Integration of Design and Fabrication

Proceedings of the International Association for Shell and Spatial Structures Annual Symposium 2023

IASS 2023
July 10–14 Melbourne
Integration of Design and Fabrication

Preface

The International Association for Shell and Spatial Structures (IASS) symposia are a unique forum for engineers, architects and researchers to exchange exciting ideas and latest developments in the field of shell and spatial structures. The IASS symposia have been successfully held for over 60 years in various countries such as Brazil, China, Germany, Japan, the Netherlands, Poland, South Korea, Spain, the UK and the USA.

After three years of travel restrictions due to the worldwide COVID-19 pandemic, it is wonderful that the IASS community is able to meet face-to-face again, this time in Melbourne, Australia. The theme of the IASS 2023 symposium is *Integration of Design and Fabrication*, which is becoming an increasingly important topic with the rapid developments of digital technologies in both design and manufacturing.

The present proceedings contain a collection of 246 papers on various aspects of design, analysis, construction and maintenance of shell and spatial structures.

The editors would like to take this opportunity to thank all authors for submitting their contributions, the Scientific Committee for reviewing the abstracts and full papers, the sponsors and supporters for their generous support, and the Organising Committee and many other people for their tireless effort in making the symposium a success.

Yi Min Xie, Jane Burry, Ting-Uei Lee, Jiaming Ma

Committees

Local organising committee

Yi Min 'Mike' Xie (Co-Chair, RMIT University)
Jane Burry (Co-Chair, Swinburne University)
Ding Wen 'Nic' Bao (RMIT University)
Sascha Bohnenberger-Fehr (Swinburne University)
Canhui Chen (Swinburne University)
Sofia Colabella (The University of Melbourne)
Joe Gattas (The University of Queensland)
Ting-Uei 'Jeff' Lee (RMIT University)
Peter Lim (Lightweight Structures Association of Australasia)
Guoxing Lu (Swinburne University)
Dan Luo (The University of Queensland)
Jiaming Ma (RMIT University)
Nico Pietroni (University of Technology Sydney)
Alberto Pugnale (The University of Melbourne)
Tim Schork (Queensland University of Technology)
Mary Tomlinson (RMIT University)

International advisory committee

Görün Arun (Turkey)
Alireza Behnejad (UK)
Ken'ichi Kawaguchi (Japan)
Olga Popovic Larsen (Denmark)
Carlos Lázaro (Spain)
Juan Gerardo Oliva Salinas (Mexico)
Sergio Pellegrino (USA)
Jenny Sabin (USA)
Su-Duo Xue (China)

Scientific committee

Karim Abedi (Iran)
John F. Abel (USA)
Sigrid Adriaenssens (USA)
Masoud Akbarzadeh (USA)
Nayar Gutierrez Astudillo (Mexico)
Ding Wen 'Nic' Bao (Australia)
Minghao Bi (Australia)
Annette Boegle (Germany)
Dan Bomba (UK)
Andrew Borgart (Netherlands)
Maurizio Brocato (France)
Peter Von Buelow (USA)
Jane Burry (Australia)
Michael Burt (Israel)
Jianguo Cai (China)
Wujun Chen (China)
Yao Chen (China)
Zhihua Chen (China)
John Chilton (UK)
Kok Keong Choong (Malaysia)
Paolo Cignoni (Italy)
Jeroen Coenders (Netherlands)
Pierluigi D'Acunto (Germany)
Fevzi Dansik (Turkey)
Raj Das (Australia)

Contents

Active bending 17
Calculation method for restoring force of member and deformation occurred by in curved surface combined with flat plates and bolts
Daichi MORI, Keisuke NOMURA, Shigehiro MOROOKA 18
Expanding the design freedom of spatial patterns by combined elastic bending and twisting: a parametric study
Fereshteh KHOJASTEHMEHR, Günther H. FILZ 28
Interlocking connections for bending-active timber structures with variable stiffness
Maren ZYWIETZ, Annette BÖGLE, Ehsan TAGHIYAR 40
Investigation of cross-sections for hybrid gridshells based on bending-active formwork
Yasaman YAVARIBAJESTANI, Michael HERRMANN, Khalid M. MOSALAM, Simon SCHLEICHER 51
Study on shape control method for active bending arch structures using kerf bending technique
Yuki OZAWA, Akihito YOKOTA, Satoshi OHKI 61
Additive manufacturing/ 3D printing 70
4D printed textile formwork for robotic concrete spraying
Guillaume JAMI, Selen Ercan JENNY, Chenguyan WEI, Hamilton FORSYTHE, Nicolas FEIHL, Skylar TIBBITS, Ena LLORET-FRITSCHI 71
Additive manufacturing of fully recyclable walls solely made from renewables – a possible quantum leap in sustainable building construction
Benjamin KROMOSER, Bernhard REINHOLZ, Roman MYNA, Sara REICHENBACH, Falk LIEBNER, Rupert WIMMER 83
Additively manufactured steel joints for structural frames: concept proposal and numerical simulations
Seyed Pouya AFSHAR IMANI, Mani KHEZRI, Kim J.R. RASMUSSEN 90
An assembly-oriented novel low-carbon masonry building method with unfired 3D printed earthen blocks
Yelda GIN, Darshil U. SHAH, Michael H. RAMAGE 102
Continuous fibre additive manufacturing of topological spatial lattices for fabrication-aware design processes
Eduardo CHAMORRO, Mark BURRY, Mathilde MARENGO 114
Continuous multi-filament 3D printing for tension-compression structure components
Teng TENG, Yefan ZHI, Kun-Hao YU, Shu YANG, Masoud AKBARZADEH 126
Design optimization workflow for 3D concrete printing of spanning structures
Gonçalo DUARTE, Jose Pinto DUARTE, Nathan C. BROWN, Ali MEMARI, Shadi NAZARIAN 139
Digital Ceramics: High hyperbolic curvature fabrication technologies in paste-based additive manufacturing
Philip F. YUAN, Lei GONG 151
Liquid printed reusable dredged-based material for concrete formwork
BoSheng LIU, Tzu-Hsien LO, Cheng-Hsuan YEH 163
Local optimization of self-supporting shell structures in 3D printing: a skeleton method
Yefan ZHI, Hua CHAI, Teng TENG, Masoud AKBARZADEH 171
Model test of sunflower triple-strut cable dome structure with metal additive manufacturing nodes
Yang ZHAO, Ruolan FAN, Zhen WANG, Ruhao WANG, Shilin DONG 182
Rapid fabrication system for large-scale free-form double curved shell
Zhuoyang XIN, Guanqi ZHU, Dan LUO 189
Architectural geometry 199

A multi-objective progressive optimization method for free-form canopy based on fabrication morphology
Sijia GU, Li HAN, Philip F. YUAN 200
Designing the West Gate Tunnel portals: Timber gridshells
Andre F. PEREIRA, Benjamin COOP, Dmitry ZELENKIN, Richard WHITFIELD, Kevin BERRY 210
Form dictated by material-specific properties of a mycelium composite
Dana SAEZ, Alexandra BERTSCH, Denis GRIZMANN, Martin TRAUTZ, Anett WERNER 224
Rethinking geometry of grapevine structure proposed by Konrad Wachsmann
Tsubasa INOUE, Toshiaki KIMURA, Yosuke KOMIYAMA, Satoru KIMURA 235
Shape generation of hexagonal lattice shell consisting of edge offset mesh
Ryo WATADA, Makoto OHSAKI 244
Structural features of Dong'an lake stadium roof
Yuan FENG, Quan ZHOU, Xin An XIANG, Wen Ming CHEN, Li YAO 251
Bamboo for sustainable construction and quality of life improvement 264
Experimental evaluation of load-induced cracking in moso bamboo tubes
Dan V. BOMPA, S. Alireza BEHNEJAD, Holmer SAVASTANO Jr, Arash AZADEH, Moe POURGHAZ 265
Preliminary study on relationship between culm morphology and mechanical characteristics of Japanese bamboo
Takuo NAGAI 277
Study on compression strength of Japanese full-culm bamboo columns using short-length specimens
Keisuke OKI, Takuo NAGAI 288
Bio-inspired structures and architecture 297
Comparison of four current low-density concrete technologies emphasis on the criteria's of performance, fabrication, and mixtures
Ferdinand OSWALD, Richard HENRY, Djordje NIKOLIC 298
Vibration analysis of the real shaped bi-valve shell model created by CT images
Minori OGOSHI, Masaki TERANISHI 310
Bridge structures 318
Innovative design of a pedestrian bridge using multi-material topology optimisation
Yaping LAI, Yu LI, Peixin CHEN, Yanchen LIU, Lijun ZHAO, Jin LI, Yi Min XIE 319
Integrated bridge structure design process through finite element analysis (FEA) and pixel-based visibility culling method
Ana Gabriela LOAYZA, Taeyong KIM 331
Computational form-finding 341
A BESO aid to efficient form finding
Izak LEE, Andre BROWN 342
A novel approach to generating diverse and competitive structural designs through load perturbation in topology optimisation
Yulin XIONG, Hongjia LU, Yi Min XIE 348
A numerical comparison between geometric stiffness- and elastic stiffness-based structural shape optimization for gridshells
Gaoyuan WU, Rafael PASTRANA, Sigrid ADRIGENSSENS, Maria E. Moreyra GARLOCK 360
Cognitive multi-pattern gridshell design: a method inspired by weaverbirds' nest building strategies
Mohammad Hassan SALEH TABARI, Günther H. FILZ 373
Computational conceptual design – typological exploration of spatial truss systems through optimization
Jonas WARMUTH, Pierluigi D'ACUNTO, Corentin FIVET 385
Form finding for post tensioned, 3D printed fluid containers
Patrick SCHÄFERLING, Matthias BECKH 395
Form finding of tensile membrane structures by solving the generalized laplace equation using physics informed neural network
Sounak KABASI, Allan L. MARBANIANG, Siddhartha GHOSH 407
Form-finding of membrane structures using transfinite interpolated initial shapes
Allan L. MARBANIANG, Sounak KABASI, Siddhartha GHOSH, Subhrajit DUTTA 414

Generation of a compression-tension combined funicular polyhedral beam structure
Hua CHAI, Yao LU, Ma´rton HABLICSEK, Masoud AKBARZADEH 423
Graphic statics and topology optimization: An integrated approach to designing architecture structures
Xinjie ZHOU, Yu LI, Philip F. YUAN 432
Conceptual design 444
Conceptual design and parametric modelling of pretensioned stiffened membranes
Iuliia LEBEDEVA, Martin F. EICHENAUER, Peer HALLER 445
Structural design of flat and spiral buildings with inclined pillars
Ken NODA, Yoshiharu KANEBAKO 459
Concrete structures 469
A group-theoretic approach for constructing spherical-interlocking assemblies
Reymond AKPANYA, Tom GOERTZEN, Alice C. NIEMEYER 470
Influence of biochar in alkali-activated slag composites upon engineering properties and impact resistance
Harshani EGODAGAMAGE, Hiran YAPA, Satheeskumar NAVARATNAM, H.A.D. Samith BUDDIKA, Kate NGUYEN 482
Construction techniques 494
Anti-fragile shell aggregations on the moon
Xavier DE KESTELIER, Levent OZRUH, Jonathan IRAWAN 495
Cast glass arches, vaults and domes: case studies and design methodology
Telesilla BRISTOGIANNI, Faidra OIKONOMOPOULOU 507
Enhancing construction of complex compression-based structures through holographic-assisted assembly
Ertunç HÜNKAR, David LEE 519
Fabrication methods for topology-optimized massive glass structures
Faidra OIKONOMOPOULOU, Menandros IOANNIDIS, Anna Maria KONIARI, Telesilla BRISTOGIANNI 531
Inflatable flexible factory formwork construction: most recent construction techniques and details
Alex Morgan BELL, Tyler ROBINS 543
Research on digital design and optimisation method for large-scale reciprocal frame structure: The case of Chengdu agricultural expo exhibition hall
Philip F. YUAN, Tianyi GAO, Yingzi HU, Liming ZHANG 555
Study on the dismantling method of cable-strut tension structures
Jiaqi YANG, Yue WU, Guangyao XIN 567
Deployable and inflatable structures 578
A foldable modular structure unit inspired by kirigami
Zafira Nur Ezzati MUSTAFA, Kok Keong CHOONG, Jae-Yeol KIM 579
Comparison of biologically inspired functionally graded deployable geosystems with experimental measurements
Ann C. SYCHTERZ, Kaylee A. TUCKER 587
Manual deployment and shape determining method of guide frame for tunnel inspection by force control
Fumihiro INOUE, Momoe TERATA, Shu LI, Suzuno FUKUNAGA, Satoru NAKAMURA 599
Modular design of multistable pneumatic structures from a flat pattern of air pouches
Yiwei ZHANG, Tomoya TENDO, Tomohiro TACHI 608
Section design and performance optimization of C-cross section thin-walled deployable boom
Fengyuan LIU, Minger WU, Ping XIANG 620
Surface accuracy analysis and test on 0.5 m aperture wrap-rib deployable antenna
Han ZHANG, Minger WU, Ping XIANG 632
Design competition (WG21) 644
A reconfigurable construction system based on hypar timber components
Markus HUDERT, László MANGLIÁR 645
Clustering and optimisation of nodes, beams and panels for cost effective fabrication of free-form surfaces
Minghao BI, Yuanpeng LIU, Yi Min XIE 652
Constructing topologically optimized spatial structure using innovative mortise-and-tenon joints
Xin YAN, Ding Wen BAO, Congcong REN, Yi Min XIE 664

