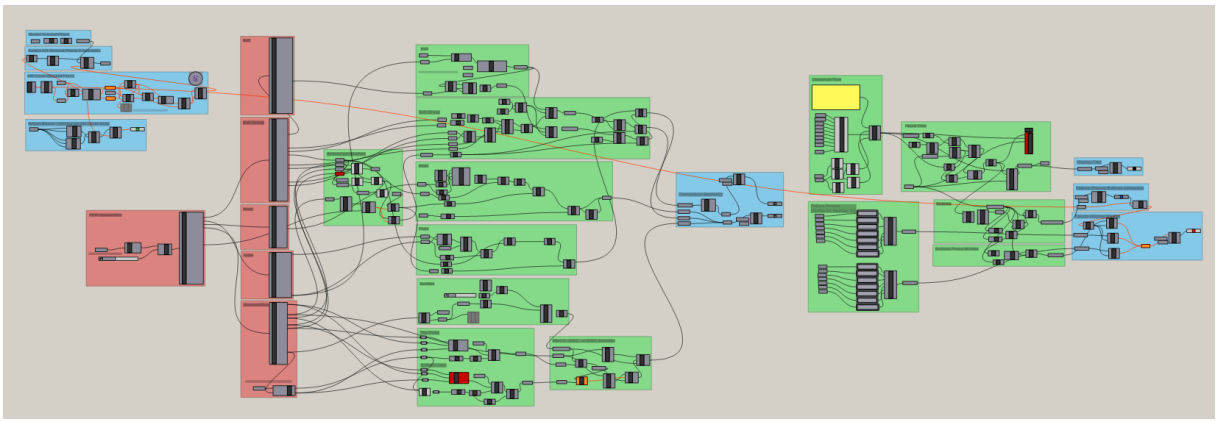

Figure 5. Grasshopper script for AR connection model construction.

The Fologram Grasshopper provides the visualisation and interaction of the virtual connection model with Microsoft HoloLens headsets or mobile devices installed with the accompanying 'Fologram' program. Users first need to connect the AR devices to access 'Fologram' mixed reality environment and AR interface by scanning a QR code. Three ArUco markers, placed in orthogonal direction on a ground plane, are then detected as reference points for virtual model display. By detecting the markers sequentially with an AR device, the coordinates of the markers' location are input into the parametric model with the orientations of markers solved in Grasshopper. A green box is placed onto the markers denoting the marker has been detected correctly (Fig. 6a). The central point, orientation direction, and length scale of the virtual model are determined from the distance and vectors derived from the three coordinates. The virtual connection model is then superimposed in the mixed environment at life-sized scale.

4.2 Model interaction

After placing the virtual connection model in a mixed reality, users can easily implement the two proposed input and interaction methods to observe the structural performance and evaluate the validity and efficiency of various connection designs. For the first method, user browse standard connection designs by selecting key-name index of a specific connection. Users click on the spherical buttons in the AR interface to switch the display of failure modes under each load capacity. The failure region is highlighted on the component part with an arrow, facilitating inspection from all angles (Fig. 6b).

a) b)

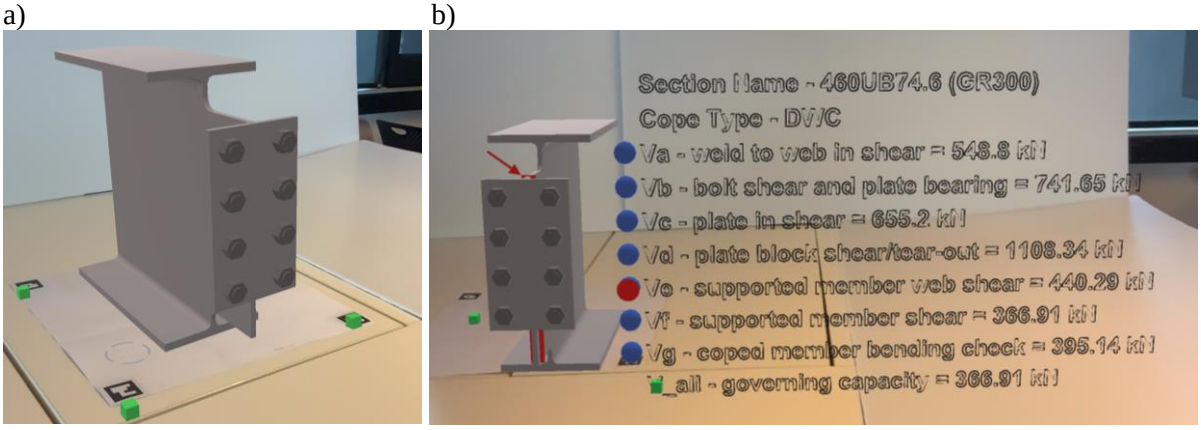

Figure 6. Virtual connection model. a) Detected ArUco markers. b) Failure region and structural capacity annotations.

With the second method, users are able to customise a connection design with specific size and arrangement of components by selecting options from dropdown lists. Textual annotations are displayed by the side of connection model denoting the validity and efficiency of the connection relative to standardised designs. User can then examine and compare the geometric characteristics of assembled components, in order to identify the origin of invalid detailing conditions and understand potential causes of structural inefficiencies. For example, Fig. 7a illustrates an example of a standardised connection design for a 460UB82.1 section. It incorporates a 150 mm wide plate and ten M20 bolts arranged in two columns, with a bolt gauge of 90 millimetres separating each bolt. An inefficient design has an increased plate width (Fig. 7b), which adds to connection weight without increasing the governing design capacity. An invalid design (Fig. 7c) selects an overly-large bolt group, which violates detailing requirements for both minimum bolt-to-plate edge distance and maximum plate-to-section depth ratio.

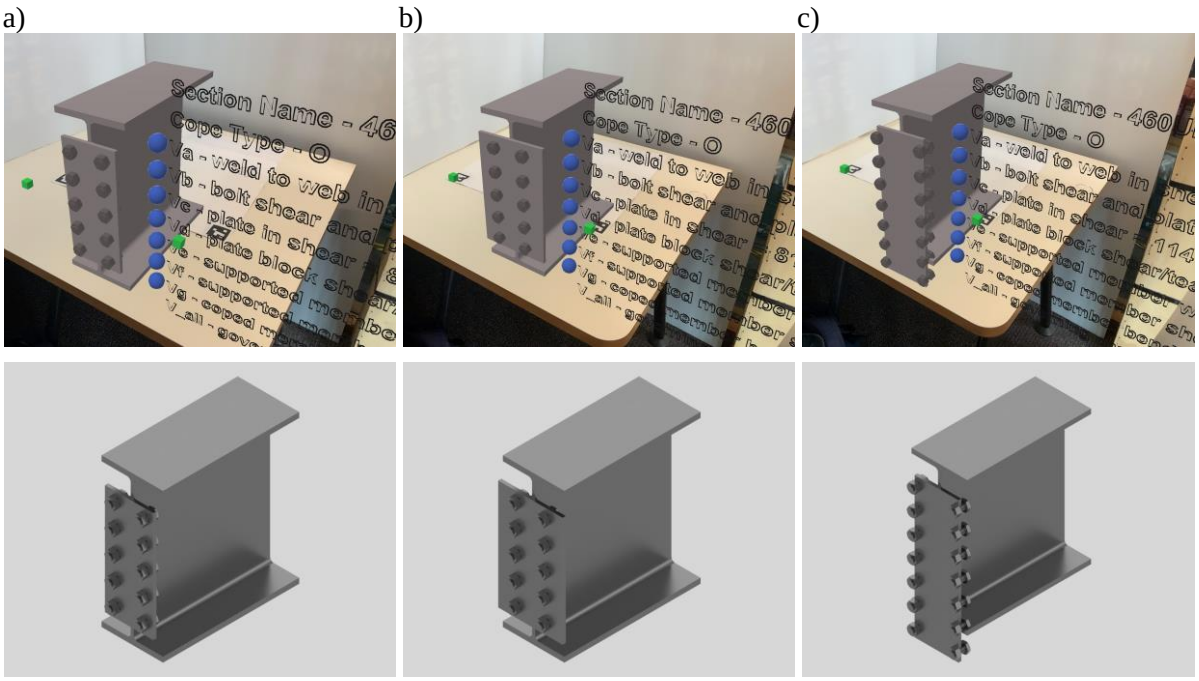

Figure 7. Virtual connection model with user defined component selection for a) standardised, b) inefficient; and c) invalid connection designs. Top row: virtual model in mixed reality, bottom row: Rhino rendered model.

5. Conclusion

This paper presents a parametric virtual 3D steel connection model linked to a connection database that contains many 'ready-to-use' designs. By leveraging the immersive environment and interactivity created by AR tools, users can evaluate various connection designs in real-time via inspection of connection geometric details and semantic information. This parametric AR model is highly valuable for educational purposes and value engineering, as it enables junior engineers to develop a more intuitive understanding of the influence of component selection on validity and efficiency of connection design, as well as the structural performance of steel connections.

For future development, the connection design database will incorporate process-based fabrication cost for connections. Both designers and fabricators will then be able to evaluate the cost variations among different connection design alternatives and make design improvement. The semantic model annotations could also be extended to support guided user exploration toward the cost-efficient standardised connections. The design database can also be expanded with broader range of design information, encompassing different types of structural members and building materials (e.g. steel open sections, steel hollow sections, cold-formed structural steel, timber, and reinforced concrete). Furthermore, by utilising AR tools, users can capture real-world structural elements and their surroundings from the real world and understand the impact of design modifications on structural performance or behaviour in video form through visually augmented physical objects.

Using data-rich objects in geometric parametric modelling

Lennert LOOS*

* Katholieke Universiteit Leuven
lennert.loos@kuleuven.be

Abstract

Earlier research by the author investigated how using data visualisations could be helpful to structural designers. The research implicitly showed that the versatile handling, management and manipulation of data is important in order to fully exploit the benefits of parametric design. This paper presents the development of *Inkbeagle Data*, a new Grasshopper3d plugin that aims to facilitate data management in parametric modelling. The paper discusses how the use of data-rich objects can help make it easier to work with geometric objects and the custom data associated with them. The implementation of the plugin is explained, as well as its user interface, and a small example of its use in practical applications in the field of structural design is given.

Keywords: computational design, data management, parametric design

1. Introduction

The use of data visualisations to gain specific insights during the structural design process has been extensively researched by the author [1-3]. The research observed the typical workflows and processes of the structural designer and identified some of the problems they face. One of the main problems appeared to be the difficulty of comparing design alternatives with the commonly used finite element analysis tools. However, comparison is an important part of the design process as it allows an understanding of how design solutions are behaving and performing in a relative way. These commonly used analysis tools are well-suited for understanding the structural behaviour of a single design, dimensioning the members of the structure, and performing the regular code checks. However, they do not necessarily guide designers to better designs, nor do they allow the structural behaviour and performance of different design options to be compared.

Based on this practical observation and the fact that a huge amount of structural data (model, loads and results) is contained in the finite element models that engineers use during design, data visualisation has been proposed and investigated earlier as a way to facilitate an informed structural design process by digesting the data more efficiently. This previous research evaluated data visualisation as a way to present complex data sets from finite element models in a compact but meaningful way. With visual representations of the data from multiple structural design alternatives at hand, the structural designer is assisted in an informed structural design process and is better able to understand the influence of certain design parameters on the structural behaviour of complex structures.

To be meaningful and informative to the designer's problem, the right visualisation should be chosen or developed by the designer. Therefore, to facilitate informed decision-making, the choice of data and how to visualise it must therefore lie with the designer. The research provoked an approach that forces designers to create and develop graphs themselves that are meaningful to the current state of the design process and the corresponding questions and interests. When designing structures in practice, the questions and interests are often very different and context-specific. For this reason, case-dependent approaches (in this case visualisations) need to be used. The research implicitly showed the need to be able to handle all structural data easily. Irrespective of the specific topic of data visualisation for

structural design, the need to handle data in a versatile way is a general theme and concern in modern digital design processes, according to the author's experience in professional design offices.

This paper discusses a new Grasshopper plugin that has been developed to allow the use of data-rich objects in a parametric design environment. Object-oriented elements in parametric design will be discussed briefly. Furthermore, the implementation of the plugin is explained, as well as its user interface and a small example showing its use for practical applications in the field of structural design. Finally, an evaluation of the implementation is carried out to point out the strengths and weaknesses of the developed plugin and the use of data-rich objects within the Grasshopper3d environment.

2. Problem statement and background

The idea of working with data-rich objects in a geometric parametric design environment such as Grasshopper was initiated by the need to handle structural data more easily for the assembly of graphs in earlier research, but also originates from practical needs in a professional design office, as observed and experienced by the author.

2.1. Parametric design environments and its application in practice

Parametric and computational design approaches are widely used in architectural and structural design practices. All kinds of software, scripts, algorithms and tools are provided by the community, often even open source. In architecture and structural design practice, the last decade has seen a move away from text-based programming in computational design towards the use of visual programming and coding with tools like Grasshopper [4] or Dynamo [5]. One of the reasons for this is the reduced effort required to learn visual programming languages compared to textual programming [6]. Another reason is the speed with which designers can set up scripts to perform tasks. In addition, it can be argued that many architects and engineers in design practices do not have the skills or time to become proficient in developing custom software and algorithms through textual coding. It is important to note that this makes designers often reliant on other people's implementations and third party software; as a result, there is a risk that this software may not accurately meet their needs [7].

From personal experience as a structural designer, the author observed that Grasshopper3d in particular is used for all sorts of tasks by both engineers and architects. Although this parametric design environment has its main focus on parametric geometry, the tasks for which this tool is used in practice are not limited to this purpose. Beside generating and manipulating geometries, the parametric design environment of Grasshopper3d seems to be a well-suited framework for analysing structural models [8], preliminary form-finding of structures [9], quickly performing geometrical operations, executing small geometric and numerical checks on designs [10], importing, manipulating and exporting data and/or geometries [11], or even working with remote databases [12].

In other words, when working on structural projects, Grasshopper3d is often not used to create fully parameterised models from A to Z, but rather as a very versatile tool for a series of small, different and unrelated operations. This allows the designer to stay within a single digital design environment without having to switch between different interfaces which requires frequently exporting and importing data. Often the geometry (possibly with attributes) is saved as a Rhino3d file, which serves both as a starting point for new parametric scripts and as a snapshot of the current state of the design.

2.2. Data and BIM

Parametric design is almost exclusively geometry driven and therefore has an inherent focus on modelling [14]. Working with related data is not impossible, but rather cumbersome in current implementations of popular parametric design environments. However, working freely with data in parametric interfaces is crucial if we are to make informed design decisions in a conscious way. Indeed, preliminary analyses and checks based on numerical data are regularly performed when working with parametric models at different stages of the design process.

Data in digital architectural and structural design is often referred to as Building Information Modelling (BIM). The structure of current BIM software may lack support for the actual design process and is generally used to document a more finished design [13]. BIM has however important and useful features that can be of value in any design phase, such as a structured model with clear semantic information, user-defined properties and data values, spatial relationships between elements, etc. Greater similarity between parametric design and BIM approaches is desirable, but not easy to achieve [13-14].

2.3. Expressing the needs for a more object-oriented parametric design

To maximise the potential of parametric and computational tools in the digital design process, data-rich parametric design environments will be essential. A BIM or object-oriented approach that supports the actual design process could serve these needs well [13]. In order to make informed decisions, to react to design data, e.g. from analyses, and to make use of (associated) data, versatile and flexible but simple tools are needed that can be easily integrated into existing design approaches and practices [7]. Convenient data management is of utmost importance for understanding and digesting the data/results/information generated during design.

As visual programming languages such as Grasshopper3d are often used by computational designers with limited textual programming skills, the parametric design environment should allow working with data without relying on textual programming. In addition, the author's experience has shown that parametric modelling is also used in practice as a way to perform small operations (geometric parametric modelling, import and export, data processing) quickly. For this reason too, the implementation of data-rich objects in parametric design must be closely aligned with the existing parametric design environment.

Recently there has been the robust development of BHoM (Buildings and Habitats object Model) [15]. BHoM aims to standardise the data and functionality that are used in the architecture, engineering and construction industry. It proposes a central Object Model, which is a schema, therefore BHoM's main focus and value lies in interoperability between software tools by sharing the same schema, the central common language. Although it shows a lot of potential to also work in a more object-oriented way in parametric design environments, it does not actually support design processes and tasks that computational designers do on a daily basis within parametric design environments.

Performing basic operations such as selecting, sorting, evaluating and modifying objects should be an inseparable part of parametric geometric design. These types of operations are relatively easy to perform in database environments (for instance BIM interfaces) and using textual programming. In parametric design environments such as Grasshopper3d, however, it becomes very tedious to set up without the use of third-party plugins. In the following paragraphs, the new *Inkbeagle Data* plugin [18] for Grasshopper3d is introduced and discussed. It allows the creation of objects from named keys and corresponding values, including basic data types (textual and numerical) as well as geometry. This implementation can be seen as an attempt to facilitate object-oriented parametric design within the Grasshopper interface.

3. Implementation and user interface

This section describes the implementation of *Inkbeagle Data* [18], a custom plugin written in C# developed for Grasshopper3d. *Inkbeagle Data* allows to assemble data keys and corresponding values into an *InkObject* on which basic operations such as list filtering, evaluating expressions and list sorting can be performed, fully based on Grasshopper's native data types. Furthermore various methods are included to import and export the InkObjects as a file to and from Grasshopper.

3.1. Implementation

The *Inkbeagle Data* plugin is based on the idea of the *Objectify* plugin [16]. However, the implementation of *Inkbeagle Data* takes the basic idea a step further by the operations that can be performed on the *InkObjects* and the methods for exporting and importing.

The main logic of an *InkObject* follows the idea of a dictionary that stores key-value pairs in no particular order. The key is of type *string*, while the corresponding value is of type *IGH_Goo*, the base interface for all data inside Grasshopper. Any data type that inherits from the *IGH_Goo* type can be used as data for the *InkObject* assembly: e.g. *GH_Curve, GH_Colour, GH_Integer, GH_Line, GH_String…* As a result, any supported data type can be assembled into an *InkObject*. Additionally, information about the "bakability" and "visibility" of the geometric values is included and can be set.

Grasshopper uses the *GH_InkObject* class as the GH-wrapper for *InkObjects* and is derived from *GH_GeometricGoo<InkObject>*, *IGH_PreviewData*, *IGH_BakeAwareData* and *GH_ISerializable*. As a result, the *InkObjects* are fully serialisable and their geometric values are bakable in Rhino3d. Since *GH_InkObjects* are derived from the abstract class *GH_GeometricGoo*, *InkObject*s can contain *InkObjects* themselves; in other words *InkObjects* can be nested.

Since the implementation as described above does not allow to store a list of *IGH_Goo* objects as a value in the *InkObject*, it is possible to wrap a *List<IGH_Goo>* in a custom class *GH_InkList* derived from *GH_GeometricGoo*. This way lists can be packed, stored in an *InkObject* and unpacked later.

In the following paragraphs, the most important features of the plugin are shown.

3.2. User interface (UI)

3.2.1. Constructing and deconstructing InkObjects

The *Construct InkObject* and *Deconstruct InkObject* components (Figure 1) allow *InkObjects* with named keys and corresponding values to respectively be assembled and to be separated into its different values.

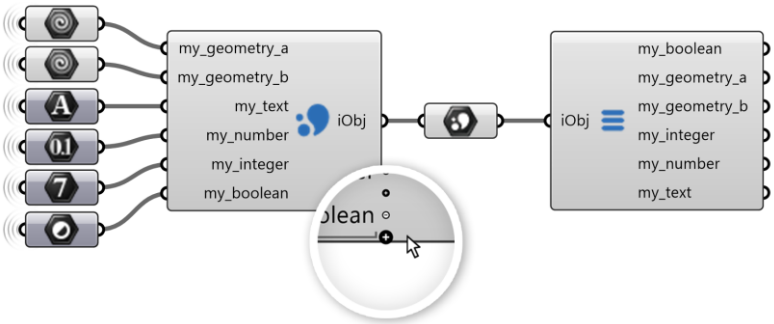

Figure 1. The components used to construct and deconstruct *InkObjects*.

Inkbeagle Data's implementation aims to provide a seamless user experience by closely following the native Grasshopper UI. To achieve this, the component for constructing an *InkObject* is implemented as a variable parameter component, allowing dynamic input and output parameters to be created at runtime (adding or removing input parameters). The key name can be set by right-clicking on the input parameter label. This makes the plugin's UI similar to native Grasshopper components, ensuring that users can easily integrate the plugin into their existing workflows.

An *InkObject* is created with data attached to each named key. Adding lists of data to the *Construct InkObject* component, creates a list of *InkObjects* with all the individual data items from the input lists

attached to the corresponding named keys. If lists of different lengths are used for different keys, the component will be solved according to Grasshopper's default solving routine. Also when data trees are used, the default Grasshopper logic is maintained.

3.2.2. Working with InkObjects

The following components (Figure 2) can be used to work with associated data in *InkObjects*: *Add Key*, *Modify Value*, *Remove Key* and *Get Value*. The functionalities of these components are considered as self-explanatory.

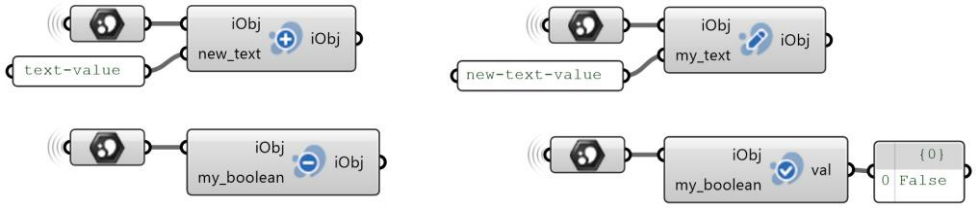

Figure 2. The components that allow to add new key-value pairs (Add Key), modify the value of key-value pairs (Modify Value), remove key-value pairs (Remove Key), get the values of key-value pairs by the textual key (Get Value).

The UI of these components aims to be as consistent as possible with Grasshopper's default UI. For example, the values of multiple keys can be retrieved by adding and selecting multiple existing keys as input parameters from the right-click parameter menu (Figure 3). A similar UI is provided for the other components that are listed in Figure 3.

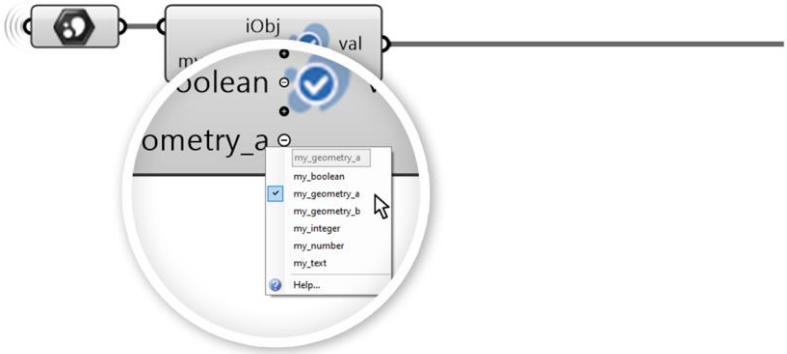

Figure 3. Compact UI for adding and selecting key-value pairs, similar to Grasshopper's default UI.

3.2.3. Operations

In order to perform operations on (lists of) *InkObjects*, a few helpful components have been developed: *Evaluate*, *Filter*, *Sort by Key* and *Search by Value*, each with a specific purpose.

The *Evaluate* component (Figure 4) allows to execute basic expressions with the same syntax as used for the native Grasshopper components *Expression* and *Evaluate*. The *Evaluate* component can be used to solve expression syntax and return numeric or string values as the result or to perform conditional evaluations which will return a boolean value. The key names of the *InkObjects* are directly used as

parameters in the expression to be evaluated. If for instance an *InkObject* contains numerical values in certain keys (*key_a*, *key_b*, *key_c*), the following logical and numerical expressions can be constructed:

- `key_a > (key_b - key_c)` logical expression
- `key_a / (key_b^3 * sqrt(key_c))` numerical expression

If one wants to filter a list of *InkObjects* based on a logical expression, the *Filter* component (Figure 4) can be used. It has similar functionality to Grasshopper's native *Dispatch* component, but the logical expression can be expressed based on the named keys of the *InkObjects*.

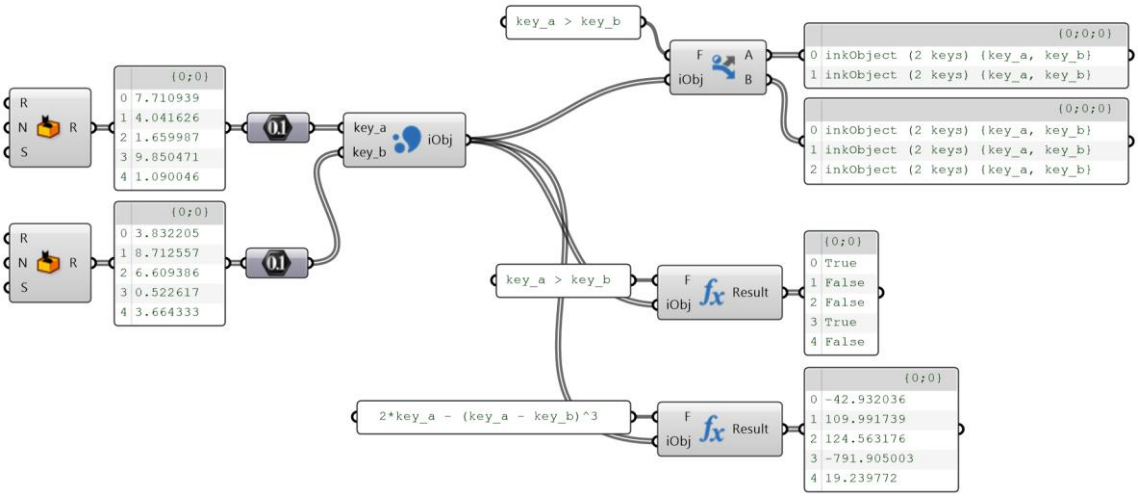

Figure 4. The use of components that allow to execute expressions and filter a list of *InkObjects*.

The *Sort by Key* component (Figure 5) sorts a list of *InkObjects* based on the value of a specified key, while the *Search by Value* component (Figure 5) allows users to search for *InkObjects* with specific key values.

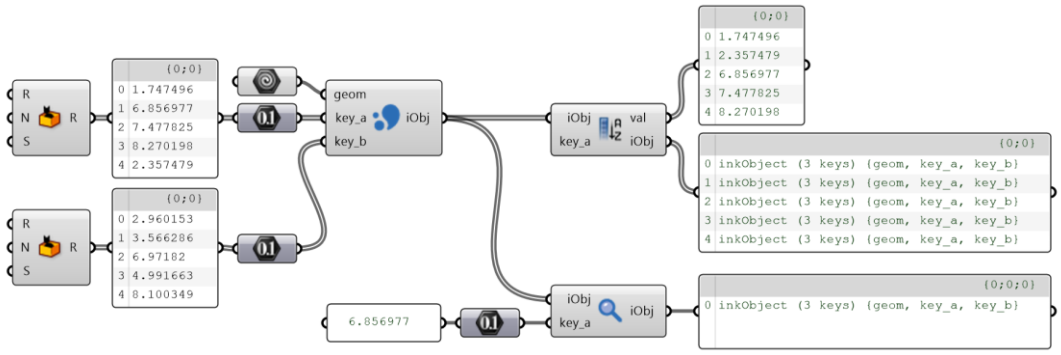

Figure 5. The use of the components that allow to sort a list of *InkObjects* and to search for *InkObjects* in a list that have a specific value assigned to a certain key. Note that it is important that the correct type must be used to look up certain values: the string "6.856977" is casted to a *GH_Number* first. Searching by the string value would not return any *InkObjects*.

3.2.4. Export-Import

A series of components have been developed to facilitate exporting and importing *InkObjects*. The user is able to *Bake* one or more *InkObjects* as geometries in Rhino3d with textual or numerical attributes, based on the non-geometric key-value pairs of the *InkObject*. Geometries with attributes can be referenced from Rhino3d back into Grasshopper3d as well, where the attributes will become textual or numerical key-value pairs of the *InkObject*. The *Serialize* component allows to save a data tree of *InkObjects* as a binary file. This way one is able to work with data and Grasshopper geometries between various files. A binary file containing the serialised data and geometry can be deserialized into the Grasshopper3d environment. To conclude, *InkObjects* containing basic data type values (textual or numerical) can be exported to *csv*, *xml* or *json* data files and imported from data files in corresponding format.

4. Practical use cases

In practice, the author uses the developed plugin mostly to work more efficiently with data and FEA results within a parametric design context.

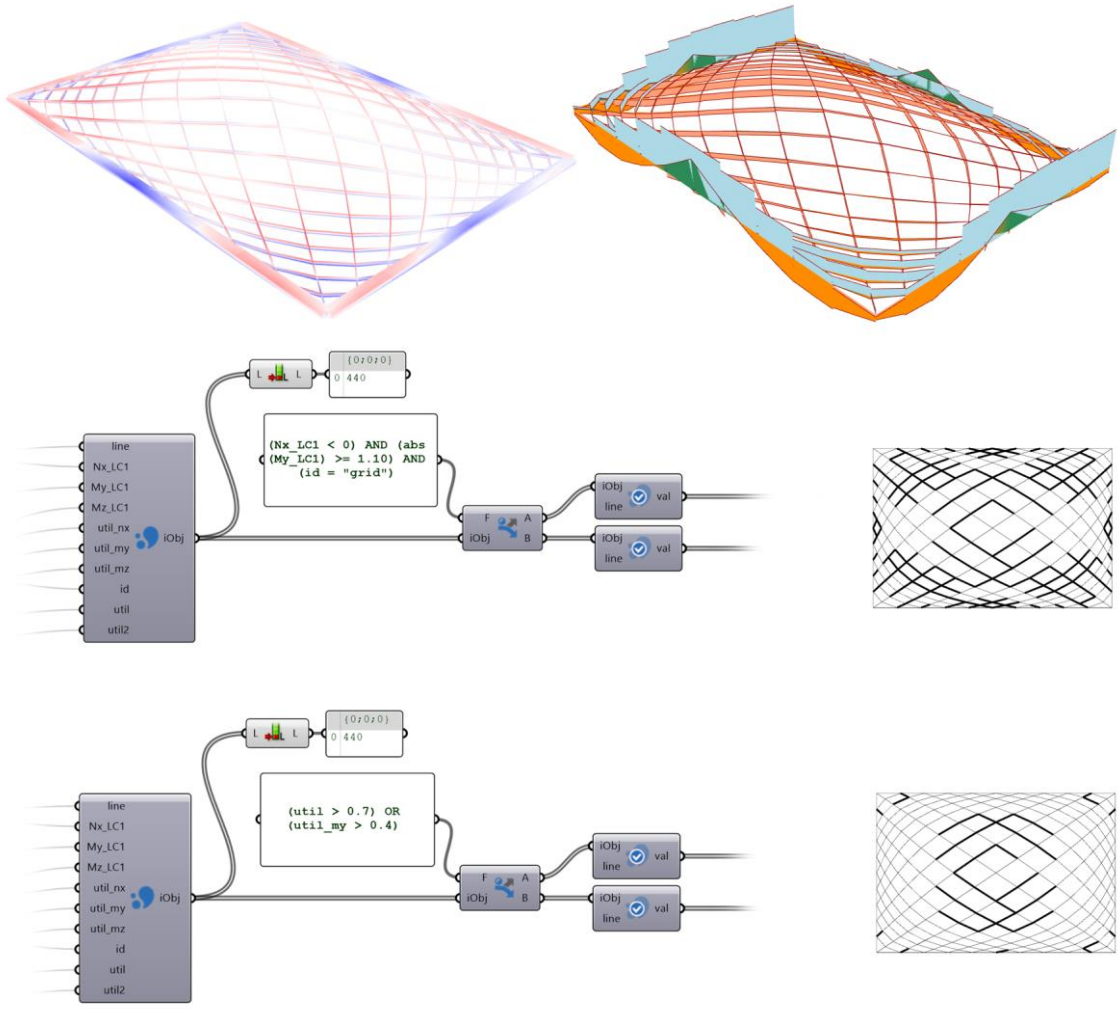

Figure 6. The beam elements are filtered based on the following more complex logical expressions:
Expression 1: `(Nx_LC1 < 0) AND (abs(My_LC1) >= 1.10) AND (id = "grid")`
Expression 2: `(util > 0.7) OR (util_my > 0.4)`

When using for instance Karamba3d [8], all result data is available in the parametric environment and can now be attached to structural geometries and processed further, without leaving the design interface. For instance, the plugin can be used to filter structural elements based on the structural results. This way the behavioural characteristics of the structural elements can be identified more easily. Figure 6 illustrates this with a small example.

Inkbeagle Data makes filtering of objects/elements more easy. This provides users with the capability to effectively manage and digest large volumes of structural results without leaving the parametric design environment. In the example shown above, more complex logical expressions are used to filter structural elements based on their *internal forces*, *utilisation* and *type*. These values are retrieved from the Karamba3d plugin and assigned to line elements, representing each beam. The key names such as *Nx_LC1* or *util_my* can be chosen freely, according to the needs of the structural designer.

Another example where the author used *Inkbeagle Data* is to prepare the definition of the pretension loadcase for a SOFiSTiK finite element model. The form-found geometry of a pretensioned cable structure is baked in Rhino3d as snapshot of the project's current design state. The baked geometry contains User Attributes with information such as the form-found force (F), E-modulus (E), cable id (cable_id), cross-sectional area (E), etc.

When the line objects in Rhino3d are referenced in Grasshopper3d, the User Attributes can be attached to the geometry as *InkObjects* with the help of the *Inkbeagle Data* plugin (Figure 7). Based on the data values, the shortening of each cable can easily be calculated with the help of the *Evaluate* component and added as a key "shortening" to the *InkObjects*. The *Evaluate* component is then used once more to format a specific string with variables, to match the desired SOFiSTiK Teddy syntax.

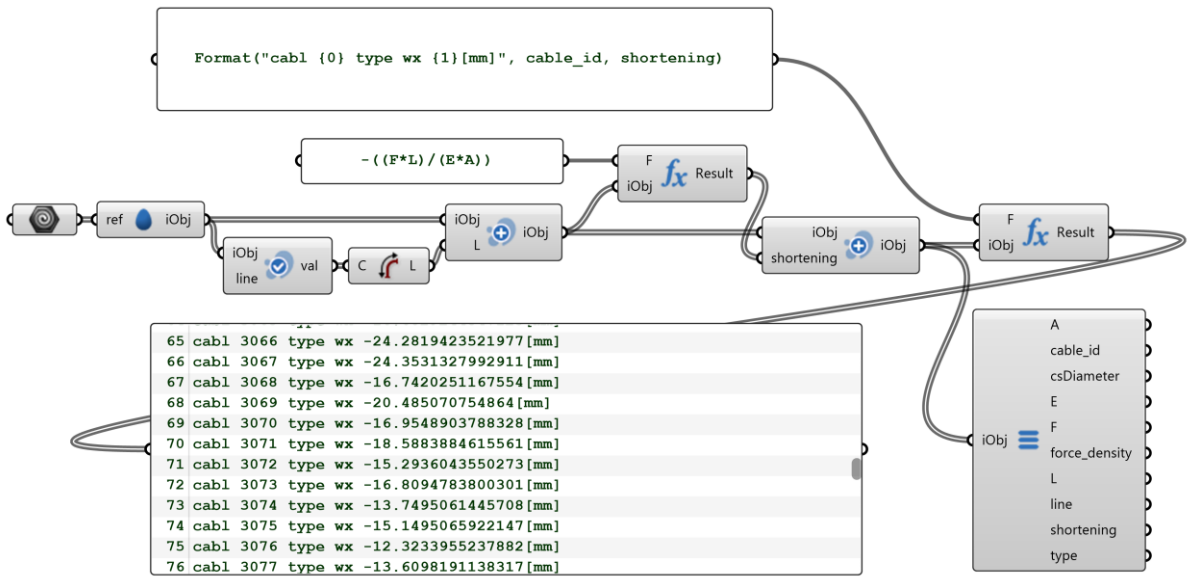

Figure 7. Without too much effort the pretension load can be formatted as a shortening of the cables in the desired SOFiSTiK Teddy syntax, without the need to do this data processing in another computational environment.

5. Discussion and conclusion

Based on the author's observations and experiences of how Grasshopper3d is used in practice and that the parametric framework is used for all kinds of tasks of different nature became clear from the practical use cases. The presented cases show that a more object-oriented approach in parametric modelling has some direct benefits for the workflow of architects and structural designers, especially when it comes to supporting daily custom operations with data and geometries. This was the main reason for the development of the plugin.

The idea of combining all kinds of Grasshopper3d data types into one "object" seems to be reasonable as an approach. However, there is no such thing as a free lunch. The goal of supporting all possible data types implies using the *IGH_Goo* type for the values of the object. While this has many advantages such as the ability to work with Grasshopper3d's expression syntax, it also has drawbacks. For example the *Sort by Key* component must first check that all values corresponding to the given key are in fact numeric. Other operations like casting of types can also reduce the performance of the implementation. However, for sorting, evaluating expressions, looking up *InkObjects* from a list of manageable size (up to about 50 000), the implementation seems to be competitive with a native Grasshopper3d solution performing the same task.

Although nesting of *InkObjects* is possible, the current implementation is very much geared towards a flat application. In fact, it is not possible to retrieve the values of nested *InkObjects* using the plugin's components alone; instead, custom scripting is required. Also, the evaluation of the expression syntax is not applicable to nested values either. It may be worth investigating thoroughly to what extent such features are feasible without compromising on the UI which should remain as similar as possible to the native Grasshopper3d UI and its user experience. The workaround method of using *InkLists* may be helpful in some cases, but a more general approach is desirable.