Controlling frills of bending-active negative curvature surface
Fuki ONO, Miwako KASE, Kotaro SEMPUKU, Mizuki SHIGEMATSU, Hiroki TAMAI, Seri NISHIMOTO, Tomohiro TACHI 676
Coupled thick-panel origami tubes along creases for stiff deployable structures
Sunao TOMITA, Kento SHIMANUKI, Kazuhiko UMEMOTO, Atsushi KAWAMOTO, Tsuyoshi NOMURA,Tomohiro TACHI 688
Triply periodic discrete surface of constant negative curvature constructed from one type of piece
Kanata WARISAYA, Seri NISHIMOTO, Toshiyuki MORISHIMA, Tomohiro TACHI 697
Digital modelling and fabrication 706
A novel modular technique for manufacturing free-form rammed earth walls
Ahmed ABDELAAL, Mohamed GOMAA, Yi Min XIE 707
Complex digital modelling for low-cost construction of East African vernacular architecture
Joanna Maria LESNA, Xavier de KESTELIER 719
Design and construction complex shell structure using U-shaped glass and steel frame with collaborative robotics and human expertise
Lei YU, Guanqi ZHU 730
Digital design, optimisation and automated construction of a curved wooden truss – housing for the BOKU Robot Laboratory
Benjamin KROMOSER, Maximilian ORTNER, Matthias BRAUN 742
Digitization and construction of steel-frame double curvature façade with a spatial element: with the example of Chongqing Center for Planning and Exhibition
Philip F. YUAN, Menghao YUAN 754
Generative design of isostatic ribbed slabs using anisotropic Reaction-Diffusion
Alessandro ZOMPARELLI, Roberto NABONI 766
Guided irregular cement geometry stacking using real-time optimization and motion tracking
Alex ORSHOLITS, Ren IMAI, Hirotaka UJIOKA, Shimpei KOJIMA, Mika ARAKI, Yusuke OBUCHI, Jun SATO 778
KNOTSHELL pavilion – Development of a low-tech approach for transferring complex digital data to building elements
Kristina Viktoria KRÖLL, Alec Bikramjit SINGH, Felipe RIOLA-PARADA 790
Morphogenesis method for thin metal plate with non-uniform stiffness distribution by applying auxetic mechanism
Hirotaka UJIOKA, Mika ARAKI, Kai MORINAGA, Masaaki IWAMOTO, Yuri IWATA, Akitoshi IWAMOTO, Miki KATSUKI, Hanano TANAKA 802
Nonlinear analysis of multi-scale coupling based on coordinated distributing method
Junjie YAO, Yanfeng ZHENG, Yaozhi LUO 814
Optical parametric component referencing for the facilitated prefabrication of timber wall elements
Felix SCHMIDT-KLEESPIES, Laurenz ANDRITZ, Cristoph DIJOUX, Alexander STAHR 824
Process simulation for enhancing self-supporting printability in 3D curvature-oriented clay form printing with an additional-axis base
Xuanyu LU, Yasushi IKEDA, Arastoo KHAJEHEE, Koki ITO 834
Sequential augmented assembly of interlocking timber elements for circular wood construction
Nima ZAHIRI 847
Structural design and construction of a large building with a 3D 'circle truss' and ETFE membrane roof
Idogawa TATSUYA, Miyasaka TAISUKE, Ueda MASAHIRO, Komiya MASAYA, Kurata TAKASHI 859
Towards upscaling membrane tensegrity shells: A design-to-fabrication workflow
Ying Yi TAN, Kenneth J. TRACY, Christine YOGIAMAN 871
Xtect: a digital intelligence platform for off-site prefabricated construction
Jackie Leong Shong YONG, Wanyu HE, Lei GU, Peiwen LI, Ying WANG 881
Dynamic response of metal spatial structures 892
Collapse mechanism under strong earthquake and seismic design of single-layer aluminum alloy latticed shells
Jinzhi WU, Yu LIU, Guojun SUN, Jianhua ZHENG, Miao FENG, Yigang ZHANG, Jie HU, Yafang GU, Xianquan CHANG 893
Influence of axial force on the dynamic response of the aluminum foam-filled 6082-T6 aluminum tube under lateral impact
Ximei ZHAI, Lingzhao MENG, Guangming CUI 905

Mechanical properties of the curvature-consistent frictional pendulum isolation system and vibration control of spherical reticulated shell
Niyi LIANG, Xudong ZHI 916
Seismic force reduction factor evaluation for double-layered domes supported by single-story substructures
Yuki TERAZAWA, Haruna SHIJO, Deepshikha NAIR, Toru TAKEUCHI 927
Seismic response modification factors of space structures in the horizontal and vertical directions
Mehdi POURSHA, Karim ABEDI, Hamed JAFARZADEH, Pouya HEIDARIAN, Ali ABDOLLAHI 937
Study on finite element numerical simulation of seismic response of suspended-dome structure
Guojun SUN, Shuo XIAO, Xiongyan LI, Cong ZHANG, Jinzhi WU, Suduo XUE 949
Dynamic response of other structures 961
Modal identifications of a scaling stratospheric airship in still air
Longlong CHEN, Wujun CHEN 962
Form-finding and structural optimisation of interlocking discrete assemblages 970
Chain mail assembly: a new model of programmable modular structure

Abstract

Morooka et al. proposed a method of creating a curved surface structure by stacking multiple bent flat plates and bolting them together. The shape of the plates is determined by dividing the targeted original surface, but there are differences between the model created by this method and the original surface. The purpose of this study is to investigate the cause of the difference in the shapes and to examine a division method to minimize the difference. In this method, the plates are elastically bent, and a restoring force is generated to recover the shape before bent. The restoring force acts on the next overlapping plate from the holding bolts, causing the plates to be deformed differently from the target shape. The restoring forces on all the plates, and their interaction with each other, are assumed to cause the shape difference. The validity of this assumption was confirmed by comparing the shape differences measured from the model with the displacements obtained by numerical analysis considering the restoring force. The restoring force was the reaction force obtained by forcibly deforming a single plate member to a target bending shape. The displacements were obtained by numerical analysis with the analytical model in which all plates were applied with the restoring force. On the other hand, the flat plate shape of the model depends on the division shape of the original surface, and the restoring force also changes when the division shape is changed. A general equation for the restoring force that considers the effect of the flat plate shape was developed by geometrical parametric study. By using the equation, the restoring force can be obtained even if the division shape is changed, and the displacement considering the restoring force can also be obtained. Division shapes with reduced displacement were explored.

Keywords: curved surface structure, restoring force, shape difference, numerical analysis, large deformation analysis

1. Introduction

Morooka[1] proposed a method of creating curved structures by stacking bent flat members and securing them with bolts. Figure 1 shows the steps for creating a curved surface structure. First, create the target curved surface, and then divide it into triangular facets to make it suitable for tessellation. Project the triangular elements onto a plane, and then connect neighboring elements to create quadrilateral elements. At this point, duplicate elements are allowed. Create thin flat material quadrilateral elements, overlap the common triangular parts, and secure them with bolts. Repeat this process, and gradually bend each element to create a curved structure that closely matches the target curved surface. This is a method for creating a curved structure. In this structure, the shape error that arises between the target curved surface and the model varies depending on factors such as the shape of the target curved surface, the dividing rules, and the materials used. This makes it difficult to predict the shape of the model. While it is

Copyright © 2023 by Daichi MORI, Keisuke NOMURA and Shigehiro MOROOKA. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

impossible for the shape of the model to perfectly match that of the target curved surface, it is necessary to have a method for predicting the degree of error.

Murata [2] thought that if he divided a bent flat member so that the restoring force, which is the force that returns it to its original shape, would be small, the differences in shape would also be small. However, there is a possibility that the mechanical model used to determine the restoring force does not follow the behavior of bending the flat plate during model creation. On the other hand, Watanabe [3] created a model by unifying the division rules with multiple curved surfaces and examined the correlation between the evaluation values created by the width of the member and the bending angle and the differences in shape. However, unlike Murata, Watanabe's evaluation values do not have a physical meaning, and when the division rules differ, they are not correlated.

From the above, the authors have studied a method to estimate shape error before creating a model by numerical analysis. In the model using this method, members are forcibly deformed in bending from a flat state, and the shape after deformation is maintained by restraining them with overlapping members and bolts. At this time, the bent flat plate generates a restoring force that tries to return it to its original flat shape. This restoring force acts on each plate through the bolt, deforming each plate and resulting in a shape error. In order to verify the validity of this idea, in this paper, an analytical model of the polyhedron after division is analyzed by applying a restoring force, and the shapes after deformation are compared with those of the model. The restoring force in this case is considered to be the force required to forcibly deform each flat plate member into the shape of the polyhedron. Section 2 of this paper describes how the model was constructed, and Section 3 describes the formulation of the formula for calculating the restoring force. Section 4 compares the deformed shapes by numerical analysis with those of the model and discusses the validity of the ideas presented in this paper.

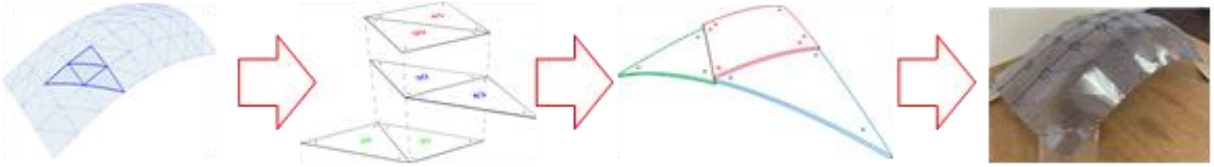

Figure 1. Assembly produce

2. Curved surface structure creation method using flat plates and bolts

2.1. Creation of 3D models and drawings

This section describes how to create a model using this method. Create a design plan for a model based on a 3D model. First, create a curved surface of the desired shape as shown in Figure 2. Next, divide the target surface into a polyhedron with triangular faces, as shown in Figure 3. Finally, project the triangular elements of the polyhedron onto a plane and create quadrilateral elements by connecting all combinations of adjacent triangles. As shown in Figure 4, the layers are divided considering the order of layering. After the bolt positions are determined, the design diagram of the model can be created. Note that the bolt positions are the intersections of the lines offset from each boundary side of the triangular elements by an arbitrary distance.

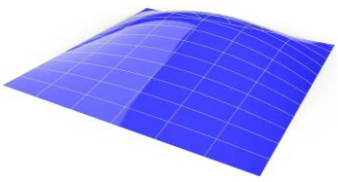

Figure 2. Curved surface

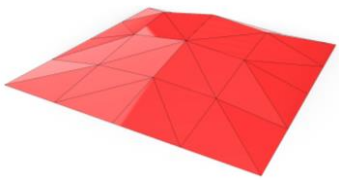

Figure 3. Divide a curved surface

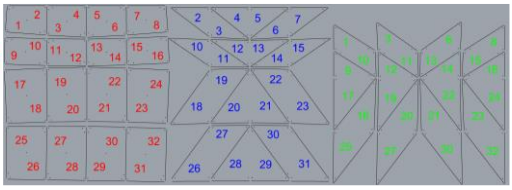

Figure 4. design drawing of the model

with triangular elements

2.2. Assembling the model

Cut out the flat plate member as shown in the design drawing in Fig. 4. Also, as shown in Figure 5, the cutting process and drilling of holes for bolts will be performed by CNC. Overlap the common triangular components of the flat components and fasten them with bolts as shown in Figure 6. Furthermore, to prevent interference between the stacked flat components when they bend, place two washers between the flat components.

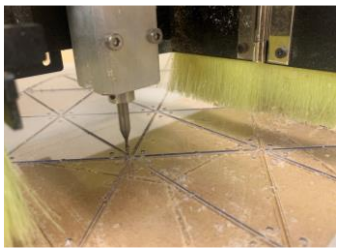

Figure 5. Cutting and drilling

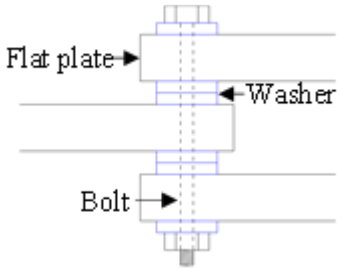

Figure 6. How to fasten flat plate members

Figure 7. Bent flat plate member

3. Formula for calculating restoring force

3.1. Concept of restoring force

The restoring force of a bent flat plate member is considered to be the force required to bend the plate, in order to return it to its original flat shape. Moreover, since each flat plate member is fixed by bolts, the restoring force was considered at the bolt position. Therefore, the restoring force was calculated as the force required to deform the plate member to a certain angle at the bolt positions. In the next section, we will describe the formulation of the calculation formula.