While the plugin was being developed, Grasshopper 2.0 [17] had not yet been released. This second major release of Grasshopper3d comes with the support for so-called metadata. This means that meta values can be attached to any regular value, similar to the assembly of *InkObjects*. This provides the ability to associate certain values with their main value, but also offers a way to control in more detail how Grasshopper handles data. This particular feature is an important one in the development of parametric design environments and may even suggest that object-oriented approaches are essential to the future development of visual programming and parametric design interfaces.

Abstract

In a previous work the classical funicularity definition for shell structures has been extended to the so called Relaxed Funicularity (R-Funicularity). A parameter called generalized eccentricity has been used for this purpose, following that a shell is R-Funicular when the generalized eccentricity on each shell's point doesn't exceed an admissibility limit. A shells' shape optimization process aiming at finding R-Funicular analytical shells, previously developed by some of the authors, is here modified at the geometry definition level by describing the shells' shape with spline surfaces and using the coordinates of the control polygon vertices as optimization variables. Compared to existing works in which this approach was used, here an isogeometric (IG) refinement is applied in order to improve the local control of the shape in the optimization process. In fact, an advantage of this approach is that, since it introduces new vertices in the control polygon, the number of optimization variables becomes tunable. Namely, starting with the lowest number used to generate the initial geometry, the additional vertices can possibly be entered as new variables whenever a more accurate local control of the surface is needed. We present significant numerical examples.

Keywords: shape optimization, NURBS, generalized eccentricity, R-funicularity, isogeometric refinement

1. Introduction

Funicular shell structures are characterized by a shape that follows the flow of forces and are ideally able to bear the design load without introducing bending. As a result, they pursue a full exploitation of the resistant cross section and a minimum waste of material. Thus, funicular shells are an example of efficiency and many form finding techniques have been developed in order to find the "right" shape in accordance with the applied load [1].

Nevertheless, when shell structures have a non negligible bending stiffness and/or the boundary conditions are not properly assigned, a funicular behaviour is not possible and bending arises. In order to take into account this occurrence and quantify the actual funicular behaviour of shells, a method based on Relaxed Funicularity (R-Funicularity) has been developed in [2]; the parameter used to quantify the funicularity is the generalized eccentricity. In these cases, the amount of bending moments exploited by a shell to resist applied loads can be reduced by means of a shape optimization process, i.e. an inverse problem properly formulated to minimize an objective function somehow measuring the shell's bending moments. The minimization is pursued by updating some shell geometric features, i.e. variables, that are admitted to vary within a range. The goal of bending moments reduction is usually approached by minimizing the strain energy [3, 4, 5]; other objectives of shape optimization can be, for example, the minimization of the weight, the stress levelling [3, 4] or the minimization of displacements [6].

In [7] a shells' shape optimization process aimed at finding a shape that minimizes the generalized eccentricity extrema, i.e. an as much as possible R-Funicular shell, has been developed. Considered the

strict link between geometry and mechanical behaviour of shells, the description of the first strongly influences the solution quality and the computational time. Similarly to what proposed, for example, in [5, 6], when an R-Funicular shell has been sought, the shape has been described by means of an analytical function [8], in some cases obtained by a linear combination of analytical functions [7, 9] and a finite element analysis has been performed.

In this work we propose a modification at the geometry definition level of the shape optimization process shown in [8] by introducing the shell's surface description by means of B-spline surfaces [10]. Compared to existing works in which this approach was used (see, for example, [5, 11]), here an isogeometric (IG) refinement is applied in order to improve the local control of the shape in the optimization process. In fact, an advantage of this approach is that, since it introduces new vertices in the control polygon, the number of optimization variables becomes tunable. This feature is exploited by performing a shape optimization where, starting with the lowest number used to generate the initial geometry, all or some of the additional vertices are then entered as new variables whenever a more accurate local control of the surface is needed. A similar approach has been employed in [12], where, in order to expand the feasible design space, a refinement of the initial geometry has been performed.

After a brief description of the concepts of R-Funicularity and generalized eccentricity $e(\alpha)$, we discuss the optimization strategy with a major focus on the geometry description. Two effective numerical examples are then proposed and the conclusions are drawn.

2. Generalized eccentricity and R-funicularity

The generalized eccentricity measure and its use to define the R-Funicularity concept are briefly introduced in this section. For a complete discussion, please refer to [2].

Let us consider a point P belonging to the surface S, endowed with its orthonormal basis $\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3$, and a generic direction of the tangent plane represented by the unit vector $\boldsymbol{u} = (cos\theta, sin\theta)$ (Fig. 1).

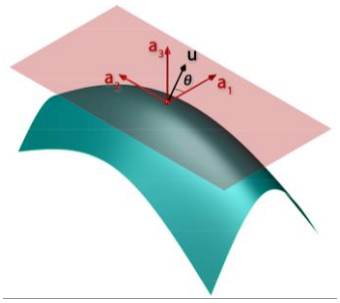

Figure 1. Local orthonormal basis on P belonging to the surface S.

The local tensors $\boldsymbol{N}$ and $\boldsymbol{M}$, respectively associated with the membrane forces and the bending moments, can be evaluated in each point P:

$$\boldsymbol{N} = \begin{pmatrix} N_{11} & N_{12} \\ N_{12} & N_{22} \end{pmatrix}, \quad \boldsymbol{M} = \begin{pmatrix} M_{11} & M_{12} \\ M_{12} & M_{22} \end{pmatrix} \tag{1a, b}$$

Then, $N(\theta) = \boldsymbol{u}^T \boldsymbol{N} \boldsymbol{u}$ and $M(\theta) = \boldsymbol{u}^T \boldsymbol{M} \boldsymbol{u}$ are, respectively, the generalized membrane force acting along $\boldsymbol{u}$ and the generalized bending moment acting in the plane $(\boldsymbol{u}, \boldsymbol{a}_3)$. Using the multiple-angle and the power-reduction trigonometric formulae and setting $\alpha = 2\theta$, it has been possible to write the following explicit form for Eq. $N(\theta)$ and $M(\theta)$:

$$\begin{aligned} N(\alpha) &= \bar{N} + \hat{N} cos\alpha + N_{12} sin\alpha \\ M(\alpha) &= \bar{M} + \hat{M} cos\alpha + M_{12} sin\alpha \end{aligned} \tag{2}$$

where $\overline{N} = \frac{N_{11}+N_{22}}{2}$, $\widehat{N} = \frac{N_{11}-N_{22}}{2}$, $\overline{M} = \frac{M_{11}+M_{22}}{2}$, $\widehat{M} = \frac{M_{11}-M_{22}}{2}$. Then, the generalized eccentricity is defined as the ratio:

$$e(\alpha) = \frac{M(\alpha)}{N(\alpha)} \tag{3}$$

Eq. 2 is the equation of a parametric curve in the plane $(N, M) \in \mathbb{R}^2$, that is an ellipse when $\alpha \in [0,\ 2\pi]$, called *ellipse of eccentricity* or *Relaxed Funicularity (RF) ellipse* (Fig. 2).

It is well known that a surface structure is funicular, for a given load, if the condition (4) is verified.

$$M(\alpha) = 0 \quad \forall\ \alpha \tag{4}$$

The actual behaviour exhibited by shells with non negligible thickness shows that the nullity of bending internal forces is an ideal that never verifies. The aim of R-Funicularity is to define a criteria to consider a structure funicular in a relaxed manner even if Eq. 4 is not respected, when $e(\alpha)$ belongs to an admissible range set as $[-\lambda h,\ \lambda h]$, where h is the thickness of the surface and $\lambda \in \left[0,\ {}^{1}/_{2}\right]$ an admissibility coefficient that depends on the applications.

In the light of above, the Relaxed Funicularity (RF) is defined as follow: "a shell is R-Funicular if, $e(\alpha) \in [-\lambda h,\ \lambda h]\ \forall\ \alpha \in [0,\ 2\pi]$, for each point of the surface". In practice the problem of the R-Funicularity is that of verifying:

$$\left[min\big(e(\alpha)\big),\ max\big(e(\alpha)\big)\right] \subset [-\lambda h,\ \lambda h] \tag{5}$$

For completeness, we show the graphical representation of $e(\alpha)$ in the (N, M) plane. More details about its use are given in [2].

Considered the definitions below, the generalized eccentricity is the Rayleigh quotient: $e(\theta) = \frac{\boldsymbol{u^T M u}}{\boldsymbol{u^T N u}}$, and the maximum and minimum eccentricities (e_{max}, e_{min}) are found by solving the associated eigenvalue problem:

$$(\boldsymbol{M} - e\boldsymbol{N})\ \boldsymbol{u} = 0 \tag{6}$$

The solution of (6) depends on the algebraic conditioning of $\boldsymbol{M}$ and $\boldsymbol{N}$ and has been discussed in [2]. It gives the local extrema e_{max} and e_{min}, shown in the equation (17) of [2].

The global extrema of the eccentricities can be finally evaluated as follows:

$$min\big(e(\alpha)\big), max\big(e(\alpha)\big) = \begin{cases} -\infty, +\infty & if\ \det(N) < 0 \\ e_{min}, e_{max} & if\ \det(N) \geq 0 \end{cases} \tag{7}$$

The angles $\varphi_{max} = \text{atan}\ (e_{max})$ and $\varphi_{min} = \text{atan}\ (e_{min})$ in Fig. 2 have been used to define the functional to be minimized with the aim of improving the shells' mechanical behaviour.

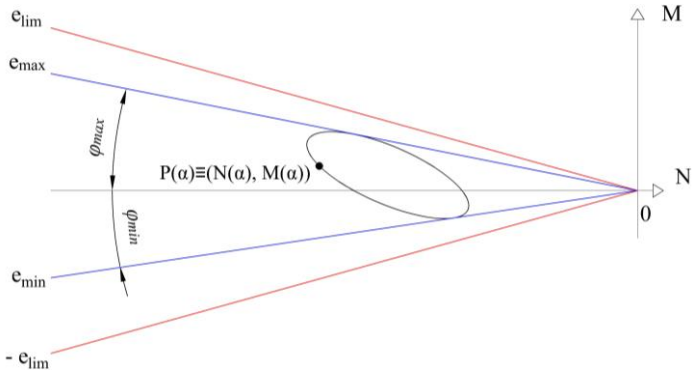

Figure 2. RF ellipse with eccentricity extrema e_{max} and e_{min}, eccentricity limits e_{lim} and $-e_{lim}$, respectively equal to the slope of the upper and lower blue and red lines and eccentricity angles φ_{max}, φ_{min}

3. Shells' shape optimization for R-funicularity

The main goal of the shells' shape optimization process proposed in [7] is to obtain a shape for the shell to be R-Funicular as much as possible and is pursued by minimizing the generalized eccentricity extrema e_{max} and e_{min} all over the shell. Here the procedure is modified at the geometry definition level. Aiming at a wider design freedom, the shell shape is now described with B-spline surfaces and an isogeometric refinement is applied and exploited to obtain a major local control of the shape.

3.1. Modelling of geometry and isogeometric refinement

The shell geometry has been modelled by means of a non-rational B-splines surface, obtained by fixing a bidirectional net of control points $\mathbf{P}_{i,j}$, two knots vectors $\mathbf{U} = \{0, \dots, 0, u_{p+1}, \dots, u_{r-p-1}, 1, \dots, 1\}$ and $\mathbf{V} = \{0, \dots, 0, v_{q+1}, \dots, v_{r-q-1}, 1, \dots, 1\}$ and the products of the two univariate B-spline functions of degree p and q, $N_{i,p}(u)$ and $N_{j,q}(v)$:

$$\mathbf{S}(u,v) = \sum_{i=0}^{n} \sum_{j=0}^{m} N_{i,p}(u) N_{j,q}(v) \mathbf{P}_{i,j} \tag{8}$$

The vectors **U** and **V** contain, respectively, $r+1$ and $s+1$ knots, being:

$$r = n + p + 1 \qquad s = m + q + 1 \tag{9a,b}$$

The surface resulting from (8) is then manipulated by performing the isogeometric *h*-refinement that consists in the well-known algorithm of knots insertion. This type of refinement has multiple uses, among which: evaluating points and derivatives on curves and surfaces, subdividing curves and surfaces, adding control points in order to increase flexibility in shape control [10].

In order to understand the effect of knot insertion, let us consider a B-spline curve $\mathbf{C} = \sum_{i=0}^{n} N_{i,p}(u)\mathbf{P}_i$ defined on $\mathbf{U} = \{\mathrm{u}_0, \dots, \mathrm{u}_m\}$, whose vector space is $\mathcal{V}_U$. If we insert $\bar{u} \in [u_k, u_{k+1})$ into U we obtain the new vector $\bar{\mathbf{U}} = \{\bar{u}_0 = u_0, \dots, \bar{u}_k = u_k, \dots, \bar{u}_{k+1} = \bar{u}, \bar{u}_{k+2} = u_{k+1}, \dots, \bar{u}_{m+1} = u_m\}$, whose vector space $\mathcal{V}_{\bar{\mathrm{U}}}$ has dimension $\dim(\mathcal{V}_{\bar{\mathrm{U}}}) = \dim(\mathcal{V}_U) + 1$ and, since $\mathcal{V}_U \subset \mathcal{V}_{\bar{\mathrm{U}}}$, it is possible to represent **C** on $\bar{\mathbf{U}}$:

$$\mathbf{C}(\mathrm{u}) = \sum_{i=0}^{n+1} \bar{N}_{i,p}(u) \mathbf{Q}_i \tag{10}$$

where $\mathbf{Q}_i$ are the new control points that can be obtained by exploiting the following equality:

$$\sum_{i=0}^{n} N_{i,p}(u)\mathbf{P}_i = \sum_{i=0}^{n+1} \bar{N}_{i,p}(u)\mathbf{Q}_i \tag{11}$$

and the property according to which in a given knot span $[u_j, u_{j+1})$, at most $p+1$ $N_{i,p}$ are nonzero. Omitting the intermediate mathematical steps, that can be found in [10] together with an exhaustive treatment of the topic, the new control points (Fig. 3) are:

$$\mathbf{Q_i} = \alpha_i \mathbf{P}_i + (1-\alpha_i)\mathbf{P}_{i-1} \tag{12}$$

where

$$\alpha_i = \begin{cases} 1 & i \le k-p \\ \dfrac{\bar{u}-u_i}{u_{i+p}-u_i} & k-p+1 \le i \le k \\ 0 & i \ge k+1 \end{cases}$$

and k is an index that locates the inserted knots in the vector $\bar{\mathbf{U}}$.

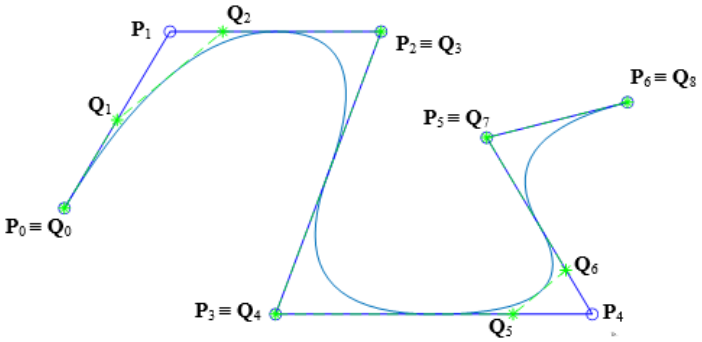

Figure 3. Effect of knots insertion into a quadratic curve. Blue, solid line: control polygon before knot insertion; green, dashed line: control polygon after inserting $u = 0.1$ and $u = 0.7$ into $\mathbf{U} = \{0\ 0\ 0\ 0.2\ 0.4\ 0.6\ 0.8\ 1\ 1\ 1\}$.

In this specific case, basis functions of degree 2 have been employed. Initially, a net of 3×5 control points and the following knots vectors $\mathbf{U} = \{0\ 0\ 0\ 1\ 1\ 1\}$ and $\mathbf{V} = \{0\ 0\ 0\ 1/3\ 2/3\ 1\ 1\ 1\}$ have been considered. **U** and **V** contain, respectively 6 and 8 knots, accordingly to the equations (9a,b). The resulting shape and the control net are depicted in Figure 4.

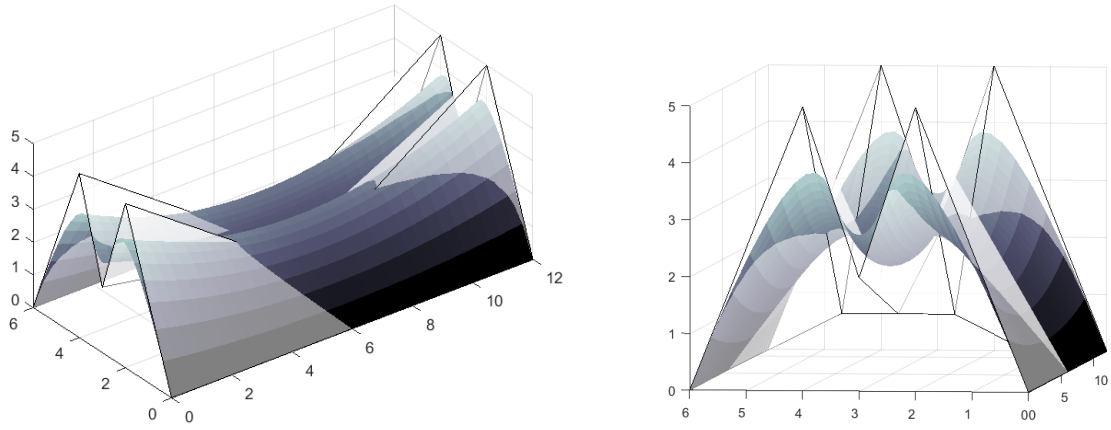

Figure 4. Starting shape and control net

The positions of the 9 inner control points (Fig. 5) have been updated in the optimization process by varying 4 different coefficients, each multiplying the z-coordinates of the points marked with the same colour in Figure 5; the black ones are maintained fixed. Thus, each control point admitted to vary is

defined as $\boldsymbol{P}_i \equiv (x_i, y_i, z_i c_i)$, where c_i are the optimization variables. The variables of the starting shape, denoted as c_{oi} are equal to 1.

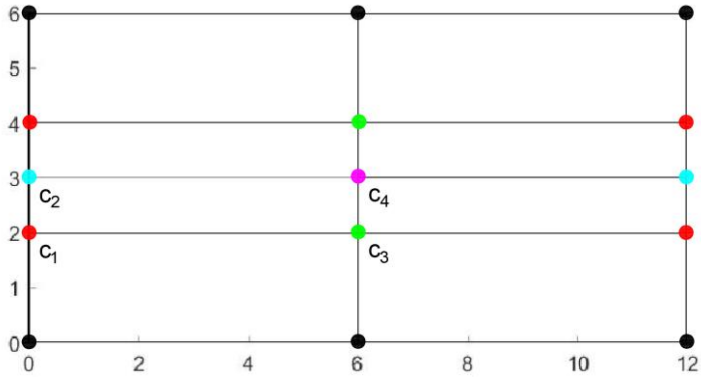

Figure 5. Plane view of the initial control net. Black dots: control points maintained fixed in the optimization process; Coloured dots: control points updated in the optimization process.

The two knot vectors $\mathbf{U_1} = \{1/3 \;\; 2/3\}$ and $\mathbf{V_1} = \{1/6 \;\; 1/2 \;\; 5/6\}$ have been inserted, respectively into **U** and **V**, obtaining the new control net shown in Figure 6.

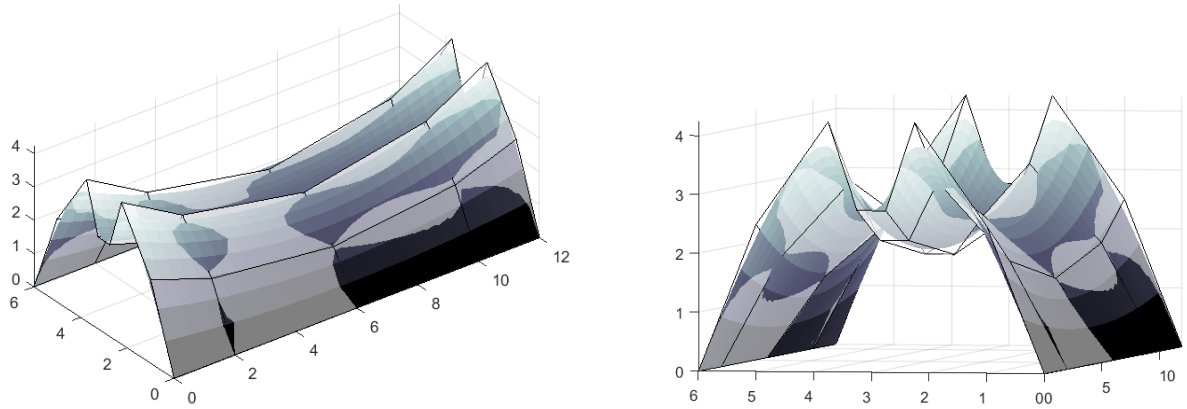

Figure 6. Starting shape and new control net

Also in this case, the positions of the 30 inner control points (Fig. 7) have been updated in the optimization process by varying 9 different coefficients, each multiplying the z-coordinates of the points marked with the same colour in Figure 7; the black ones are maintained fixed. The coordinates of the control points are defined analogously to the previous case.

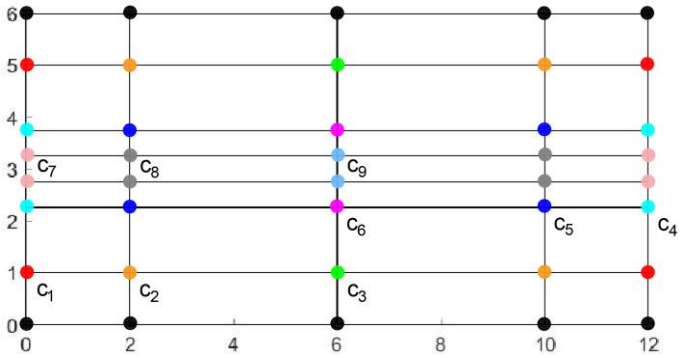

Figure 7. Plane view of the refined control net. Black dots: control points maintained fixed in the optimization process; Coloured dots: control points updated in the optimization process.

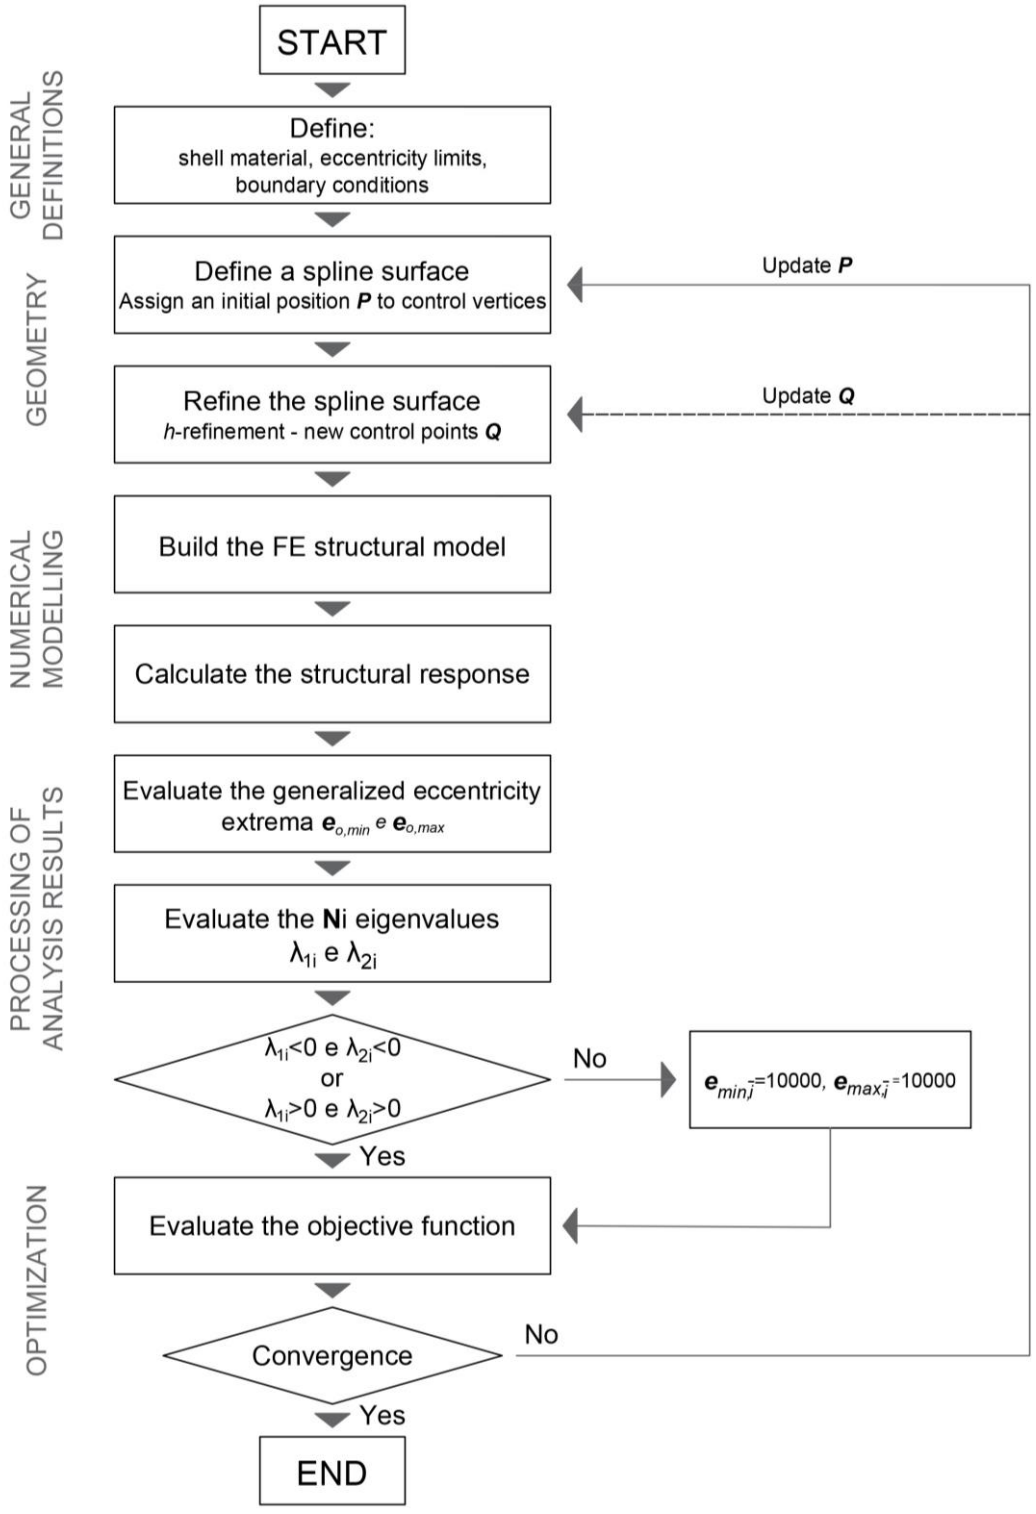
3.2. Optimization strategy

The shape optimization process is illustrated in Figure 8. Firstly, a few general definitions should be provided: shell material, eccentricity limits and boundary conditions. The initial geometry is the B-spline surface described in §3.1 and shown in Figure 4, properly discretized to build a Finite Element (FE) model. In the following step a linear static analysis of the structure subject to the self-weight load and an in plan uniform vertical load of 5 kN/m^2 is performed and the internal moments and forces are stored for each *i-th* area element of the model. The minimum and maximum eccentricities of each *i-th* element are computed by using bending moments normalized with respect to the shell thickness and collected in the vectors $\boldsymbol{e}_{0,min}, \boldsymbol{e}_{0,max}$ respectively. In addition, the eigenvalues $\lambda_{1,i}$ and $\lambda_{2,i}$ of the tensor $\boldsymbol{N}_i$ (Eq. 1a) are evaluated and used to check if the ellipse of eccentricity of the *i-th* element crosses the M axis, that is $\lambda_{1,i}$ and $\lambda_{2,i}$ have different signs. Then, the values of eccentricity extrema $e_{min,\bar{\imath}} = 10000$ and $e_{max,\bar{\imath}} = 10000$ are imposed to the $\bar{\imath}$th areas with discordant eigenvalues. The eccentricities ~~vectors~~ that result from these computations, $\boldsymbol{e}_{min}, \boldsymbol{e}_{max}$, are used to evaluate the objective function to be minimized. If convergence is reached the process stops, otherwise the shape is updated by moving the position of the control points $\boldsymbol{P}$ or $\boldsymbol{Q}$ and the procedure is repeated until convergence.



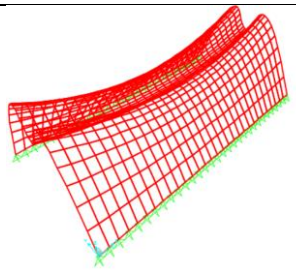


Figure 8. Overview of the shape optimization process

Defining $\varphi_{M,i} = \max\left(\left|\varphi_{max,i}\right|, \left|\varphi_{min,i}\right|\right)$, where $i = 1, \ldots, N$, being N the number of shell elements in the FE model, the objective function is defined as the root mean square of $\varphi_{M,i}$:

$$f_{obj} = \sqrt{\frac{\sum_i \varphi_{M,i}^2}{N}}$$

In Table 1, the optimization settings are summarized:

Table 1. Optimization settings

Parameter	**Value/Description**
Shell thickness h	0.1 m
Material	Concrete: $w = 25\ \frac{kN}{m^3};\ E = 3 \times 10^7\ \frac{kN}{m^2}$
Admissible eccentricity	$e_{adm} = h\,\lambda$ with $\lambda = 1/6$ or $e_{adm} = \lambda$ when bending moments normalized with respect to h are used (middle third rule)
Starting shape	Non-rational B-spline surface. Control points multipliers: $c_{oi} = 1$
Mesh Boundary conditions Shell formulation	 Quadrangular mesh; pinned x edges; shell-thin element formulation.
Objective function	$f_{obj} = \sqrt{\frac{\sum_i \varphi_{M,i}^2}{N}}$
Software	MATLAB (scripts for evaluation of eccentricities, optimization, shape update) SAP2000 (FE solver)
Optimization algorithm	Sequential quadratic programming (SQP): find local minimum of constrained nonlinear multivariable function
Variables constraints	$0.01 \leq c_i \leq 2$

4. Results and conclusions

The shape optimization results are expressed in terms of shape variation and eccentricity distribution. As shown in Figure 9, left, the starting shell is mostly non R-Funicular, being the eccentricity extrema larger than e_{adm} and the value of the objective function $f_{obj} = 1.28$.

The image in the centre of Figure 9 shows the results obtained by means of the first shape optimization, where only 4 variables were updated to modify the control net and, consequently, the shell's shape. The optimization variables, starting from $c_{o1} = c_{o2} = c_{o3} = c_{o4} = 1$, turn $c_1 = 0.1, c_2 = 0.16, c_3 = 0.24, c_4 = 0.12$ after optimization. A notable improvement of the shell funicular behaviour has been obtained, especially in the central areas of the shell, also proved by the objective function that reaches the value $f_{obj} = 0.42$.

The right image (Fig. 9) shows the results obtained by performing the shape optimization after knots insertion. Also in this case, the starting variables have been fixed to 1, the parameters after shape optimization are:

$c_1 = 0.59, c_2 = 0.53\ c_3 = 0.39\ c_4 = 0.57, c_5 = 0.49, c_6 = 0.33, c_7 = 0.91, c_8 = 0.76, c_9 = 0.47.$

It can be observed that the increased local control and thus the major number of optimization parameters obtained by knot insertion allowed to obtain a shell mostly R-Funicular. The objective function, starting from 1.28, reduces to 0.32.

According to R-Funicularity, a good shell has been obtained in both examples. Nevertheless, by comparing the shapes and the eccentricity distribution, it can be stated that enriching the initial geometry description by means of IG refinement allowed for a better shape adjustment, also confirmed by the initial and the final f_{obj} in the two proposed cases. The objective function, in fact, providing the root mean square of the eccentricity angles (Fig. 2), gives a summary measure of how much the shell behaviour differs from the R-Funicular one, which is immediately evident by comparing the values assumed by f_{obj} before and after the optimization with $\mathrm{atan}(e_{adm}) = 0.165$.

In the light of above, we believe that this approach could be useful when the accuracy of the shape local control should be modulated according to design and computational demands. Further studies about this approach could be devoted to observing the objective function trend as the number of optimization variables increase, in order to state whether if there is a threshold number over which the function no longer decreases.

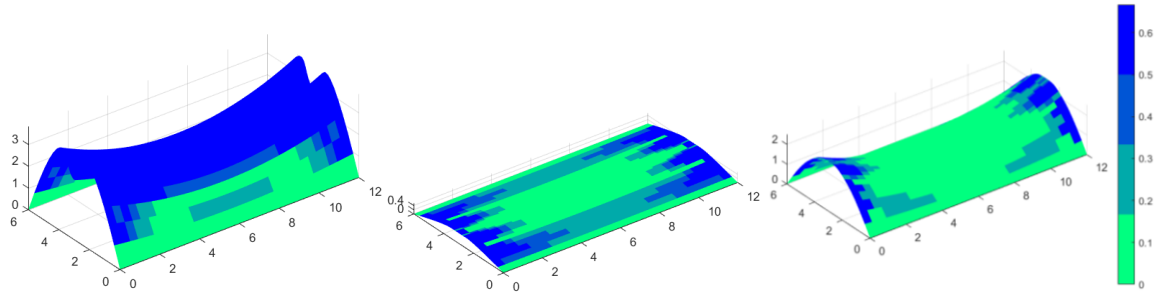

Figure 9. Shells' shape and eccentricity distribution. The colorbar represents the values of the $e_{M,i} = max\,(|e_{max,i}|, |e_{min,i}|)$ that increases going from green to blue, the latter meaning that the eccentricity falls out of the cross section. The shell is R-Funicular in the light green areas. Left: before optimization, $f_{obj} = 1.28$; centre: after optimization with 4 variables, $f_{obj} = 0.42$; right: after optimization with 9 variables, $f_{obj} = 0.32$.

Leaned brick shells with Mexican quoins and steel edges

Juan Gerardo OLIVA[*], Marcos Javier ONTIVEROS[a]

Abstract

The Lightweight Structures Laboratory – LSL constructed the experimental pavilion PabUNAM at the Faculty of Architecture in the Universidad Nacional Autónoma de México – UNAM. The LSL Research Group aims to demonstrate that bricks are still in force for conceiving, designing, and constructing continuous shells with a complex geometry, which shape may vary beyond the traditional geometric forms. The Mexican Technique, "leaned bricks," is practiced in many areas of central Mexico to construct shells and was applied to build this pavilion. The so-called quoins *("cuñas"* in Spanish) are the most used burnt bricks, with 20 X 10 X 5 cm dimensions. No falsework is necessary. Oliva et al [1 and 2]. The designers used the parametric program Rhino Vault_2 developed by the Block Research Group. Besides bricks, steel profiles fix all shell edges. The LSL Research Group constructed the pavilion on top of a layer of volcanic stones in the main yard of the Faculty of Architecture and developed a foundation system consisting of five curved horizontal steel supports with variable curvature and length. There are four openings surrounding the pavilion and another one inside. These openings are arches with uneven curvature. Building these arches with steel profiles was one of the challenges to overcome during the design process. One professional vault worker ("*bovedero"* in Spanish) and eight Architecture and Civil Engineering students constructed the pavilion in 4 weeks.

Keywords: continuous shells, complex geometry, form-finding, burnt bricks, sustainability

1. Introduction

Research groups at various universities worldwide develop proposals to build continuous roof shells. In addition, these groups are developing new modeling, optimization, and construction methods to improve the design and construction process and reduce the carbon footprint. Among these groups, the universities of Stuttgart in Germany, the ETH of Switzerland, and the universities of Princeton and MIT in the USA stand out. The proposals developed can be grouped into two procedures. The first one explores the construction of continuous shells by discretizing the surface, in which the stereotomy of each piece is controlled. Examples of this trend are the shells of the research group headed by Jan Knippers (Vuga Vault) at the University of Stuttgart and the vaults led by Phillipe Block (Armadillo Vault) of the ETH research group. The second group explores the construction of continuous shells through a small module, as is the case of brick, which is assembled based on various courses. Alfonso Ramírez Ponce's vaults in Figure 1 are examples of these cases [3].

In this paper, the LSL Research Group proposes constructing complex geometries with burnt bricks manufactured in Mexico. Since more than 10.000 years ago, ancient constructions have been built with bricks in many regions worldwide. Burnt bricks are environment-friendly, recyclable, and fire-resistant. In central Mexico, many brick shells have been constructed in different locations applying the "leaning bricks vaults technique." Oliva et al. [1 and 4]. Using this technique, no falsework is required, and conventional materials such as reinforced concrete can be strongly diminished, which turns into an excellent opportunity for reducing the footprint of continuous roof shells.

2. Project PabUNAM

The LSL Research Group designed and constructed the PabUNAM, See Fig. 2, A burnt brick pavilion focussed on demonstrating that today bricks are still in force to build continuous roof shells with conventional and nonconventional geometries.

Figure 2: The experimental pavilion PabUNAM

The PabUNAM is a leaned brick shell designed and constructed with Mexican quoins and steel edges. It was conceived and designed as an opened pavilion in the main yard of the Faculty of Architecture at the UNAM as a sporadic gathering place for the students and Professors. See Fig. 3. More than ten enthusiastic students and five Professors of the faculties of Architecture and Engineering were involved during the design and construction process.