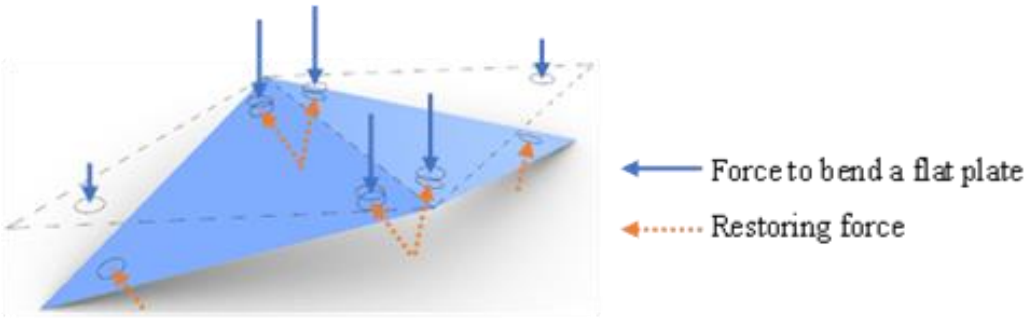

Figure 8. Concept of restoring force

3.2. Formula for calculating restoring force

The figure 9 shows a mechanical model for calculating the equation of the restoring force. We assumed one of the triangular element parts of the flat plate member as a cantilever beam and applied a concentrated force at each bolt position. The triangular elements are isosceles triangles. We define the distance from the joint of the triangular elements to the nearest bolt as l_1, the distance to the furthest bolt as l_2, and the distance between them as l_3. Calculate the force required to bend the flat component to a displacement of δ_1 and δ_2 at the bolt positions, which is represented as P_1 and P_2, respectively. Assuming that P_1 and P_2 are obtained from the shape of the polyhedron, δ_1 and δ_2 were determined using the normal angles θ between the triangular elements of the polyhedron and the distances l_1 and l_2 to the bolt positions as equation (1). (See Figure 10.)

$$\delta_1 = \frac{l_1}{\cos\theta}$$
$$\delta_2 = \frac{l_2}{\cos\theta} \tag{1}$$

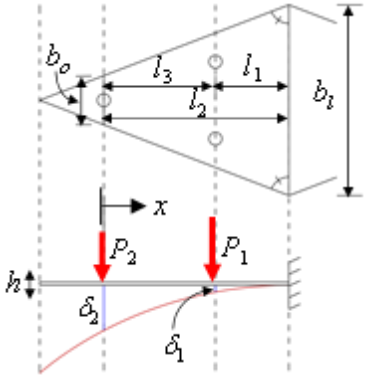

Figure 9. Mechanical model

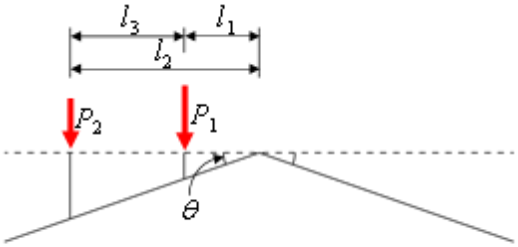

Figure 10. Size of δ_1 and δ_2

The calculation formulas for P_1 and P_2 were derived by solving the differential equation represented as equation (2) based on the theory of beams and arranging the solutions for P_1 and P_2.

$$\frac{\partial^2 \delta(x)}{\partial x^2} = -\frac{M(x)}{EI(x)} \tag{2}$$

Here, $\delta(x)$ is the deflection equation, $M(x)$ is the bending moment equation, E is the Young's modulus, and $I(x)$ is the cross-sectional quadratic moment equation at the deformed section. As shown in Figure 9, assuming the width of the fixed end side to be b_l, the width at the far bolt position to be b_o, and the thickness of the plate to be h, $I(x)$ can be expressed as equation (3).

$$I(x) = \frac{(\alpha x + \beta)h^3}{12}$$
$$\alpha = \frac{b_l - b_o}{l_2} \tag{3}$$
$$\beta = b_o$$

Additionally, the bending moment equation $M(x)$ can be expressed as equation (4).

$$M(x) = \begin{cases} -P_2 x & \text{if } 0 \le x \le l_3, \\ -(P_1 + P_2)x + P_1 l_3 & \text{if } l_3 \le x \le l_2 \end{cases} \tag{4}$$

Furthermore, equation (5) can be considered as the boundary conditions for deflection and deformation angle.

$$\begin{aligned}
&\theta(l_2) = 0 \\
&\delta(l_2) = 0 \\
&\theta(l_3)_{:0\le x\le l_3} = \theta(l_3)_{:l_3\le x\le l_2} \\
&\delta(l_3)_{:0\le x\le l_3} = \delta(l_3)_{:l_3\le x\le l_2}
\end{aligned} \tag{5}$$

From the above, by solving the differential equation in equation (2), the deflection equation can be expressed as equation (6).

$$\delta(x) = \begin{cases} \dfrac{12P_2}{Eh^3}\left\{\dfrac{\alpha x\{\alpha(2\alpha C_1 + x) + 2\beta\} - 2\beta(\alpha x + \beta)\log(\alpha x + \beta)}{2\alpha^3} + C_2\right\} & \text{if } 0 \le x \le l_3, \\ \dfrac{12(P_1 + P_2)}{Eh^3}\left\{\dfrac{\alpha x\{\alpha(2\alpha C_3 + x - 2\zeta) + 2\beta\} - 2(\alpha x + \beta)(\beta - \alpha\zeta)\log(\alpha x + \beta)}{2\alpha^3} + C_4\right\} & \text{if } l_3 \le x \le l_2 \end{cases} \tag{6}$$

Here

$$C_1 = \frac{P_1 + P_2}{P_2}\left\{\frac{(\alpha\zeta - \beta)\log(\alpha l_3 + \beta) + \alpha l_3}{\alpha^2} + C_3\right\} - \left\{\frac{\alpha l_3 - \beta\log(\alpha l_3 + \beta)}{\alpha^2}\right\}$$

$$C_2 = \frac{P_1 + P_2}{P_2}\left[\frac{\alpha l_3\{\alpha(2\alpha C_3 + l_3 - 2\zeta) + 2\beta\} - 2(\alpha l_3 + \beta)(\beta - \alpha\zeta)\log(\alpha l_3 + \beta)}{2\alpha^3} + C_4\right]$$
$$- \frac{\alpha l_3\{\alpha(2\alpha C_3 + l_3) + 2\beta\} - 2\beta(\alpha l_3 + \beta)\log(\alpha l_3 + \beta)}{2\alpha^3}$$

$$C_3 = -\frac{(\alpha\zeta - \beta)\log(\alpha l_2 + \beta) + \alpha l_2}{\alpha^2}$$

$$C_4 = -\frac{\alpha l_2\{\alpha(2\alpha C_3 + l_2 - 2\zeta) + 2\beta\} - 2(\alpha l_2 + \beta)(\beta - \alpha\zeta)\log(\alpha l_2 + \beta)}{2\alpha^3}$$

$$\zeta = -\frac{P_1 l_3}{P_1 + P_2}$$

Assuming the displacement of the bolt position as δ_1 or δ_2,

$$\begin{aligned}
&\delta(0) = \delta_2 \\
&\delta(l_2) = \delta_1
\end{aligned} \tag{7}$$

From this, solving for P_1 and P_2, the formula for calculating the restoring force can be expressed as equation (8).

$$\begin{aligned}
P_1 &= \frac{F_3G_2 - F_2G_3}{F_1G_2 - F_2G_1} \\
P_2 &= \frac{F_3G_1 - F_1G_3}{F_2G_1 - F_1G_2}
\end{aligned} \tag{8}$$

Here

$$F_1 = \left\{\frac{l_3}{\alpha} - l_3D_3 - \frac{D_1D_2}{\alpha^2} - D_5\right\}l_3 + \left\{l_2D_4 + \frac{l_3^2}{2\alpha} + \frac{\beta l_3}{\alpha^2} - \frac{\beta D_1D_2}{\alpha^3} + D_6\right\}$$

$$F_2 = \left\{ l_3 D_4 + \frac{l_3^2}{2\alpha} + \frac{\beta l_3}{\alpha^2} - \frac{\beta D_1 D_2}{\alpha^3} + D_6 \right\}$$

$$F_3 = \frac{E h^3 \delta_1}{12}$$

$$G_1 = -\frac{\beta D_1 D_2}{\alpha^3} + \frac{\beta l_3 (1 + D_2)}{\alpha^2} - \frac{l_3^2}{2\alpha} + D_6 - \left(\frac{D_1 D_2}{\alpha^2} - \frac{l_3 (1 + D_2)}{\alpha} + D_5 \right) l_3$$

$$G_2 = -\frac{\beta D_1 D_2}{\alpha^3} + \frac{\beta l_3 (1 + D_2)}{\alpha^2} - \frac{l_3^2}{2\alpha} + D_6 + \frac{\beta}{\alpha^3} (\alpha l_3 + \alpha l_3 D_2 - D_1 D_2) - \frac{l_3^2}{2\alpha} - \frac{\beta^2}{\alpha^3} \log(\beta)$$

$$G_3 = \frac{E h^3 \delta_2}{12}$$

$$D_1 = \alpha l_3 + \beta$$

$$D_2 = \log(\alpha l_3 + \beta)$$

$$D_3 = \frac{-\log(\alpha l_2 + \beta)}{\alpha}$$

$$D_4 = \frac{\beta \log(\alpha l_2 + \beta) - \alpha l_2}{\alpha^2}$$

$$D_5 = l_2 \left(\frac{1}{\alpha} - D_3 \right) - \frac{(\alpha l_2 + \beta) \log(\alpha l_2 + \beta)}{\alpha^2}$$

$$D_6 = \frac{\beta (\alpha l_2 + \beta) \log(\alpha l_2 + \beta)}{\alpha^3} - l_2 \left(D_4 + \frac{l_2}{2\alpha} + \frac{\beta}{\alpha^2} \right)$$

3.3. Validity of the formula for calculating restoring force

As this calculation formula is extremely complex, we compared its results to those of numerical analysis to confirm the validity of the formula. First, P_1 and P_2 were obtained using the formula. Assuming that l_1 is 5 mm, l_2 is 88 mm, b_l is 100 mm, b_o is 20 mm, h is 1 mm, θ is 10 degrees, and Young's modulus is 3000 N/mm^2, δ_1 is 0.87 mm and δ_2 is 15.42 mm. Solving for P_1 and P_2 using equation (8), we obtained P_1 as 534 N and P_2 as -0.664 N. Next, an analytical model was created using the numerical analysis software midas[4]. The model was created using 100 equally divided beam elements, and the width of the member was varied in steps from the fulcrum to the tip. The model was analyzed with P_1 = 534 N and P_2 = -0.664 N obtained from the calculation formula, and the deformations δ_1 and δ_2 were obtained. The δ_1 was 0.87 mm and the δ_2 was 15.10 mm. Since the values of the calculation formula and the numerical analysis are in general agreement, it can be said that the calculation formula is reasonable.

4. Numerical results of a three-dimensional model subjected to restoring forces and shape differences of the model

4.1. Geometry of the model

Figure 11 shows the shape of the model used as a comparison target. In this model, the polyhedral shape after division was created by combining triangular elements instead of dividing the curved surface. The shapes of elements 1-6 are equilateral triangles with a side length of 90mm, while elements 7-14 are isosceles triangles with a vertex length of 0.7 times the side length of an equilateral triangle measured from the boundary edge. The normal angle between the elements was set to be 10 degrees. A model and a numerical model were created with this geometry.

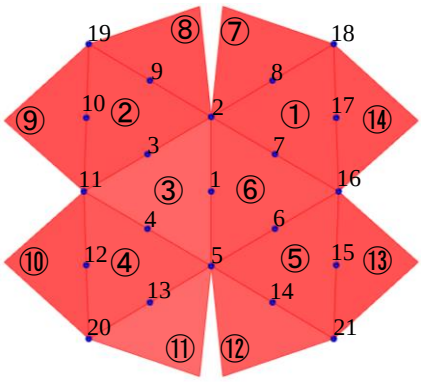

Figure 11. Subject model

4.2. Shape differences in models

The model was made as described in Section 2, Section 2. The flat plates were made of 1 mm thick PVC plates, and M3 bolts were used. The position of the bolts was set at the intersection of a line offset 5mm from the boundary edge. The outermost bolt was fixed to a base member created to match its orientation and height. Figure 12 shows a photo of the created model. The black or gray parts in the figure are the base member. The shape of the base member was determined by a 3D model, and a 3D printer was used to create the base members. The base member was constructed within 5 mm inside the bolt position. The base members were bolted to an MDF board, and its position was also determined by the 3D model. The holes in the MDF board were drilled by CNC.