Figure 3: Students building the experimental pavilion PabUNAM

The UNAM central campus was built from 1949 to 1952. In 2007, UNESCO declared it a World Heritage Site. Therefore, modifying or constructing any new building inside this area is forbidden. The UNAM permitted the LSL Research Group to build the PabUNAM on a volcanic stone floor, but they were warned to avoid sinking or damaging the stones. This experimental pavilion will be dismantled at the end of this year. The construction of this experimental prototype turned into an excellent opportunity for the students to learn the leaned brick technique. Nevertheless, it was necessary to hire the services

of a specialist brick-vault worker who oversaw the building process and whose skills and experience, combined with the researchers' theoretical knowledge, were essential to construct the pavilion successfully and adequately.

2.1. Form-finding process.

The LSL Research Group conceived a prototype of leaned brick with complex geometry. The shells combine synclastic and anticlastic curved surfaces. The aims were to explore their construction feasibility and offer new possibilities to architects and engineers for designing vaults with continuous brick surfaces. A first proposal arose with the bachelor's thesis of the student Rodolfo Rodríguez Muñoz. His proposal was used to build a 1:5 scale model. The purpose of the model was to deliver guidelines and tips for the PabUNAM future construction process. The full-scale prototype would later be made with the Mexican quoins measuring 20 cm X 10 cm X 5 cm. This brick is the most used material to build vaults in central Mexico. An enthusiastic group of students manufactured ca. 7,000 small bricks on a 1:5 scale whose dimensions are 4 cm X 2 cm X 1 cm. Unfortunately, the budget available for the final prototype construction was scarce. Therefore, it was necessary to reduce the pavilion dimensions.

Figure 4: Students manufacturing the small quoins and building the PabUNAM model on a scale of 1:5: a) Brick manufacturing, b) Gide structure, c, and d) Model in progress.

The LSL Research Group determined the form of the shells with the digital tool RhinoVault2 developed by the Block Research Group – BRG, using the TNA algorithm to emulate a hanging Net mechanical behavior.

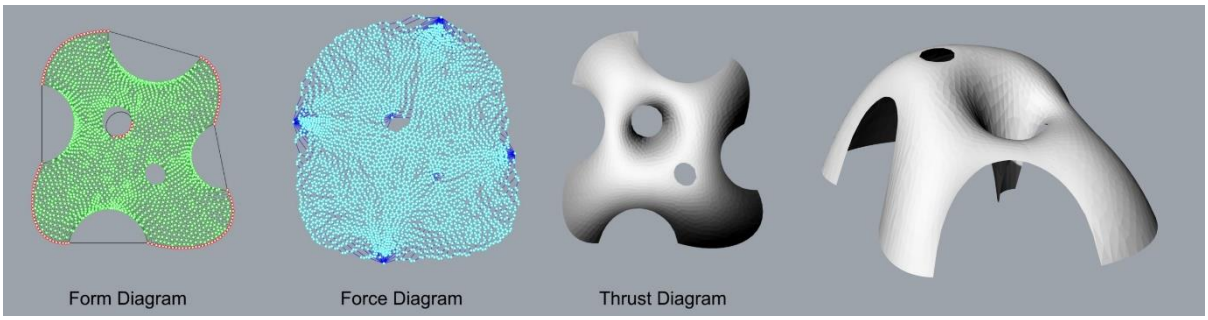

Figure 5: Applying RhinoVault2

The fundamental principle of design and execution of the leaned brick technique is that it must be built with concave curved courses in the shape of an arch, supported at its ends and on the previous lower layer, thereby making possible the absence of falsework.

Subsequently, the following practical conditions come out:

- It is built from the bottom up.

- The line of action of the gravity vector, located at the mass centroid of each brick, must intersect the support face of the previous course.
- It is built with small bricks (of low mass) that remain stable in their position even before the joint mortar has set.
- Straight courses with a convex curvature are unacceptable.

Considering these previous requirements, it was possible to determine the initial RhinoVault design parameters to fix the final shape of the PabUNAM.

Figure 6: PabUNAM model on a scale of 1:5

The LSL Research Group used a timber grid to control the shape of the vaults. This procedure helped the students to fix the small quoins in the correct position. However, some students were more sensible than others in adequately improving the quoins' location. Often, it was necessary to dismantle some brick courses of the surface and reconstruct it again. Finally, the model was completed; however, several uneven parts arose on the continuous surface of the vaults.

The model construction delivered the following teaching:

- The proper continuous curved surface depends on the vault worker's skills. Therefore, hiring an experienced worker to build leaned brick vaults was indispensable.

- Traditional methods like active-bending tubes or timber grids to control the complex geometry are insufficient. For example, a grid with timber panels inside the vaults would disturb the building process of the brick-vault worker. Therefore, developing and applying other, more efficient control methods and techniques was essential.

To overcome the first issue, the vault worker Ignacio Dorantes Gómez, called "Nachín," was hired to construct the PabUNAM. Nachín lives and works in the Hidalgo State, 300 km from Mexico City. The building process lasted four weeks, and several students helped without any break, except for the weekends. There was an exciting and fruitful collaboration between Nachín and the LSL Research Group.

On the other side, to control the complex geometry in the second issue, the five steel edges on the borders of the vaults and the four steel edges on the floor turned into the best guides. Some temporary timber panels and PVC tubes also helped Nachín control the curvature of the proper vaults. In addition, the augmented reality digital tool "Fologram" allowed the vault workers and supervisors to review frequently the vault's curvature. Just twice it was necessary to dismantle a few brick courses and reconstruct them again to improve the proper shape.

2.2. Steel edges

As described, each brick course in a leaned brick vault must be supported at its ends, usually with reinforced concrete elements. The PabUNAM's support elements are steel edges manufactured with 76.2 mm X 4.8 mm plates. The volcanic stones on the yard surface were used as fundament, where four curved profiles were fixed with 9.5 mm high-strength steel rods stuck 12 cm between the joints of the stones.

The four entrances to the vault and the opening in the central support are arches that do not lie on a plane, and that turn around in space. Therefore, the four steel edges were manufactured, joining two flat screed bars with diagonal plates to fix and control the variable angle between the bars. To fulfill the form of this complex geometry, the designers delivered the blacksmith the printed cutting patterns on a scale of 1:1. This procedure was a great help at the workshop. Besides, during the erection process of these arches, a topographic team overviewed the proper geometry continuously.

Besides guides, these arches supported the dead weight of the first vault segments before they were all joined at the upper parts of the vaults. To fix the final position of all arches, they were propped up with 3.8 mm PTR poles, which were removed at the end of the building process.

Figure 7: Steel arches at the four entrances and the central support.

The form-finding process emulating funicular nets required several optimization steps modifying the location and the curvature parameters of the supports, tessellations, and nets density, as well as the high proportions or the vertical deformation vector. The aim was to validate all technical, economic, and manufacturing possibilities. A particular case was how to control the geometry of the arches at the openings, which should be manufactured with traditional standard methods. RhinoVault was a beneficial tool for finding the equilibrium between the funicular form and opening arches. The directrix of the edge arches was obtained from the final network. This directrix was the intersection axis of the steel edges.

Figure 8: Geometric control whit Fologram, mixed reality viewer device

3. Conclusion

The LSL Research Group presented in this paper the entire design and construction process of the experimental pavilion PabUNAM. This pavilion was built applying the Mexican leaned quoins technique. The aim was to demonstrate that bricks are still in force today to make continuous roof shells with complex geometries and that using this technique helps reduce the carbon footprint.

A novel generatively designed and additively fabricated ankle-foot orthosis

Abstract

An ankle-foot orthosis (AFO) is an external mechanical device that is prescribed to patients that require assistance to control or support their ankle-foot complex. Traditionally, AFOs are designed and fabricated manually using resource-intensive methods that may restrict design outcomes. Additive manufacturing (AM) presents an exciting opportunity to radically streamline and improve AFO design by enabling fabrication of more complex designs. However, despite the ability to produce optimised topology with AM, traditional designs are often retained, missing out on the numerous benefits of AM. Although desired, the expanded design freedom of AM presents a new challenge to AFO designers, who have only been educated to develop solutions within the scope of the traditional manufacturing method using basic design tools. Instead of few design parameters to adjust, the potential design choices are now infinite. Therefore, although AM can produce an optimised topology, there is a lack of knowledge of its application in this context. This paper features a design methodology that leverages generative design and shape optimisation to produce an AFO with reduced mass whilst maintaining the fundamental mechanical behaviour of the traditionally fabricated device. The enabler driving the iterations of digital design is a high-fidelity computational model within the commercial finite element package – Abaqus, which facilitated improved representations of loading and boundary conditions and a comprehensive material model. The final outcome of this study was an optimised digital AFO design that is 30% lighter and suitable for fabrication with HP multi-jet fusion (MJF).

Keywords: generative design, additive manufacturing, ankle-foot orthosis, finite element analysis, multi-jet fusion

1. Introduction

An ankle-foot orthosis (AFO) is an external mechanical device that is prescribed to both children and adults that require assistance to control or support their ankle-foot complex [1]. AFOs aim to improve dysfunctional gait patterns typically caused by neuromuscular disorders [2], by mechanically providing passive support at the patient's ankle-foot complex to improve stability and ambulation [3-5]. Traditionally, bespoke passive AFOs are designed and fabricated manually, with manufacture utilising a vacuum thermoforming method whereby a sheet of heated thermoplastic, typically polypropylene, is shaped by draping it over a plaster mould [6]. To achieve a patient specific fit and necessary therapeutic correction, the mould is derived from a patient plaster cast, which is taken and modified prior to draping by a clinician. The mechanical performance and therapeutic corrections are controlled by the material, AFO thickness, the trimline that describes the anatomy coverage of the shell, and the geometry of the patient's morphology [7].

Due to manufacturing constraints, clinicians are required to select and modify the most suitable AFO design from a range of templates, characterised by their mechanical properties. Solid AFOs (SAFO) are

Copyright © 2023 by Ryan BLAKIS, Peter DABNICHKI and Mladenko KAJTAZ. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

a type of AFO that aim to block movement throughout gait in all three anatomical planes of motion. A considerable challenge for this design is limiting dorsiflexion movement at the ankle during the second rocker of gait to a maximum of 2-3°. This requires a high level of stiffness around the ankle joint in the sagittal plane, known as the ankle stiffness. This is characterised by the AFO angle-moment relationship reported in Newton-meters per degree of ankle rotation (Nm/°) [8]. The clinician aims to achieve a desired level of ankle stiffness through the AFO design parameters that are within their control, which are the material thickness and trimline.

A continual challenge for clinicians is reliably predicting the ankle stiffness of an AFO design prior to manufacture [9]. Prediction is impossible with classical methods or handbook formulae due to the complexities related to the material properties, geometries, and loading & boundary conditions [10]. To address this, the research community has made numerous attempts to develop methods for objective AFO ankle stiffness prediction prior to manufacture with computational techniques like finite element analysis (FEA), and evaluation post manufacture via bench-testing with custom fixtures or functional analysis [11]. Despite its importance, the ankle stiffness of bespoke AFOs are rarely predicted or measured outside of research studies. This appears to be due to the lack of in-clinic characterisation equipment, and the inability to precisely manufacture designs with desired mechanical properties. This is because the traditional manufacturing method, although a straightforward process, is difficult to control. The most considerable challenge is shell thinning, whereby the initial constant material thickness of the shell reduces unpredictably during the draping process. This is observed predominately around the ankle region, which is the area having the greatest influence over ankle stiffness. This issue is compounded further by the manual marking and cutting of the trimline, which often relies on good judgement by the clinician and tends to be subject to human error.

Despite the majority of orthotic & prosthetic clinics still employing the traditional manufacturing method, a transition to alternative design and manufacturing methods have been explored for some time now [12]. Of particular interest is additive manufacturing (AM). AM is attractive because it significantly eases design constraints by enabling the manufacture of more complex geometry whilst eliminating manual workflows that both limit design outcomes and prohibit manufacturing consistency. Crucially, it can ensure the desired shape and functional characteristics established in design are realised with consistency [13]. For more than a decade, researchers have increasingly investigated AM produced AFOs, with feasibility studies determining that AM AFOs can have at least equivalent performance to their traditionally manufactured counterparts [2, 14, 15]. Whilst AM is beginning to be successfully implemented by some clinics, both research and commercial outputs do not appear to have fully exploited the extended capabilities that are available to the designer. Instead of innovative designs, those reflective of traditional designs with slightly modified topology have instead been produced with AM. The expanded design freedom creates and demands more design decision, which present a new challenge to clinicians. With AM, instead of only selecting the constant material thickness and the trimline, the potential design choices are infinite. Therefore, although additive manufacturing can produce optimised topology, there is a lack of design tools and knowledge for application of AM in this context.

To address this gap, we propose a novel design method for the generation of an AFO design with optimised topology for AM, without compromising the fundamental mechanical behaviour of a benchmarked traditional device. This paper describes the developed method, which utilises generative design to inform the optimal placement and distribution of material for a parametric design that is subsequently refined with shape optimisation to achieve the desired behaviour. This is illustrated using a case-study, to produce a patient-specific lightweighted SAFO that was optimised for fabrication via HP multi-jet fusion (MJF) polyamide-11 (PA11).

2. Method

The design method proposed in this research was developed on two key ideas: (i) leveraging generative design to inspire novel topology potentially inconceivable by a designer in isolation, and (ii) utilising shape optimisation coupled with high-fidelity prediction models to achieved desired mechanical behaviour. The developed method includes the following three distinct steps: traditional design for benchmarking only, generative design, and shape optimisation. These are visually presented with key sub-steps in Figure 1.

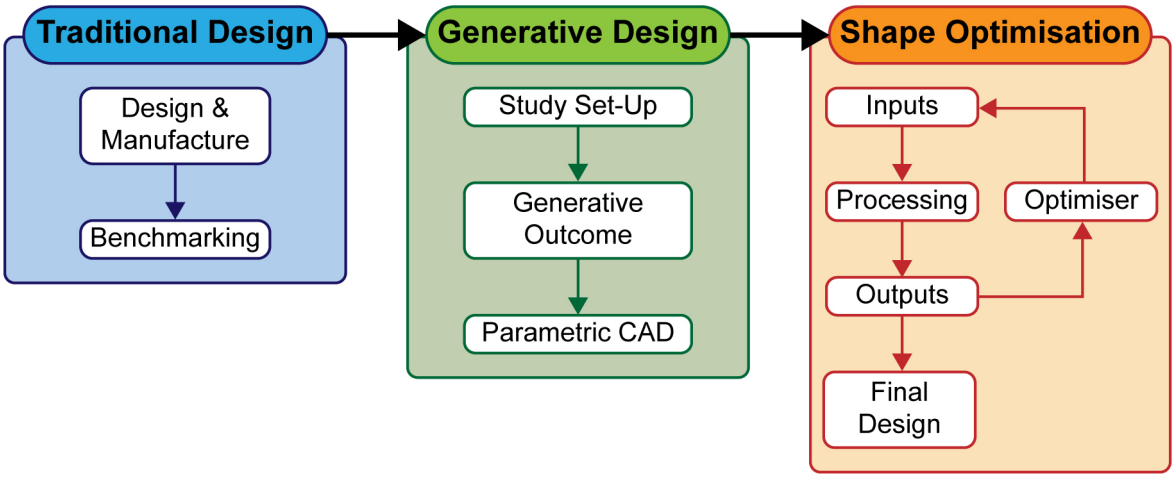

Figure 1. Flowchart representing the key steps and sub-steps of the proposed design method.

2.1. Traditional design

Clinical experts were consulted to design and manufacture a patient specific traditional AFO. The manufactured AFO was used to benchmark physical and mechanical properties. Physical measurements were taken to obtain its mass, average thickness, and trimline details. Computer aided design (CAD) was used to generate the AFO geometry for computational evaluation in FEA. The FEA prediction model was developed to characterise the mechanical behaviour of interest during the defined phase of gait.

2.2. Generative design

Generative design was employed to produce novel optimised topology. Although similar to topology optimisation, used to generate a single lightweight design from a defined design space, generative design is a design exploration process whereby a number of potential optimal designs are generated in an evolutionary way from a set of system requirements [16]. A generative design study was established with the necessary components and key sub-components outlined in Figure 2.(a). The generative study was conducted in an iterative manner, whereby study parameters were modified until a satisfactory outcome was generated. The final generative outcome (Figure 2.(b)) was used to create a parametric design to be refined via shape optimisation (Figure 3).

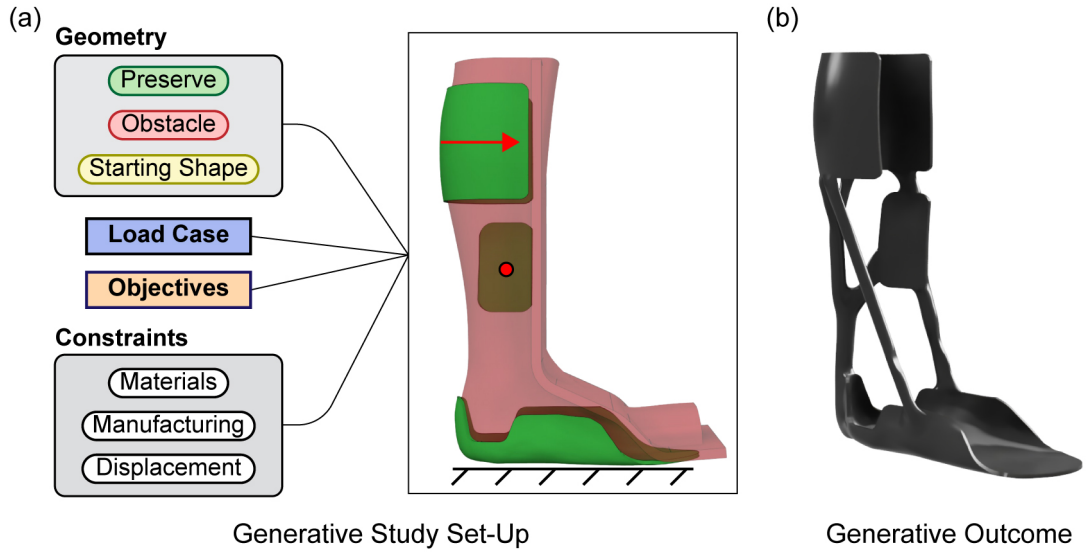

Figure 2. Generative study: (a) generative study set-up with key sub-steps, (b) final generative outcome.

2.3. Shape optimisation

Shape optimisation was conducted on the parametric design based on the generative outcome. This leveraged high fidelity computational FEA models to evaluate the performance of different parameter combinations to meet the constraints and objectives by coupling the FEA evaluation model with an optimisation engine. The applied design search method featured three distinct sections which are common in a typical optimisation problem: input, processing, and constraints & objectives. The inputs consisted of constant and variable parameters that were associated with the parametric design. The processing section consisted of two distinctive parts which were differentiated by their functionality. These were geometry creation (employing CAD) and design evaluation (employing FEA). The results were then assessed for feasibility by the constraints and ranked by the objectives. The optimiser then generated a new set of values for the variable input parameters and repeated the process for the set number of iterations. The workflow can be seen in Figure 3.

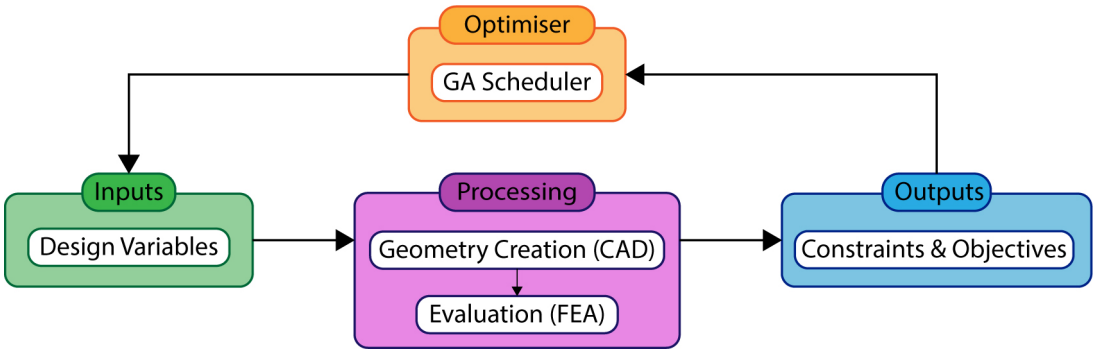

Figure 3. Shape optimisation flowchart with key sub-steps.

3. Traditional design

In collaboration with clinical experts, a traditional SAFO was designed and manufactured for a healthy male patient with the aim of achieving sufficient rigidity at the ankle in the sagittal plane to limit dorsiflexion during the second rocker to 2-3°. Despite the adult patient in this study being non-pathological, a slight foot valgus (rolling in of the foot) was observed and corrected during casting. The SAFO was made from a sheet of 6mm thick polypropylene, with a conservative trimline described as beginning approximately 2cm below the fibula head, passing slightly anterior to the tip of the malleoli,

and leaving the sides of the toes and head of the metatarsus completely clear. Representations of these design parameters can be seen in Figure 4.(a).

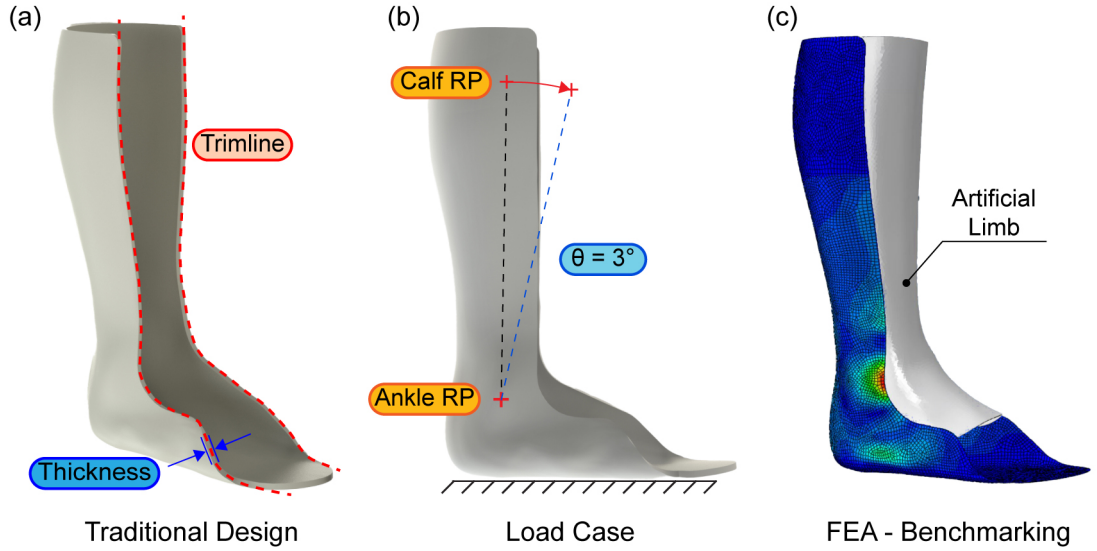

Figure 4. Traditional design: (a) traditional AFO with design parameters, (b) second rocker FEA load case, (c) FEA benchmarking of traditional AFO design.

3.1. Benchmarking

The final fabricated SAFO had a mass of 491g without straps. Finite element analysis was used to characterise the ankle stiffness using a load case reflective of the second rocker during gait adapted from Lelapi et al. (2019) [13] and Schrank et al. (2013) [17]. The static analysis was conducted using the commercial FEA software ABAQUS CAE from Dassault Systemes [18]. The geometry of the traditional SAFO was generated as a surface externally using the commercial CAD software SolidWorks, also from Dassault Systemes [19], using a method inspired by Dal Maso & Cosmi (2019) [1]. In the evaluation model, the SAFO geometry was modelled as a 3D deformable shell. The material properties for polypropylene were obtained from the literature [20], and defined as linear, elastic and isotropic, with a Young's Modulus of 1000MPa and Poisson's Ratio as 0.35. The constant thickness of 4.8mm was obtained by measuring along the trimline of the physical SAFO in the ankle region and averaging the values. A static general load step was created, and nonlinear geometry (nlgeom) enabled. The load case as seen in Figure 4.(b) fixed the underside of the foot plate in all 6 degrees of freedom (DOF) with an appropriate boundary condition, whilst rotation about the virtual ankle joint was enforced at the calf reference point. This reference point was connected to the ankle reference point via a revolute connector. The calf reference point was linked to a partitioned section of the internal surface of the SAFO that represented the calf cuff by a kinematic coupling. In this study, additional geometry representing a partial artificial limb was modelled as a 3D discrete rigid shell to combat excessive buckling in the SAFO shell. This geometry was connected to the calf reference point via a rigid body constraint. Contact between the SAFO and limb was defined as frictionless. All geometry was meshed using the free meshing technique and quad-dominate element shape with shell elements S4R and S3. A mesh sensitivity study was conducted until the peak stress converged within 2%, resulting in an element seed size of 3mm. Two loading conditions were considered. The first applied a concentrated force of 100N in the negative Y-direction at the cuff reference point to induce rotation about the ankle axis so ankle stiffness could be calculated. The second applied an enforced rotation boundary condition to achieve 3° dorsiflexion, which was used to evaluate the maximum stress over the articulation expected during use. The stress distribution typical of the deformed traditional SAFO can be seen in Figure 4.(c).

4. Generative design

Generative design was employed to inspire novel topology that both varied from the traditional AFO design philosophy and was potentially inconceivable by a human designer. To perform this task, the generative design workbench within Fusion 360 from Autodesk [21] was employed.

4.1. Generative study set-up

4.1.1. Objectives

The objective was set to maximise stiffness whilst aiming for a target mass off 375g or less.

4.1.2. Geometry

Included as preserved geometry bodies (Figure 2.(a) green) were the calf cuff, the independent valgus correction patch, and the footplate which included valgus correction contacts. These bodies were excluded from the optimisation envelope but incorporated into the final shape of the design. The patient's limb and an additional body were defined as obstacle geometry bodies (Figure 2.(a) red) and represented spaces material could not be placed. Defining the leg as only obstacle geometry is insufficient as it leads to geometry that is not compatible with footwear or clothing.

4.1.3. Load case

The load case described in *3.1.* was modelled as closely as allowable within the Fusion 360 generative environment. A concentrated force of 100N was applied to the calf cuff to induce dorsiflexion rotation, whilst the underside of the footplate was fixed. To account for the resistance of the patient's limb on the valgus correction patch, a concentrated force was applied normal to its surface. The magnitude of this force was estimated to be substantially lower than that acting on the calf cuff. Thus, a magnitude of 25N (a quarter of the calf cuff force) was deemed to be sufficient. The load case can be seen in Figure 2.(a).

4.1.4 Constraints

PA11 – Nylon-HP 11-30 was selected as the study material from the in-built material library, and the manufacturing method was set to unrestricted, placing no manufacturing constraints on the generative solver. A local displacement limit of 6mm was placed on the calf cuff in the direction of its applied force and 3mm on the valgus correction patch in the direction of its assigned force. These limits were enforced to provide bounds of acceptable displacement for the desired rigidity.

4.2. Generative outcome

The resulting topology was an organic scaffold that in retrospect was quite intuitive, visible in Figure 2.(b). Due to the directness of the scaffold paths between preserve geometries, the structure is less conformal with the patient anatomy than the traditional shell design. This outcome revealed several large areas of the traditional shell design from where material could be removed, and areas where additional material would add value.

4.3. Parametric CAD model

The generative outcome was translated into a parametric design with a conformal surface that was scaffold like. The conformal surface was partitioned into the following regions: cuff, valgus correction patch, footplate, and lateral and medial halves. The geometry and thickness of the cuff, valgus correction patch, and footplate remained the same as the geometry used in the generative studies. For the rest of the model, parametric sketches driven by input parameters were used to produce trimming surfaces to remove sections of the surface to approximate the material distribution as suggested by the generative outcome. The medial sketch had a total of five modifiable parameters whilst the lateral sketches had six. The shape of the lateral sketch outlines can be seen in Figure 5.(b), with grey surfaces representing original geometry, and yellow and blue surfaces those for shape optimisation.

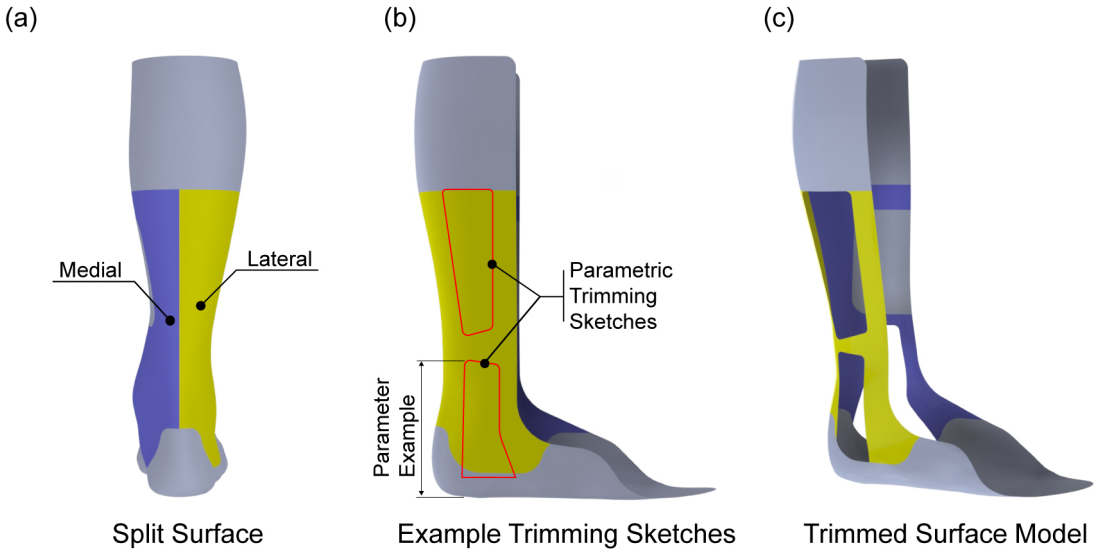

Figure 5. Parametric design: (a) rear view of parametric surface model, (b) examples of lateral trimming sketches, (c) trimmed parametric AFO design.

5. Shape optimisation

Shape optimisation, as outlined in *2.3.*, was performed on the parametric design to achieve the desired mechanical properties of the SAFO. Shape optimisation was conducted in the commercial optimisation software package modeFRONTIER provided by ESTECO [22]. Implementation in modeFRONTIER can be seen in Figure 6.

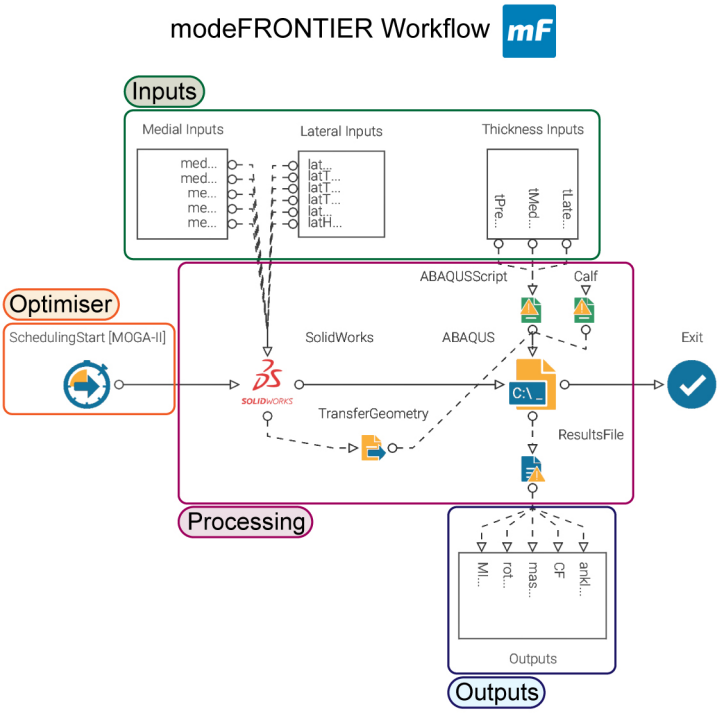

Figure 6. Implementation of shape optimisation in modeFRONTIER with key sub-systems outlined.

5.1. Input parameters

The parametric design used in this study had 14 parameters, 13 of which were variables. The variable parameters were defined as discrete and continuous, with a range (lower and upper value) and step size defined for each parameter. Table 1. presents three example input parameters and their respective properties.

Table 1. Example input parameters for shape optimisation.

Name	Association	Type	Lower (mm)	Upper (mm)	Step Size (mm)
medTrimline1	Medial	Discrete ordered	10	40	1
tMedialGeo	Thickness	Discrete ordered	5	12	0.5
tPreserveGeo	Thickness	Constant	3	3	-

5.2. Processing

The SolidWorks node was used in modeFRONTIER with the parametric design embedded within. The design input parameters were linked to the equations in the part file which directly modified trimming sketch parameters. Once the design was updated, the surface model was exported as a STEP file and transferred to the FEA environment.

A Python script was developed to automatically generate and run the FEA model described in *3.1.* to characterise the ankle stiffness and evaluate the stress-strain response. The script allowed the input parameters to make appropriate model modifications such as shell thicknesses. The material was modelled with the ABAQUS native elastic-plastic combined hardening (EPC) model as reported by Kajtaz & Lee [23]. The Python script was also used to analyse and report the FEA results.

5.3. Constraints & objectives

Three constraints and two objectives were defined to evaluate design feasibility and rank performance of feasible outcomes. The first constraint was the average ankle stiffness, which had a target value of 14Nm/° and a tolerance of ±0.5Nm/°. The second constraint was the upper limit of the mass of the SAFO, which was 375g and calculated directly using the volume of a design concept and the material density of HP-MJF PA11. The third constraint was the upper limit of the peak mises stress, which was defined as 30MPa. The limiting stress was based on the stress-strain response of HP-MJF PA11, which becomes substantially nonlinear beyond this magnitude. The first objective was mass minimisation, and the second objective was peak stress minimisation.

5.4. Optimisation scheduler

The defined objectives in this study were conflicting, thus, a suitable optimiser was required that was capable of finding a compromise and producing a Pareto Front. In this study, the multi-objective genetic algorithm (MOGA-II) was employed due to the reported performance equivalence with well-tested evolutionary multi-objective methods such as NSGA-II [24] and its ability to handle the ankle stiffness constraint tolerance. The algorithm was set to self-initialising and 500 evaluations. After approximately 200 evaluations, the optimisation schedular was regularly producing parameter sets for feasible designs. Once this occurred, the majority of the designs populated a small area between 345 and 365g. This area is magnified and highlighted in the red box in Figure 7.a).

5.5. Final design

The selected optimal design was the lightest feasible solution on the Pareto Front. It was generated during shape optimisation on the 204th evaluation. With a mass of 345.5g, the selected design was 30%

lighter than the benchmarked device, which had a mass of 491g. A render of the final design is presented in Figure 7.b).

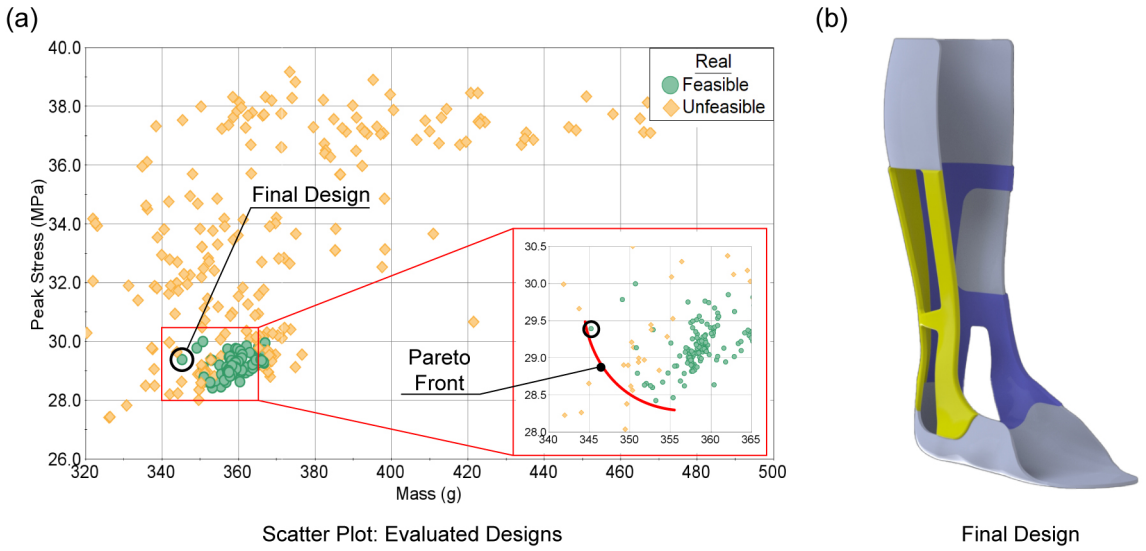

Figure 7. Shape optimisation outcomes: (a) scatter plot of peak stress and mass for evaluated designs, (b) final shape optimised AFO design render.

6. Conclusions

The design method proposed in this research leverages generative design and shape optimisation to produce novel AFO designs for additive manufacture with reduced mass whilst maintaining the fundamental mechanical behaviour of the traditionally fabricated device. The design method deploys two concepts: (i) leveraging generative design to inspire novel topology potentially inconceivable by a designer in isolation, and (ii) utilising shape optimisation coupled with high-fidelity prediction models to achieve desired mechanical behaviour. As demonstrated in this paper, the proposed method has capabilities to:

- yield an accurate and lightweight solution that satisfies the benchmarked mechanical performance requirement
- leverage generative design to provide patient and load-case specific insight into optimal material placement and distribution that may not be obvious to a designer in isolation
- speed up design refinement through automatic and intelligent shape optimisation

The proposed design method was successfully applied to a case study which demonstrated its effectiveness by generating a final design that was 30% lighter than the traditionally manufactured benchmarked device. This study is considered as a valuable starting point for further exploration of the benefits that can be obtained through the implementation of computational design tools for design of AFOs for additive manufacture.

Abstract

In this paper, a novel and efficient shape optimisation algorithm for gridshells, especially for cantilevering structures, is proposed based on the evolutionary node shifting method, where the nodal positions are iteratively updated to minimise the structural compliance. The sensitivity numbers for both structural compliance and volume against nodal shifting are explicitly derived. The surface smoothness is significantly improved by the introduction of the distributed load filter scheme, where the negative sensitivity numbers are applied to each node as the fictitious external load to ensure both the smoothness of surfaces and the sustained reduction of structural compliance at each iteration. A much more stable and faster convergence is achieved compared to the conventional nodal shifting methods. The numerical example of a rectangular gridshell is presented to demonstrate the effectiveness and the efficiency of the proposed algorithm.

Keywords: gridshells, shape optimisation, node shifting, distributed load filter

1. Introduction

The widely application of free-form gridshells results in an increasing demand for robust and efficient shape design methodologies connecting architectural intent and mechanical performance. Early form-finding works mainly relied on the physical experiments [1,2] and their computational simulations [3–5]. Many form finding techniques have been developed for the last four decades, such as the force density method [6–8], the thrust network analysis method [9] and the dynamic equilibrium methods [10–12]. Although being successfully applied for decades, conventional form-finding methodologies and their extensions based on the physical experiments are limited to shape generation of structures in pure tension or compression, and would fail in the cases where bending moments cannot be eliminated such as cantilevering shells or the cases with the objectives not related to stress conditions such as the buckling capacity maximization problems. Therefore, the shape design for such structures should turn to more generalized shape optimisation approaches [13–17]. However, due to the strong nonlinearity and massive variables for shape optimisation problems, the optimisation algorithms often pay for a high computational cost and lead to jagged surfaces when applied in large span structures.

In this paper, a novel and efficient shape optimisation algorithm based on the evolutionary node shifting method is proposed for gridshells especially those with cantilevering parts. The nodal coordinates are chosen as the design variables and are iteratively updated to minimize the structural compliance under a volume constraint. In order to smooth the jagged surfaces caused by the non-smooth gradient fields, fictitious distributed forces based on the sensitivity analysis are applied as a filter scheme to construct

the configurations instead of the sensitivity numbers. The example of a cantilevering rectangular gridshell is presented to demonstrate the effectiveness and the efficiency of the proposed algorithm.

2. The evolutionary node shifting method

The evolutionary node shifting method is a recently developed non-parametric shape optimisation approach for grid structures, in which nodal positions are iteratively updated according to the sensitivity information of the objective functions based on the gradient method [17–20]. Due to the non-smooth gradient fields, it may fall into premature convergence with jagged surfaces when applied in large span structures, thus extra smoothing procedure is required for optimal solutions [21–23]. However, the smoothing procedure generally follows the geometry principles, which means nodal shifting determined by the smoothing filter is independent of mechanical properties and may be opposite to the physical objectives, therefore leading to an oscillation around the optimal solution, i.e. unstable convergence. Thousands of iterations are required for the final convergence, making the method quite time-consuming. This article aims to develop a more efficient and smoother shape updating scheme to alleviate the oscillated convergence.

2.1. Objective function and sensitivity analysis

This article mainly concerns the general shape optimisation problems of maximizing structural stiffness under the volume constraint, which is equivalent to minimise the structural compliance. It is noteworthy that the algorithm can also be extended for other objectives based on similar principles. The objective of compliance minimization can be formulated as

$$\text{Minimise} \quad C = \frac{1}{2}\boldsymbol{f}^{\mathrm{T}}\boldsymbol{u}(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}) \tag{1a}$$

$$\text{Subject to} \quad V \le V^{*} \tag{1b}$$

where C indicates the mean compliance. $\boldsymbol{F}$ is the external load vector, and $\boldsymbol{u}$ is the unknown nodal displacement vector which is related to structural shapes. $\boldsymbol{x}$, $\boldsymbol{y}$ and $\boldsymbol{z}$ represent the vectors of design variables, namely x-, y-, z-coordinates of the free nodes. V and V^{*} denote the actual and constraint volume of the structure respectively.

The sensitivity analysis can be carried out using the adjoint method [22], by which the differentiation of the objective function with respect to design variables is explicit derived as

$$\frac{\partial C}{\partial x_i} = -\frac{1}{2}\boldsymbol{u}^{\mathrm{T}}\frac{\partial \boldsymbol{K}}{\partial x_i}\boldsymbol{u}, \quad \frac{\partial C}{\partial y_i} = -\frac{1}{2}\boldsymbol{u}^{\mathrm{T}}\frac{\partial \boldsymbol{K}}{\partial y_i}\boldsymbol{u}, \quad \frac{\partial C}{\partial z_i} = -\frac{1}{2}\boldsymbol{u}^{\mathrm{T}}\frac{\partial \boldsymbol{K}}{\partial z_i}\boldsymbol{u} \tag{2}$$

where the subscript i represents the ith node. $\boldsymbol{K}$ represents the global stiffness matrix. Since the position of the ith node only affects the stiffness of the beam elements connected to it, the sensitivity number for node i can be discretized as the summation of all the related elements as

$$\boldsymbol{S}_i^{c} = \left\{\frac{\partial C}{\partial x_i}, \frac{\partial C}{\partial y_i}, \frac{\partial C}{\partial z_i}\right\} = \left\{-\sum_e \frac{1}{2}\boldsymbol{u}_e^{\mathrm{T}}\frac{\partial \boldsymbol{k}_e}{\partial x_i}\boldsymbol{u}_e, -\sum_e \frac{1}{2}\boldsymbol{u}_e^{\mathrm{T}}\frac{\partial \boldsymbol{k}_e}{\partial y_i}\boldsymbol{u}_e, -\sum_e \frac{1}{2}\boldsymbol{u}_e^{\mathrm{T}}\frac{\partial \boldsymbol{k}_e}{\partial z_i}\boldsymbol{u}_e\right\} \tag{3}$$

where S^{c}_i indicates the sensitivity number for node i. $\boldsymbol{k}_e$ and $\boldsymbol{u}_e$ represent the stiffness matrix and the displacement vector of the eth element connected to node i in the global coordinate system respectively.

The structural shape may not be optimal when the structural volume reaches the limitation if only the compliance sensitivity numbers are involved, as they are independent with material consumptions. Thus, a volume adjustment subroutine of Eq. (1b) should be introduced in the updating process. The sensitivity of structural volume against the nodal shifting is derived as

$$\boldsymbol{S}_i^{v} = \left\{\frac{\partial V}{\partial x_i}, \frac{\partial V}{\partial y_i}, \frac{\partial V}{\partial z_i}\right\} = \left\{\sum_e \frac{\partial A_e l_e}{\partial x_i}, \sum_e \frac{\partial A_e l_e}{\partial y_i}, \sum_e \frac{\partial A_e l_e}{\partial z_i}\right\} = \left\{\sum_e A_e \frac{x_i - x_j}{l_e}, \sum_e A_e \frac{y_i - y_j}{l_e}, \sum_e A_e \frac{z_i - z_j}{l_e}\right\} \tag{4}$$

where A_e and l_e denote the cross-sectional area and the current length of element e respectively.

2.2. Shape updating scheme

As the sensitivity numbers reflect the influence on the structural compliance against nodal movements, nodes with larger sensitivity numbers are regarded as more important and supposed to be updated in priority. Thus, the conventional evolutionary node shifting method finds the optimal nodal movements in proportion to the normalized sensitivity numbers based on the gradient method. The shape updating procedure follows the strategy as

$$\boldsymbol{L}^{k+1} = \boldsymbol{L}^{k} + \alpha l_{\min} \left\{ -\boldsymbol{S}_i^{c} \right\}^{k}_{\text{normalized}} + \beta l_{\min} \left\{ -\boldsymbol{S}_i^{v} \right\}^{k}_{\text{normalized}} \tag{5}$$

in which $\boldsymbol{L}^{k+1}$ and $\boldsymbol{L}^{k}$ indicate the nodal coordinates in the current and the past iterations, the superscript k indicates the kth iteration. $l_{\min}$ represents the minimum length among all the beams. α is the step size for each iteration and is suggested not to exceed 5% for a stable convergence. β corresponds to the volume adjustment factor, which can be obtained by the bisection method between 0 and 0.5. The subscript of normalized means the normalization of the sensitivity matrix as,

$$\left\{ -\boldsymbol{S}_i \right\}_{\text{normalized}} = \left\{ -\boldsymbol{S}_i \right\} / \max\left(\text{abs}\left\{ -\boldsymbol{S}_i \right\} \right) \tag{6}$$

The volume adjustment subroutine is performed once the structural volume exceeds the constraint. It has also been verified effective for smoothing jagged edges as nodes tend to gather in the same plane with the surrounding connected nodes to decrease the structural volume, hence helps generate smooth surfaces. Although the volume subroutine gives the rectification for shape updating scheme by a perturbation at each step, it may force the nodes to move in the direction against compliance sensitivities, which is opposite to the objective. The interaction between the two subroutines results in an oscillation of the updating scheme and therefore leads to a slow convergence with thousands of iterations. Thus, it is essential to smooth the jagged surfaces caused by the non-smooth gradient field at each step to alleviate the oscillation after reaching the volume limitation. Although Wang *et al.* [23] introduced a double filter scheme for irregular edges, the surfaces are partially smoothed due to a limited filter radius, thus a high computation cost is still required. Considering that structures deformed smoothly under distributed load, instead of sensitivity numbers, fictitious distributed forces are introduced in this article to determine the nodal movements for maintaining the smoothness at each iteration. The shape updating scheme of Eq. (5) is then modified as

$$\boldsymbol{L}^{k+1} = \boldsymbol{L}^{k} + \alpha l_{\min} \left\{ \Delta x_i, \Delta y_i, \Delta z_i \right\}^{k}_{\text{normalized}} + \beta l_{\min} \left\{ -S_i^{v} \right\}^{k}_{\text{normalized}} \tag{7}$$

in which Δx_i, Δy_i and Δz_i indicate the nodal displacements of node i in the x-, y- and z-direction under the fictitious distributed load, and can be evaluated from the equilibrium equation of the shape updating analysis,

$$\boldsymbol{u}_{op} = \left\{ \Delta x_i, \Delta y_i, \Delta z_i, \Delta \theta_{xi}, \Delta \theta_{yi}, \Delta \theta_{zi} \right\}^{\mathrm{T}} = \boldsymbol{f}_{op} / \boldsymbol{K}_{op} \tag{8}$$

where $\boldsymbol{u}_{op}$ represents the structural deformations composed of nodal displacements and rotations with respect to x-, y- and z-axis under the fictitious distributed load $\boldsymbol{f}_{op}$, and $\boldsymbol{K}_{op}$ corresponds to the global stiffness matrix with respect to the shape updating analysis, which depends on the architectural intents and only differs in a few corresponding elements with $\boldsymbol{K}$ according to the boundary condition changes, thus no extra numerical modelling procedure is needed for the reconstruction of global stiffness matrix.

As nodal updating movements at each iteration are in proportion to the nodal displacements under the fictitious distributed load, the change for the compliance at each iteration is estimated as

$$\Delta C \approx \gamma \sum \left(\frac{\partial C}{\partial x_i} \Delta x_i + \frac{\partial C}{\partial y_i} \Delta y_i + \frac{\partial C}{\partial z_i} \Delta z_i \right) = \gamma \sum \left\{ \frac{\partial C}{\partial x_i}, \frac{\partial C}{\partial y_i}, \frac{\partial C}{\partial z_i} \right\} \cdot \left\{ \Delta x_i, \Delta y_i, \Delta z_i \right\}^{\mathrm{T}} \tag{9}$$

where γ is the positive factor related to step size. It can be extended in the form of structural deformations according to Eq. (8) as

$$\begin{aligned} \Delta C &\approx \gamma \sum \left\{ \frac{\partial C}{\partial x_i}, \frac{\partial C}{\partial y_i}, \frac{\partial C}{\partial z_i}, 0, 0, 0 \right\} \cdot \left\{ \Delta x_i, \Delta y_i, \Delta z_i, \Delta \theta_i, \Delta \beta_i, \Delta \gamma_i \right\}^{\mathrm{T}} \\ &= \gamma \left\{ \boldsymbol{S}_i^c, 0, 0, 0 \right\} \cdot \boldsymbol{u}_{op} = \gamma \left\{ \boldsymbol{S}_i^c, 0, 0, 0 \right\} \cdot \boldsymbol{K}_{op}^{-1} \cdot \boldsymbol{f}_{op} \end{aligned} \tag{10}$$

In order to keep the compliance declining at each iteration, the fictitious distributed forces are defined as the negative compliance sensitivities,

$$\boldsymbol{f}_{op} = \left\{ -\boldsymbol{S}_i^c, 0, 0, 0 \right\}^{\mathrm{T}} = \left\{ -\frac{\partial C}{\partial x_i}, -\frac{\partial C}{\partial y_i}, -\frac{\partial C}{\partial z_i}, 0, 0, 0 \right\} \tag{11}$$

which means that the negative sensitivities are applied as distributed load to each free node along the *x*-, *y*-, *z*-direction respectively to erect the structures. Consequently, the compliance change for nodal shifting becomes

$$\Delta C \approx -\gamma \, \boldsymbol{f}_{op}^{\mathrm{T}} \boldsymbol{K}_{op}^{-1} \boldsymbol{f}_{op} < 0 \tag{12}$$

As the stiffness matrix is positive definite for stable structures, Eq. (12) is guaranteed negative, which gives a sustained reduction for the structural compliance during the optimisation process, meanwhile the smoothness of updated surfaces at each step is significantly improved as structures tend to deform uniformly under distributed load. In fact, the strategy of introducing distributed load instead of sensitivity numbers makes all the nodes deformed interactively, as sensitivities in the form of nodal load would also result in a change for other nodes rather than the loading node only, which can be regarded as a filter scheme over all the free nodes. Considering that the models for sensitivity and shape updating analysis are the same, the non-smooth gradient fields are offset by the dual operation, makes it more effective than the previous filter schemes.

2.3. Optimisation procedure

The proposed shape updating scheme determines the nodal shifting at each iteration in a much smoother or in other words a more efficient way by the fictitious distributed load filter. The distributed forces based on sensitivity numbers are applied to evolutionarily erect the stiffest structural shape. The optimisation procedure is illustrated as follows:

1. Define the initial conditions, including the starting grid model, the boundary conditions and the architectural constraints.
2. Perform the finite element analysis (FEA) for the nodal displacements under external load. The global stiffness matrix corresponding to the current shape is constructed at this step.
3. Evaluate the sensitivity numbers according to Eq. (3), then assign them to the distributed load for the following shape updating analysis as Eq. (11).
4. Revise the global stiffness matrix with respect to architectural constraints, then perform the shape updating analysis for the nodal displacements by Eq. (8).
5. Update the nodal coordinates according to Eq. (7), where the step size α is defined adaptive in this article for more stable convergence, by endowing with 5% when under the volume constraint and 5‰ otherwise. Evaluate the current structural volume, perform the volume adjustment scheme if necessary, otherwise continue step 2 to 5 until the convergence criterion referring to the literature [24] is satisfied:

$$\left| \frac{\sum_{m=1}^{M} \left(C^{k-m+1} - C^{k-M-m+1} \right)}{\sum_{m=1}^{M} C^{k-m+1}} \right| \leq \tau_1 \tag{14a}$$

$$\left| \frac{V^k - V^*}{V^*} \right| \leq \tau_2 \tag{14b}$$

where τ_1 and τ_2 are the convergence tolerances with respect to the structural compliance and volume, and is defined 10^{-3} and 10^{-5} respectively for the numerical examples in Section 3. $M = 10$ is applied in this article for a stable convergence of at least 20 iterations.

It is noteworthy that although an extra shape updating analysis is required for the proposed algorithm, the computational time for each iteration only increased limitedly with regard to the matrix calculation in Eq. (8). There is no need to reconstruct the global stiffness matrix for shape updating analysis as it can be easily obtained by revising the corresponding elements of $\boldsymbol{K}$, which is already known in the compliance analysis. Furthermore, if the boundary conditions for shape updating analysis remain the same with the compliance analysis, the inverse global stiffness matrix can be applied directly to the updating analysis for multiplication, which is much faster than matrix division. Although the computational time slightly increased at each iteration, it is worthy to do so if the recursive steps are reduced more. In fact, as the distributed load filter offers a much smoother and more efficient way for nodal shifting, the non-smooth gradient fields are significantly alleviated, thus leading to a remarkable reduction in recursive steps with a more stable convergence.

3. Numerical example

The numerical example of a cantilevering rectangular gridshell is presented in this section to verify the effectiveness of the proposed algorithm. The node shifting methods proposed in the literature [22,23] are also applied as comparison to demonstrate the advantage of the fictitious distributed load filter. For simplicity, the non-unit parameters are used, as the material is defined with an elastic modulus and a shearing modulus both of 1. All the beam elements are endowed with a uniform square cross section of 20×20. The initial model and the boundary conditions are shown in Fig. 1. A vertical point load of $F = 1$ is applied to the cantilevering corner, which makes the conventional form-finding techniques for tension- or compression-only structures inapplicable as non-negligible bending moments are generated for the beam elements. The target volume is defined as 110% of the initial flat shell, and the *z*-coordinates of all the free nodes except the ones on the four red sidelines are defined as the design variables, as shown in Fig. 1(b). The optimisation procedure is implemented in MATLAB and run on a PC with 16 GB RAM and 2.10 GHz Intel Core i7 processor.

The sensitivity numbers would be zero for the initial fat shell as it stays at a stagnation state, where the nodes moving upward or downward bring the same effect on the structural compliance symmetrically, thus an initial perturbation is needed for this special state, but not necessary in other cases where nodes are not all in the same horizontal plane. It has been verified that the perturbation in proportion to the initial structural deformation gives a more stable and stiffer solution [23], therefore the same perturbation scheme is applied in this article. To further improve the computational efficiency, all the nodes are constrained at *x*- and *y*-direction in the shape updating analysis as they are not design variables. The optimised shape generated by different filter schemes are shown in Fig. 2(a)-(c). The compliance and volume histories are given in Fig. 2(d).

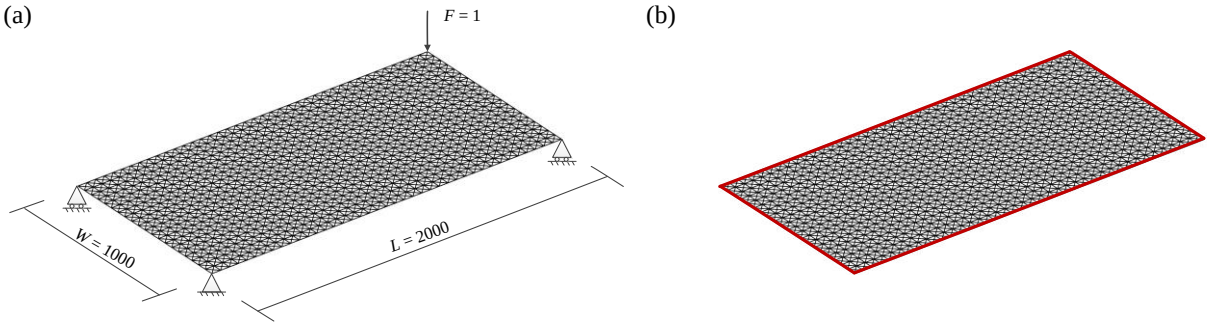

Figure 1. The initial model and boundary conditions for (a) compliance analysis and (b) shape updating analysis.

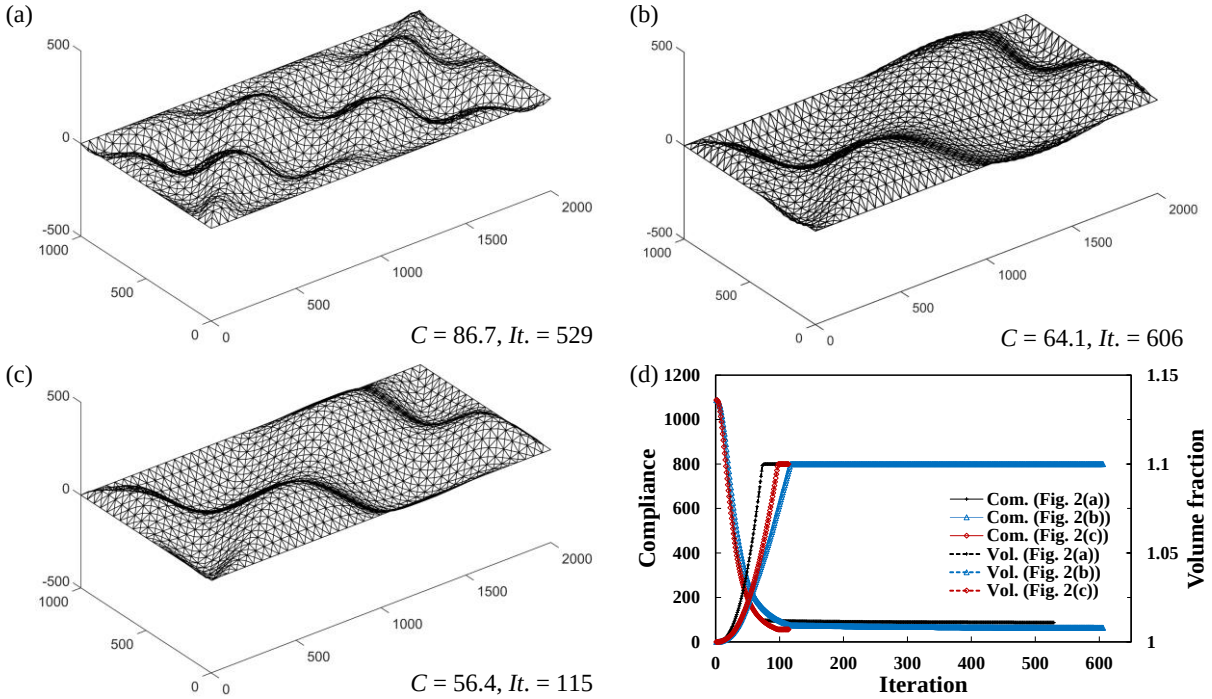

Figure 2. The optimised shapes generated by the evolutionary node shifting method: (a) without filter [22], (b) with the double filter scheme [23], (c) with the distributed load filter scheme, and (d) evolutionary histories for structural compliance and volume.

The optimised shape obtained by the distributed load filter is similar to the one by the double-filter, but with smoother surface and lower compliance, while the model without any filter obviously falls into premature convergence. The contradiction between compliance and volume adjustment subroutines leads to a very slow nodal shifting towards the optimal positions, which makes the compliance vary very little at each step and finally leads to a premature convergence for the first two models. As nodes are still moving towards the optimal positions slowly, a stricter convergence criterion is needed to allow further optimisation for the compared methods. Fig. 3 shows the further optimised shapes for the models in Fig. 2(a) and (b) with respect to the same compliance level of the new method. The final optimised shapes are similar to the one or its inverse form in Fig. 2(c), but with far more iterations. The shape updating scheme with fictitious distributed load filter only takes 115 steps for the optimal shape while the other two strategies need more than 5,000 steps. Although the double filter scheme alleviates the non-smooth gradient field compared to the conventional node shifting method without any filter, it cannot avoid the contradiction between the compliance and volume adjustment scheme as it only gives local smoothness within the filter radius, massive iterations are still required after reaching the volume limitation. The in-process optimised shapes when reaching the volume constraint with respect to the three approaches are shown in Fig. 4, where obvious jagged surfaces are observed for the first two

shapes while the nearly optimal shape is already obtained by the proposed method. The nodal movements determined by the sensitivity numbers only ensure the decline of structural compliance, but not by the most efficient way, thus premature shapes are generated when the structural volume reaches the limitation. A sustained perturbation by the volume adjustment subroutine is needed for the revision of nodal shifting scheme, but this strategy could result in a ponderous evolutionary process. The new proposed approach avoids the trouble by shifting the nodes in a smoother and more efficient way at each step, a nearly optimal shape is generated when the volume limitation is reached, thus no more perturbation is needed. The time consumptions for the three methods are listed in Table 1. It is shown that even though the average computing time for each step is increased due to the updating analysis, the new algorithm with distributed load filter saves more than 97% time in total.

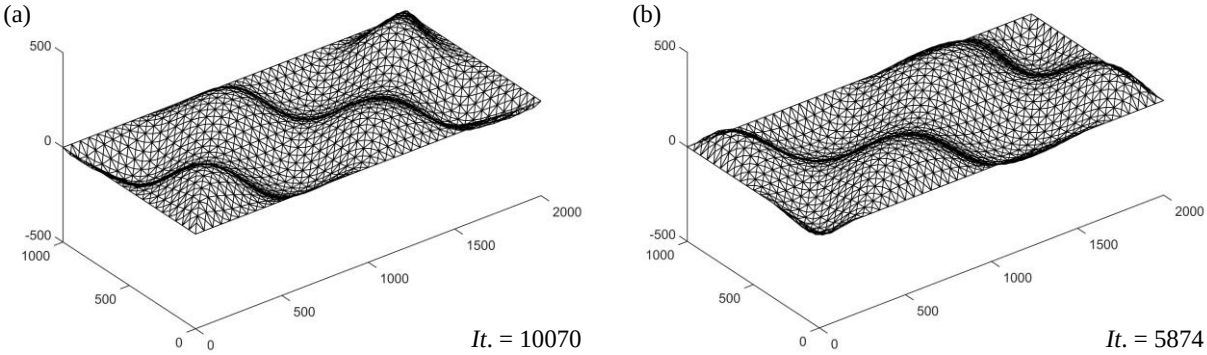

Figure 3. The further optimised shapes (a) without filter, (b) with the double filter scheme.

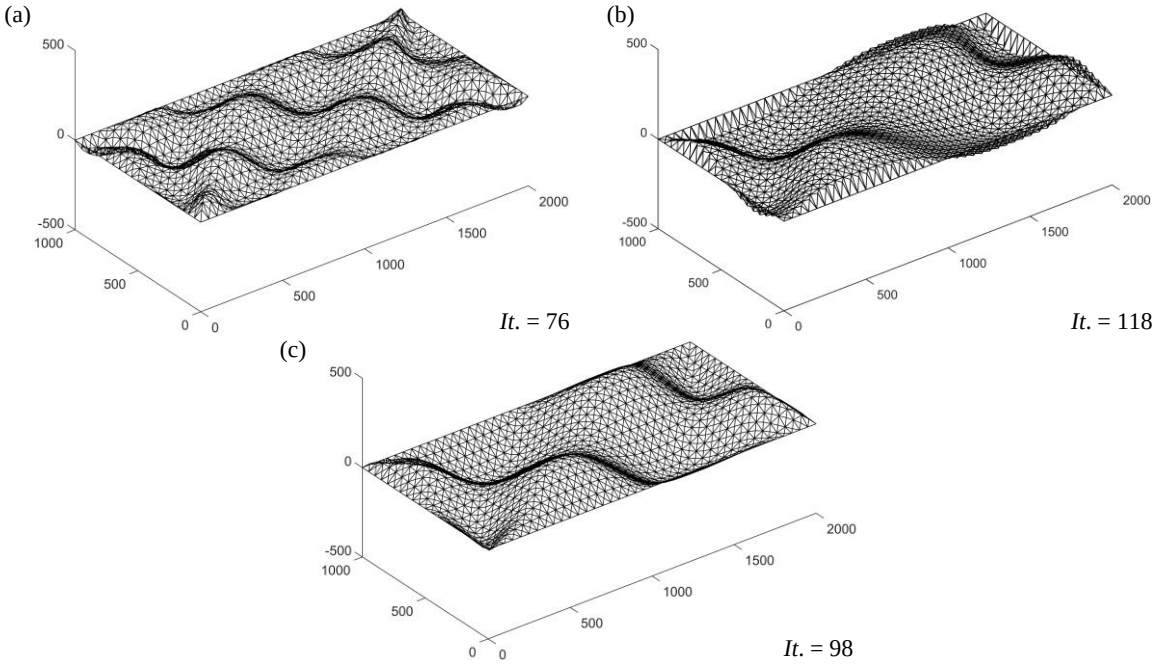

Figure 4. The in-process optimised shapes when reaching the volume constraint (a) without filter, (b) with the double filter scheme and (c) with the distributed load filter scheme.

Table 1. Time consumptions for the same compliance level with different strategies.

Strategy	Compliance	Total iterations	Time for each iteration	Total time consumption
without filter	56.4	10070	3.03s	30522.6s
double filter		5874	3.72s	21860.4s
distributed load filter		115	5.88s	676.7s

4. Conclusion

The shape optimisation algorithm proposed in this study offers a more efficient and robust computational designing tool for freeform gridshells, especially those with non-negligible bending moments where the conventional form-finding methodologies would fail. Nodal coordinates are treated as design variables without any extra parameterisation. A smoother and more efficient shape updating scheme by introducing the distributed load filter is proposed. The negative sensitivity numbers are applied to each node as the fictitious external load to ensure both the smoothness of surfaces and the sustained reduction of structural compliance at each step. With the nodes shifting interactively under external load, the distributed load filter scheme acts as a global filter over all the free nodes based on structural mechanic properties, thus significantly alleviates the non-smooth gradient field caused by the structural nonlinear effect. A much more stable and faster convergence is achieved compared to the conventional nodal shifting methods. The numerical example indicates that although the average computing time for each iteration is increased with the shape updating analysis, the proposed method can save more than 97% computational time overall due to a significant drop in the iteration number, which makes it applicable for large span structures with complex curvatures. As the method is developed from general mechanical principles, it is possible to be extended in the future to more general fields such as maximising the buckling load or being combined with concurrent size and topology optimisation.

Abstract

The West Gate Tunnel Project in Melbourne, a toll road alternative to the West Gate Bridge, includes decorative entrance and exit exhaust vent structures designed by Wood Marsh Architecture. This paper examines the design process of the Northern and Southern vents undertaken by Taylor Thomson Whitting, specifically surrounding the aluminium façade and supporting structural steel. The design process focused on panelising the freeform façade and optimising the supporting structure. A distorted grid in the surface envelope's UV space was used to ensure a continuous flow between the timber portal and aluminium structures topologies. Further geometric optimisation employed k-means clustering to minimise discrepancies in connection lengths and member bend radii. The structural design process was automated using C# libraries and Grasshopper scripts, in conjunction with FEA models, AS4100 design checks, and an optimisation framework inspired by bone mechanobiology research. Computational design methods implemented on the project allowed for rapid and precise structural feedback, prompting informed decision-making among stakeholders regarding geometric changes impacting architectural intent and structural design.

1. Introduction

The West Gate Tunnel Project aims to provide a crucial alternative to the West Gate Bridge, resulting in faster and safer commutes while redirecting a significant number of trucks away from residential areas. The project is composed of three major elements: a tunnel structure, an elevated roadway section, and an upgraded segment of the West Gate Freeway. At each of the three entrances/exits to the tunnel, there exists an architectural timber and aluminium structure that serves as a decorative feature and, in the case of the two largest structures, housing the tunnel's ventilation systems within the aluminium portion of the design.

The vent structures are formed from a double layered structural steel system supporting a triangulated aluminium facade with expressed diamond panalisation. The largest of the two vent structures, the Northern portal, is located adjacent to Yarraville Gardens on Whitehall Street, measuring 136 meters long, 38 meters wide, and 46 meters high (Figure *1*).

Taylor Thomson Whitting (TTW) was engaged by the managing contractor for the tunnel project, CPBJH Consortium, to develop the structural design and façade engineering for the aluminium vent structures of both the Northern and Southern outbound vents. The design approach adopted took into account various constraints, including structural design standards, durability, transportation, fabrication, erection, and maintenance. However, this paper focuses solely on the generation of the geometry and topology of the aluminium panels, as well as the façade design and the structural optimisation work carried out to design the vent structures support system.

This paper is organised into three main sections. Section 2 describes the geometry work carried out to unify the vent structures with their paired architectural timber structures [1]. Section 3 details the façade optimisation carried out, and Section 4 explores the structural optimisation targets and processes of the façade support system.

2. Geometry

One of the aesthetic aspects deemed of high importance to the architect's vision was achieving a seamless transition between the timber gridshell topology and the vent aluminium cladding. To accomplish this, a geometric constraint was to the match nodal locations and member tangency at the transition between the two zones. The timber gridshell was designed to a parallel hoop scheme with infill diagonal members in between each hoop as seen in Figure *1* and a changing its geometry was not within the scope of works for this project. An additional complexity of this task was that both vent structure surfaces are asymmetrical, unlike the timber structures that were designed with a central symmetry plane, as seen in Figure *2*.

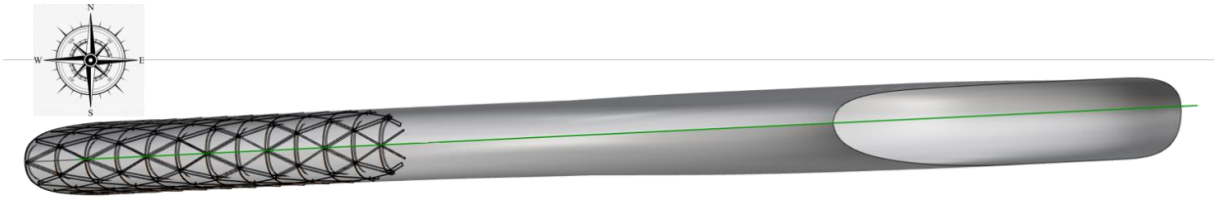

Figure 2. Plan view of the Southern Outbound portal, with Wood Marsh envelope surface shown in grey and architectural timber structure symmetry plane in green.

2.1 Methods

The first step in developing the panelisation geometry was to perform minor alterations to the original Wood Marsh envelope surface to avoid clashes within the structure. This process involved offsetting the surface inward to the estimated maximum offset of the internal structural steel system, analysing the

new offset surface for clashes and then rebuilding the original surface control points accordingly to prevent these clashes. The rebuilt surface went through multiple iterations to avoid external road sway envelopes as well as to blend the changed control points such that the differences between the original and modified sock surface were as subtle as possible. Once a suitable initial surface was produced, the panelisation process could proceed, following the process described in the subsections below.

2.1.1 General panel logic

There was a degree of common logic shared between both the north and south vent structures. Both structures used two sets of reference curves to form the panels of the façade. The first set of curves were generated from cutting planes of changing orientation starting oriented parallel to the timber hoops and finishing aligned with the outlet plane. The intersect of these planes with the envelope surface created the first set of curves nominated Plane Set Curves (PSC's). By using these PSC's as the diagonal of the panels we allow node planarity and avoid the timber hoop direction to be visually expressed in the panels. To ensure a smooth and even transition from the timber topology to the rest of the geometry, a transition zone was imposed where the first planes in the plane set were aligned with the timber parallel hoop direction. This process is illustrated in Figure *3*.

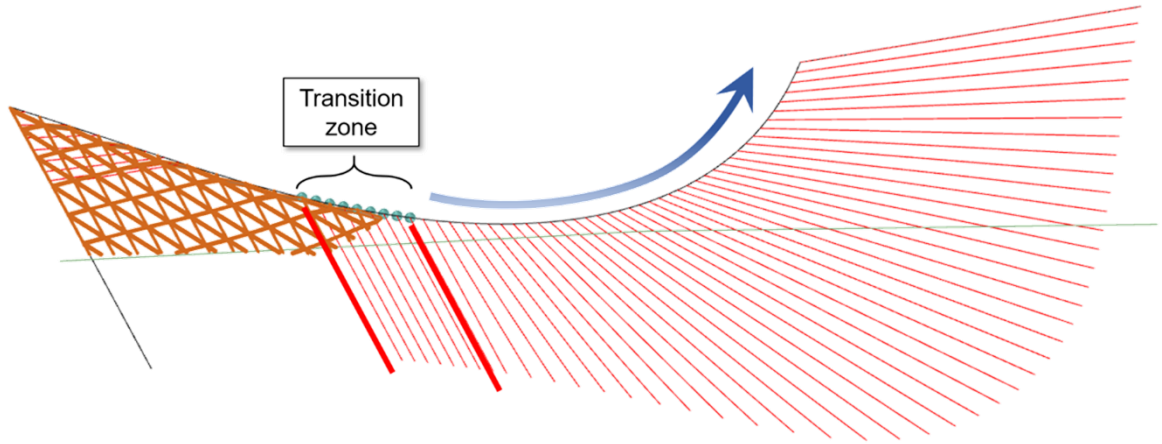

Figure 3. A transition zone is used to seamlessly transition from the architectural timber parallel hoop planes to the outlet vent cap plane at the top of the structure generating the Panel Set Curves (PSC's).

The second set of curves used to define a grid differed for the two portals. The Southern portal utilised logintudinal iso-curves whilst the Northern portal used a distorted UV grid both described below.

2.1.2 South portal specific panel logic

The Southern portal utilised longitudinal iso-curves as shown in Figure *4*. The iso-curves are set to start at equidistant points along the top outlet boundary. The intersection point of the PSC and iso-curves are then used as corner nodes for each diamond in the final panelisation.