After creating the model, the coordinates of the position indicated by the circular mark in Figure 11 were measured using photogrammetry. The number on the upper right corner of the blue dotin in figure 11 is the number of the measurement point. We attached measurement marks to the measuring points of the model, and took photographs from various angles. Then, we used the image processing software Metashape[5] to obtain the coordinates of the measurement marks. The difference between these coordinates and the coordinates of the corresponding points on the 3D model was calculated. In order to calculate the difference between the measurement results and the 3D model, the measured points were translated and rotated so that the first measurement point coincided and the direction from that point to the second measurement point was aligned.

Figure 13 shows the shape difference of the model. The arrows represent the x and y components of the shape difference, and the color of the markers represent the z component. The figure also shows the reference length of the arrows and the color scale. The figure shows that the shape difference in the x,y direction increases as it spreads outward from the center, and the points at the four corners are deformed toward the center, while the other points are deformed outward. In addition, the shape difference in the z direction is increasing upward. The model has a more swollen shape than the 3D model.

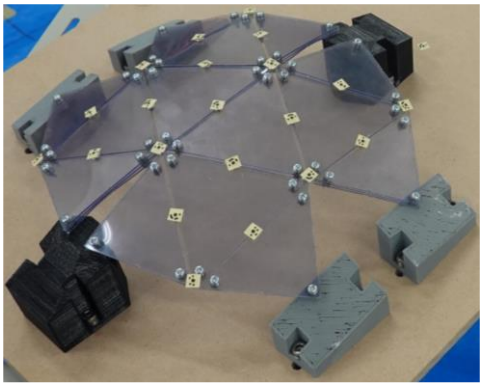

Figure 12. Created model

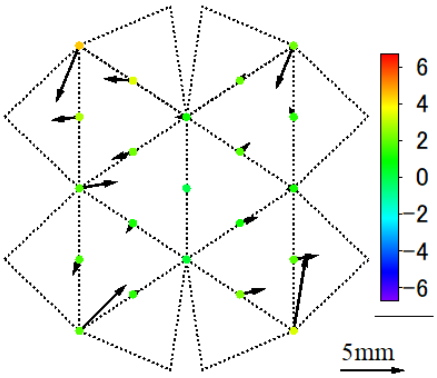

Figure 13. Shape differences in model [unit: mm]

4.3. Numerical analysis of the 3D model with applied restoring forces

Describe the numerical analysis. A numerical analysis model was created in a polyhedral shape, and the restoring force was applied to it, and calculated the displacement. Figure 14 shows the numerical analysis model. The material was assumed to have a Young's modulus E = 3000 N/mm^2 and a Poisson's ratio of ν = 0.38. The element used was a quadrilateral plate element with a thickness of 1 mm and was meshed in a square shape with a spacing of 0.5 mm (triangular shape near vertices and boundary edges). The nodes on the green line in the figure were used as pin supports. This position is on the boundary of the base member. The restoring force was obtained using the method described in Section 3. The restoring force was assumed to be the force that causes the flat plate member to return to its original shape, so when the flat plate members overlap, the restoring forces obtained for each flat plate member were combined. For example, elements numbered 1 to 6 have three overlapping flat plate members. For these elements, we assumed three boundary edges as fixed ends, calculated the restoring forces for each condition, and added up the restoring forces at each bolt position to obtain the total restoring force at that position. Numerical analysis was performed using Karamba3D[6] in Grasshopper, an extension of Rhinoceros. The analysis method used was large deformation analysis, and the number of increments was set to 100. Only the restoring force was used as the load, and no dead weight was applied.

Figure 15 shows the displacement diagram obtained from the analysis. The pink color indicates greater deformation. The maximum displacement value was 7.38 mm. The displacements at each measurement point were summarized in the same format as the shape differences of the model shown in Figure 13, and are shown in Figure 16. From the figure, the deformation in the x- and y-directions increases from the center to the outside, mostly deforming to the center; the deformation in the z-direction deforms to the upper side at the position of the apex of the triangular element and to the lower side at the position of the center of the boundary edge.

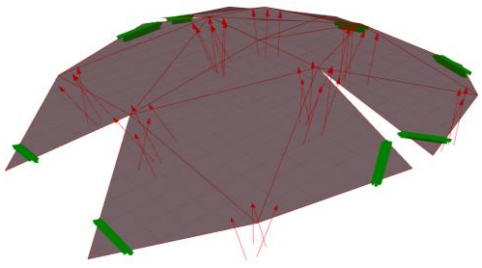

Figure 14. Numerical analysis model

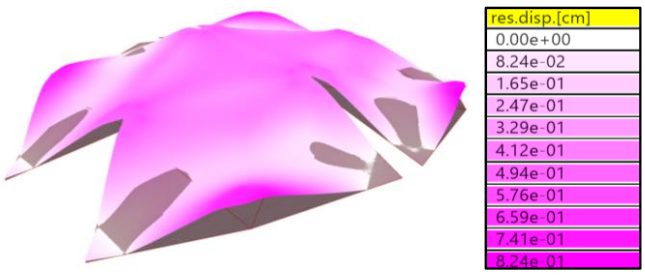

Figure 15. Deformation diagram

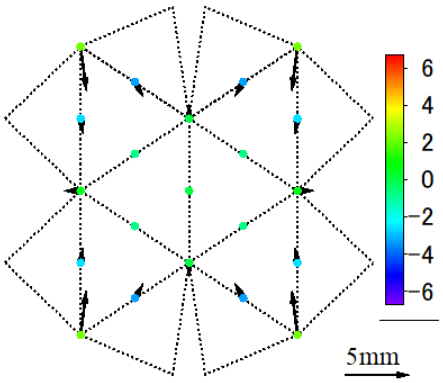

Figure 16. Results of numerical analysis [unit: mm]

4.4. Comparison of the model and numerical analysis, and discussion

The shape differences of the models were compared with the results of the numerical analysis. Figure 17 shows the shape difference of the model minus the numerical analysis.

The maximum error in the x-y directions was found to be around 2.8 mm at point 11, where the shape difference of the model was greatly deformed inward, and it is assumed that the accuracy of the measured mark position at point 11 was low. For points other than point 11, 86% of the points had errors less than 2 mm, and 38% of the points had errors less than 1 mm.

Regarding the z-direction, all points except for 18 and 20 have positive values, and the values for 18 and 20 are almost zero. This indicates that the model has a more swollen shape than the numerical analysis. The errors for the triangle vertices (points 2, 5, 11, 16, and 18-21) are small, ranging from -0.4 to 2.2 mm, while the errors for the center points of the boundary edges (points other than the vertices) range from 1.7 to 6.7 mm, indicating that the errors are large. In particular, the errors for the points farther from the reference point (points 8-10, 12-15, and 17) are even larger, ranging from 3.9 to 6.7 mm. Therefore, while the numerical analysis yields values equivalent to the model's shape differences for the triangle vertices, the errors for the center points of the boundary edges are large. Furthermore, for all points relative to the inflated model, the numerical analysis results in the center points of the boundary edges being concave.

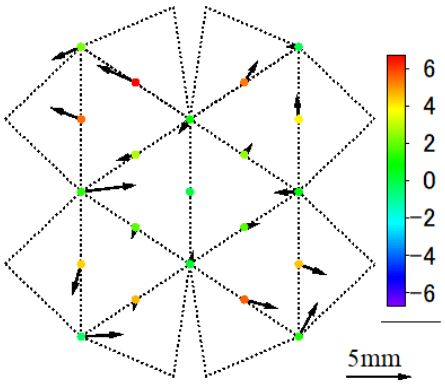

Figure 17. Comparison of geometrical differences between models and numerical analysis [unit: mm]

this suggests that this is the cause by only giving forces to the bolt positions. As a solution, it is necessary to reconsider how to calculate the restoring forces and where to apply them. In addition, during numerical analysis, as shown in Figure 18, the restoring forces are applied in the normal direction of the pre-deformation surface. However, to maintain that angle even after deformation, it is necessary to

consider a method to modify the restoring forces to face the normal direction of the deformed surface with each iterative calculation.

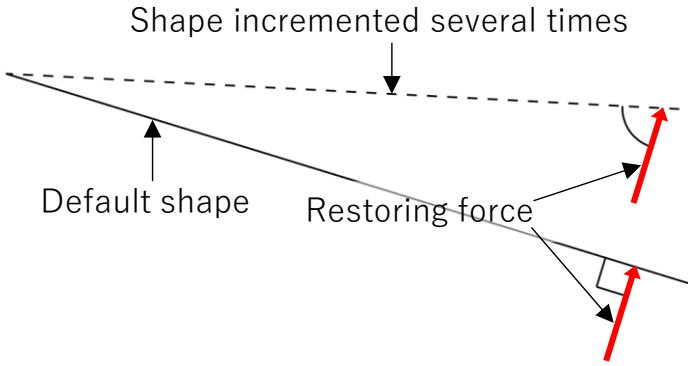

Figure 18. The direction of the restoring force after deformation

5. Conclusion

In this study, we verified a method to estimate the shape difference between a model and a 3D model in a curved structure made of a plate and bolts. We compared the deformation obtained by giving restoring force to the 3D model with that of the model, assuming that the deformation obtained by giving restoring force to the 3D model is similar to the shape of the model, and validated its validity. The restoring force was considered as the force that the plate member forming the model tries to return to its original position. Also, this force was considered as the force required to bend the plate member to the target position. The formula for calculating this restoring force was formulated by treating the plate member as a beam element and solving the mechanical model where force was applied to the bolt position.

From the comparison of the shape difference between the model and the numerical analysis, it is suggested that the errors at the vertices of the triangles are small, and the shape difference can be estimated by numerical analysis. On the other hand, the errors are large at the center of the boundary edge of the triangles, indicating the need to reexamine the concept and application of the restoring force, the method of applying it, and the numerical analysis approach.

Abstract

Elastic bending, nowadays referred to as bending active, of initially straight elements has become increasingly popular in the construction of spatial structures, such as elastic gridshells. According to our previous review [1], despite the introduction of modern gridshells over 80 years ago, their geometric patterns tend to be similar and a clear relationship between the pattern and the Gaussian curvature of the surface could not be observed. To gain more design freedom in creating bespoke architectural and structural patterns, in addition to elastic bending the potential of torsion as a design driver may be explored [2]. However, the naturally emerging shape of the strips and their geometrical limitations imposed by the material need to be understood [3]. This paper presents a parametric study on combined bending and twisting of one single or several interacting, linear wooden strips. Presently, our main focus is on the two aspects of the minimum achievable bending radius and pattern curvature and the maximum twistability of the strips in the elastic range of the material. Our investigations and experiments are conducted in both digital and physical environments starting from the strips and patterns rather than from a form-found predefined shape, to which the patterns are applied. Our studies (i) show the geometrical possibilities of wooden strips in terms of elastic bending and twisting, in dependence from their cross-section and support conditions, (ii) identify the limitations of wooden strips in terms of geometrical rules, and (iii) compare the digital modelling to physical prototypes. Feature-driven, the created patterns are applied to different shapes. These features can be structurally informed, taking into account, for example, the Gaussian curvature of the target surface, fabrication-driven, or architecturally driven, such as the density of patterns, visibility, depth of the surface, or other aesthetic aspects. Future investigations will include different cutting patterns of the strips, further increasing the technical and architectural design space.

Keywords: spatial structures, elastic gridshell, torsion, geometrical pattern, Gaussian curvature, architecture

1. Introduction: a review on elastic bending and torsion

Spatial structures are a type of structures that can be made out of curved or linear elements. While using linear elements is more common in spatial space structures, curved elements are used in grid spatial structures, gridshells. The material used for curved elements is mostly wood and its fabrication process in architectural structures is possible with different methods of pre-forming using CNC milling machines, non-industrial techniques [4, 5, 6] or natural self-shaped methods [7], and post-forming using the potential of elastic bending. Spatial structures that use the advantage of elastic bending can be used for different purposes. They can be a lattice structure such as Rise project [8], Mangrove [9], Vartwisted & Varschoba [10], Loop [11], elastic habitat [12], triaxially woven structures [13], bio-inspired lamellar structure [14], and zip-bent prototype [15] or elastic gridshells that can have different subcategories of regular such as Essen pavilion [16], Multihalle Mannheim [17], Toledo gridshell [18, 19], Portalen pavilion [20] and irregular patterns including examples of SG2012 gridshell [21], Mantashell [22], UWE research pavilion [23], geodesic winding gridshell [24], inside/out gridshell [25], and computational

bamboo [26]. While elastic gridshells are efficient structures in terms of material use, structural behavior, and facilitation in transportation, their geometric patterns tend to be similar and a clear relationship between the pattern and the Gaussian curvature of the surface could not be observed [1]. Complex forms can be realized by the use of twists for changing the direction of the strip and the use of strong or weak axis of the lath in the elastic elements in simple grids. This is useful when combining two different patterns, for example combining a pattern with elements perpendicular to the surface using their strong axis with patterns that are aligned on the surface and use their weak axis. In addition to responding to the curvature shift, the twist may change the overall shape of the structure and increase the design freedom in elastic spatial structures. Using twists in geometries is not new and dates back to past times [27]. Twist refers to the action of turning or warping one object around another one [28]. Torque is also defined as a force that results in rotation or torsion [29, 30]. Elastic torque has been used in different research but still, its power on spatial structures is not fully explored. Elmas et al. [31] showed the power of twisting in designing efficient cantilevered beam structures. Twist as a design derivative has been introduced for combining elastic strips with fabric [32]. Naboni et al. [15] developed a method for the fabrication of elastic elements with a zip-bending possibility that enable the potential of twisting in curved wooden elements.