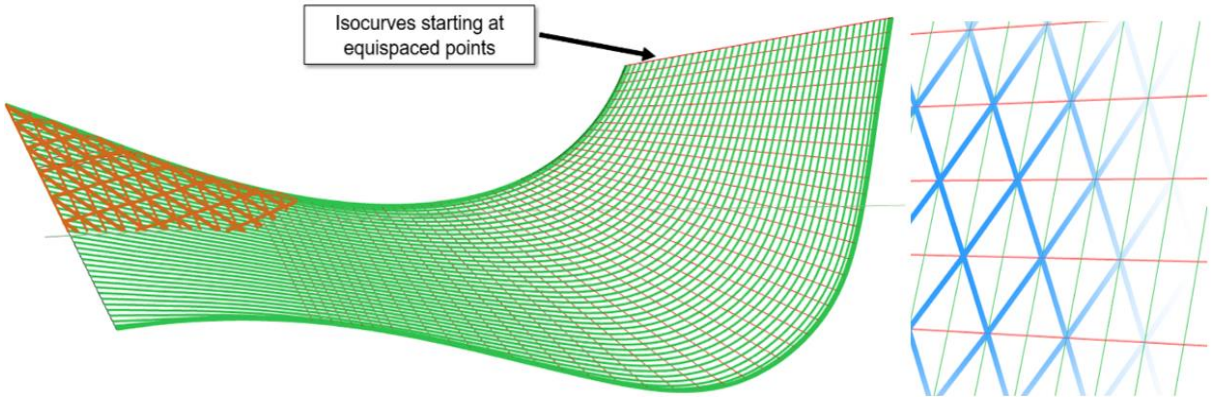

Figure 4. Panels are expressed from grid generated using the plane set curves (in red) and a set of surface iso-curves (in green). (a) Isocurves are generated starting at equispaced points along the outlet boundary. (b) Panels (in blue) are created from the intersection between planes and iso-curves.

These steps, however, do not guarantee a consistent transition between the timber and vent topologies. This is due to the shallower profile of the envelope surface close to the timber gridshell and start of the vent regions. It is noticeable in Figure *4* that the iso-curves are closer when the surface constricts, making the panels narrower than required for a smooth transition in the topologies. A simple strategy to address this is to adjust the surface depth, stretching the cladding panels up to the point they approximately match the timber topology in terms of node location and edge tangency. This is illustrated in Figure *5*.

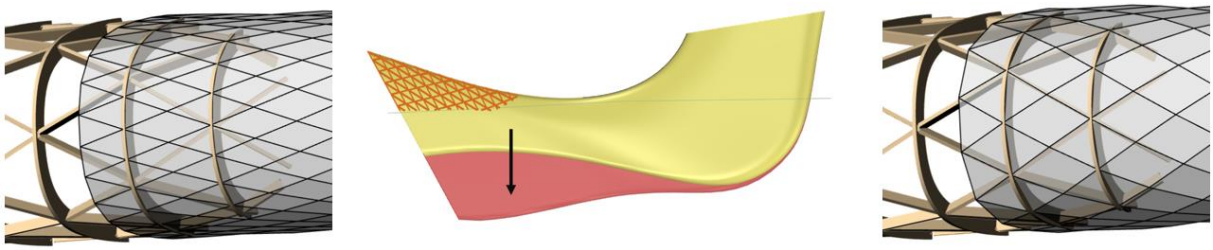

Figure 5. Accomplishing a smooth transition between timber gridshell topology and cladding panels. (1.) Transition between timber and cladding is not consistent (2.) The original surface (yellow) can be stretched to adjust the distance between iso-curves and, consequently, (3.) modify the panel proportions to match the timber gridshell topology.

2.1.3 North portal specific panel logic

Whilst the estimation of the best fit longitudinal iso-curves based on a modified surface was sufficient to seamlessly blend the timber members and vent panels on the Southern portal, on the Northern portal, the varying pattern densities between the two structures prevented the use of this technique. Figure *6* shows a superposition of the timber topology and the longitudinal iso-curves of the envelope surface, where this misalignment is evident.

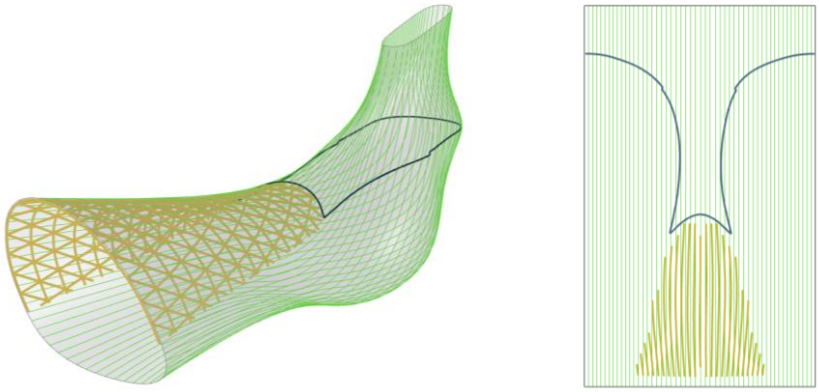

Figure 6. Misalignment between longitudinal iso-curves (in green) and timber gridshell reference curves (in yellow) for the North Portal (left) in 3D and (right) in UV mapping coordinates.

To improve continuity between the two geometries, a new set of longitudinal iso-curves was created in UV mapping coordinates, which maintained panel aesthetics around the vent region and gradually transitioned to the pattern of the timber portal. These curves were modelled as B-splines, starting "vertically" at the top in the UV space (the vent region), and matching the direction and curvature of the timber reference curves. The process of creating these curves is illustrated in Figure *7*.

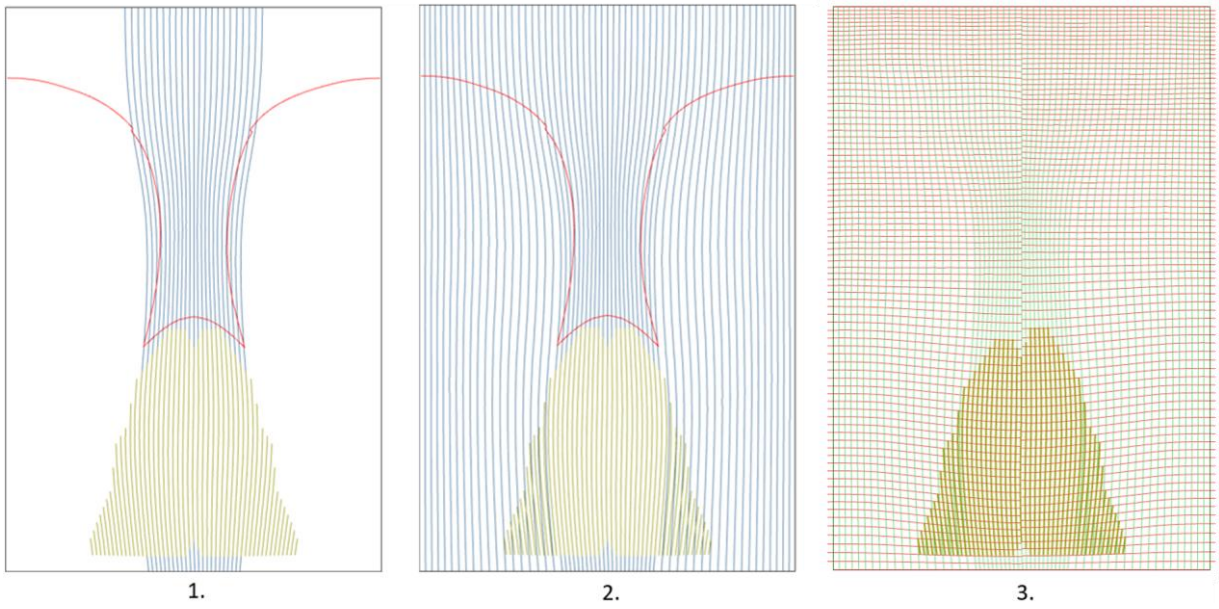

Figure 7. Development of North Portal panelisation curve sets. (1.) Develop internal spline curves between existing timber curves and vertical curves at exhaust. (2.) Tween curves to edge of UV coordinates (3.) Finalise grid with the placement of PSC's (in red).

2.2 Results

By varying the frequency of iso-curves in each curve set that generated the panelisation grid in the section above, the number of panels could be increased or decreased to accommodate varying shape parameters. Several iterations of different panel division options were produced with the aim of minimising the number of panels with edge lengths greater than 6.5m (an additional geometric constraint discussed in Section 3), while also minimising the total number of panels. The final subdivisions seen in Figure *8* had a small number of panels that exceeded the maximum edge length parameter; however, the façade team was confident that a unique solution could be found for these zones at a lower cost than

the fabrication and construction costs associated with further subdividing the panels of the structure to produce smaller panels.

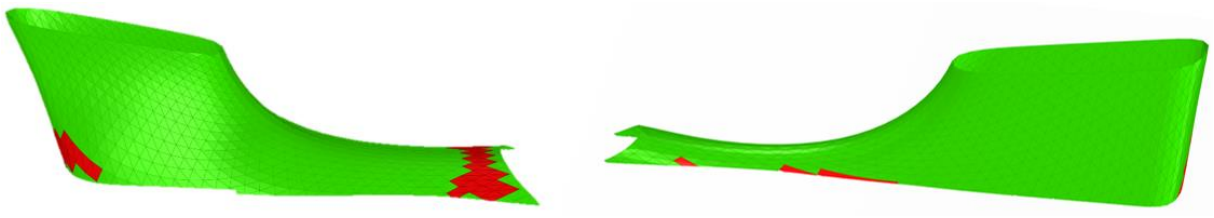

Figure 8. Panel compliance to maximum 6.5m edge. North Portal 94% compliant (Left) South Portal 99.3% compliant (Right)

3. Façade

A key architectural constraint of the project, as described in Section 0 of this paper, was to maintain the timber gridshell topology across into the vent structure. This geometry called for expressed joints around non-planar diamond panels with diagonal lengths up to 6.5m. The 6.5m edge length limitation was a direct result of the panel system described in this section. Aluminium extrusions are used under each panel, and feedback from the market suggested that by limiting the extrusion length to this value, we would increase the number of companies that could compete for the fabrication of the façade. Significant effort was made to simplify these expressed diamonds into planar triangular panels with minimal material wastage.

3.1 Method

Early feedback from builders indicated that the best aluminium source for the façade would be coils of aluminium instead of sourcing metal sheets. The standard maximum width available for aluminium coils is 1500mm, with thickness ranging from 0.6mm to 3mm. To avoid curving the aluminium to fit the non-planar diamond shapes, each panel was divided into a pair of triangles. A study was conducted to assess the visual impacts of dividing the diamonds along either the U or V gridlines as specified in Section 2 It was determined that dividing the panels in the longitudinal direction, or "Iso" as shown in Figure *9* was most appropriate for maintaining the architectural intent of the structure.

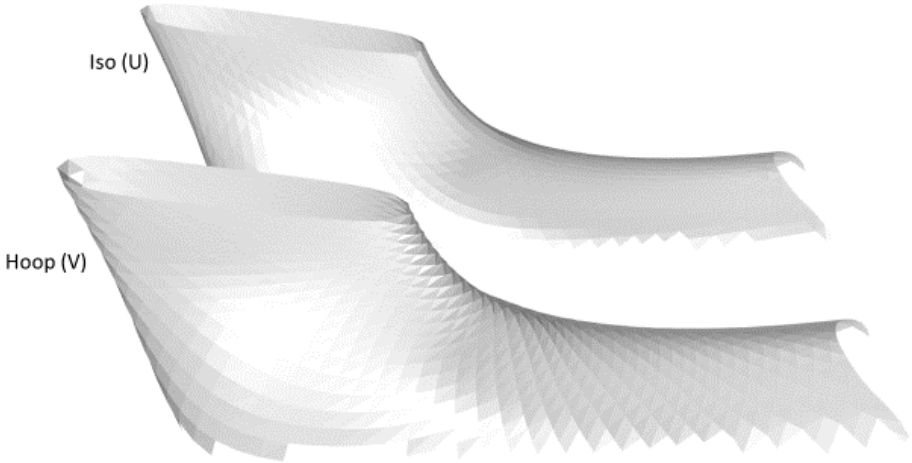

Figure 9. Comparison of alternative iso-curve subdivisions of diamond panels

With a maximum edge length of 6.5m each planar triangle panel still required multiple strips of aluminium. In order to minimise wastage, strips of aluminium were placed from the leading edge of a triangle at their full width of 1500mm. By starting the placement of the strips from a straight factory edge tolerance, issues were minimised compared to using a cut edge where a slight angle difference

could cause a cumulative misalignment with the addition of subsequent panels panel. It is for this reason that the panels on each triangle do not align with one another as the leading edge is on opposite sides of the diamonds (right-hand side for the top triangle and left-hand side for the bottom triangle in Figure *10*).

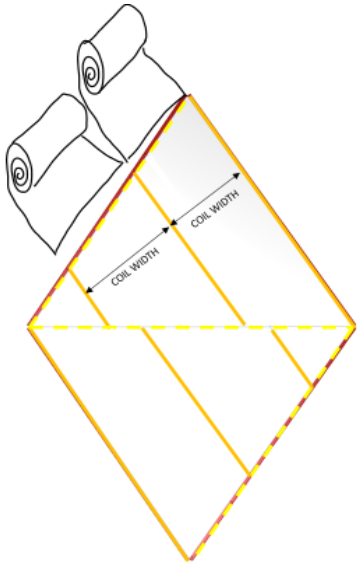

Figure 10. Panel strip layout, yellow dotted lines represent cuts whilst orange solid lines represent factory straight edges.

In addition to having an aluminium extrusion running under each panel edge to provide a surface to fasten to, additional stiffeners were required to reduce panel deflections. These framing members were structurally optimised by grouping panels based on similar surface area and then designing the stiffener elements to withstand the maximum wind load experienced by all panels in the group.

In some cases, we observed large panels in areas of high wind loads, which required substantial stiffening. In order to avoid a high density of stiffeners in these locations, we adjusted the panelisation of the aluminium facade (following the approach detailed in Section 2 of this paper) to reduce the affected panel areas. The final façade system can be seen in Figure 11.

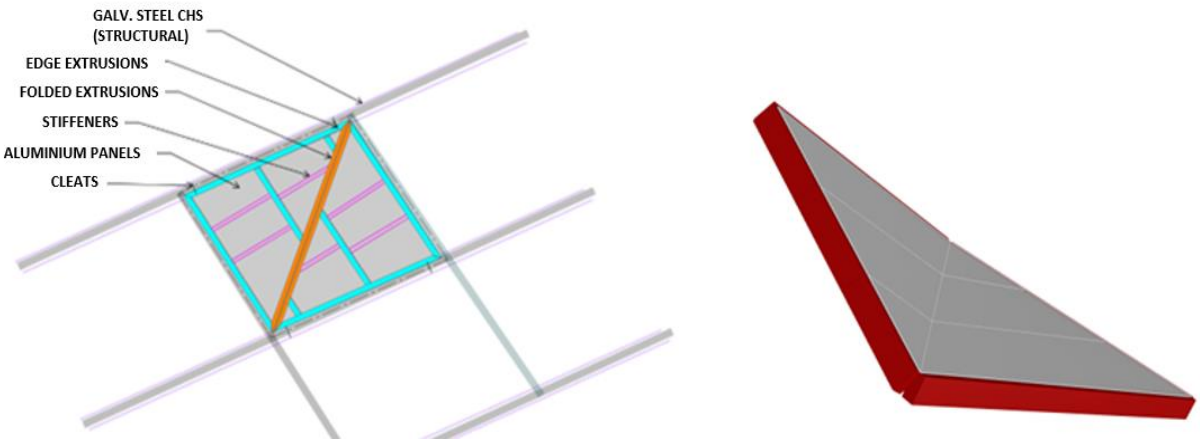

Figure 11. Façade Panel Setout.

3.2 Results

The final panel count across the structures came to 1785 triangular panels on the Northern portal and 1644 on the Southern. With an average panel area of 5m^2 and 5.67m^2, respectively, this resulted in the bulk of panels being comprised of three aluminium coil strips as displayed in Figure *12* which portrays the final structures appearance with exaggerated seams between the coil strips.

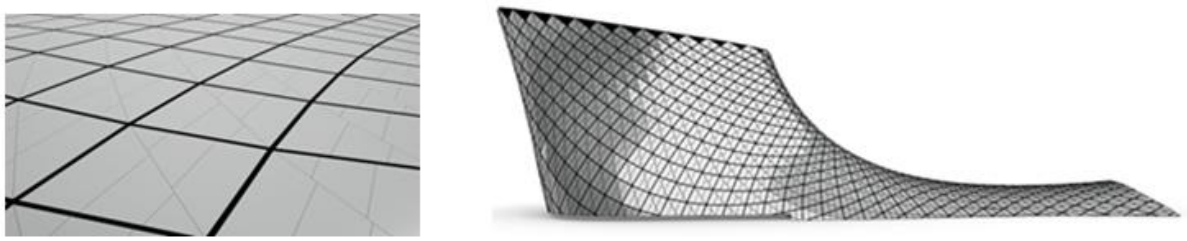

Figure 12. Final panelisation with exaggerated panel seams.

4. Structure

The façade support system consists of two layers of steel structure. The primary members shown as red in Figure are offset inwards from the yellow secondaries, this allows the secondary members to run continuously. The secondary members provide the structure to which the aluminium façade support extrusions described in Section 0 will connect. The resulting load path is as follows; the aluminium extrusions distribute the load to the secondary structure at the vertices of the triangular panels. The secondary structure runs continuously over columns and arches which will pick up the load and distribute it either into the core through brace members or directly down to the footings in the case of the arches. This scheme seeks to improve structural efficiency by providing continuity of steelwork members where possible, rationalising the number of arc radii required and utilising stock member lengths where possible to simplify fabrication.

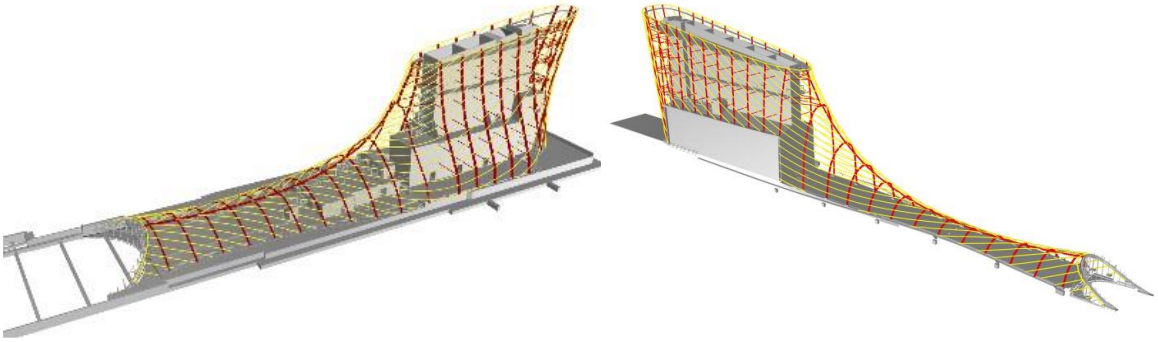

Figure 13. Façade Support System.

4.1 Method

The entirety of the structural design process, from generating of the geometry to analysing of the steel to AS 4100, was automated to accommodate sudden geometric changes driven by both changing architectural requirements and functional constraints such as access walkways and traffic sway envelopes. This was achieved by developing multiple Grasshopper scripts for the project, so that a change at any stage of design could be quickly filtered through a series of parametric models to provide near immediate feedback on the structural implications such a change would have.

4.1.1 Geometric optimisation

Geometry optimisation was a major component of the project. Beyond the initial architectural geometry rework described in Section 0, TTW further manipulated the geometry to improve structural efficiency by maximising the continuity of steelwork members, utilising stock member lengths where possible to simplify fabrication, rationalising the number of arc radii required and minimising the variation between support members and facade.

Segment rationalisation attempted to maximise the number of secondary CHS members that were of stock lengths 9 or 12m. This was achieved by alternating the "bays" of the structure between ladder bays with segments at stock length and filler bays of variable length in between, as shown in Figure . This process had the added benefit of aiding the construction sequencing, as the ladder bays could be built in liftable segments and then once positioned with temporary bracing, the infill members could complete the structure.

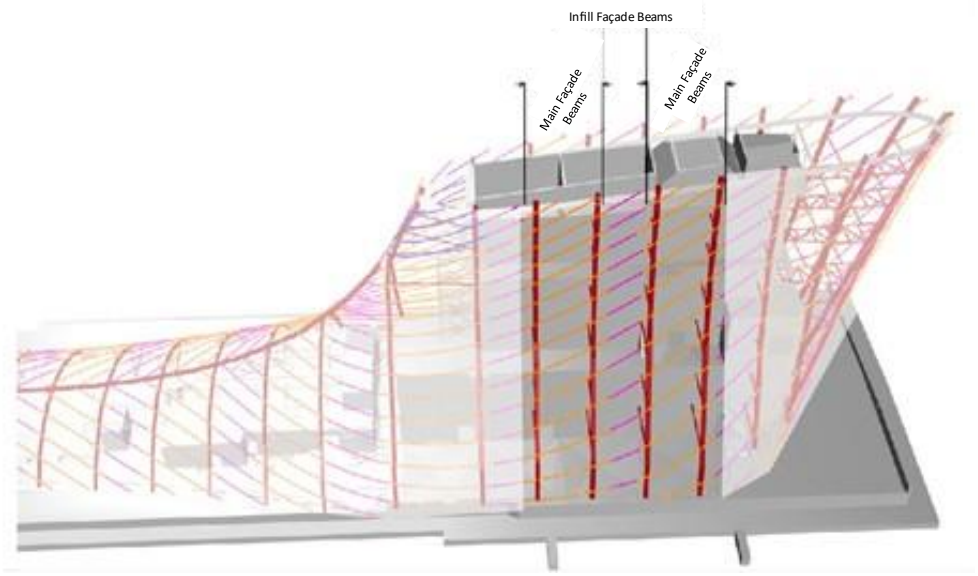

Figure 14. Alternated Main (Orange) and Infill (Purple) Bays.

The secondary steelwork of the structure follows the longitudinal iso-curves of the "sock surface" described in Section 0 of this paper (in the case of the Northern portal, the adjusted curves were used instead). These members have a varying curvature across their length, so simple segmentation would result in nearly all secondary structural members needing to be bent to different radii. This represents not only an enormous cost in terms of fabrication but also a complication on-site as each member would be unique, resulting in the need for more micromanagement of materials during construction. A k-means clustering algorithm was applied to the different bend radii across each the Northern and Southern portals to minimise the number of these unique bend radii. The centroid of each cluster was set as the radius of the grouped members.

After simplifying the secondary members across the structure, the original mesh had no consistent connection length to the new secondary members. Again, having unique connection lengths across the structure would result in high fabrication costs and increased complexity in the construction phase. As such, another clustering process was undertaken to minimise the number of unique connection lengths across the structure, rebuilding the panel mesh out from the secondary members at these clustered offsets.

Utilising stock lengths has a secondary benefit for fabrication, as stock CHS members come prepped with bevelled ends for butt welding.

The combined effects of clustering both the secondary steel bend radii and connection lengths caused variations in the final mesh position that represented the vent structure panel location. As such, the impacts of both clustering algorithms had to be evaluated for deviation from architectural intent and egress outside of allowable construction envelopes.

4.1.2 Structural optimisation

Structural optimisation of the varying geometric concepts outlined above was undertaken using a combination of Strand7 for finite element analysis and in-house steel design Grasshopper modules. Strand7 interoperability was achieved by TTW's in-house Grasshopper plugin called Kookaburra. The optimisation process aimed to satisfy structural requirements while minimising total steel volume.

The iterative Grasshopper/Strand7 script (shown in Figure and simplified in 16) either increased or decreased member sizes based on their compliance within predefined criteria. A member with a strength utilisation ratio greater than 0.9 would increase in section size whilst those under 0.7 would decrease in size (limited to a preselected range of sizes of a given section type). The range in utilisation between 0.7 and 0.9 was considered a 'lazy zone', and members within that range would not change in size. Although a simple approach, this method of redistributing steel volume around the structure is inspired by the mechanoadaptation process of bones. More specifically, it was inspired by the mechanostat hypothesis where bone formation accumulates in areas of high stress and bone resorption in areas of low stress [2].

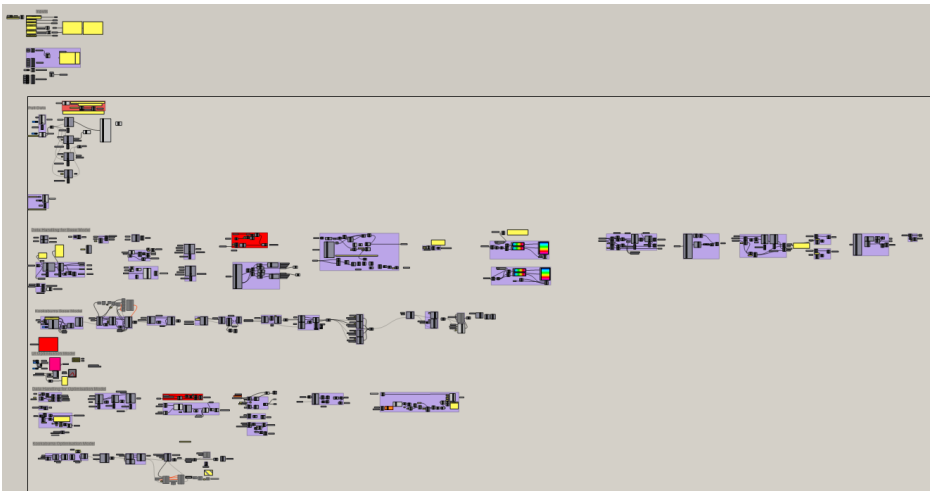

Figure 15. Grasshopper Optimisation Script.

Members in the structure were grouped such that each group was optimised to have a single section work for all its members. This was to ensure that the number of unique section profiles used on the project did not become too high.

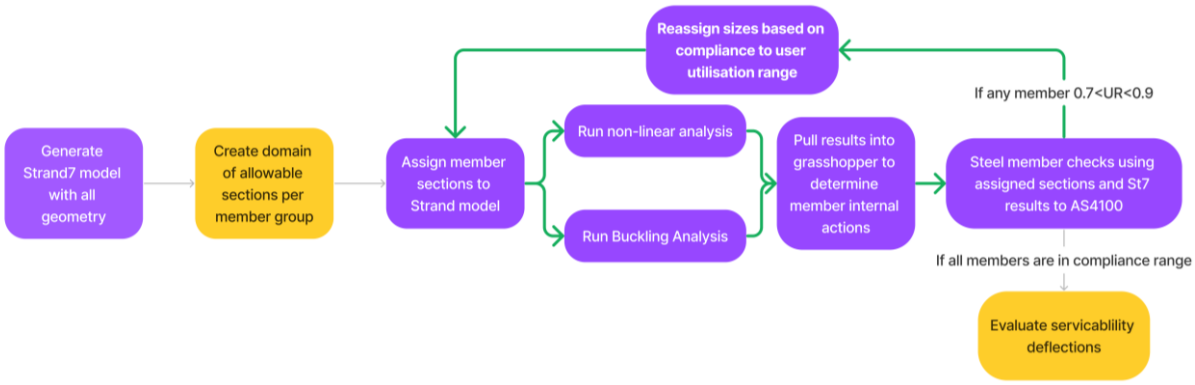

Figure 16. Flowchart of the optimisation process. Automatic Tasks (Purple), Manual Tasks (Yellow), Optimisation Loop (Green Arrows).

4.2 Results

4.2.1 Segment length rationalization

For the Northern portal 64% of secondary steel members were of standard stock length whilst for the Southern Outbound portal the number rose to 67%. The distribution of these members in the Northern structure is shown in Figure .

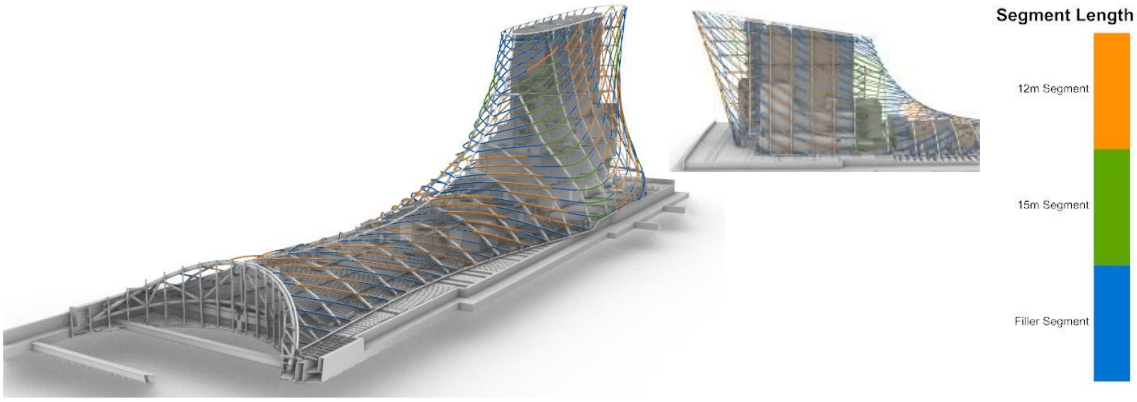

Figure 17. North Vent Secondary Segment Length Distribution (15m segments chosen for a common member length across the largest arch gap, not as a common stock length)

4.2.2 Segment radii rationalization and connection length

Both structures targeted 10 unique bend radii along with utilising straight members to best fit the original architectural intent of the vent surface. The distribution of these bend radii sets for the Northern structure are displayed in Figure *13*.

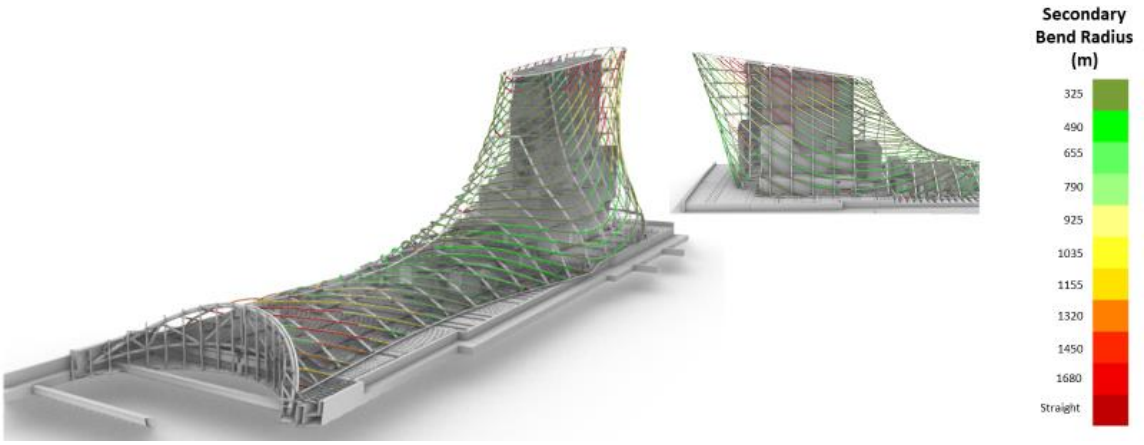

Figure 13. North Vent Secondary Bend Radius Distribution.

In combination with these clustered bend radii, it was determined that a grouping of 5 unique connection lengths on the Northern and 10 on the Southern structure between the façade panels and secondary steel work, allowed for the preservation of architectural intent in the façade.

4.2.3 Structural optimisation

For the purpose of project confidentiality, the exact tonnage of the structure is not provided in this paper. However, it is worth noting that the optimisation process undertaken by TTW reduced the structural steel tonnage of the structures (exclusive of connection details) on average between the two structures to 60% of the original design prior to our engagement on the project.

5. Conclusion

Overall, the West Gate Tunnel Project vent structures showcase the benefits of integrating digital modelling and optimisation techniques into the design and construction process of complex architectural structures. By utilising computational processes, the project was able to achieve significant efficiencies in design and construction that would have been difficult to achieve using traditional engineering methods. As the use of computational processes in engineering continues to grow, it is likely that more complex and innovative structures will be able to be designed and built in a more streamlined and cost-effective manner.

Acknowledgements

The authors express our heartfelt thanks and appreciation to the entire West Gate Tunnel team for their exceptional collaboration and support throughout the project. We extend special thanks to Dean Anderson, Hii King, and John Haralabakos from CPBJHJV, as well as Armin Voelske, Moshe Chong, and Roger Wood from Wood Marsh, for their invaluable contributions to the project. Their expertise, dedication, and hard work played a vital role in bringing the project to fruition, and we greatly appreciate their guidance throughout the process.

Abstract

A new 50 m class single dish telescope, the Large Submillimeter Telescope (LST), is planned. From the view of construction, it is essential to reduce the weight of the antenna mounts because LST will be constructed at high altitudes. Furthermore, despite the large-scale structure, the deformation needs to be kept to a minimal value (e.g., 1/100 mm order) required for light collection performance. Additionally, it is necessary to consider the effects of temperature changes and wind loads in addition to deformation due to their weight because such large telescopes are installed outside, and long periods are needed for the observation. A novel structural design approach is required to realize a backup structure because it is tough to achieve with the conventional design approach. This study proposed a new multi-objective optimization for such large telescope structures by extending to previous papers. In addition to the total mass, the surface accuracy of the primary reflector, which is expressed by root-mean-square (RMS) of deformation subjected to vertical and thermal load for the normal direction of the reflector, is assigned as the objective function. The shape of the primary reflector is evaluated by considering homologous structures. Its focus point can vary through optimization to obtain the optimal shape. The effectiveness of the proposed method is discussed through numerical examples.

Keywords: large submillimeter telescope, multi-objective optimization, space structure

1. Introduction

In an effort to increase the diameter of submillimeter telescopes to meet the scientific need for deep space exploration, the construction of a 50-m diameter Large Submillimeter Telescope (LST) is planned as shown in Figure 1 (a) [1]. Because the Large Submillimeter Telescope requires high sensitivity and high-resolution optical performance, the support structure of the mirror surface must be lightweight and highly rigid. In addition, homologous deformation performance [2, 3], in which the mirror surface maintains a rotating paraboloidal plane after deformation under various loading conditions, is required for optical performance. The present paper describes a numerical method to design the LST structure using topology optimization considering its design requirements.

The large aperture of submillimeter-wave telescopes is a necessary performance required to achieve a large light-gathering area and high resolution. The telescope's primary mirror is required to have a high mirror surface accuracy (e.g., less than 45 μm), and as the mirror surface becomes larger, the primary mirror must maintain that accuracy in a variety of observation postures. Figure 1 shows a conceptual diagram of the LST. The surface accuracy of the primary mirror is important to collect electromagnetic

waves from deep space with high accuracy. Therefore, the backup structure supporting the primary mirror must have high rigidity. For example, the allowable deformation of an ordinary large building is about 1/300 of its span, but if this is applied to a 50-m class large telescope, the maximum deflection would be 50 m/300 = 167 mm, and the mirror surface accuracy requirement cannot be satisfied using ordinary building structure design methods. However, the mass of the structure generally increases as the rigidity of the primary mirror increases. Requirement-1). Therefore, an optimal design that satisfies both rigidity and mass performance is necessary. Although there are some examples of optimal design for improving the accuracy of the mirror surface in engineering telescopes with relatively small apertures as shown in Figure 1 (b) [4], there are few studies on large radio telescopes with apertures in the 50-m class.

This study proposed a new multi-objective optimization for such large telescope structures by extending to previous papers. We aim to obtain the configuration of the large-scale buck-up structure such as the LST plan by using the proposed method.

2. Problem formulation

2.1. Structural optimization considering homologous deformation.

Figure 2 illustrates a cross-section image of a paraboloid antenna. The surface of the primary reflector is deformed by mechanical or thermal loadings. The design domain of LST backup structure Ω is the supporting structure that consists of truss elements with the cross-sectional area as design variables $\boldsymbol{x} = (x_1, x_2, \dots, x_n)$. Cross-sectional area $\boldsymbol{x}$ is considered about the selection from the material list $\boldsymbol{a}$ which consists of m kinds of materials for each truss element. The solution set $\mathcal{D}$ is expressed by $\mathcal{D} = \{\boldsymbol{x} \in \boldsymbol{a} \mid \boldsymbol{a} = (a_1, a_2, \dots, a_m) \in \mathbb{R}^{n \times m}\}$. The displacement vector $\boldsymbol{u}$ of the supporting structure are obtained by solving the equilibrium equation as follows:

$$\boldsymbol{K}(\boldsymbol{x})\boldsymbol{u} = \boldsymbol{f} \tag{1}$$

where, the global stiffness matrix is $\boldsymbol{K}(\boldsymbol{x}) = \sum_{i=1}^{n} \boldsymbol{K}_i(x_i)$, with the element stiffness matrix $\boldsymbol{K}_i(x_i)$. Furthermore, the homologous deformation $h = h(\boldsymbol{u})$ is defined as follows:

$$h(\boldsymbol{u}) = \int_{\Gamma_D} (\boldsymbol{u}(\boldsymbol{x}) - \overline{\boldsymbol{u}}) \cdot (\boldsymbol{u}(\boldsymbol{x}) - \overline{\boldsymbol{u}})\, d\Gamma_D \tag{2}$$

where, $\overline{\boldsymbol{u}} \in \mathbb{R}$ is the pre-described deformation vector which can be defined as follows:

$$\overline{\boldsymbol{u}} = S(\boldsymbol{c}, \boldsymbol{p}) - S_0 \tag{3}$$

where $S(\boldsymbol{c}, \boldsymbol{p})$ is the paraboloid function with given vertex coordinate $c = \{x_c, y_c, z_c\}^T$ and focus $\boldsymbol{p}$. S_0 is the surface of the undeformed primary reflector. Paraboloid parameters $\boldsymbol{c}$ and $\boldsymbol{p}$ are given as follows:

$$\boldsymbol{c}, \boldsymbol{p} = \min_{\boldsymbol{c} \in \mathbb{R}^3, p \in \mathbb{R}} \int_{\Gamma_D} (\boldsymbol{u}(\boldsymbol{x}) + S_0 - S(\boldsymbol{c}, \boldsymbol{p})) \cdot (\boldsymbol{u}(\boldsymbol{x}) + S_0 - S(\boldsymbol{c}, \boldsymbol{p}))\, d\Gamma_D \tag{4}$$

Using the homologous deformation $h_\varphi(\boldsymbol{u}, t, \boldsymbol{b})$ with loading condition t on the boundary Γ_t and body force $\boldsymbol{b} = \boldsymbol{b}(\boldsymbol{x})$ in the design domain Ω, we defined an objective function as follows:

$$J_\varphi = \int_t \boldsymbol{w}_\varphi(t) \cdot h_\varphi(\boldsymbol{u}, t, \boldsymbol{b}) dt \tag{5}$$

where, $\varphi \in [\varphi_{min}, \varphi_{max}]$ is the elevation angle of the reflector and $w_\varphi(t)$ is weight function to the loading condition t at the elevation angle. For constraint functions, the stress $i \in \{1, \dots, m\}$ of truss element are constrained as follows:

$$J_{t,i}(\boldsymbol{x}) = \prod_{j}^{i} \sigma_{t,j} - c_i \leq 0 \tag{6}$$

where, c_i is constraint value of the elemental stress of element i and $\sigma_{t,i}$ is elemental stress of the i-th truss element under loading condition t. The optimization problem to minimize the objective function Eq. (4) while satisfying subjective functions Eq. (5) can be described as follows:

$$\min_{\boldsymbol{x} \in X} \{J_\varphi(\boldsymbol{u}) \mid J_{t,i}(\boldsymbol{x}) \leq 0, i \in \{1, \dots, m\}, \boldsymbol{K}(\boldsymbol{x})\boldsymbol{u} = \boldsymbol{f}_t\} \tag{7}$$

3.1. Configurations of the test model

We conduct the optimization for the test model to validate the effectiveness of the proposed method. Figure 3 represents the initial model with the isometric view. Figure 3 (b) and (c) show the cross-section diagram of the ground structure at *y*=0. The diameter of the reflector dish is 50 m, and the two-layered truss structure supports the reflector. The truss structure is constrained by the rigid ring, called Hub, with 12 m diameter. In this figure, the white marker indicates nodes of the truss structure, and the black marker indicates fixed nodes to Hub.