By combining bending with twisting in elements with elastic behavior, this paper introduces innovative structures that can improve the quality of elastic spatial structures in terms of geometrical, architectural, structural, and environmental aspects. In particular, this paper (i) shows the geometrical possibilities of wooden strips in terms of elastic bending and twisting, depending on their cross-section and support conditions, (ii) identifies the limitations of wooden strips in terms of geometrical rules, and (iii) compares the digital modeling to physical prototypes from birch plywood strips. Simultaneously we provide an evaluation of the applied digital simulations. Our method is based on experiments in the digital and physical environment. The physical prototypes are used to evaluate the simulations and improve them in terms of realistic results. The two design methods that are used in most elastic gridshells are top-down (shape-first) and bottom-up (pattern-first) [33]. In our research, we start with a pattern-first approach and explore the possible forms for elastic strips in terms of geometrical rules and restrictions including the minimum and maximum possible curvature. In the next steps, we will combine these understanding and geometric rules with shape-first where an overall shape is considered as a first input but the structural form at the end can follow the material behavior and self-organizing principles.

2. A geometric approach to elastic-forming

We explore the geometrical features of patterns that are formed based on a combination of elastic bending and twisting. By twist, we mean the action of twisting of material around a longitudinal axis resulting in a torqued shape. The observation consists of one-strip explorations, two-strip connections and joint planes, and the exploration of a network of strips. Figure 1 shows the feasible range for one strip in combined elastic bending and twisting with hinged supports in a defined platform.

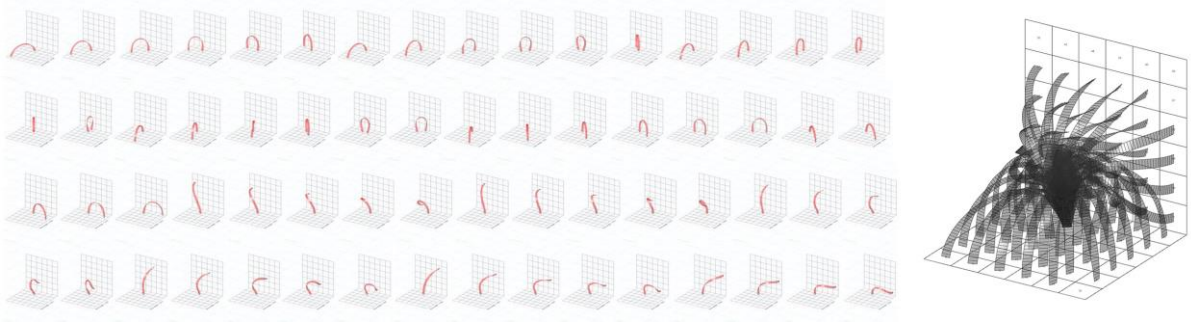

Figure 1. Parametric study and feasible range for one strip in combined elastic bending and twisting with hinged supports.

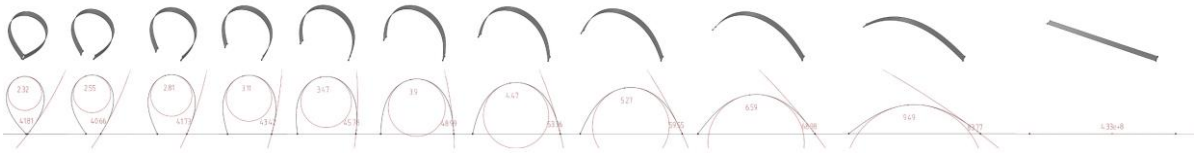
The focus of our work is on the two aspects of the minimum achievable bending radius and pattern curvature and the maximum twistability of the strips in the elastic range of the material. The bending radius depends on the length of the elements and the support conditions. It seems clear that in longer strips, with the same width and thickness of material, the bendability of the material increases. For example, in comparing two strips with the size of 10 mm x 100 mm and 10 mm x 200 mm, and a thickness of 0.6 mm, the strip with the length of 200 mm shows more flexibility. But in the same length and proportions of the strip and same support conditions and changing the span, different minimum and maximum bending radius are achieved (Figure 2). As the smallest and largest bending circles show, for both hinged and fixed supports the minimum bending radius is usually in the middle of the curve, and the maximum bending radius is at the ends of the strip.



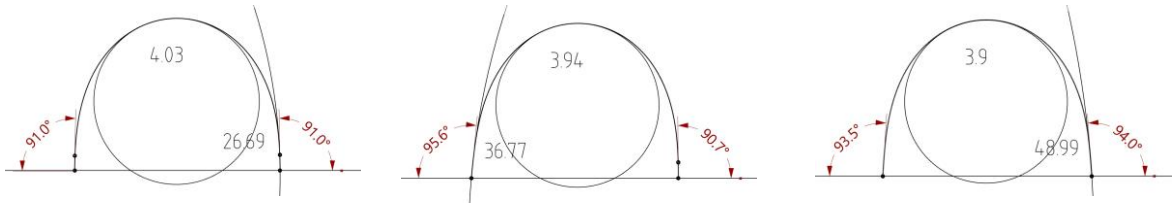


Figure 2. The smallest and largest bending radius for one strip with proportions of 1/20.

By changing the supports from fixed to hinged, a smaller minimum bending radius, and larger maximum bending radius can be achieved. Figure 3 shows one strip with the same proportions and three different support types. Also, the outer angle at the fixed support is almost 90 degrees and increases by changing to hinged supports which means more flexibility in the curvature is possible for hinged supports.

fixed-fixed hinged-fixed hinged-hinged

Figure 3. Examples of support types in one strip and their corresponding curvature radius and angles at supports, left: fixed-fixed, center: hinged-fixed, and right: hinged-hinged.

The elastica curve of strips for four different proportions of 1/20, 1/10, 1/6.66, and 1/5 show the same bending radius, that means by keeping the same length and thickness of the material and changing the width of the strips, the bendability of the material in straight line stays almost the same (Figure 4).

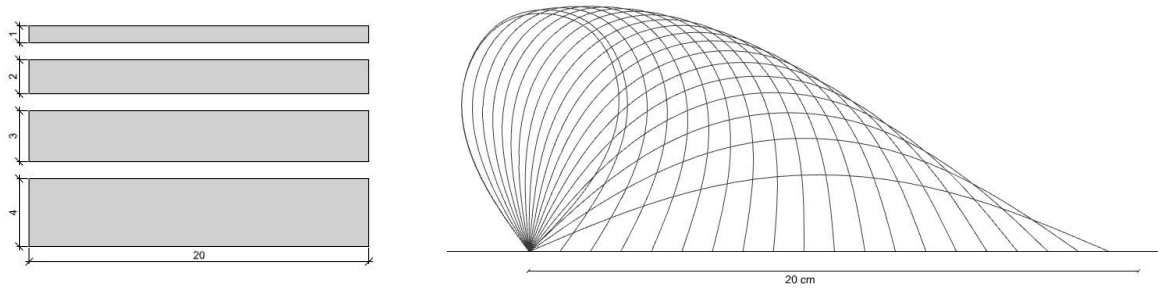

Figure 4. Four strip proportions and the corresponding curvature for 20 spans.

The effect of proportions however is understandable when introducing twist by rotating one or both endpoints of a strip, or by shifting one or both endpoints of a strip from the initially straight axis, or by combining both aforementioned options. Figure 5 shows four strips with different proportions, the same

span of 40 mm, hinged supports, and a rotation angle of 90 degrees. By keeping the same span and twist angle but changing the proportions from 1/20 to 1/5, the minimum bending radius reduces which means higher curvature is allowed. As shown below, the minimum bending radii for the strips with the sizes of 10 mm x 200 mm, 20 mm x 200 mm, 30 mm x 200 mm, and 40 mm x 200 mm are 24.9 mm, 23.7 mm, 22.1 mm, and 17.6 mm respectively. One possible reason is that by increasing the width of the material, the number of osculating circles, fitting the points of the surface, will be increased and smaller circles can result.

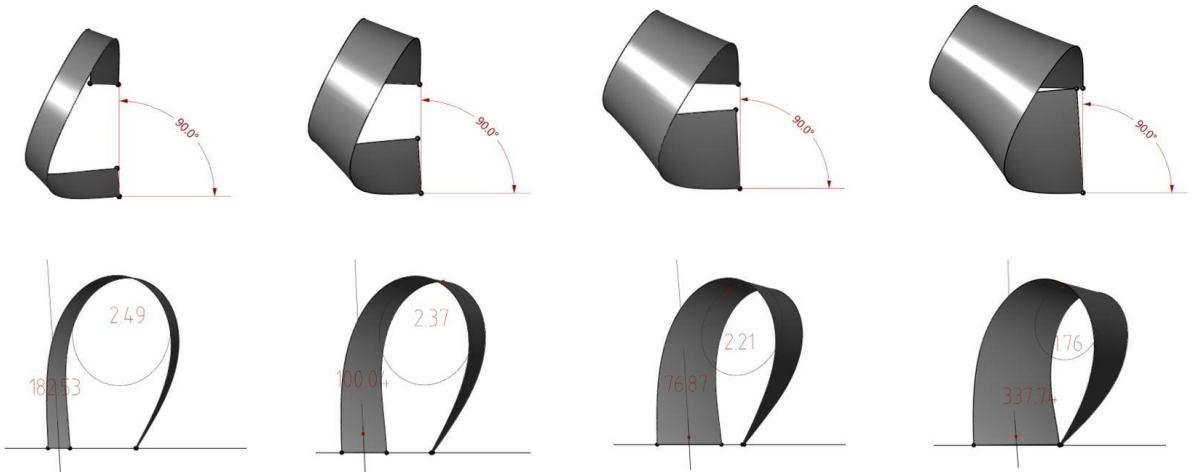

Figure 5. The minimum and maximum bending radius for four strips with the span of 40 mm, and the twist angle of 90 degrees (up: top view, down: side view).

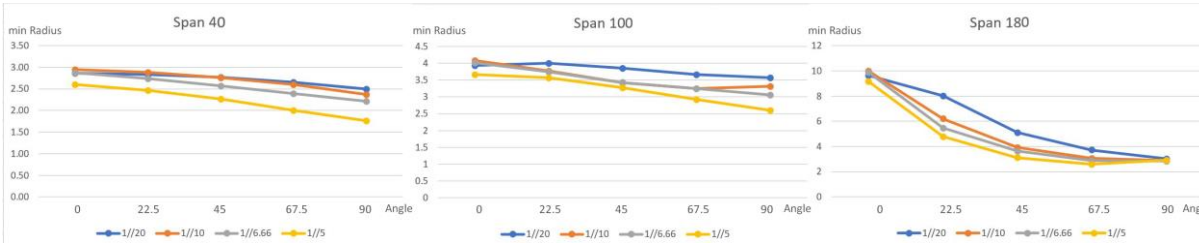
To better compare the relevance of twist, strip proportions, and the bending radius, we explore and compare the minimum bending radii of four 90-degree twisted strips with four proportions of 1/20, 1/10, 1/6.66, and 1/5 and in three different spans of 40 mm, 100 mm, and 180 mm (Figure 6). As the charts show, the minimum bending radius for each of these spans is almost the same between all these proportions when there is no twist. By increasing the twist degree, the effect of change in proportions and the minimum bending radius is more understandable. In both spans 40 mm and 100 mm, the behavior of the material is similar, the higher bending curvature is achievable in wider strips, proportion of 1 to 5, and in larger twist angles, 90 degrees. In span 180 mm, however, it is somehow different where the smallest bending radius is achievable by the twist angle of 67.5 degrees. Also, almost in each of the angles and in all spans, the minimum bending radius has the smallest amount for strips with proportions of 1/5 and the largest amount for strips with proportions of 1/20.



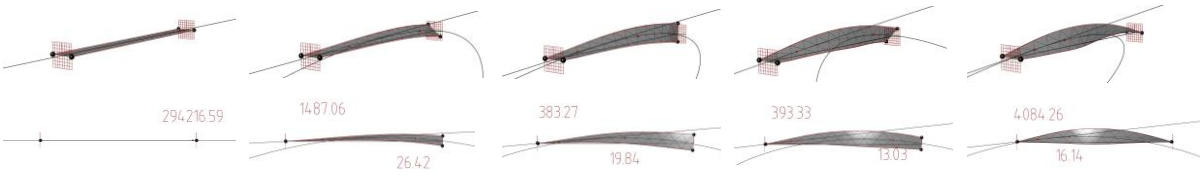


Figure 6. The minimum curvature radius for one strip with four proportions of 1/20, 1/10, 1/6.66, and 1/5, three spans of 40 mm, 100 mm, 180 mm, and the twist angle of 90 degrees.

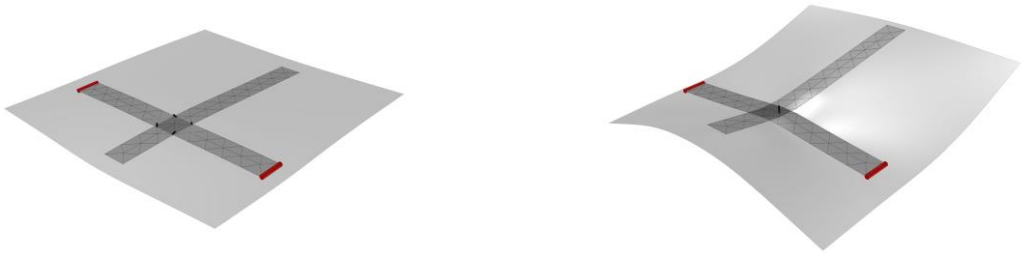
Twisting one strip can be helpful for curvature shifts and changing the direction of the weak axis of the material. It also helps to have different curvature radius in places where higher curvature is needed. The effect of the twist of one strip on the minimum and maximum bending radius is shown in Figure 7. The

strip has the proportions of 1 to 10 and 5 twisting degrees of 0°, 45°, 90°, 135°, and 180° at its right end and around the strip axis. As it is shown, the minimum bending radii for these degrees are 2942165.9 mm, 264.2 mm, 198.4 mm, 130.3 mm, and 161.4 mm which means the minimum bending radius for one strip by considering the twist in its axis (parallel to the length of the strip) is 135 degrees between these explored twist angles.



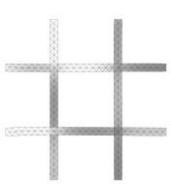
0 45 90 135 180

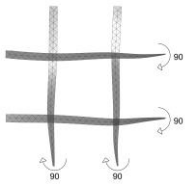
Figure 7. The effect of different twist angles on the minimum and maximum bending radius of one strip with proportion of 1/10 (top: perspective view, down: side view).

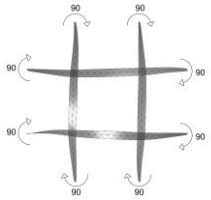
2.1. Connections of elements

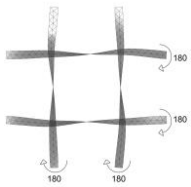
Joining twisted elements to create a connected network raises challenging geometrical questions with practical relevance. We consider two joint types, a fixed one, where translations and rotations are blocked, and a pinned one where only translations are blocked. Figure 8 shows two strips with the same proportions of 1/20, two support edges, and two different joints pinned or fixed connecting them. The other two edges are considered free to let the structure self-form the curvature. The change in the connection type will also change the curvature of the resulting structure and therefore change the output surface that is generated based on the curvature of these strips. A visual explanation of how this surface is generated is shown in Figure 9. As shown below, pinned joints due to allowing for rotations, enable higher surface curvature and might be more suitable options for parts of the structure that need a higher curvature. To clarify the curvature intensity as a result of each connection we introduce the deformation value (dv) of the surfaces that represents the difference between the minimum and maximum z value of all the points on the two strips in millimeters. As the values show, using pinned joints in these two strips results in a surface deformation that is almost 10 times larger than with fixed joints.

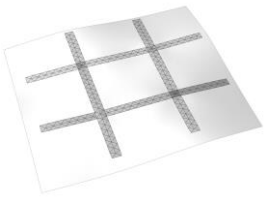
dv = 2.11 mm dv = 20.78 mm

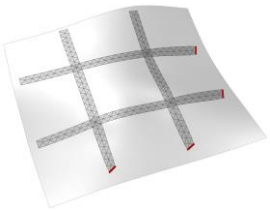


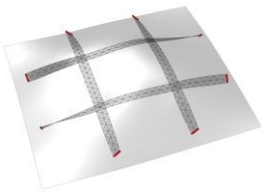


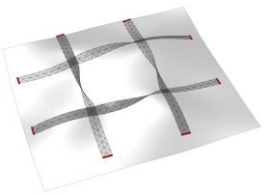


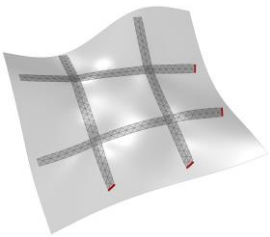


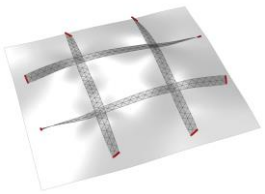












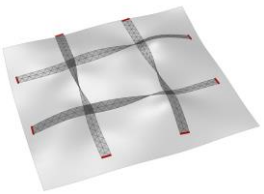


Figure 8. Two types of connection between two strips and the corresponding surface curvature result; left: fixed, right: pinned (if there is a red line at the end it means that the end points are supports).

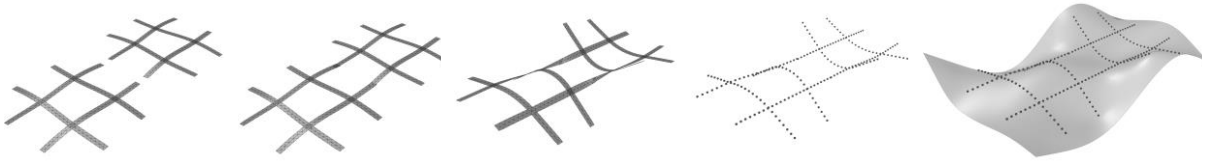
2.2. Pattern of strips and surface curvature



In a pattern-first approach and by considering a simple rectangular grid, we twisted four strips with a proportion of 1/20 and explored how twist imposes a curvature on the structure. Table 1 shows four types of twists on these four strips with different joint types of fixed and pinned and the corresponding surface curvature that is post-generated for visualization reasons. In types 2 and 3 all of the strips are 90 degrees twisted in one or both ends. The twist angle of type 4 is increased for all strips to 180 degrees at one end each. Similar to Figure 8, to clarify the curvature intensity in each pattern we use the deformation value of the surfaces of the strips in a pattern. The twisted end edges are considered supports to apply the curvature on the form. As shown in types 3 and 4, when all of the strips` ends are considered

supports, the final surface curvature is almost the same in the two different joint types and the change has a range of 0.98 mm. This means that the effect of change in the joint types is more understandable when there is a mix between the free end edges and the support ones, such as types 1 and 2.

Table 1. Four patterns with four types of twist and the corresponding surface curvature for two joint types.

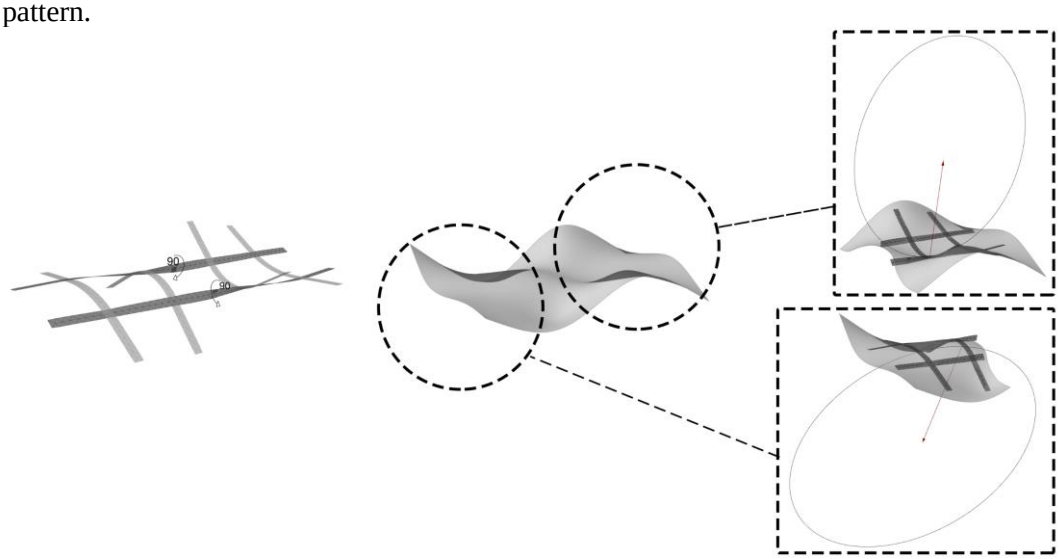
	Type 1	Type 2	Type 3	Type 4
joint type				
fixed				
	dv = 3.82 mm	dv = 31.63 mm	dv = 12.82 mm	dv = 10.95 mm
pinned				
	dv = 37.37 mm	dv = 51.62 mm	dv = 11.84 mm	dv = 11.32 mm

As mentioned, the surfaces shown in Table 1 are added to the digitally generated strips to visualize the curvature of the structural elements using a patch surface. In Rhino3D, a patch surface is defined as a surface that fits to a defined set of meshes, curves, points, or point clouds [34]. Figure 9 shows the process of combining two 4-strips patches into one pattern by twisting the connection between them. To simplify the modeling in both digital and physical environment, we use the same size of the strips and consider changing the distance of the two patches and connecting them with an overlap value of 10 mm. We achieve similar results, especially in digital environment, if we consider two continuous strips instead of having separate pieces. To visualize the shape, we add a patch surface to show the effect of twist on the final surface curvature. This is to make it clear that we start with strips and not with a surface.

a b c d e

Figure 9. From left to right; (a) the two 4-strips patches, (b) connecting the two patches with an overlap of 10 mm, (c) twisting the joints in between, (d) extracting the points of the strip meshes, and (e) the resulting patch surface from the mesh points.

As it is shown in Figure 9, twisting the connection between the two patches by 90 degrees provides the possibility to convert a convex shape into a concave shape. Figure 10 shows this shift in the curvature in a graphical way. The circles of curvature show the direction of the surface curvature in two parts of the pattern.



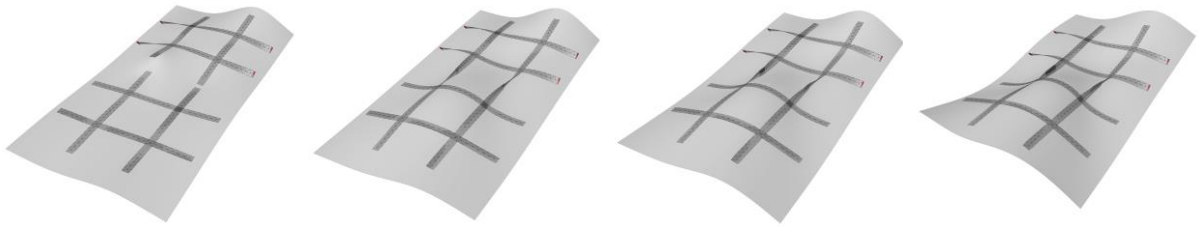


Figure 10. Two separate patches with different curvature directions are connected together and 90 degrees twisting the connection made the conversion between them possible.

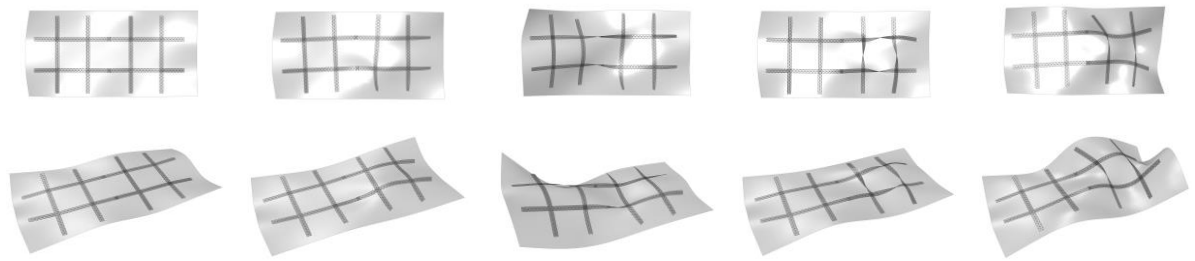
Similar to the pattern shown in Figure 9, the amount of overlap, respectively the distance between separate patches defines the effect of the twist on the whole structure. Figure 11 shows one pattern consisting of two separate 4-strips patches in 4 states before connecting and connecting with three different overlap values of 10 mm, 20 mm, and 30 mm. In all of these patterns, only 4 edges are kept in their place to show the effect of twist on the whole structure.