Figure 4 shows the top view of the ground structure. The colour of each element indicates the group of elements. Note that there are 232 element groups in this model. Each element has the same cross-section property in the same element groups. Table 1 shows loading cases for the structural optimization problem. There are three cases, two kinds of mechanical loading and thermal loading.

Table 1 shows optimization parameters for the diameters of each truss member. DEAP, which is the python library for the genetic algorithm is adopted for the optimizer [5]. NSGA-II is adopted for the selection algorithm for multi-objective optimization [6]. OpenSees is used to obtain the displacement for computing the homologous deformation performance of each solution [7]. Table 2 shows loading conditions for multi-objective optimization. Table 3 shows the diameters of pipes for each truss member group. The tube cross-section is selected from fifteen standard sizes based of the JIS G3444, which is carbon steel pipes for general structural purposes STK400.

3.2. Numerical results and discussion

Figure 5 shows the convergence history of objective functions. In this case, the objective function of the thermal loading condition shows earlier convergence than in other loading cases. Figure 6 shows the distribution of the non-inferior solutions according to the value of the objective functions. The objective function in the dead loading with elevation angle $\varphi = 90$ has a wider range distribution than in other loading conditions.

Figure 7 shows the configuration of truss elements in obtained solutions. Each element color indicates axial stress (red: tension, blue: compression). In the case of the elevation angle $\varphi = 30$, truss elements in the lower part (marked as "A" in Figure 7(b)) are thicker than the upper part (marked as "B"). It indicates that this result is effective for improving the homologous deformation performance in the angled loading condition.

4. Conclusion: submission of contributions

This paper describes a multi-objective optimization method of the backup structure of the Large Scale Telescope (LST). In this paper, the new objective functions are proposed for each elevation angle of the dish with not only mechanical but also thermal loading conditions. Obtained solutions have reasonable element configurations for several loading conditions.

Abstract

A shape optimization method of curved surfaces is presented for the limited class of surface, namely, piecewise developable surfaces. The surfaces are generated using the nonparametric method proposed by the authors based on the formulations of discrete differential geometry, and the locations of selected points on the surface are optimized for minimizing the compliance that is a measure of flexibility of the structure. The developability of the polyhedral surface with triangular mesh is defined using the discretized Gauss map at each vertex; i.e., the area of local Gauss map vanishes for a developable surface. The heights of the specified points are optimized using simulated annealing which is classified as a heuristic algorithm based on local search. Responses to static loads are evaluated using finite element analysis with quadrilateral elements. It is shown in the numerical examples, that various optimal shapes in view of structural performance and constructional cost can be generated using the proposed method by limiting the surface class to the piecewise developable surface.

Keywords: developable surface, discrete differential geometry, Gauss map, shape optimization

1. Introduction

One of the drawbacks for designing a free-form shell surface is that it requires large cost for construction. For example, it is difficult to manufacture formworks for a doubly curved concrete shell. The construction cost can be significantly reduced if the surface is designed as an assembly of developable surface patches [1], because the surface or the formwork can be generated by simply bending a plate. Furthermore, for latticed shells, straight beams can be used in the direction of the ruling of a developable surface that is classified as a ruled surface [2]. Another aspect of designing free-form surfaces is that structural performances are evaluated using finite element analysis after discretization into a polyhedral surface. Therefore, it is desirable to use discretized model and formulations throughout the process of design, analysis, and optimization.

In this paper, we utilize the formulations of discrete differental geometry for structural optimization of piecewise smooth shell surfaces consisting of a limited class of desirable property; namely, piecewise developable surfaces. The developable surface patches are generate using the nonparametric meshless approach proposed by the authors [3]. The stiffness of shell surface is maximized by minimizing the total strain energy under the specified loads using a heuristic search method called simulated annealing (SA).

2. Meshless approach to design of piecewise developable surface

In this section, we briefly summarize the shape generation method proposed in Ref. [3] for completeness of paper.

Consider a surface with grid points as shown in Fig. 1, where the dashed grid lines are drawn for convenience of visualizing the surface. The auxiliary edges are generated for defining the discretized form of Gauss map that is a unit sphere consisting of unit normal vectors. For example, point A in Fig. 2 is connected to eight neighborhood points by the red dotted auxiliary edges. By generating the auxiliary edges at other grid points, the surface as shown in Fig. 3 is generated from the grid points in Fig. 1.

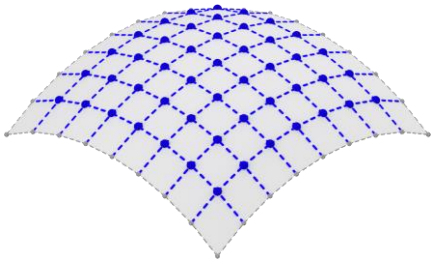

Figure 1. Surface with grid points

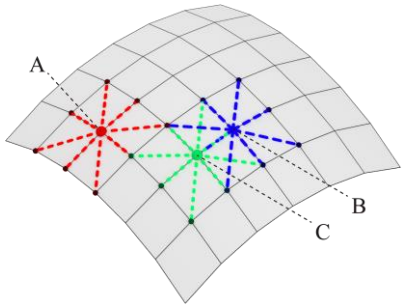

Figure 2. Grid points A, B, C and auxiliary edges connecting to their neighborhood points

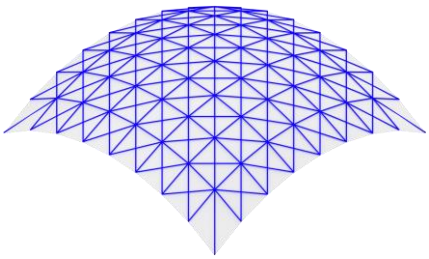

Figure 3. Grid points and auxiliary edges on a curved surface

The condition for developability of surface is formulated by the vanishing area of the Gauss map [3]. Here, the normal vector at a grid point is defined as the average of the unit normal vectors of the adjacent faces defined by the auxiliary edges. The area of local Gauss map is computed without any mesh discretization. Let $\mathbf{q}_1,\ldots,\mathbf{q}_{m_i}$ denote the location vectors of m_i points, which are simply denoted by points $1,\ldots,m_i$, in the neighborhood of point *i*, for which the location vector is denoted by $\mathbf{p}_i$, as shown in Fig. 2. Auxiliary edges are drawn between $\mathbf{p}_i$ and $\mathbf{q}_1,\ldots,\mathbf{q}_{m_i}$ which are denoted by edges $1,\ldots,m_i$.

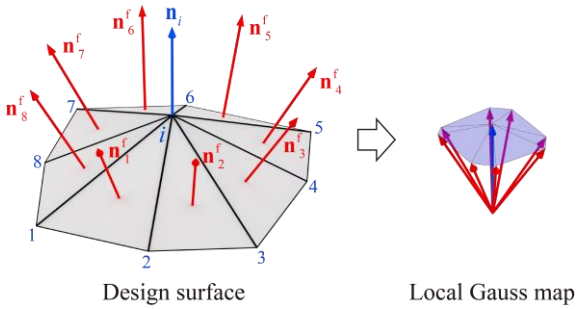

Figure 4. Local Gauss map at a point on a surface

The unit normal vector of the region between edges *j* and $j+1$, denoted by $\mathbf{n}_j^{\mathrm{f}}$, is computed as

$$\mathbf{n}_j^{\mathrm{f}} = \frac{\hat{\mathbf{n}}_j^{\mathrm{f}}}{\left\|\hat{\mathbf{n}}_j^{\mathrm{f}}\right\|},\ \hat{\mathbf{n}}_j^{\mathrm{f}} = (\mathbf{q}_j - \mathbf{p}_i)\times(\mathbf{q}_{j+1} - \mathbf{p}_i),\ \ (j = 1,\ldots,m_i) \tag{1}$$

Then the unit normal vector $\mathbf{n}_i$ at point i is computed as the average of the unit normal vectors of the surrounding regions as

$$\mathbf{n}_i = \frac{\hat{\mathbf{n}}_i}{\|\hat{\mathbf{n}}_i\|}, \quad \hat{\mathbf{n}}_i = \frac{1}{m_i}\sum_{j=1}^{m_i} \mathbf{n}_j^{\mathrm{f}} \tag{2}$$

The unit normal vector at a grid point, indicated with blue in the left figure of Fig. 4, is computed from those of the regions indicated with red defined by the locations of the neighborhood points. The normal vectors are translated to have the same origin to generate the local Gauss map as shown in the right figure of Fig. 4. The *area of local Gauss map* is to be reduced to zero to obtain a developable surface. It is easily seen that the local Gauss map degenerates to a point if the surface is locally planar, and the area vanishes for a cylindrical surface. It should be noted here that the area of local Gauss map vanishes also for a conical surface, if the points are appropriately located along a ruling of the surface.

The area A_i of local Gauss map in the neighborhood of point i is computed as

$$A_i = \sum_{j=1}^{m_i} a_{ij}, \quad a_{ij} = \frac{1}{2}\|\mathbf{v}_{ij}\|, \quad \mathbf{v}_{ij} = (\mathbf{n}_j^{\mathrm{f}} - \mathbf{n}_i) \times (\mathbf{n}_{j+1}^{\mathrm{f}} - \mathbf{n}_i) \tag{3}$$

Let I denote the set of indices of the interior grid points at which the area of local Gauss map is to be computed. The vector of variables $\mathbf{x}$ consists of the coordinates of grid points that are to be varied. To prevent divergence of gradients of a_{ij} in the vicinity of optimal solutions obtained using a gradient based method, the square area of the local Gauss map is to be minimized, and the optimization problem is formulated as

$$\begin{aligned} &\text{Minimize} \quad F(\mathbf{x}) = \sum_{i \in I} \sum_{j=1}^{m_i} (a_{ij})^2 \\ &\text{subject to} \quad \mathbf{x} \in \chi \end{aligned} \tag{4}$$

where χ is the feasible region of $\mathbf{x}$ defined by its upper and lower bounds. Note that some selected points are excluded from the set I to obtain piecewise approximately developable surfaces with specified locations of points on the internal boundary of patches.

3. Shape optimization of piecewise developable surface

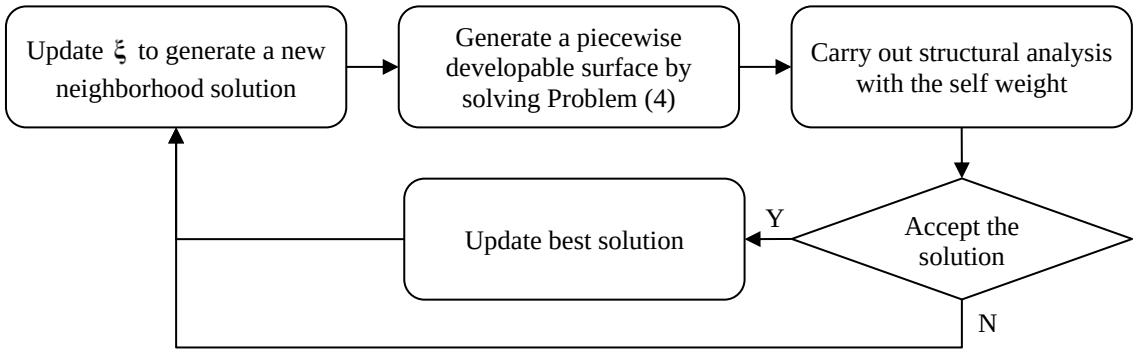
Stiffness of the piecewise developable surface generated using the method in Sec. 2 is maximized by minimizing the total strain energy against static loads. The quadrilateral mesh is generated from the grid points, and static responses are evaluated by the finite element analysis. The design variable vector $\boldsymbol{\xi}$ consists of the coordinates of some grid points that are to be specified in the form-finding problem in Sec. 2. Hence, the vector $\mathbf{x}$ in Eq. (4) is considered as function of $\boldsymbol{\xi}$ and denoted by $\mathbf{x}(\boldsymbol{\xi})$.

The shell is pin-supported at the boundary, and the static loads are calculated from the self-weight proportional to the covering area of each grid point. Let M denote the number of grid points. The load and displacement vectors at point i $(i = 1, \ldots, M)$ are denoted by $\mathbf{p}_i \in \mathbb{R}^3$ and $\mathbf{d}_i \in \mathbb{R}^3$, respectively. The optimization problem is formulated as

$$\begin{aligned} &\text{Minimize} \quad S(\boldsymbol{\xi}) = \frac{1}{2}\sum_{i=1}^{M} \mathbf{p}_i^{\mathrm{T}}(\xi)\mathbf{d}_i(\xi) \\ &\text{subject to} \quad \mathbf{x}(\boldsymbol{\xi}) = \underset{\mathbf{x} \in \chi}{\operatorname{argmin}} F(\mathbf{x}), \quad z \in \zeta \end{aligned} \tag{5}$$

where ζ is the feasible region of $\mathbf{z}$ defined by its upper and lower bounds. Figure 5 shows the process

of solving Problem (5) using SA. At each step of SA, Problem (4) is solved for $\boldsymbol{\xi}$ using a gradient based algorithm, and the structural response is evaluated to update the solution.



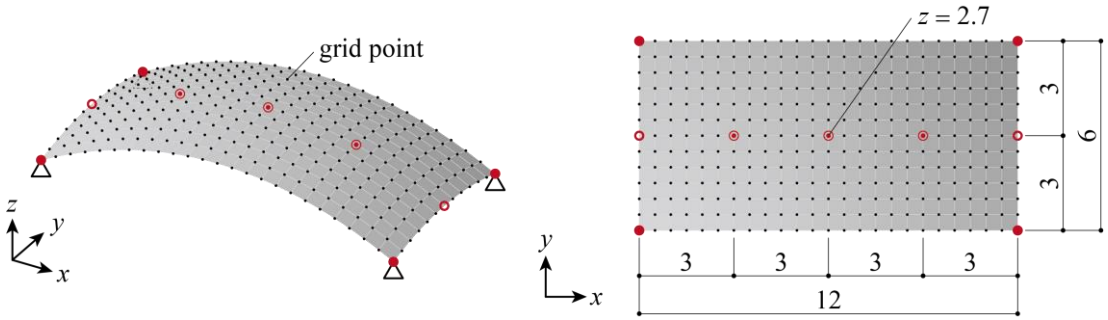


Figure 5. Procedure at an iterative step of SA

fixed in the generation of a piecewise developable surface

4. Examples

Optimal shapes are found from the initial shape in Fig. 6. The red internal grid points are excluded from calculation of the area of Gauss map in $F(\mathbf{x})$ of Problem (4) to generate internal boundaries of developable surface patches. The variables in Problem (4) are the *z*-coordinates of the points without marks in Fig. 6. Problem (4) is solved using SNOPT ver. 7 [5] implemented in pyOpt [6]. The lower and upper bounds of the *z*-coordinates at each grid point are $z_0 - 5$ and $z_0 + 12$, respectively, where z_0 is the value at the initial shape in Fig. 6. Note that symmetry of the model is not considered here.

The boundary condition for structural analysis is given as shown in Fig. 7. Young's modulus and Poisson's ratio of the material are 2.0×10^7 kN/m^2 and 0.2, respectively, and the load is given as 1.0×10^3 kN/m^2. The size of shell on the plane is 12×6 m, and the thickness is 0.1 m. Dual-annealing [7] implemented in SciPy is used for solving the structural optimization problem (5). The maximum number of temperature reduction steps is 200, and neighborhood search is carried out 10 times at each temperature; i.e., the total number of analysis is 2000. Local search is not used, and the default values are used for other parameters. The lower and upper bounds of the variable *z*-coordinates are $z_0 - 1$ and $z_0 + 1$, respectively, for the structural optimization.

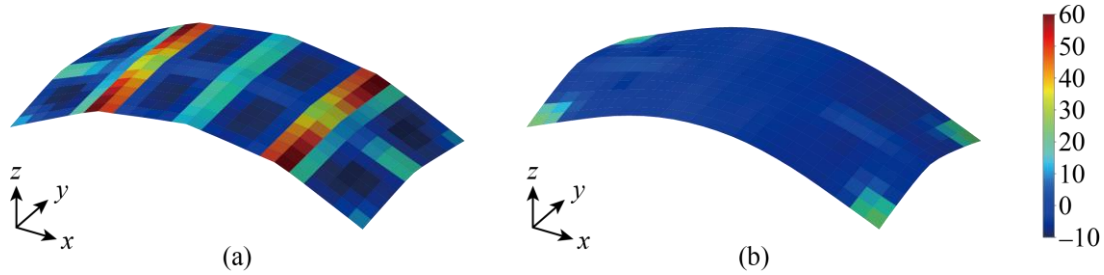

Figure 9. Maximum bending stress (kN); (a) initial surface, (b) optimal surface

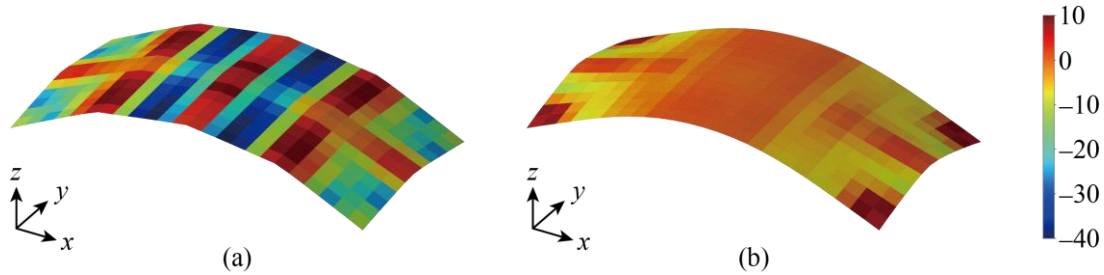

Figure 10. Minimum bending stress (kN); (a) initial surface, (b) optimal surface

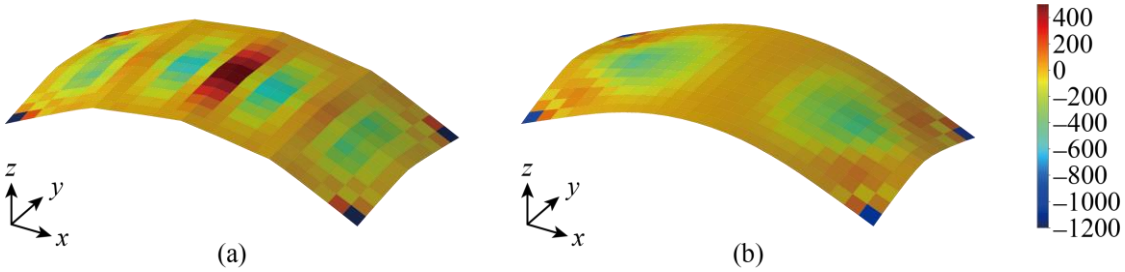

Figure 11. Maximum in-plane stress (kN/m); (a) initial surface, (b) optimal surface

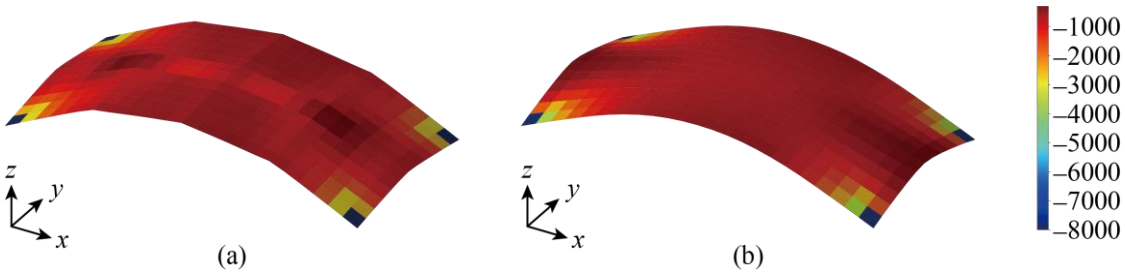

Figure 12. Minimum in-plane stress (kN/m); (a) initial surface, (b) optimal surface

Figures 7 shows the initial and optimal shapes of Problem (5). It can be seen that the initial surface consists of eight planar patches, while the optimal surface has a smooth cylindrical patch around the center and two ridges near the boundary. The height of the shell is slightly reduced at the center and increased at the exterior boundary. The total strain energy decreases from 66.91 to 47.09 (kNm) as a result of optimization. The nodal displacement in z-direction is shown in Fig. 8, and we can see that the magnitude of the displacement is reduced in the optimal shape. It can also be seen that, in the optimal shape, the distribution of displacement is smoother than in the initial shape. Figures 9–12 show the contour of the maximum bending moment, minimum bending stress, maximum in-plane stress, and minimum in-plane stress, respectively, evaluated as force per unit length of section. The overall trend is that the magnitude of stress is smaller in the optimal shape. Since the initial shape has the significant ridges, stress concentration occurs and the magnitude of the stress tends to be large around the ridges. On the other hand, the optimal shape has the smoother distribution of stress, while the stress slightly concentrates at the ridges near the boundary.

5. Conclusions

A shape optimization method has been proposed for shells consisting of piecewise developable surface, which is generated by using a meshless approach for minimizing the sum of squares of areas of local Gauss map. The locations of some selected points are regarsed as fixed in the process of generating the piecewise developable surface, and they are considered as design variables of the structural optimization problem for minimizing the toral strain energy, which is solved using the SA. It has been shown in the numerical examples that various mechanically efficient surface can be generated by limiting the surface class to the piecewise developable surface that is efficient also in view of construction cost.

Abstract

This paper proposes a method for sizing optimization of free-form lattice shells using a Deep Deterministic Policy Gradient (DDPG) agent with Graph Convolutional Networks (GCNs). The problem aims to minimize the volume of the structure by choosing sizes of structural members where the objective function is the total structural volume subjected to the stress constraints of the members. DDPG is a type of reinforcement learning (RL) that trains an agent to accomplish tasks using reward signal. This method represents a latticed shell structure as a graph and utilizes neural networks and GCNs as an agent. In each optimization step, the nodes and elements in lattice shells are represented as a graph by node and adjacency matrices which contain structural information on the current structure. The agent observes the structure through these matrices and chooses the elements to reduce the size. The agent receives a reward computed from the reduction of the structural volume and the maximum stress to be constrained. Results show that the GCN-DDPG agent can learn to minimize the structural volume. It can be applied to large free-form lattice shells using a small computational cost and has competitive performance compared to the genetic algorithm and simulated annealing.

Keywords: sizing optimization, lattice shell, machine learning, reinforcement learning, deep deterministic policy gradient, graph convolutional networks

1. Introduction

Structural optimization is a procedure that aims to obtain the best structures determined by design variables where the structural performance is evaluated by the objective function and constraints. Sizing optimization is a class of structural optimization that aims to find suitable sizes of structural components. For discrete structures such as trusses and frames, the sizing optimization can provide solutions with the smallest amount of structural material. In this type of structure, the sizes of the structural elements and the total structural volume are usually selected as the design variables and the objective function, respectively. Since the optimized structures must withstand the loads, the constraints should be assigned for the responses such as stress and displacement.

The choice of design variables also affects how the optimization methods are to be used since the availability of the gradients of the objective and constraint functions depends on the type of the design variables. In continuum structures such as concrete beams and shells, the mathematical programming methods can be utilized if the structures can have continuous geometrical dimensions and the gradient of the objective and constraint functions with respect to the design variables (i.e., size or sections) can be computed. However, in discrete structures, the sizes of structural elements are often chosen from available structural sections from the manufacturers, making it difficult to obtain the gradient of the functions. The sizing optimization problem of trusses and frames can be defined as a combinatorial optimization problem and solved using heuristic methods such as genetic algorithm (GA) and simulated

annealing (SA) without the gradient of the objective function. In general, heuristic methods randomly generate solutions and improve them based on some rules. Hence multiple trials of optimization are required to find the best solution.

Machine learning (ML) is a method to train or instruct computational models to do given tasks. In recent years, ML approaches have been shown to be effective for many engineering problems. ML can be classified into three classes, including supervised learning, where the data-label pairs are initially provided for the training; unsupervised learning, where the data without a label is provided; and reinforcement learning (RL), where the data-label pairs are not initially provided but gradually collected during the training. Note that suitable ML models depend on the data type to be processed; for example, the neural networks [1] are applicable to the tabular data, and the convolutional neural networks [2] are suitable for processing image data. In recent years, the RL approach has been applied to structural optimization together with representing the structure as graph data. Hayashi and Ohsaki [3] proposed a graph embedding and RL agent method to optimize the structural volume of the planar truss. Zhu et al. [4] proposed an RL agent that generated the initial ground structures for topology optimization of trusses. Kupwiwat et al. [5–7] proposed RL agents for topology optimization of grid shells, topology optimization of building frames, and geometry optimization of latticed shells. It should be noted that RL methods in these researches are more computationally efficient than benchmark heuristic methods.

This paper proposes a method of sizing optimization of lattice shell for minimizing the structural volume under stress constraint using a type of RL named deep deterministic policy gradient (DDPG) [8] and graph convolutional networks (GCNs) [9]. DDPG is effective when multiple design variables are to be modified simultaneously because it reduces the number of optimization steps and computational cost. Furthermore, the GCN allows the DDPG agent to observe the whole structure and modify the sizes of all structural elements. The proposed method sequentially reduces the indices of structural element sizes of the elements until it violates the stress constraint or reaches the maximum computational step. The rest of the paper is organized as follows: Section 2 outlines the optimization problem. Section 3 introduces the concept of RL, DDPG, and GCNs. Section 4 explains the proposed optimization method. Section 5 shows numerical examples of the proposed method against the GA and SA. The summary of this paper is indicated in Section 6.

2. Objective function of the sizing optimization of lattice shells

The objective function is to minimize the structural volume of the lattice shell subjected to external loads under stress constraints. Let $c_i \in \{0,1,\dots,n_c\}$, $\mathbf{c}$, and l_i denote predetermined indices of cross-sectional properties, a vector that represents all indices of cross-sectional properties in the structure, and lengths of structural element i, respectively. The structural volume V of a lattice shell, which has n lattice elements, is derived from the sectional areas $H(c_i)$ and the lengths l_i as follows:

$$V(\mathbf{c}) = \sum_{i=1}^{n} H(c_i) l_i \tag{1}$$

In this paper, the lattice elements are three-dimensional beam elements with 12 degrees of freedom (DoFs). The internal stress can be obtained from the local displacement of each element after solving the stiffness equation (i.e., structural analysis) $\mathbf{p} = \mathbf{K}\mathbf{u}$ where $\mathbf{p}$, $\mathbf{K}$, and $\mathbf{u}$ are the nodal load vector, the global stiffness matrix, and the global displacement vector, respectively. The ratio of internal stress to the yield stress σ_i of an element i is computed similarly to Lagaros et al. [10] as follows:

$$\sigma_i = \begin{cases} \frac{|\sigma_x|}{\bar{\sigma}_x} + \frac{|\sigma_y|}{\bar{\sigma}_y} + \frac{|\sigma_z|}{\bar{\sigma}_z} & : \ \frac{|\sigma_x|}{\bar{\sigma}_x} \leq 0.15 \\ \frac{|\sigma_x|}{0.6\bar{\sigma}_x} + \frac{|\sigma_y|}{\bar{\sigma}_y} + \frac{|\sigma_z|}{\bar{\sigma}_z} & : \ \frac{|\sigma_x|}{\bar{\sigma}_x} > 0.15 \end{cases} \tag{2}$$

where σ_x, σ_y, and σ_z are the axial stress, maximum stress due to the bending moment in the local y axis, and in the local z axis, respectively, and $\bar{\sigma}_x$, $\bar{\sigma}_y$, and $\bar{\sigma}_z$ denote their upper bounds.

The optimization problem of lattice shell to minimize the structural volume is formulated as follows:

$$\begin{aligned} \text{minimize} \quad & V(\mathbf{c}) && \text{(3a)} \\ \text{subject to} \quad & \sigma_{\max} \leq 1 && \text{(3b)} \\ & c_i \in \{0,1,\dots,n_c\} && \text{(3c)} \end{aligned}$$

where $\boldsymbol{\sigma}_{\mathbf{max}}$ denotes the largest ratio of internal stress to the yield stress among the structural elements.

3. DDPG agent with GCN

This research proposes a method to utilize an RL agent to solve the sizing optimization of lattice shells. RL is a type of ML that trains an agent to accomplish a given task through interaction within an environment. Components of RL are a policy function to determine action, a reward signal to evaluate the outcome from the action, and a value function to estimate future rewards [11]. The interaction between an agent and the environment is modeled using Markov decision process (MDP). Figure 1 illustrates the MDP in this research. In a discrete timestep t, the agent observes the state S_t which is the graph representation of the current structural configuration shown in Figure 1(a). The agent uses its policy function to determine the action A_t to reduce the cross-sectional indices of elements illustrated in Figure 1(b). The sizes of structural members are modified and structural responses are computed. The agent obtains a reward R_{t+1} based on the changed structure shown in Figure 1(c) and proceeds to the next timestep.

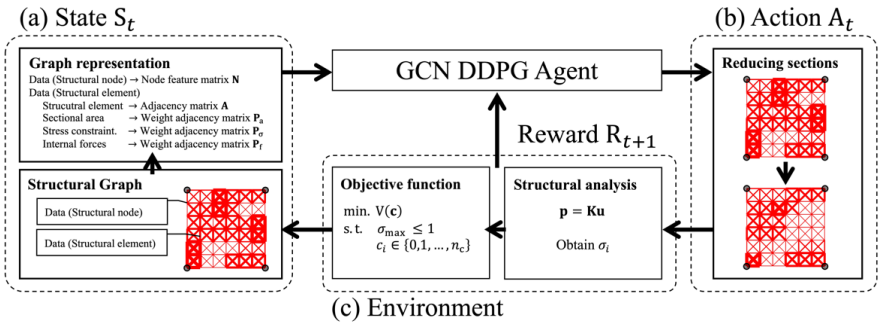

Figure 1. Propose MDP for sizing optimization of lattice shells.

DDPG is a type of RL that can take multiple actions simultaneously in an MDP, which can reduce the number of steps in the optimization and the cost of structural analyses. The DDPG agent has a policy function $\boldsymbol{\pi}_{\theta_1}$ (*actor network*) to determine the probability of taking action i, denoted by $\mathrm{P}(\mathrm{A}_t^i|\mathrm{S}_t)$, in a state S_t and a value function Q_{θ_2} (*critic network*) to predict the reward obtained by executing action i in a state S_t, defined as follows:

$$\boldsymbol{\pi}_{\theta_1}(\mathrm{S}_t) = \mathrm{P}(\mathrm{A}_t^i|\mathrm{S}_t) \quad \text{(4a)}$$

$$\mathrm{Q}_{\theta_2}\left(\mathrm{S}_t, \boldsymbol{\pi}_{\theta_1}(\mathrm{S}_t)\right) = \sum_{v=1}^{\infty} \gamma^{v-1} \mathrm{R}_{t+v} \quad \text{(4b)}$$

where $\gamma \in [0,1)$ is a discount factor that is proportionate to the importance of future rewards. θ_1 and θ_2 are trainable parameters that are adjusted during the training.

Both functions of the DDPG agent are trained using training data gradually collected from the MDP as $\{\mathrm{S}_t, \mathrm{A}_t, \mathrm{R}_{t+1}, \mathrm{S}_{t+1}\}$ and stored in a *replay buffer*. The value function is trained to predict the accumulated rewards to be obtained, and the policy function is trained to maximize the obtained reward using the prediction of the value function. For training surrogate policy and value functions, the *tau update* method [12] is utilized to stabilize the training, in which their weight parameters are updated using a value τ

($\tau \ll 1$) at every tau update interval. The training algorithm of DDPG, where $\mathcal{L}(y, \hat{y})$ signifies a loss function between the correct value y and a predicted value $\hat{y}$, is as follows:

DDPG algorithm

1. Sample n_{batch} training data $\{S_t, A_t, R_{t+1}, S_{t+1}\}$ from the stored replay buffer and aggregate them into a set of vectors $\{\mathbf{S}_t, \mathbf{A}_t, \mathbf{R}_{t+1}, \mathbf{S}_{t+1}\}$.
2. Update the parameters as follows:

$\boldsymbol{\pi}'_{\theta'_1}(\mathbf{S}_t) = \widehat{\mathbf{A}}_t$

$\boldsymbol{\pi}_{\theta_1}(\mathbf{S}_{t+1}) = \widehat{\mathbf{A}}_{t+1}$

$Q'_{\theta'_2}(\mathbf{S}_t, \mathbf{A}_t) = \widehat{\mathbf{Q}}_t$

$Q_{\theta_2}(\mathbf{S}_{t+1}, \widehat{\mathbf{A}}_{t+1}) = \mathbf{Q}_{t+1}$

$\nabla Q'_{\theta'_2} = \nabla_{\theta'_2} Q'_{\theta'_2}(\mathbf{S}_t, \mathbf{A}_t) \nabla_{\widehat{\mathbf{Q}}_t} \mathcal{L}(\mathbf{R}_{t+1} + \mathbf{Q}_{t+1}, \widehat{\mathbf{Q}}_t)$

$\nabla J'_{\theta'_1} = -\mathbb{E}\left[\nabla_{\theta'_1} \boldsymbol{\pi}'_{\theta'_1}(\mathbf{S}_t) \nabla_{\widehat{\mathbf{A}}_t} Q'_{\theta'_2}(\mathbf{S}_t, \widehat{\mathbf{A}}_t)|_{\widehat{\mathbf{A}}_t = \boldsymbol{\pi}'_{\theta'_1}(\mathbf{S}_t)}\right]$

Update $\boldsymbol{\theta}'_2$ in $Q'_{\theta'_2}$ using $\nabla Q'_{\theta'_2}$

Update $\boldsymbol{\theta}'_1$ in $\boldsymbol{\pi}'_{\theta'_1}$ using $\nabla J'_{\theta'_1}$

If *tau update* interval is reached:

$\boldsymbol{\theta}_1 = (1-\tau)\boldsymbol{\theta}_1 + \tau \boldsymbol{\theta}'_1$

$\boldsymbol{\theta}_2 = (1-\tau)\boldsymbol{\theta}_2 + \tau \boldsymbol{\theta}'_2$

In this paper, Adam [13] optimizer is utilized to find the optimal weights of the agent (i.e., training), and Ornstein-Uhlenbeck noise is added to the output of the policy function to activate the exploration of the DDPG agent.

The DDPG agent is built from GCNs which can compute graph signals (i.e., action) from graph representation of the structure (i.e., state). The computation of GCN is explained in this section. A graph that has n nodes with g features per node can be represented using a node feature matrix $\mathbf{N} \in \mathbb{R}^{n \times g}$, an adjacency matrix $\mathbf{A} \in \mathbb{R}^{n \times n}$, a degree matrix $\mathbf{D} \in \mathbb{R}^{n \times n}$, and a weighted adjacency matrix $\mathbf{P} \in \mathbb{R}^{n \times n}$, containing information of features in each node, nodal connections, numbers of connections of the node, and weights of nodal connections, respectively. Node signal $\mathbf{N}' \in \mathbb{R}^{n \times h}$ is computed from the summation of the features of nodes and their adjacent nodes, where h denotes the dimension of embedding space, using a GCN unit (i.e., *layer*) as follows:

$$\mathbf{N}' = \mu(\boldsymbol{\Phi}\mathbf{N}\mathbf{w}) \tag{5}$$

where $\mu(\cdot)$ and $\mathbf{w}$ are a non-linear activation function and parameterized weights in the GCN layer, respectively. $\boldsymbol{\Phi}$ denotes either a weighted adjacency matrix $\mathbf{P}$ or a normalized form of adjacency matrix $\widetilde{\mathbf{A}} = \mathbf{D}^{-1/2}[\mathbf{A} + \mathbf{I}]\mathbf{D}^{-1/2}$ where $\mathbf{I} \in \mathbb{R}^{n \times n}$ is the identity matrix, and $\mathbf{D}^{-1/2}$ is the inverse of the matrix $\mathbf{D}^{1/2}$ satisfying $\mathbf{D}^{1/2}\mathbf{D}^{1/2} = \mathbf{D}$. Note that GCN layers can be stacked to construct a computation model. When stacked, the next layer can take the embedded node signal $\mathbf{N}'$ of the previous layer as one of the inputs.