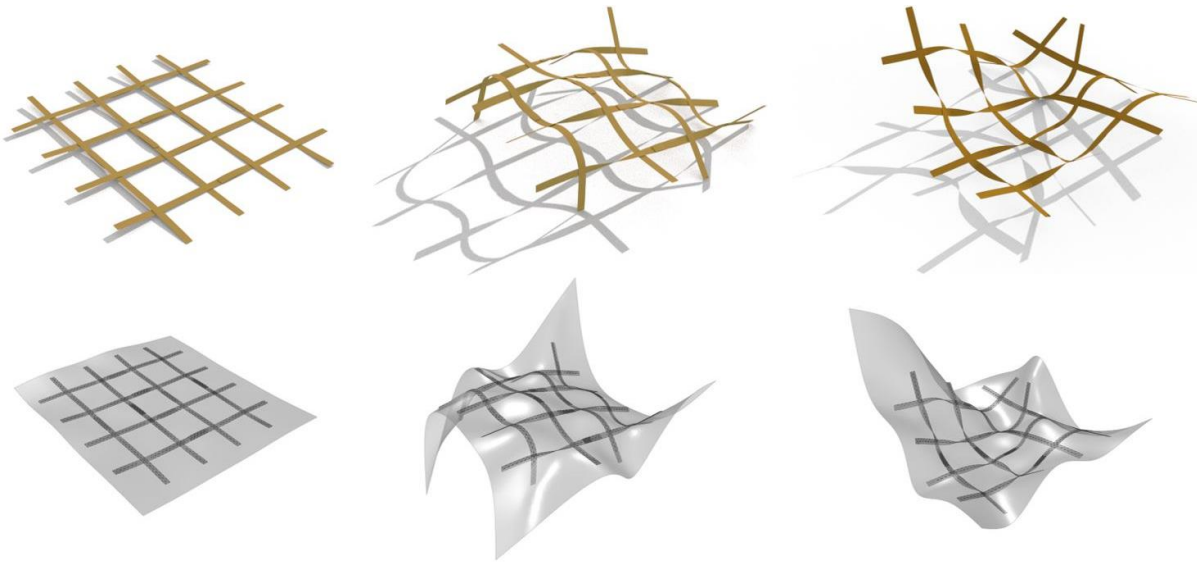
The patch surface is also added to show the change in the curvature of the final form. The dv values show that by increasing the overlap (shortening the distance) in the connection, the twist results in higher curvature for the whole form which means that the effect of twist is not locally on the connection part and can influence the whole curvature of the form. It should be noticed that the overlap of the strips causes extra stiffness to the whole structure and results in less flexibility for bending and twisting. We therefore limit the overlap to a range of 30 mm in our small-scale models.



dv = 22.72 mm | dv = 24.24 mm | dv = 26.58 mm | dv = 39.92 mm

a | b | c | d

Figure 11. A pattern made of two 4-strips patches, (a) without connection between the section, and connection with overlap of (b) 10 mm, (c) 20 mm, and (d) 30 mm. The red lines at the end of the edges represents the supports.



The same process was applied to eight strips with the same size and proportions as in the experiment in Table 1. By adding to the number of strips and extending the pattern, the change in the surface curvature is clearer. Figure 12 shows how the output surface has different curvatures by twisting these strips in five different versions with the same overlap value of 10 mm.

dv = 9.06 mm | dv = 22.09 mm | dv = 73.82 mm | dv = 20.22 mm | dv = 71.56 mm

Figure 12. Five different twist types for eight strips and the corresponding surface curvature in two views of top (up) and perspective (down).

Continuing the process with more strips, the change in the curvature is more clearly shown in Figure 13 where 16 strips are connected together with the same square pattern and type of joints (fixed), but with three different levels of twist. Now the effect of twist on the curvature and the shadow is very different from the flat grid. Different degrees of twists in elements result in different surface curvatures, also shown with the deformation values, and can be used for different functions and design demands. To reach a self-organized form and let the structural forms shape themselves only based on the material behavior, twist, and joints, the endpoints are not considered supports.

dv = 12.33 mm | dv = 88.18 mm | dv = 142.41 mm

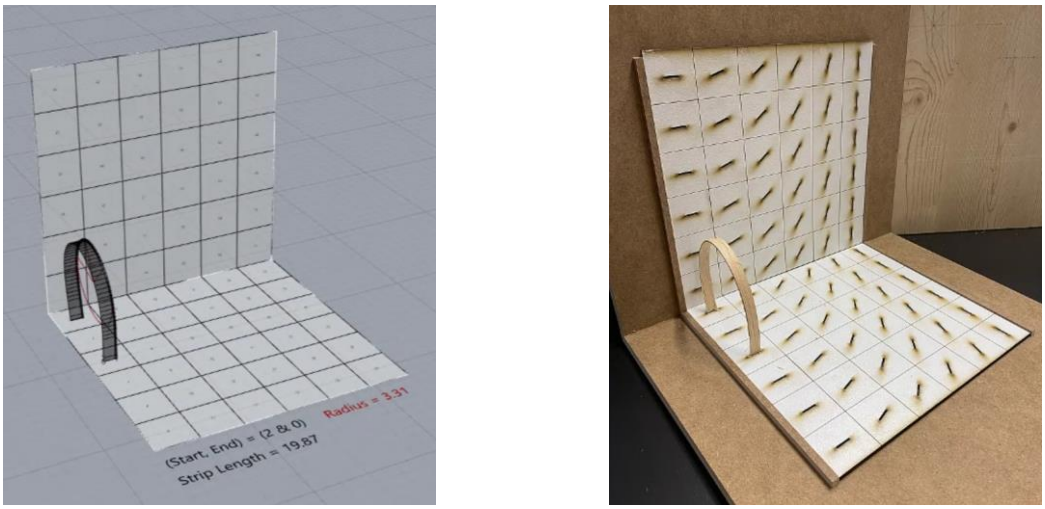
Figure 13. A square pattern with 16 strips (left) and two versions of twisting the strips (center and right).

3. Findings on geometrical explorations of elastic elements

3.1. Geometrical considerations and rules

We refer to geometric rules that make restrictions for elastic elements in the process of post-forming. One important rule is the minimum bending radius for the curved strip, which depends on the material dimensions and elasticity. The maximum radius is not a problem because the material starts from the

flat state and returns to flatness due to its elasticity. We used birch plywood strips with the size of 10 mm x 200 mm and the thickness of 0.6 mm for our scaled models. Here, the minimum bending radius is 12.0 mm. In the digital environment, less than this value is possible but when adding the material properties and trying to fabricate it that would not be possible. The maximum twistability is also another important factor, which of course depends on the strip length. For our scaled models and a predefined length of 200 mm this value is limited to 180 degrees, especially in a network of strips where the twist in one strip affects the other ones as well. Twist degrees in the range of 270° result in breakage of the strip as the tension in the material dramatically increases. Figure 14 shows the twist test in three states of 180°, 270°, and the breakage as a result of tension in the material for one strip with the aforementioned size and thickness.



a b c

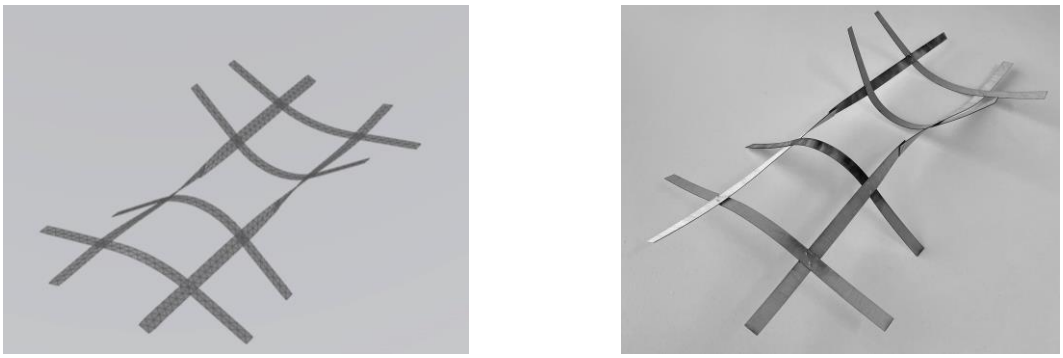
3.2. Digital simulation vs physical simulation



The simulation is physics-based modeling using Kangaroo Physics. The specific rules are set to simulate the elastic behavior of the material in bending and twisting. The material stretch in the modeling is limited to 0.6 mm. To test and evaluate our simulation, we consider birch plywood strips with the size of 10 mm x 200 mm and the thickness of 0.6 mm consisting of three layers for our scaled models. An experimental platform of two perpendicular planes with a grid of 6*6 consisting of cells with a dimension of 20 mm x 20 mm on each plane is considered as a first step and the curvature of one strip with different start and end points is investigated. The results from the digital simulation are also compared to the physical models of the same built platform. Figure 15 shows the same state of one strip in two different environments of digital and physical. The minimum bending radii are compared between the two models and the results shows that they are closely aligned. The model building verified the digital model being in a range of 0.6 mm accuracy. This is considered acceptable for small-scale results and not of practical relevance. For larger scales, the relative deviations may be even smaller, even though imperfections of material etc. may play a bigger role.

bending radius = 33.1 mm bending radius = 33.0 mm

Figure 15. Comparison between digital simulation (left) and physical prototype with plywood (right).

The behavior of the system is also checked in a network of strips with the same size of 10 mm x 200 mm and the thickness of 0.6 mm with or without twists. Figure 16 shows the simulation and the physical prototype of a square pattern consisting of twisted elements. As shown, the curvature in the final form is similar in both of the models. To verify our results, we calculated the deformation value of the physical model in parallel to the digital one and the results show the deviation of a maximum of 1.4 mm, which is assumed acceptable for the small-scale prototypes. It should be noted that there might be small errors in the physical prototypes because of the connection methods, using staples instead of four connecting points as in the digital simulation.

dv = 60.6 mm dv = 62.0 mm

Figure 16. Comparison between the digital simulation (left) and the physical prototype from birch plywood strips (right) of a square pattern with twist.

4. Discussion, conclusion, and future work

This paper shows the possibilities of twist for elastic spatial structures that include changing the curvature of the form from convex to concave shape and increasing the design freedom in elastic gridshells. The process follows a pattern-first approach and explores the possible forms and surface curvatures by twisting the strips, considering different joints and support conditions. The proposed approach improves and increases the variety in the design of elastic spatial structures by following the material behavior in a self-organized process. We show the first results of using twist in small-scale prototypes and they are acceptable due to having minor deviations. For larger scales still, the accuracy and similarity of the physical and digital environment could be improved. The effect of twist on the structural performance and the maintenance of the material should be evaluated in large-scale prototypes and by adding the vertical and lateral forces. In the next steps, we will work on shape-first approaches and combine the knowledge from the pattern-first with it. This will lead to the design of elastic structures based on an approach that starts from a defined surface but is not limited to it. Modifications in the curvature of the final form is possible based on considering the material behavior. The application of these structures can be from small-scale products such as furniture to large-scale projects including buildings with different functions.

Having control over the design of spatial structures results in generating improved forms. The resulting structures can have different pattern types and different profiles based on the designer's wishes such as the need for interior lighting or controlling the views to the outside. We can imagine lamellas with profiles perpendicular to the surface curvature guiding views or controlling natural light. Conversely, the grids and profiles could be denser and less transparent if they follow geodesic curves as strips. Also, from a structural perspective, the intentional use of strong and weak axes of the strip material can be used to adjust structural performance as needed. Such complex requirements and shapes allow architectural and structural designers to generate spaces that respond to environmental, structural and architectural wishes and necessities. Although the use of twist can pose some challenges to the manufacturing process and specific geometric rules regarding material elasticity must be considered, we expect significant impact on the design space and thus design outcomes for elastic gridshells.

Abstract

Material and energy shortages make efficient material use, reuse and recycling urgent issues in 21st century construction. Wood as a renewable raw material is back in focus, with potential use in lightweight and structurally efficient gridshells. Many timber gridshells use the principle of bending-active structural behaviour, with their shape largely determined by material and cross-sectional properties. However, commonly used timber with non-biodegradable glue and inseparable steel connections cannot be returned to the material cycle. Consequently, this challenges sustainable building practices. This paper presents a reconfigurable modular system for elastically bent solid timber laths using interlocking connections and segmented cross-sections, while providing novel design possibilities through variable stiffness. The results of the research show that circular design in bending-active timber structures can contribute to quality craftsmanship and a new language in architecture and engineering.