4. DDPG and GCN for sizing optimization of lattice shells

This section explains the graph representation of the structure for the state data, the computational parts of the DDPG agent, the action interpreted from the output of the agent, the reward, and the proposed optimization algorithm.

4.1. State

The state consists of graph representations of the structure using node feature matrix $\mathbf{N}$, adjacency matrix $\mathbf{A}$, weighted adjacency matrix of sectional area $\mathbf{P}_a$, weighted adjacency matrix of stress ratio $\mathbf{P}_\sigma$, and weighted adjacency matrix of internal forces $\mathbf{P}_f$, whose entries are shown in Tables 1 and 2. Note that all values in Tables 1 and 2 are normalized using the min-max normalization method.

Table 1. Entries in node feature matrix **N**.

$n_{i,1}$	x-coordinate of node i
$n_{i,2}$	y-coordinate of node i
$n_{i,3}$	z-coordinate of node i
$n_{i,4}$	1 if the node has fixed support, else 0
$n_{i,5}$	1 if the node has no support, else 0

Table 2. Entries in adjacency and weighted adjacency matrices **A**, $\mathbf{P}_\mathrm{a}$, $\mathbf{P}_\sigma$, and $\mathbf{P}_\mathrm{f}$.

$a_{i,j}$	1 if there is an element connecting nodes i and j else 0
$p_{a\,i,j}$	Cross-sectional area of an element if there is an element connecting nodes i and j else 0
$p_{\sigma\,i,j}$	Ratio of internal stress to the yield stress of an element if there is an element connecting nodes i and j else 0
$p_{f\,i,j}$	Ratio of the summation of internal bending forces in y and z axes (f_y, f_z) to the axial force (f_x) of an element if there is an element connecting nodes i and j else 0 where $p_{f\,i,j} = (\lvert f_y\rvert + \lvert f_z\rvert)/(1 + \lvert f_x\rvert)$

4.2. Agent

The agent consists of a policy function **π** that computes the action and a value function **Q** that computes the expected reward (Q-value). These functions are made of GCN layers with activation function $\mathrm{ReLU}(\cdot) = \max(0,\cdot)$, GCN layers with activation function $\mathrm{Sigmoid}(\cdot) = 1/(1+\mathrm{e}^{-(\cdot)})$, global sum pooling (GSP) operation, and a two hidden layers neural network $\mathrm{f_{NN}}$ represented as follows:

$$\mathrm{ReLU}(\mathbf{M}_1, \mathbf{M}_2) = \mathrm{ReLU}(\mathbf{M}_1\mathbf{M}_2\mathbf{w}) \tag{6a}$$

$$\mathrm{Sigmoid}(\mathbf{M}_1, \mathbf{M}_2) = \mathrm{Sigmoid}(\mathbf{M}_1\mathbf{M}_2\mathbf{w}) \tag{6b}$$

$$\mathrm{GSP}(\mathbf{M}_3 \in \mathbb{R}^{n\times g}) = \left[\sum_{i=1}^{n} \mathbf{m}_{3\,i,1} \quad \cdots \quad \sum_{i=1}^{n} \mathbf{m}_{3\,i,\mathrm{g}}\right] \in \mathbb{R}^{1\times g} \tag{6c}$$

$$\mathrm{f_{NN}}(\mathbf{M}_4) = \mathbf{w}_3\left(\mathrm{ReLU}\left(\mathbf{w}_2\left(\mathrm{ReLU}\left(\mathbf{w}_1{\mathbf{M}_4}^{\mathrm{T}} + \mathbf{b}_1\right)\right) + \mathbf{b}_2\right)\right) + \mathbf{b}_3 \tag{6d}$$

Where $(\cdot)^{\mathrm{T}}$ denotes the transpose of a matrix, $\mathbf{M}_1$ denotes a node feature matrix or a node embedding matrix. $\mathbf{M}_2$ denotes an adjacency matrix or a weighted adjacency matrix. $\mathbf{M}_3$ denotes a matrix to be changed into a one-dimensional vector. $\mathbf{M}_4$ denotes a one-dimensional vector. $\mathbf{w}_{i\in\{1,2,3\}}$ and $\mathbf{b}_{i\in\{1,2,3\}}$ denote internal weight and bias matrices in each neural network layer, respectively. The values of **w**, $\mathbf{w}_{i\in\{1,2,3\}}$ and $\mathbf{b}_{i\in\{1,2,3\}}$ are adjusted during the training phase.

Table 3 shows the inputs, computations, and outputs of the policy function (left column) and the value function (right column), where ⊙ denotes the element-wise multiplication.

Table 3. Inputs, computations, and outputs of the policy and value functions.

policy function	value function
input: **N**, **A**, $\mathbf{P}_\mathrm{a}$, $\mathbf{P}_\sigma$, $\mathbf{P}_\mathrm{f}$	input: **N**, **A**, $\mathbf{P}_\mathrm{a}$, $\mathbf{P}_\sigma$, $\mathbf{P}_\mathrm{f}$, **π**
computation: step 1: $\mathbf{X}_{1.1} = \mathrm{ReLU}(\mathrm{ReLU}(\mathbf{N}, \mathbf{P}_\mathrm{a}), \mathbf{P}_\mathrm{a})$ $\mathbf{X}_{1.2} = \mathrm{ReLU}(\mathrm{ReLU}(\mathbf{N}, \mathbf{P}_\sigma), \mathbf{P}_\sigma)$ $\mathbf{X}_{1.3} = \mathrm{ReLU}(\mathrm{ReLU}(\mathbf{N}, \mathbf{P}_\mathrm{f}), \mathbf{P}_\mathrm{f})$ step 2: $\mathbf{X}_2 = \mathbf{X}_{1.1} + \mathbf{X}_{1.2} + \mathbf{X}_{1.3}$ step 3: $\boldsymbol{\pi} = \mathrm{Sigmoid}(\mathrm{ReLU}(\mathbf{X}_2, \mathbf{P}_\sigma), \mathbf{A})$	computation: step 1: $\mathbf{X}_{1.1} = \mathrm{ReLU}(\mathrm{ReLU}(\mathbf{N}, \mathbf{P}_\mathrm{a}), \mathbf{P}_\mathrm{a})$ $\mathbf{X}_{1.2} = \mathrm{ReLU}(\mathrm{ReLU}(\mathbf{N}, \mathbf{P}_\sigma), \mathbf{P}_\sigma)$ $\mathbf{X}_{1.3} = \mathrm{ReLU}(\mathrm{ReLU}(\mathbf{N}, \mathbf{P}_\mathrm{f}), \mathbf{P}_\mathrm{f})$ step 2: $\mathbf{A}^* = (\boldsymbol{\pi}\cdot\boldsymbol{\pi}^{\mathrm{T}})\odot\mathbf{A}/100$ $\mathbf{X}_2 = \mathrm{ReLU}(\mathrm{ReLU}(\boldsymbol{\pi}, \mathbf{A}^*), \mathbf{A}^*)$ step 3: $\mathbf{X}_3 = \mathbf{X}_{1.1} + \mathbf{X}_{1.2} + \mathbf{X}_{1.3} + \mathbf{X}_2$ step 4: $\mathbf{X}_4 = \mathrm{ReLU}(\mathbf{X}_3, \mathbf{A})$ step 5: $\mathbf{X}_5 = \mathrm{GSP}(\mathbf{X}_4)$ step 6: $\mathrm{Q} = \mathrm{f_{NN}}(\mathbf{X}_5)$
output: $\boldsymbol{\pi} \in \mathbb{R}^{n\times 100}$	output: $\mathrm{Q} \in \mathbb{R}^{1\times 1}$

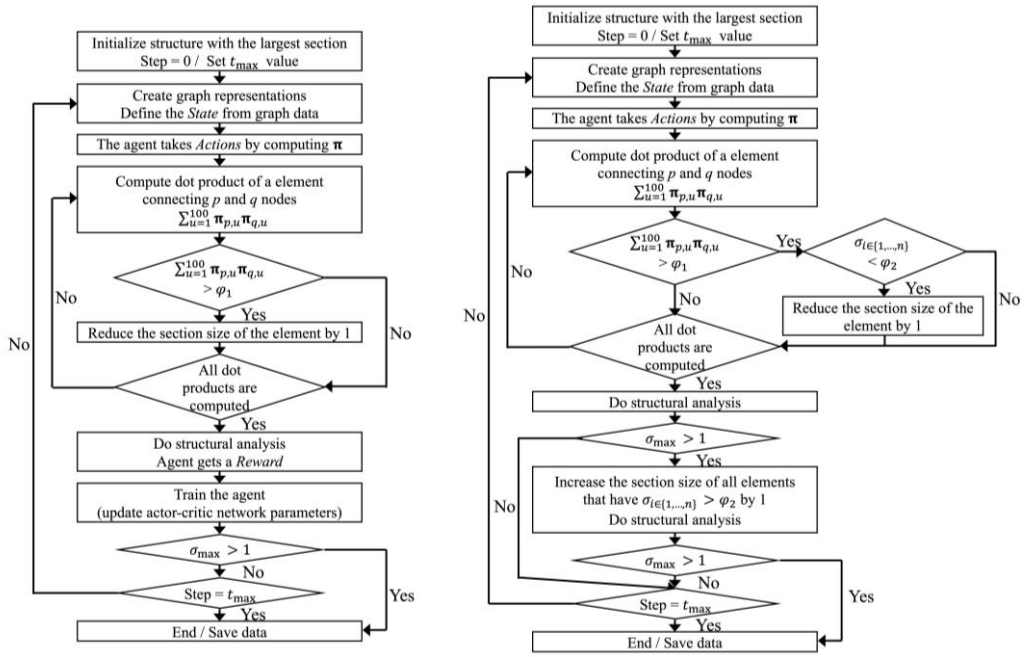
4.3. Action

The agent determines to reduce the section size of multiple elements simultaneously. Each size index c_i of an element i that connects nodes p and q is determined using an action interpreted from the output of the policy function $\boldsymbol{\pi}$ as

$$c_i = \begin{cases} c_i = \min(0, c_i - 1) & : \sum_{u=1}^{100} \boldsymbol{\pi}_{p,u} \boldsymbol{\pi}_{q,u} > \varphi_1 \\ c_i = c_i & : \sum_{u=1}^{100} \boldsymbol{\pi}_{p,u} \boldsymbol{\pi}_{q,u} \leq \varphi_1 \end{cases} \tag{7}$$

where φ_1 = 0.3 in the following examples.

4.4. Reward



The reward signal R_{t+1} that the agent obtains after modifying the structure by the action A_t in a state S_t in an optimization step t is computed from the change of the structural volume (i.e., the objective function) as follows:

$$\mathrm{R}_{t+1} = \begin{cases} (V_t - V_{t+1})/V_0 & : \quad \sigma_{\max} \leq 1 \\ -1 & : \quad \sigma_{\max} > 1 \text{ or } t = t_{\max} \end{cases} \tag{8}$$

where V_t and V_0 are the value of the objective function at step t and the initial step, respectively. $t_{\max}$ is the maximum step of the optimization.

4.5. Optimization method

In each optimization step, the DDPG agent made from GCN layers observes the graph representation of the structure. The agent chooses elements, reduces their section sizes and obtains the reward computed from the volume reduction of the structure. The optimization ends when any structural element violates the stress constraint or the number of optimization steps reaches $t_{\max}$.

(a) (b)

Figure 2. Flowcharts of the algorithm: (a) training phase, (b) test phase.

The agent is trained to optimize the structure to obtain high rewards in the training phase and applied to other structures in the test phase. Note that in the test phase, the agent cannot perform actions onto the element that has a ratio of internal stress to the yield stress larger than φ_2. If the modified structure violates the constraint, all elements with the ratio of internal stress larger than φ_2 will increase their section indices by one. Flowcharts of proposed algorithms in the training and test phases are shown in Figures 2(a) and (b), respectively.

5. Numerical examples

5.1. General experiment setting and structural properties

Frame elements used in this experiment have round hollow sections selected from Table 4 and have Young's modulus of 205 kN/mm^2. $\bar{\sigma}_x$, $\bar{\sigma}_y$, and $\bar{\sigma}_z$ are set as 235/1.5 N/mm^2, 0.66×235/1.5 N/mm^2, and 0.66×235/1.5 N/mm^2, respectively. Dimension of the embedding space h in all GCN layers is set to 300 and each layer in NN in Eq. (6d) has 300 cells.

Table 4. Frame section list.

section No.	diameter (mm)	thickness (mm)	area (cm^2)	2nd moment of area (cm^4)

5.2. Training phase

The agent is trained to optimize 6 different lattice shells illustrated in Figures 3(a)–(f) and shown in Table 5 which are subjected to different nodal loads applied to all nodes guaranteeing that the structures with the largest sections do not violate the constraints and those with the smallest sections violate the constraints. The ability of the agent to improve its policy is evaluated every 10 times (*episodes*) of training using the same 6×6-grid lattice shells in Figure 3(g) subjected to a downward load of 1kN at all nodes. Adam optimizer adjusts the trainable parameters in surrogate policy and value functions with learning rates of 10^{-6} and 10^{-5}, respectively. τ is set to 0.05 to update weights in surrogate functions to the online function every 100 steps. $t_{\max}$ of the episode for training and episode for evaluation are set to 50 and 100, respectively.

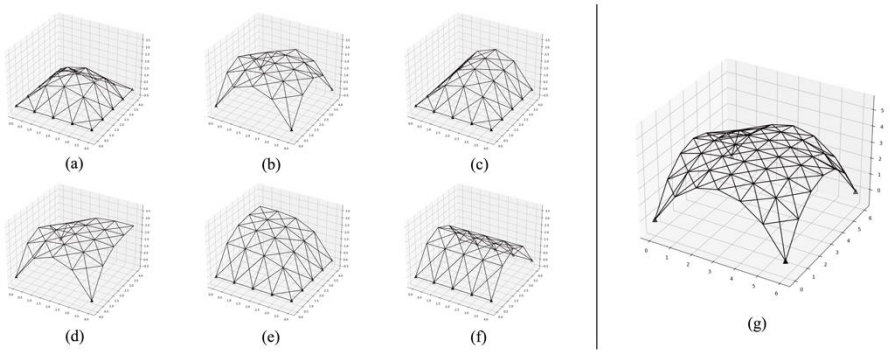

Figure 3. Structures used for training the agent: (a) S 1, (b) S 2, (c) S 3, (d) S 4, (e) S 5, (f) S 6, (g) structure used for evaluating the improvement of the trained agent.

Table 5. Structures for training.

	S 1	S 2	S 3	S 4	S 5	S 6
grid size	4×4	4×4	4×4	4×4	4×4	4×4
grid span (m.)	1	1	1	1	1	1
downward load (kN.)	25	5	10	0.5	0.2	15

Figure 4 shows variations of accumulated reward obtained in each evaluation episode where the thick red line indicates the moving average of the reward at every 20 episodes of evaluation. The total number of structural analyses in this phase is 25849. It is seen from this figure that the agent can improve its policy function to obtain a high reward to minimize the structural volume. Note again that the agent is evaluated using a structure that is different from the training data, indicating the applicability of the agent to unseen problems which will be further investigated in the test phase.

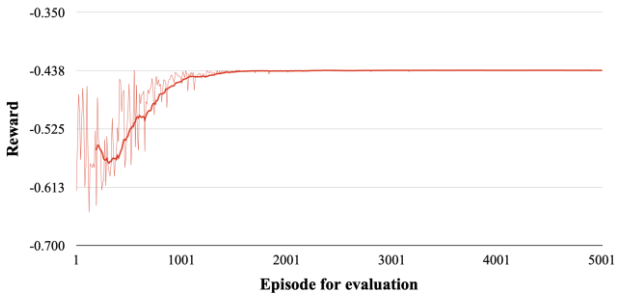

Figure 4. Variations of accumulated reward.

5.3. Test phase

The trained agent with the weights saved at the 5000th episode of the training phase is utilized for optimizing larger lattice shells shown in Table 6 ten times. In this phase, Structure A has fixed supports at the corners, Structure B has fixed supports at the corners with an irregular shape, and Structure C has fixed supports at the perimeter nodes as shown in Figures 5, 6, and 7, respectively. φ_2 is set to 0.6. Solutions from the proposed RL are compared to the result obtained by GA and SA using python libraries named DEAP [14] and SciPy [15], respectively. In GA, each gene is encoded as an integer in the list $\{0, 1, \ldots, 5\}$ to represent the sectional index of each element with numbers of the population and generation set as 100 and 10, respectively. In SA, the design parameters are the same as those of GA with a maximum number of structural analyses set as 1000. In both SA and GA, ten trials using different random seeds are implemented to minimize the penalty function $\phi(\mathbf{c})$ defined as follows:

$$\phi(\mathbf{c}) = \frac{V(\mathbf{c})}{V_0} + \sum_{i=1}^{n} w_c(\max[0, |\sigma_i| - 1])^2 \tag{9}$$

where V_0 is the total structural volume of the structure where all elements have the largest indices of cross-sectional properties, n is the number of elements in the structure, and w_c is the weight for the constraint set as 50.

Table 6. Structures for test.

	Structure A	Structure B	Structure C
grid size	10×10	20×20	20×20
grid span (m)	1	1	1
downward load (N)	200	5	300
Number of elements	420	1640	1184
$t_{\max}$	100	200	200

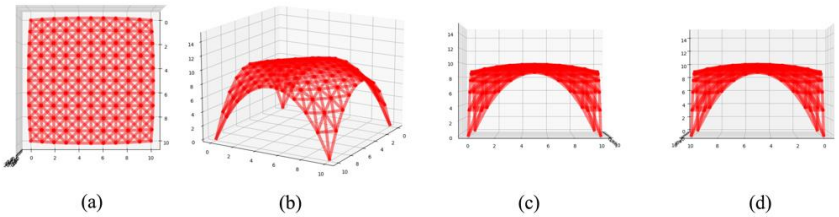

Figure 5. Structure A: (a) plan, (b) isometric, (c) elevation 1, (d) elevation 2.

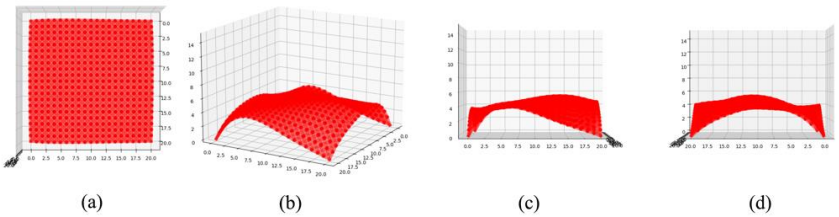

Figure 6. Structure B: (a) plan, (b) isometric, (c) elevation 1, (d) elevation 2.

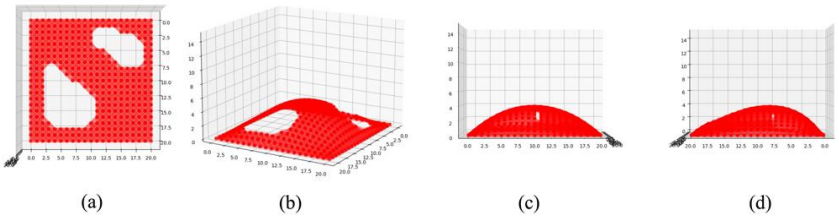

Figure 7. Structure C: (a) plan, (b) isometric, (c) elevation 1, (d) elevation 2.

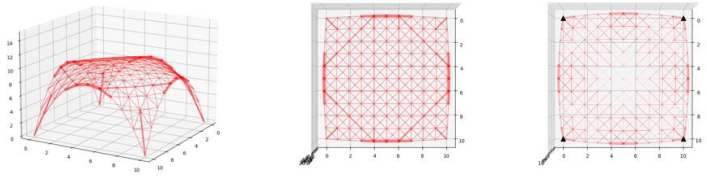
The performance of RL, GA, and SA are measured using the volume reduction of the optimized structure computed as

$$\text{volume reduction} = (V_0 - V_*)/V_0 \tag{10}$$



where V_* is the final volume of the structure.

Table 7 shows the minimum (min), the mean, the maximum (max), and the standard deviation (std) of the volume reductions and the number of structural analyses for RL, GA, and SA. In every structure, the RL agent achieved better volume reductions than those obtained by GA and SA. The standard deviations of results from RL are also low compared to those of GA and SA. These results confirms stable performance of the proposed RL.

Table 7. Test result: volume reduction (%).

	structure	min	mean	max	std	analyses(times)
RL	A	82.06	82.36	82.53	0.15	2000
	B	86.00	86.07	86.12	0.03	4000
	C	84.57	84.69	84.75	0.05	4000
GA	A	0.00	22.86	39.35	19.69	10000
	B	82.25	82.74	83.20	0.37	10000
	C	73.29	73.97	74.67	0.49	10000

4. Conclusion

This paper presents a method for sizing optimization of free-form lattice shells to minimize the structural volume under the stress constraints using DDPG and GCN. The DDPG agent observes the structure represented as a graph and reduces the sectional index of each structural element. First, the agent is trained to minimize the structural volume, where the improvement of the agent is measured using the reward obtained from the volume reduction. Note that the agent is trained using small structures and evaluated using a structure with a different configuration. The ability of the agent to optimize different structures is also verified in the test phase where the agent is not further trained and the results obtained by the RL agent are compared to those obtained by GA and SA.

The numerical result shows that the proposed method can obtain superior solutions than GA and SA for all test cases using different free-from lattice shells. The trained RL agent also has a more stable performance than GA and SA while utilizing smaller computational costs than those algorithms. However, it should be noted that the proposed method requires some computational cost during the training phase but utilizes a small computational cost during the test phase. Therefore, the benefit of the proposed method in the aspect of computational efficiency becomes large when the agent is applied to many problems.

In this paper, the lattice shell consists of only three-dimensional beam elements, and the lists of the structural section are the same in both the training and test phases. However, in practice, the types of

structural elements and sectional lists could be varied. Therefore, further investigation on the applicability of the trained agent is needed for the cases using different lists of structural sections and different types of structural elements, such as both three-dimensional beam and truss systems.

Abstract

To examine the quasi-static compression performance of a honeycomb structure with a negative Poisson's ratio, this paper employs finite element analysis software, Abaqus, and utilizes stainless steel property data for numerical simulation analysis of the honeycomb structure with a negative Poisson's ratio. Concurrently, through a comparison of honeycomb structures with zero and positive Poisson's ratios, the mechanical and energy dissipation properties of negative Poisson's ratio honeycomb structures are investigated under varying length-thickness ratios and cell configurations. Key parameters such as nominal stress-strain, platform stress, energy absorption capacity, specific energy absorption, and Poisson's ratio are considered in the study.

Keywords: re-entrant honeycomb, quasi-static compression, large deformation, energy absorption, stainless steel

1. Introduction

Honeycomb structures, characterized by their porous composition and regular hexagonal arrangement, boast low density and high strength. Consequently, they exhibit superior strength-to-weight and rigidity-to-weight ratios compared to solid structures of the same type[1, 2]. The buckling of cell walls effectively distributes compression forces across each cellular unit, resulting in a stable structure with excellent compressive deformation capabilities and energy dissipation performance. These features make honeycomb structures ideal for use as protective components in aerospace [1, 2], transportation [3, 4], construction [5, 6], and other protective fields.

In recent years, reentrant hexagonal honeycomb structures have been extensively studied due to their unique negative Poisson's ratio characteristics. This innovation significantly enhances the in-plane compression performance of honeycombs [7, 8] and effectively addresses their anisotropy, where in-plane compression performance is inferior to that of out-of-plane. Initially, Poisson's ratio was a mechanical parameter applicable only under elastic conditions, so early research on reentrant hexagonal honeycomb structures was primarily focused on the elastic range [11, 12]. However, recent studies have explored the potential of negative Poisson's ratio performance in metal materials like brass and aluminum alloy to improve energy dissipation performance in structures. For example, Ruan et al. [13] examined the in-plane fracture behavior of aluminum honeycombs in two directions, considering the effects of wall thickness and impact velocity on local deformation modes and plateau stress. They also derived an empirical formula to calculate the stress of aluminum honeycomb plateaus at high impact velocities. Yasuki et al. [14] developed an offset deformable barrier model with aluminum honeycomb

for vehicle collision simulations, while Li et al. [15] investigated the energy absorption capacity of two types of concave hexagonal honeycomb structures made from brass with negative Poisson's ratio. Stainless steel, possessing exceptional physical and mechanical properties, can better replicate the plastic buckling failure mechanism of honeycomb structures under impact [16]. Realizing a negative Poisson's ratio effect in steel honeycomb structures under large deformations has promising applications.The advent of 3D printing technology has provided advanced techniques for manufacturing stainless steel honeycomb structures. Xi et al. [17] introduced a new asymmetric rotatable concave hexagonal honeycomb structure made from stainless steel via 3D printing, based on the symmetrical concave hexagonal honeycomb structure with a negative Poisson's ratio. They demonstrated that adjusting the honeycomb structure's rotation improved its energy absorption performance. Zhou et al. [18] used 3D printing to create 316L stainless steel concave hexagonal honeycomb samples with varying length-to-thickness ratios and cell types. They studied the deformation process and associated mechanical parameters (e.g., Poisson's ratio, failure mode, plateau stress, and energy absorption capacity) under three distinct energy inputs. The results showed that negative Poisson's ratio honeycomb samples had higher plateau stress and specific absorption energy than traditional honeycomb specimens. This paper investigates negative Poisson's ratio honeycombs using material property data from 3D-printed 316L stainless steel.

To examine the quasi-static compression performance of negative Poisson's ratio honeycomb structures, finite element analysis software Abaqus was employed for numerical simulation analysis. By comparing zero and positive Poisson's ratio honeycomb structures, this study explored the mechanical properties and energy dissipation capabilities of negative Poisson's ratio honeycomb structures with different length-to-thickness ratios and cell configurations. Key parameters such as nominal stress-strain, plateau stress, energy absorption capacity, specific energy absorption, and Poisson's ratio were analyzed.

2. Specimen design

In this study, four hexagonal honeycomb samples were designed, including two negative Poisson's ratio structures (A0.6 and A1.0), one positive Poisson's ratio structure (H0.6), and one zero Poisson's ratio structure (Z0.6)[1]. To maintain uniform horizontal size, height, and cell count for each specimen, the hypotenuse length for every element type was set at 10mm [2]. The horizontal side length for the negative Poisson's ratio element was 20mm, and the angle between the horizontal side and the hypotenuse was 60°[3]. For the zero Poisson's ratio element, the horizontal side length was 15mm, with angles of 120° and 60° between the horizontal side and the hypotenuse[4].

Each Poisson's ratio honeycomb specimen had cell wall thicknesses of 0.6mm and 1.0mm [5]. Consequently, the ratio of hypotenuse length to thickness for each specimen was 50/3 and 10 [6]. Every specimen contained five elements along both vertical and horizontal directions, resulting in identical external dimensions for all specimens: 140x86.6x50mm [7]. The specific geometric parameters for specimens with different Poisson's ratio elements are depicted in the accompanying figure[8].

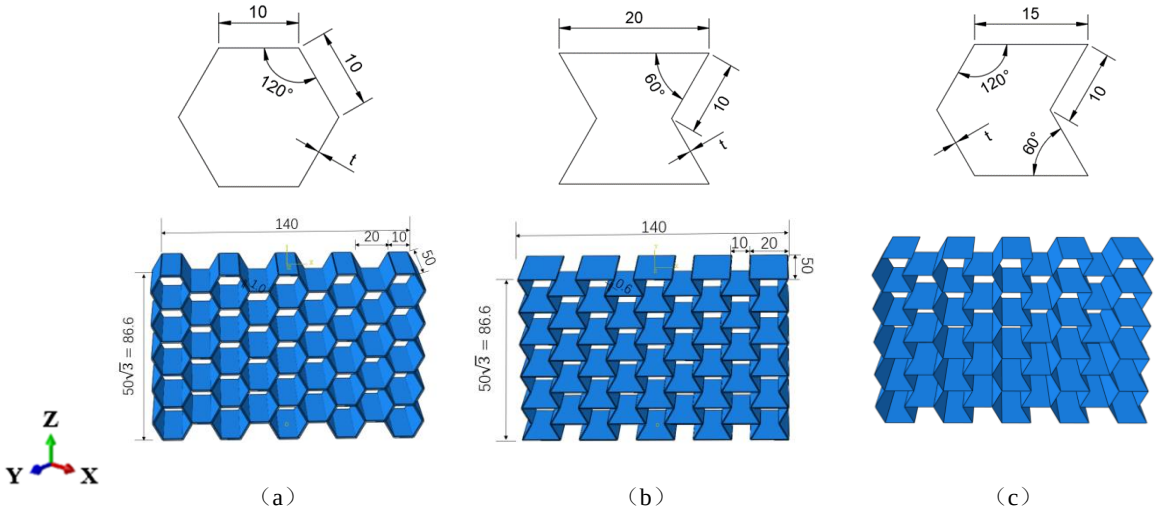

Fig. 7 Specimen model (a) positive Poisson's ratio, (b) negative Poisson's ratio, (c) zero Poisson's ratio

3. Finite element simulation

In this study, the ABAQUS explicit module is employed to investigate the quasi-static compression performance of various Poisson ratios. The model utilizes the S4R element for grid partitioning. Convergence studies indicate that the optimal mesh size is 2 mm. In the simulation, the sample is positioned on the bottom plate, and fixed constraints are applied to it. The material used is 316L stainless steel, with material parameters as follows: elastic modulus E of 200 GPa, density of 7.81 kg/m3, and Poisson ratio of 0.30. Key parameters of the Johnson-Cook model for this material are established based on material property test data by Zhou [18], as displayed in Table 5. In the analysis, the top surface of the honeycomb model and the bottom surface of the panel are set to face-to-face contact, while the remainder employs a self-contact algorithm. A tangential friction coefficient of 0.30 is assigned. The specimen is compressed in the Y direction, and a displacement load equivalent to 80% of the model's height is applied, meaning the panel's displacement is set to 70 mm. Additionally, the panel's displacement in the X and Z directions, as well as all directional angles, are restricted.

4. Simulation result

4.1 Deformation mode

The finite element simulation's compression results are displayed in the figure. A nominal strain of 0.8 is observed, which refers to the relative deformation between a sample's upper and lower edges, divided by its initial height. Post-compression, honeycomb structures with a negative Poisson's ratio achieve the dense stage under the same nominal strain, whereas those with zero or positive Poisson's ratios do not enter this stage.

Furthermore, during deformation, negative Poisson's ratio honeycomb specimens exhibit prominent cell wall aggregation and curve inward, leading to a significant negative Poisson's ratio effect. In contrast, positive Poisson's ratio honeycomb structures typically expand laterally, while zero Poisson's ratio specimens demonstrate neither noticeable expansion nor contraction.

4.2 Nominal stress and strain

The nominal stress is the transient force during compression divided by the external cross-sectional area of the specimen. By analyzing the nominal stress and strain, the elastic limit stress, compaction stress and corresponding strain values are obtained. Platform stress [19, 20] can be calculated by Equation (1) :

$$\sigma_p = \frac{1}{\varepsilon_d - \varepsilon_{cr}} \int_{\varepsilon_{cr}}^{\varepsilon_d} \sigma(\varepsilon) d\varepsilon \quad (1)$$

where σ_p is the plateau stress, $\sigma(\varepsilon)$ is the nominal stress varying with the nominal strain, ε_{cr} is the nominal strain corresponding to the elastic limit stress and ε_d is the maximum strain value before the material is compacted, and according to the literature [20], ε_d is calculated by Eq. (2):

$$\frac{d}{d\varepsilon}\left[\frac{1}{\sigma(\varepsilon)} \int_0^{\varepsilon} \sigma(\varepsilon)\, d\varepsilon\right]|_{\varepsilon=\varepsilon_d} = 0 \quad (2)$$

The nominal stress-strain curves of the four specimens can be divided into elastic stage, platform stage and compaction stage, showing the typical characteristics of honeycomb energy absorption structure. Table 3 provides complete nominal stress and strain data.

Table 3 Compaction stress and strain of test results.

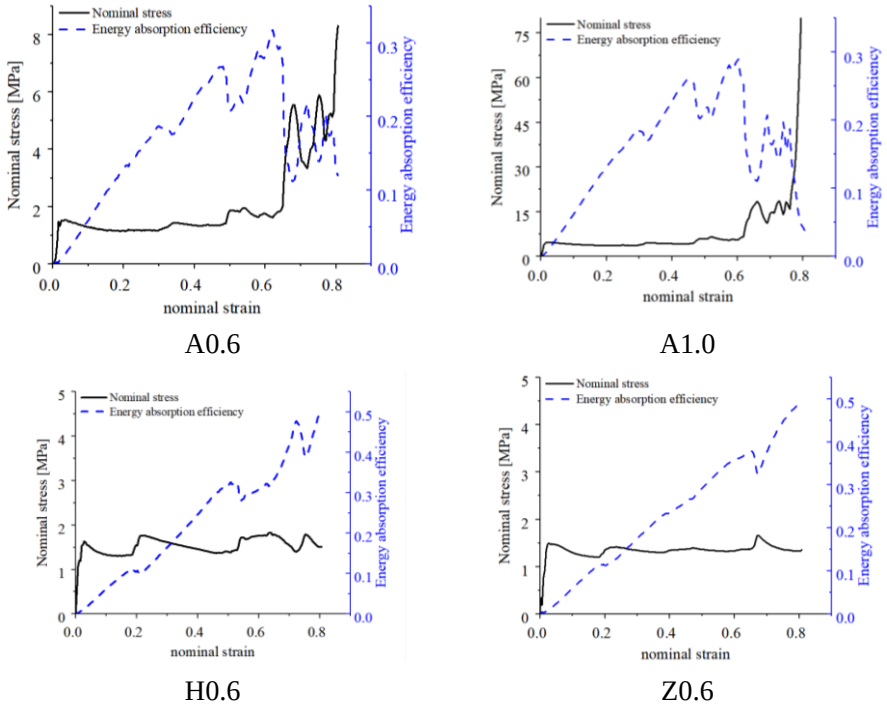
4.3 Energy absorption

The energy absorption capacity is of great importance for the auxetic structures under the impact loading, where energy absorption efficiency is an important index. According to the literature, it can be calculated by Eq. (6):

$$\beta(\varepsilon) = \frac{\int_0^{\varepsilon} \sigma(\varepsilon)\mathrm{d}\varepsilon}{\sigma(\varepsilon)} \tag{6}$$

where $\beta(\varepsilon)$ represents the energy absorption capacity and is defined as the ratio of the energy absorbed under the given nominal strain to the corresponding nominal stress. The nominal stress-strain curve and energy absorption efficiency curve are combined in Fig. 5.



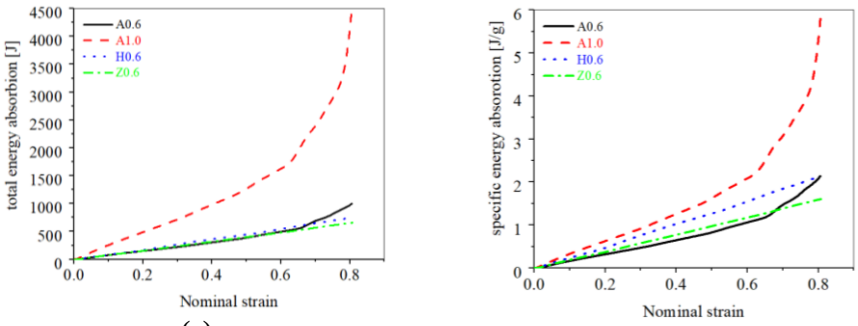


Fig. 5 Nominal stress-strain curves and energy absorption efficiency curves of A0.6, A1.0, H0.6, Z0.6.

The total energy absorbing E_{TEA} in the impact process was calculated by the transient force and the measured displacement as shown in Fig. 6(a). The energy absorbed in different deformation stages were obtained by the elastic limit stress, compaction stress and corresponding strain values given in Table 4. In order to accurately describe energy absorption of the specimen, specific energy absorption, E_{SEA} [31, 39], in Fig. 6(b), defined as energy absorption per unit mass, is computed by the following formula:

$$E_{SEA} = \frac{E_{TEA}}{Q} \tag{7}$$

where Q is the mass of the specimen.

5. Discussion

5.1 Cellular configuration

In comparison with the test outcomes for A0.6, H0.6, and Z0.6 under identical strain conditions, only the honeycomb featuring a negative Poisson's ratio initially transitions into the dense phase due to structural aggregation. This is in line with the traits of materials exhibiting negative Poisson's ratios. The area enclosed by the nominal stress-strain curve signifies the energy absorption attributes, as illustrated in Figure 9(a). There is minimal disparity in the peak stress and plateau stress among components with differing Poisson's ratios. However, as depicted in Figure 9 and Table 4, components with negative Poisson's ratios notably absorb more energy, whereas those with zero Poisson's ratios exhibit the weakest energy absorption. Despite this, the mass of components with negative Poisson ratios is greater than that of other Poisson ratio components, resulting in lower specific energy absorption during the initial phase.

(a) (b)

(c) (d)

Fig. 9 Stress-strain curves and specific energy absorption of specimens with different width/thickness ratios and cell configurations

5.2 Side length-to-thickness ratio

The specimen thicknesses in this research were 1.0 and 0.6, while the ratios of side length to thickness on the inclined side were 10 and 50/3, respectively. Based on the experimental findings, specimens with varying side length-to-thickness ratios demonstrated distinct performance characteristics. A comparison of test results for specimens A0.6 and A1.0 reveals that under the same strain, specimen A1.0, with a larger width-to-thickness ratio, exhibits significantly higher energy absorption than specimen A0.6. Additionally, its stress-strain curve and specific energy absorption surpass those of specimens with smaller width-to-thickness ratios. Consequently, it can be inferred that specimens with greater width/thickness ratios possess superior mechanical properties and energy absorption capabilities. Furthermore, the stress-strain curve trends for A1.0 and A0.6 are nearly identical, suggesting that the width/thickness ratio has minimal impact on the deformation mode of specimens

5.3 Poisson's ratio

As a typical auxetic structure, the Poisson's ratio of specimens is an important parameter, and it can be evaluated using the following formula:

$$v = -\frac{\varepsilon_x}{\varepsilon_y} \tag{9}$$

where ε_x is the transverse nominal strain and ε_y is the nominal vertical stain. The change process of Poisson's ratio was calculated by recording the position data of key points.

According to the Poisson's ratio and nominal vertical strain curve in FIG. 10, the Poisson's ratio of the test piece with negative Poisson's ratio is always in the negative range, and the Poisson's ratio decreases rapidly in the elastic stage of the specimen, gradually increases in the platform stage, and becomes stable in the dense stage. The convex specimen showed a completely different trend, that is, in the compression process, its Poisson's ratio first increased rapidly and then gradually decreased, and its Poisson's ratio was always in a positive range. The Poisson ratio of the zero Poisson ratio test piece always hovers around 0.That's exactly what theory would expect.

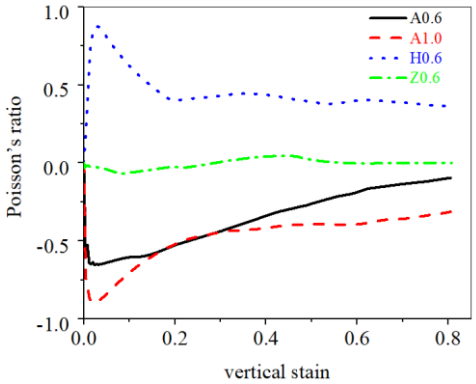

Fig. 10 Poisson's ratio curves of four specimens

6. Conclusion

(1) The deformation of 3D-printed stainless steel auxetic honeycomb structures under quasi-static compression is investigated using numerical analysis. Based on the simulation outcomes, the following conclusions can be drawn:

(2) The deformation process of honeycomb structures with a negative Poisson's ratio can be categorized into three distinct stages: elastic, plateau, and compaction. Owing to their negative Poisson's ratio properties, only auxetic specimens reach the compaction stage under the same strain.

(3) As the width-to-thickness ratio increases, both the mechanical attributes and energy absorption capabilities of the honeycomb structure see significant improvement under identical strain.

(4) Comparatively, the energy absorption potential of structures with a negative Poisson's ratio is greater than those with positive or zero Poisson's ratios. In contrast, structures with a zero Poisson's ratio exhibit the lowest energy absorption capacity.

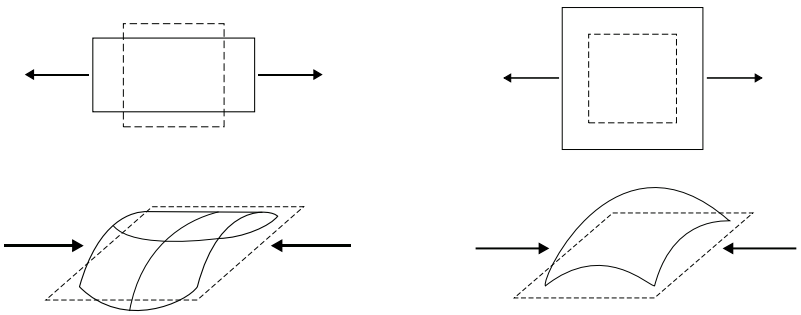
Abstract

This study proposes a shape design method for a bending-active mechanical metamaterial composed of a three-dimensional pentagonal grid with a tailorable Poisson's ratio. The specific shape of the proposed grid is derived from a dual geometry of rotating rigid squares. Slender flexible beams with rectangle cross-sections are used for components of structural units, and the connections between members are rigid. To explore the values of Poisson's ratio for in-plane deformation of the proposed grid, we parametrically alter the shape of a structural unit and the bending stiffness of a member. Shape parameters are defined as positions of connections, cross-sectional height and width of a member, and the ratio determining the convexity and concavity of a pentagonal grid. Based on geometric frustration, a nonperiodic pentagonal grid can also be designed. In numerical examples, we investigate the mechanical properties for in-plane and out-of-plane deformations of grids by carrying out finite element analysis. A wide range of Poisson's ratios ranging from –5 to 5 is observed. Moreover, we investigate the relationships between the distribution of Poisson's ratio of an initial pentagonal grid and that of discrete Gaussian curvature on nodes of a curved surface obtained by out-of-plane deformation.

Keywords: three-dimensional pentagonal grid, auxetic structures, bending-active gridshells, Poisson's ratio, geometrical frustration



1. Introduction

Active bending is a key technique in designing architectural roofs and spatial structures that are lightweight and efficient in material use [1]. By replacing traditional construction methods such as masonry and latticed shell with active bending, construction time and cost can be reduced. The use of computational design tools and fabrication technologies has greatly facilitated the design and construction of a bending-active structure. There have been a lot of studies and works on bending-active (elastic) gridshells composed of flexible beams [2]. We can obtain various curved surfaces by elastically deforming an initial flat grid. The obtained surface is dependent on the geometrical shape of a grid [3]. It is, therefore, an important challenge to develop a new type of initial flat grid for generating a more complex free-form surface that is difficult to achieve using the existing quadrilateral grid.

The burgeoning developments of mechanical metamaterials have opened a new era of designing a wide range of engineering applications because of their exotic mechanical properties that conventional structures and materials in nature are unachievable [4, 5]. Auxetic structures, which are a class of mechanical metamaterials that exhibit a negative Poisson's ratio, expand or shrink transversely under uniaxial tension or compression, respectively. Figure 1 compares the deformed shapes of conventional and auxetic structures. The unconventional deformation behavior of auxetic structures is caused by specific internal structural units, including reentrant polygons, chiral geometries, and rotating rigid polygons [6]. Naboni *et al*. [7] and La Magna and Knippers [8] applied a few types of auxetic units to

design an initial flat grid of a bending-active gridshell for easily obtaining a dome-like shape that is difficult to be deformed from a conventional structure with a positive Poisson's ratio [9]. Sakai and Ohsaki [10] proposed an initial flat grid composed of nonperiodic and/or hybrid auxetic units based on reentrant honeycomb and reentrant quadrilateral. It enables us to obtain a more complex free-form surface than that with uniform and periodic units. The prior works indicate that a bending-active gridshell with auxetic property is to be an efficient structural system for constructing a spatial structure; however, few types of internal structural units have been investigated. There has still been a challenge to expanding the range of attainable mechanical properties of auxetic bending-active structures with simple and tunable geometrical properties.

Figure 1. Comparison of relationships between Poisson's ratios and deformation behaviors. Initial and deformed shapes are represented by dotted and solid lines, respectively. In-plane and out-of-plane deformations are shown in the upper and lower figures, respectively.: (a) conventional structure with positive Poisson's ratio, (b) auxetic structure.

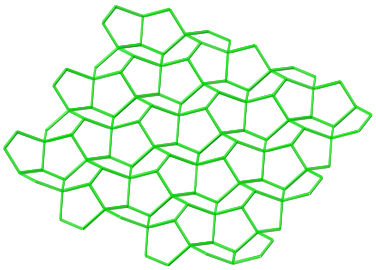

Figure 2. Geometrical configuration of penta-graphene composed of multiple periodic three-dimensional pentagons. Carbon atoms at the intersections are connected by three or four carbon bonds (green line). In numerical simulations in Refs [11, 12], the bending stiffness is not assumed, because the size of carbon allotrope is micro-scale.

In this study, we present a new bending-active mechanical metamaterial based on a three-dimensional pentagonal grid. Previous research has found penta-graphene, a carbon allotrope based on the specific three-dimensional pentagonal configuration composed of carbon atoms and bonds, using numerical simulation in 2015 [11]. Figure 2 shows the geometrical configuration of penta-graphene, which notably exhibits a negative Poisson's ratio. Additionally, artificial carbon material based on a three-dimensional pentagonal configuration is proposed by numerical simulation, and its geometrical configuration and in-plane Poisson's ratio can be parametrically designed [12]. The prior works investigated micro-scale material; therefore, the bending deformation of a beam is neglected. By contrast, our mechanical metamaterial is composed of rigid nodes and bending flexible beams connecting them. The anisotropy of bending stiffness of a beam is used for exploring the mechanical properties of pentagonal grids. By performing finite element analysis, we investigate the relationships between the shape parameters and the mechanical properties: Poisson's ratio for in-plane deformation and discrete Gaussian curvatures at nodes on a curved surface obtained by out-of-plane deformation. Furthermore, we design a nonperiodic

pentagonal grid inspired by the concept of geometric frustration. The proposed design method allows us to obtain a complex shape of a curved surface combined with positive and negative Gaussian curvatures. In numerical example, we tailor the distribution of Poisson's ratio by altering the shape parameters for designing a curved surface with a desirable distribution of discrete Gaussian curvatures.

2. Shape design of a three-dimensional pentagonal grid

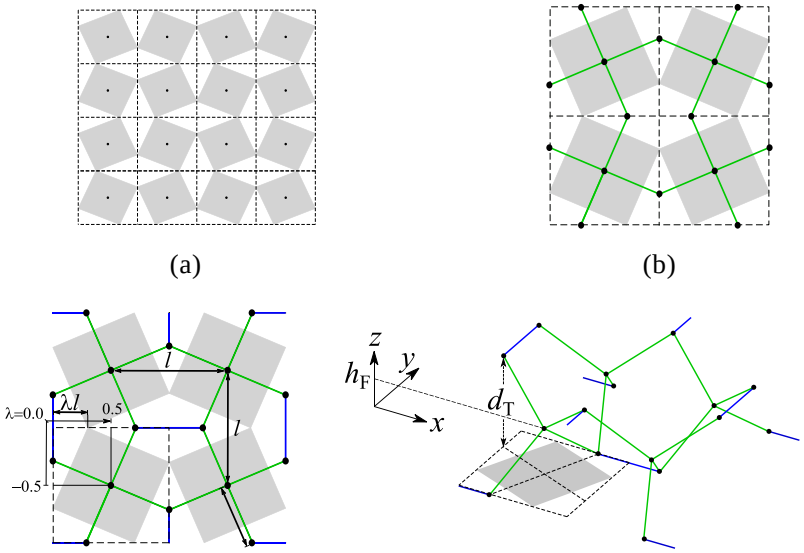

Figure 3. Design workflow of generating a geometrical configuration of a three-dimensional pentagonal grid: (a) rigid rotating squares (grey) and the square grid (dotted line), (b) dual geometry of rigid rotating squares represented as the edges (green) connecting vertices (circular marks), (c) planar pentagonal grid constructed by additional edges (blue) connecting three-valent vertices, and shape parameters λ and l, (d) three-dimensional pentagonal grid in *xyz*-coordinate system obtained by translating the vertices along *z*-direction.

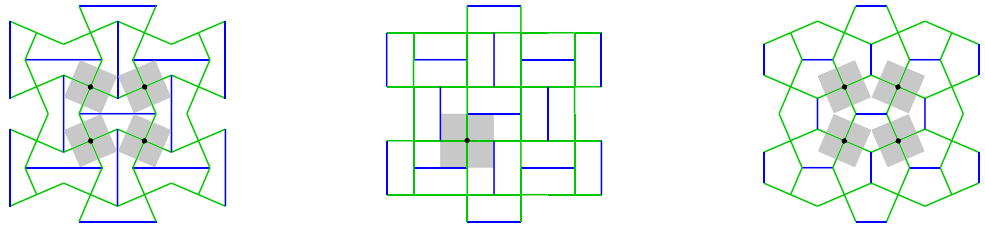

Figure 4. Geometrical shapes of planar pentagonal grid designed by three different tilting ratios λ: (a) $\lambda = -0.3$, (b) $\lambda = 0.0$, (c) $\lambda = 0.3$.

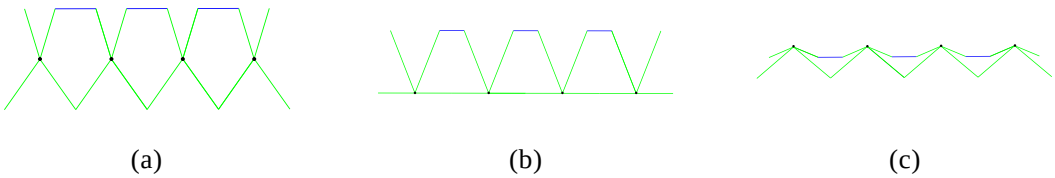

Figure 5. Geometrical shapes of three-dimensional pentagonal grids projected onto *yz*-plane: (a) $d_T = 0.5$ and $h_F = 0.0$, (b) $d_T = 0.3$ and $h_F = -0.3$, (c) $d_T = 0.1$ and $h_F = 0.2$.

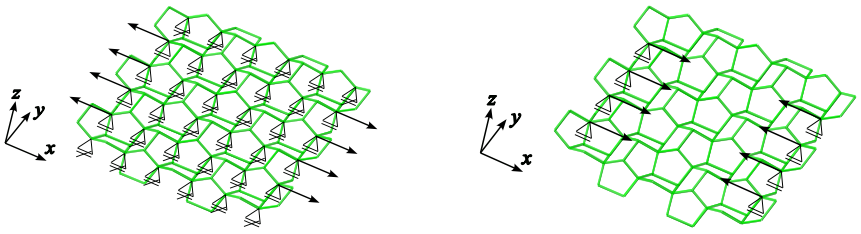
A geometrical shape of three-dimensional pentagonal grid is designed based on the dual geometry of rotating rigid squares. Figure 3 shows the design workflow of generating a geometrical shape of the

proposed metamaterial. As illustrated in Fig. 3(a), rotating rigid squares (grey) are arranged in a square grid (dotted lines). Figure 3(b) shows the dual geometry of rotating rigid squares, which is a discrete frame with edges (green) and vertices (circular marks). We can obtain a planar pentagonal grid by constructing additional edges (blue) connecting three-valent vertices, as shown in Fig. 3(c). Tilting ratio of a rotating rigid square and the distance between the centers of neighbouring squares are denoted as λ and l, respectively. A planar pentagonal grid is parametrically determined by tuning the value of λ, ranging from –0.5 to 0.5, as shown in Fig. 4. Figure 3(d) shows the geometrical shape of a three-dimensional pentagonal grid in *xyz*-coordinate system. Let h_F and d_T denote the *z*-directional coordinate of the four-valent vertices and the distance in *z*-direction between edges connecting three-valent vertices along *x*- and *y*-axis, respectively. We show, in Fig. 5, examples of three-dimensional pentagonal grids with different values of h_F and d_T projected onto *yz*-plane.



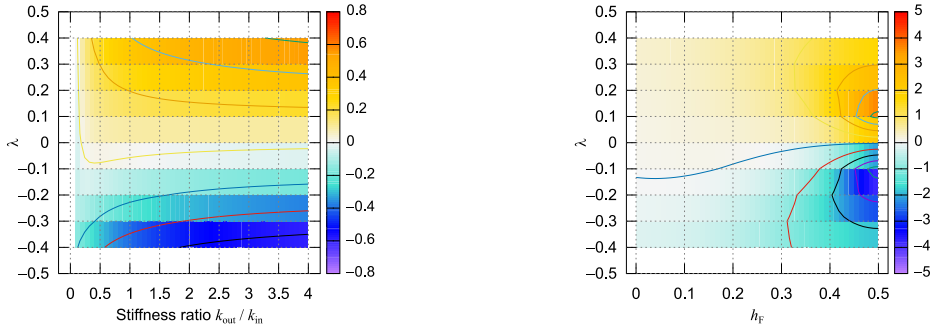
3. Mechanical properties of three-dimensional pentagonal grid

To investigate the static mechanical properties of a three-dimensional pentagonal grid, we carry out nonlinear structural analysis by finite element method. Edges are modelled as bending flexible beams that have a uniform rectangular cross-section. Vertices intersecting the edges are assumed to be elastic connections without any kinematical joints. The width and height of cross-section of all members are denoted as t_b (m) and t_h (m), respectively. The vertices are assumed as rigid nodes intersecting beams with no hinge-joints. Let E, and k_{in} and k_{out} represent Young's modulus of the material, and in-plane and out-of-plane bending stiffness, respectively. We define the bending stiffness ratio as

$$\frac{k_{out}}{k_{in}} = \frac{Et_b t_h^3}{12} \Big/ \frac{Et_h t_b^3}{12} = \left(\frac{t_h}{t_b}\right)^2 . \tag{1}$$

In the following examples, the material has Young's modulus E = 25 GPa, Poisson's ratio 0.221, and yielding stress 433 MPa. We use Abaqus Ver. 2022 for quasi-static deformation analysis [13].

3.1. Poisson's ratio for in-plane deformation



(a) (b)

Figure 6. Roller-supports (triangular marks) and forced displacements (arrows) for in-plane and out-of-plane deformation of three-dimensional pentagonal grids: (a) in-plane deformation, (b) out-of-plane deformation.

Figure 6 shows the boundary conditions for investigation of in-plane Poisson's ratio of the three-dimensional pentagonal grid under elastic small strain range. All four-valent nodes are roller-supported on *xy*-plane. The outer connections arranged along *y*-direction are supported by roller that can move along *x*-direction. Forced displacements 0.1% of the size in *x*-direction of the structure are given at the outer supports as shown with arrows in Fig. 6(b). We compute the Poisson's ratio as the signed ratio of *y*-directional (lateral) strain to *x*-directional (axial) one, which are obtained from displacements of the outer four-valent nodes except those of the corners. In the following examples, the three-dimensional pentagonal grids have 6×6 structural units, and the distance between four-valent nodes is set as $l = 1/\sqrt{2}$. Table 1 shows the values of shape parameters for Cases 1 and 2.

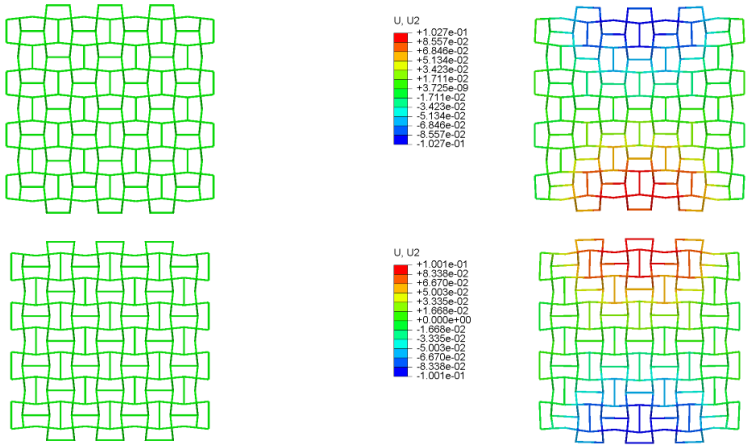


Table 1. Values of shape parameters for Cases 1 and 2.

	h_F	d_T	t_b	t_h
Case 1	0.0	0.3	0.05	–
Case 2	–	0.5	0.05	0.05

(a) (b)

Figure 7. In-plane Poisson's ratio (contour) of the proposed metamaterials specified as $\lambda \in \{-0.4, -0.3, \ldots, 0.4\}$ under elastic small tension: (a) bending stiffness ratios are changed in the range $0.08 \leq k_{out}/k_{in} \leq 4.0$, (b) height of the four-valent vertices are changed in the range of $0.0 \leq h_F \leq 0.5$.

(a) (b)

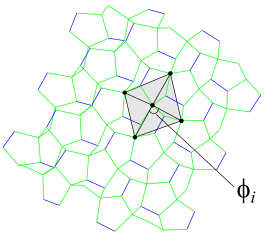
Figure 8. Comparison of in-plane deformations of three-dimensional pentagonal grids with positive and negative Poisson's ratios in the upper and lower figures, respectively: (a) initial shape, (b) deformed shape projected onto *xy*-plane with contour of *y*-directional displacement.

Figure 7 shows the relationships between the in-plane Poisson's ratio and tunable shape parameters. The contours in the figure represent the values of Poisson's ratio for in-plane deformation, while the tilting ratio is specified as $\lambda \in \{-0.4, -0.3, \ldots, 0.4\}$. In Fig. 7(a), the bending stiffness ratio is varied in the range of $0.08 \leq k_{out}/k_{in} \leq 4.0$ by increasing the cross-sectional height t_h by 0.08 m with a constant cross-sectional width $t_b = 0.05$, in Case 1. For Case 2, as shown in Fig. 7(b), we alter the values of h_F, ranging from 0.0 to 0.5, while setting $d_T = 0.5$.

As seen in both Figs. 7(a) and (b), the sign of Poisson's ratio is dependent on the shape parameter λ, because the convexity and concavity of structural units are determined by λ. In Case 1, as explained in Fig. 7(a), the absolute values of in-plane Poisson's ratio gradually increase by designing the members with a larger bending stiffness ratio. When the bending stiffness ratio is sufficiently small, an auxetic structure composed of convex pentagonal grids with $\lambda > 0$ is obtained. This result is not common, since a convex geometrical shape rarely exhibits a negative Poisson's ratio. In Case 2, as shown in Fig. 7(b), we can obtain a specific metamaterial with various values of Poisson's ratio ranging from –5 to 5. The pentagonal grids designed with shape parameters close to $|\lambda| = 0.1$ and $h_F = 0.5$ exhibit the maximum and minimum values of Poisson's ratio.

Figure 8 compares the deformed shapes of three-dimensional pentagonal grids with positive and negative Poisson's ratio under the same boundary conditions as illustrated in Fig. 6(a). Forced displacements 1% of the size of the grid in *x*-direction are given at the roller-supports. Figures 8(a) and (b) are initial and deformed shapes with contour of *y*-directional displacement of the grids, respectively. In the upper figure, the grid with a positive Poisson's ratio shrinks in the transverse direction; in the lower figure, the grid with a negative Poisson's ratio stretches. It is verified that a sign of Poisson's ratio of the pentagonal grids can be parametrically tuned.

3.2. Deformed shape and discrete Gaussian curvature of a curved surface



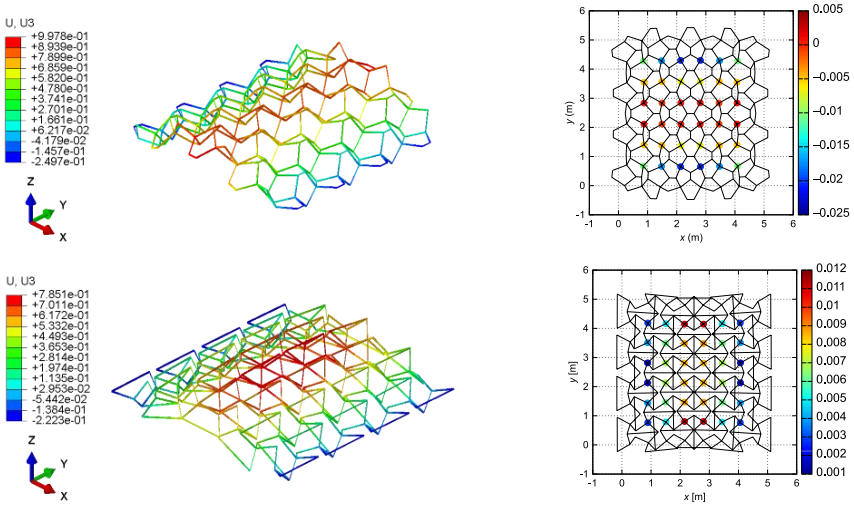


Figure 9. Quadrangular cone (grey) corresponding to a four-valent node on a surface, which is composed of four triangles for computing angle defect.

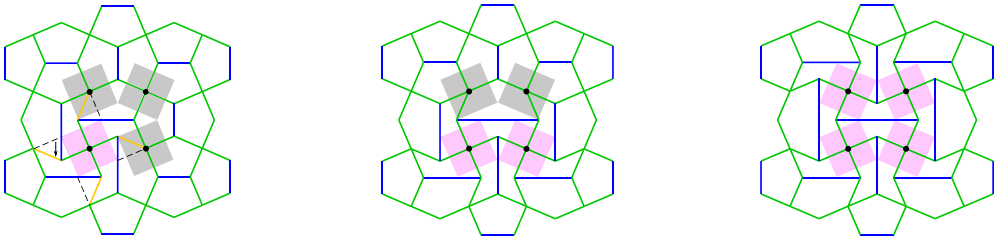
(a) (b)

Figure 10. Comparison of curved surfaces obtained by out-of-plane deformation from initial grids. The grids with positive and negative Poisson's ratios are shown in the upper and lower figures, respectively.: (a) deformed shapes with contour of *z*-directional displacement, (b) distribution of discrete Gaussian curvatures at nodes.

By carrying out large-deformation analysis, we investigate the deformed shape of a curved surface obtained from an initial grid. Loading parameter τ is linearly increased from 0.0 to 2.0 with the maximum time increment 1.0×10^{-2}. In the period $0.0 \leq \tau \leq 1.0$, upward artificial load equal to self-weight is applied to all members for avoiding the numerical difficulties due to bifurcation buckling. In the latter period from 1.0 to 2.0, we give the forced displacements at the supports along *x*-direction while applying downward artificial load equal to self-weight, and a shape of curved surface is obtained finally. As illustrated in Fig. 6(b), roller-supports that can move along *x*-direction and forced displacements given at roller-supports are represented by triangular marks and arrows, respectively.

To compute the discrete Gaussian curvature, we generate a quadrangular cone at a four-valent node on a polyhedral discrete surface, as outlined in Ref. [10]. To discretize a curved surface, we use triangulation, as illustrated in Fig. 9. Discrete Gaussian curvature can be computed as angle defect

$$2\pi - \sum_{i}^{4} \phi_i , \tag{2}$$



where ϕ_i ($i \in \{1, 2, 3, 4\}$) represents an internal angle of the *i*th triangle incident at a four-valent node.

Figure 10 compares the curved surfaces deformed from initial grids with positive and negative Poisson's ratios in the upper and lower figures, respectively. Figures 10(a) and (b) show a curved surface with contour of *z*-directional displacement and a distribution of discrete Gaussian curvature at four-valent nodes, respectively. A saddle shape is generated by out-of-plane deformation of the grid with a positive Poisson's ratio. As seen in the upper figure in Fig. 10(b), negative values of discrete Gaussian curvature are mainly distributed on a curved surface. By contrast, a dome-like shape is obtained, as shown in the lower figures, by largely deforming the pentagonal grid with negative Poisson's ratio. All values of discrete Gaussian curvatures at nodes except those on the boundaries are larger than 0. The results are consistent with the relationships between the sign of Poisson's ratio and that of Gaussian curvature based on plate theory [9].

4. Nonperiodic three-dimensional pentagonal grids

In terms of ease of design and fabrication, structural units consisting of mechanical metamaterials have usually periodic shapes. In this section, we present a nonperiodic three-dimensional pentagonal grid with both positive and negative Poisson's ratios. This extraordinary mechanical property can lead to generate a more complex free-form surface.

4.1. Shape design method based on the concept of geometrical frustration

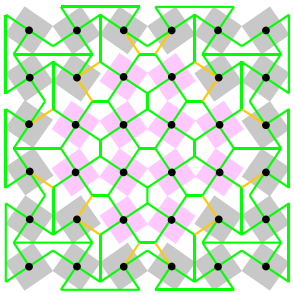
(a) (b) (c)

Figure 11. Nonperiodic three-dimensional pentagonal grids generated by introducing inverted structural units based on the frustrated rotating rigid squares (pink): (a) pentagonal grid composed of 4×4 structural units with an inverted unit and modified members (yellow) connecting units, (b) pentagonal grid with two inverted units, (c) pentagonal grid with four inverted units.

Based on the concept of geometrical frustration, which is an incompatible physical phenomenon or system due to its geometrical property [14], we design a nonperiodic three-dimensional pentagonal grid by assigning inverted structural units to the original periodic grid. Figure 11 shows several examples of

nonperiodic grids projected onto *xy*-plane. Frustrated rotating rigid squares, represented by pink square, are designed by inverting the sign of tilting ratio λ, and the corresponding inverted structural units are obtained. We delete the members represented by dotted lines and add the members represented by yellow segments, as shown in Fig. 11(a). Figures 11(b) and (c) are examples of nonperiodic grids with two and four inverted structural units, respectively. By inverting clustered structural units neighboring each other, we can design a nonperiodic pentagonal grid with multiple regions exhibiting different signs of Poisson's ratio.

4.2. Mechanical properties of nonperiodic grids under in-plane and out-of-plane deformations



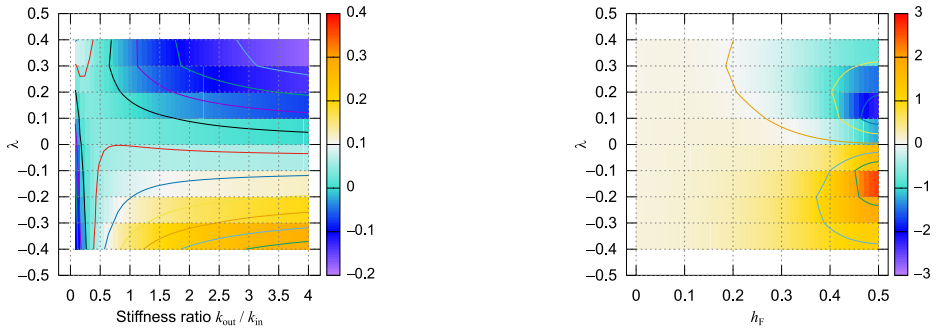


Figure 12. Example of a planar shape of the nonperiodic pentagonal grid used for the investigation of in-plane Poisson's ratio. Twelve inverted structural units are assigned to the center region of the original grid composed of 6×6 structural units.

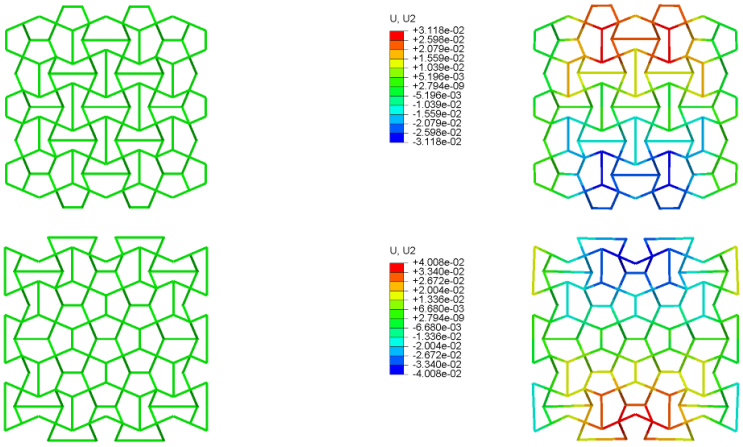
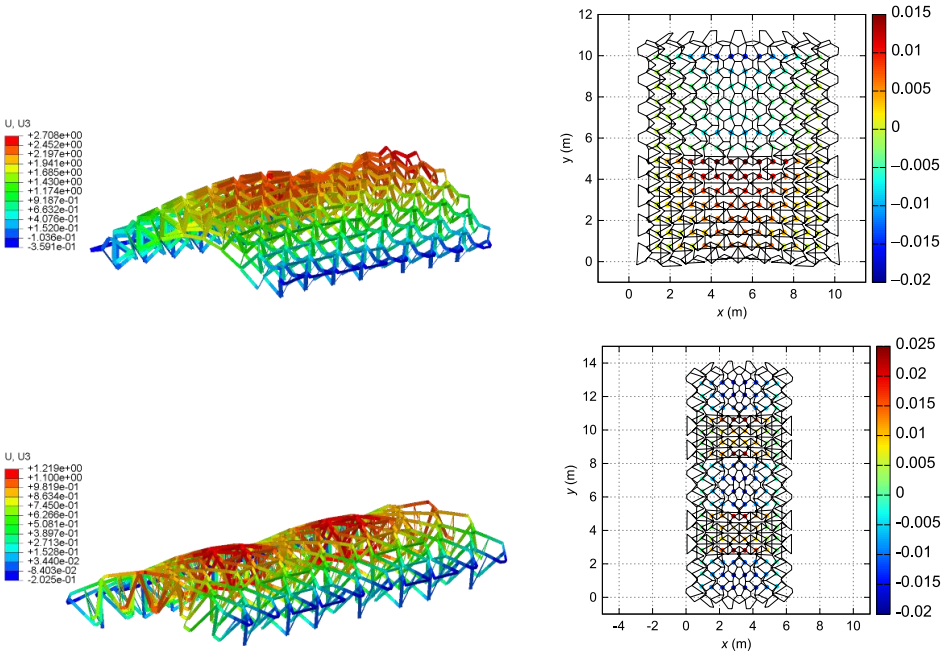


(a) (b)

Figure 13. In-plane Poisson's ratio (contour) of nonperiodic three-dimensional pentagonal grids specified as $\lambda \in \{-0.4, -0.3, \ldots, 0.4\}$ under elastic small tension: (a) bending stiffness ratios are varied in the range of $0.08 \leq k_{out}/k_{in} \leq 4.0$, (b) height of the four-valent vertices are changed in the range of $0.0 \leq h_F \leq 0.5$.

Nonperiodic three-dimensional pentagonal grids are generated to investigate their in-plane and out-of-plane mechanical properties. To compare the mechanical properties of periodic and nonperiodic pentagonal grids, the same in-plane deformation analyses are performed as detailed in Sec. 3.1. The geometrical shapes of nonperiodic pentagonal grids are designed by assigning twelve inverted units to the center region of the original periodic grid composed of 6×6 structural units, as illustrated in Fig. 12.

It is apparent from the results in Fig. 13 that the sign of Poisson's ratio tends to be negative and positive when λ is positive and negative, respectively. These results are different from those of the original periodic grids, as shown in Fig. 7. It seems possible that these results may be due to the arrangement of inverted structural units.



(a) (b)

Figure 14. Comparison of in-plane deformations of nonperiodic pentagonal grids with positive and negative Poisson's ratios in the upper and lower figures, respectively: (a) initial shape, (b) deformed shape projected onto *xy*-plane with contour of *y*-directional displacement.

Table 2. Values of shape parameters for Cases 3 and 4.

	Num. of units	λ	h_F	d_T	t_b	t_h
Case 3	16×16	0.35	0.3	0.5	0.02	0.15
Case 4	10×20	0.4	0.5	0.5	0.02	0.10

(a) (b)

Figure 15. Curved surfaces deformed from nonperiodic pentagonal grids: (a) deformed shapes with contour of *z*-directional displacement, (b) distributions of discrete Gaussian curvatures at four-valent nodes.

Figure 14 shows the in-plane deformation behaviors of 6×6 nonperiodic pentagonal grids with twelve inverted units. The tilting ratios of initial shapes of the original periodic grids in the upper and lower figures are $\lambda = 0.3$ and -0.3, respectively. The contour represents *y*-directional displacement of members. The inverted structural units assigned to the center region of the original grid affect deformation behaviors for both examples, because the deformed shapes in the upper and lower figures are similar to those of the structures with negative and positive Poisson's ratios, respectively.

Furthermore, a curved surface composed of nonperiodic pentagonal grid is obtained by performing large-deformation analysis, as detailed in Sec. 3.2. This section presents several numerical examples and distributions of discrete Gaussian curvature at four-valent nodes. Table 2 provides the shape parameters for designing the initial shapes of 16×16 and 10×20 nonperiodic pentagonal grids in Cases 3 and 4, respectively. Figure 15 shows the obtained surfaces with contour of *z*-directional displacements of members and distributions of discrete Gaussian curvatures.

In Case 3, we obtain a curved surface combined with dome-like shapes and saddle shapes, which are deformed from the nonperiodic pentagonal grid with negative and positive Poisson's ratios, respectively. The upper figure in Fig. 15(b) illustrates the distribution of positive and negative values of discrete Gaussian curvature on the two regions exhibiting negative and positive Poisson's ratios, respectively. Similarly, a curved surface in Case 4 has a more complex shape composed of dome-like and saddle shapes distributed alternately. The sign of discrete Gaussian curvatures is also dependent on the corresponding regions, as shown in the lower figure in Fig. 15(b). The results presented in this section demonstrate that designing a nonperiodic pentagonal grid allows for the generation of a desirable distribution of the sign of Poisson's ratio and Gaussian curvature.

5. Conclusions

This paper introduces a new class of bending-active mechanical metamaterials based on a three-dimensional pentagonal grid inspired by penta-graphene. The values of Poisson's ratio for in-plane deformation of the proposed metamaterial can be tailored in a broad range.

We present a design method for a geometrical shape of the pentagonal grid derived from a dual geometry of rotating rigid squares. The cross-sectional sizes t_h and t_b of a bending flexible beam are utilized as parameters for exploring the values of Poisson's ratio, because these parameters determine the bending stiffness of a beam, which plays an important role of designing a bending-active structure. As seen in Fig. 7(b), the *z*-directional coordinate of four-valent node significantly affect the absolute value of Poisson's ratio. To measure qualitatively the convexity and concavity at four-valent nodes on a curved surface, the values of discrete Gaussian curvature are computed as angle defect. Dome-like and saddle shapes are obtained from the three-dimensional pentagonal grids with negative and positive Poisson's ratios, respectively.

Based on the concept of geometrical frustration, a nonperiodic pentagonal grid can be easily designed. We can obtain a desirable distribution of the sign of Poisson's ratio by assigning inverted structural units to the original periodic grids. It is verified, in the numerical examples, that our method enables us to generate a curved surface with multiple regions exhibiting positive and negative Gaussian curvatures. Three-dimensional pentagonal grid can be a superior structural system for constructing various free-form surfaces deformed from initial grids.