Keywords: timber, bending-active structures, variable stiffness, sustainable construction, circular design, interlocking connections

1. Introduction

1.1. Background

Gridshells are a type of structural system that allow for large spans with minimal material usage due to their structural efficiency. One well-known example is Frei Otto's lightweight timber gridshell in Mannheim, which is an early example of a bending-active structure created by the deflection of previously planar elements [1]. The shape of bending-active structures is significantly influenced by the bending stiffness of the structural elements. Since the bending stiffness is the product of Young's modulus and area moment of inertia, material properties as well as the cross-sectional area thus essentially determine the geometry. Timber has gained importance in this context as part of the shift towards a sustainable circular economy in the construction industry and is frequently used for gridshells [2].

To meet the requirements of the circular economy, load-bearing structures must use materials that can be recycled into biological or technical material cycles and have detachable connections that can be separated by material type at the end of their service life. This ensures that the materials and components can be reused or recycled.

Glulam, which is commonly used in construction, only partially meets these requirements due to its non-biodegradable glue. One possibility for glulam is to reuse it in new configurations after a structure has reached the end of its life. The recovery of previously used elements is already being researched in the engineering field and addresses, for example, their optimised use in different structural typologies such

as trusses and lattice shells, both in the design phase and of reclaimed components (see [3],[4]). Solid wood materials should also be put to further use first. However, their application eliminates the compelling need for reuse, as they can also be returned to the biological cycle without leaving any residues.

Commonly used steel connections on gridshells cannot be separated from the wood after use in many cases, which can be considered problematic in terms of their recyclability. Modern timber engineering uses metallic screws, dowels, steel sheet fittings and nail connections. These can be easily calculated, and their use is also covered by the relevant standards. This guarantees economical use, whereas solid wood connections are rarely used in respect of the necessary craftsmanship of carpenters and the associated costs. However, because of the transformation to a circular economy, solid wood joints are experiencing a renaissance in scientific research, also because of their long tradition all over the world. For example, first classifications of traditional interlocking timber connections have been carried out with respect to their moment capacity for modern building construction [5]. In addition, interlocked connections are also used in built research pavilions, for example in bending-active shell structures [6] and Interlocking Particle Structures [7]. Noticeably, this research explores interlocking connections of shell- and plate-like timber structures. Novel interlocking connections of beam-like timber elements, especially beyond the connections at the beam ends, represent a special case which is yet to be investigated.

1.2. Aim and research questions

Due to their dependence on material and cross-section properties, bending-active structures represent a special type of structural behaviour. Regarding the use of this principle in gridshells, further development possibilities can be identified against the background of the scarcity of resources in the construction industry. Building on the parameters of materiality and connections, this publication therefore explores the potential of circular design for bending-active timber structures.

The aim of the work is to develop a reconfigurable modular system for bending-active members, which uses solid wood connectors and at the same time leads to novel design possibilities through variable stiffnesses due to segmented cross-sections.

The following research questions will be addressed:

(1) What are the possibilities of variable stiffnesses on bending-active systems?
(2) What are the boundary conditions for such a system under the premise of circular design? What properties must materials and cross-sections meet in order to be implemented?
(3) What can a modular system look like in practice and what challenges arise in manufacturing?

2. Methods

Different methods are used to answer the highlighted research questions. These are based on a combination of experimental and computational investigations.

System stiffnesses in closed systems can be modified either by couplings of members or by variable bending stiffnesses of the individual cross sections. To get a sense of the possibilities of variable stiffness distribution over beam length, small preliminary studies were first made using paper strips. These are intended to show the flexibility in design and construction that is possible with variable stiffnesses on bending-active systems.

Since the bending stiffness of a structural element depends to a large extent on the material properties as well as the cross-sectional dimensions, as described above, these two properties were analysed in turn in order to subsequently develop a toolkit.

In general, timber as a building material can be divided into solid wood and wood-based materials according to construction principles. Since the presented project is to consist of fully recyclable

materials that do not require glue layers, the selection is limited to solid wood. For bending-active structures in particular, sawn timber and veneer are suitable due to the necessary low cross-sectional heights. In order to identify which wood is capable of elastic bending at the same time, an analysis of different wood species was carried out in the next step. As a regenerative and renewable material, solid wood has certain mechanical and rheological properties that have different effects on the structural behaviour.

The next step is the analysis of solid wood joints to allow the coupling of members at their joints as well as over their cross-sectional length in a single type. Old techniques of traditional carpentry will be used to determine suitable methods for the construction of the demonstrator.

Based on the knowledge gained from the analyses, a modular system will be developed that allows the connection of battens both longitudinally and transversely. The result of this experimental approach is a kit of timber laths and wood-to-wood joints, which will be realised as full-scale prototypes made of a suitable wood species available in Germany.

Finally, an analytical study demonstrates the applicability of the developed principle using the example of a bending-active structural element.

3. Research findings

3.1. Preliminary study

In this study, the influence of a variable stiffness distribution on the shape of a simple curved paper strip was investigated. Higher levels of stiffness have been achieved by adding more layers of paper. The figure shows a paper strip with a constant cross-section, a paper strip with higher stiffness at the third points and a paper strip with higher stiffness in the middle. As expected, there is a clear influence on the bending radii and thus on the shape of the sheet. It can be concluded that variable stiffnesses over the cross-section length can change the design and the structure can be adapted depending on the stiffness distribution.

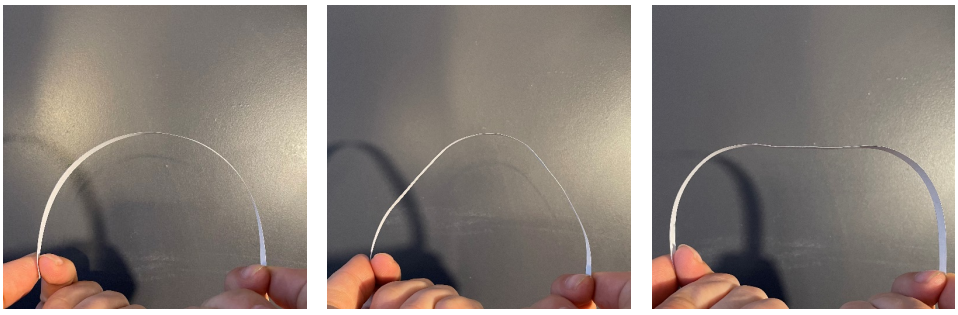

Figure 1. Preliminary study.

3.2 Results of the analyses

The results of the analyses of solid wood species and traditional carpentry joints are presented below.

3.2.1. Solid wood species

In this analysis, mechanical and rheological properties of different untreated woods were compared. Special attention was paid to the availability of the woods in Europe, so that globally available woods were not considered in detail.

The mechanical properties include the flexural modulus of elasticity E_m and the flexural strength f_m. These values were taken from DIN 68364 and not from DIN EN 338, the standard usually used for construction timber. The reason for this is that simple comparative values were sought to obtain an overview of the mechanical properties of woods. A classification into strength classes and grading

classes is not yet available at this early stage of the analysis. The minimum bending radius for a cross-section height of 11 mm and the ratio of modulus of elasticity and bending strength were determined from the available characteristic values following [8]. These values are tabulated below for eleven woods native to Europe.

The rheological properties include creep, stress relaxation and creep rupture strength and are not shown in the table.

Table 1. Mechanical properties of hardwood native to Europe [9].

Wood species	E_m [N/mm²]	f_m [N/mm²]	Ratio f_m/ E_m [MPa/GPa]	Bending radius r_{min} [cm]
Black walnut	11,850	133	11.2	49.00
Robinia	13,600	150	11.0	49.87
Limewood	8,800	88	10.0	55.00
Alder	9,500	91	9.6	57.42
Black cherry	10,250	98	9.6	57.53
Maple	10,500	95	9.0	60.79
European hornbeam	14,500	130	9.0	61.35
Chestnut	9,000	80	8.9	61.88
Birch	14,000	120	8.6	64.17
Beech	14,000	120	8.6	64.17
Ash	13,000	105	8.1	68.10

The mechanical properties of hardwoods are more suitable for bending-active structural behaviour than softwoods. Due to the availability of lime wood, it was selected for use in the demonstrator.

3.2.1. Traditional carpentry joints

In this project, a brief analysis of traditional carpentry joints in timber construction was carried out.

In general, timber connections can be classified into different schemes (see [10], [11]). One possibility is to divide them by application, by joint type (butt, tenon, leaf, etc.) or joint form. In this work, a distinction is made regarding the form of the connection: Thus, two components can be connected either longitudinally, across corners or crosswise. For each of these shapes, there are different types of connection, which differ in their ability to transmit forces. Another reason for choosing a particular wood-to-wood connection can also be the manufacturing effort. In a bending-active system, both normal forces and bending moments must be transmitted through the joints. With regard to this special situation, the dovetail joint is considered particularly advantageous for further research work: The form-fitting connection enables the transmission of these forces and can be realised as a butt joint as well as a cross and end joint. This means that a basic type of connection can be implemented for all requirements.

3.3. Design and manufacturing of a modular system

Based on the previous findings, the details for the identified connections were designed. Transportability and manageability also played a role in the design. For this reason, the maximum member length for the demonstrator was limited to one metre.

3.3.1. Stiffness matrix

The special feature of this design is the adaptability of stiffnesses over the beam length. The aim was to allow a sliding coupling of different cross-section parts in order to keep the total cross-section height and width variable. The authors call this form of coupling a stiffness matrix. Figure 2 illustrates a possible principle of division into different elements, which are held together by clamps. The cross-section resembles a matrix in its appearance, with the number of elements varying along the length of the beam. This results in variable stiffnesses for the overall structure.

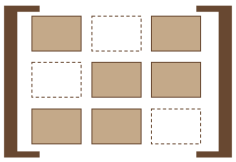

Figure 2. Principle of stiffness matrix.

Due to the variable coupling possibilities, the final cross-sectional dimensions result from the design or the desired system geometry. In the present demonstrator, a maximum of two cross-sections were coupled together in a two-dimensional manner. However, a multi-layer cross-section structure is also possible. A single cross-section layer has a height of eleven millimetres. In the following, the middle, non-milled part of the wood is referred to as the core beam. Coupled together, a higher cross-section can thus be achieved, which results in a higher moment of resistance against bending moments.

Two different variants were considered for the demonstrator. One option is the interlocking of the beams in the transverse direction, which are held in position by wooden dowels. In this variant, there is no stepless adjustment possibility; the coupling of cross sections depends on the interlocking distances.

The favoured variant is the use of dovetail joints in the longitudinal direction, so that the core beams can be joined together over the entire length. In this case, the connection is not made via dowels, but is given via the form fit.

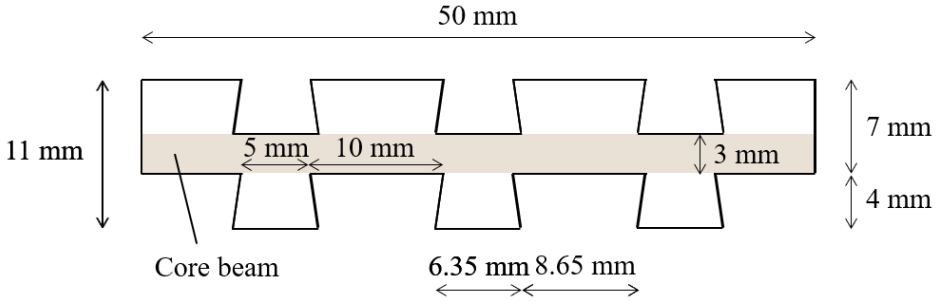

Figure 3. Final dimensions of the cross-section.

In principle, there are two possible ways of producing this connection. One is to mill the laths from a larger cross-section of wood. CNC control makes it possible to produce the joints very precisely. The other manufacturing possibility is the adhesive bonding of individual laths, whereby attention must be paid to the circularity of the joint.

In this project, the second manufacturing option was used because the necessary size of the CNC milling machine was not available. Due to the set requirement of fully recyclable and biodegradable construction, a study of suitable adhesives was therefore carried out. Animal glues, which are obtained by boiling out animal waste, are an interesting option. These differ in their adhesive strength and elasticity depending on the starting material. For this project, fish glue was chosen, which has the elasticity necessary for bending-active structures. To withstand shear, additional wooden needles were arranged across the grain direction of the wood, which can transfer the forces that occur in case the glue fails.

Figure 4. Two coupled cross-section layers.

3.3.2. Butt joints

Butt joints are intended to achieve the strongest bending-resistant coupling of two elements at their end faces. For butt-jointed beams, there are different possibilities depending on the number of cross-sectional layers.

Figure 5. Joining continuous beams.

A butt joint with more than one cross-sectional layer can be realised by continuous beams. Here, it is important to ensure a sufficient overlap length so that the beams do not slip during bending due to the resulting shear forces.

When connecting beams with a single cross-section, the type of connection depends on the thickness of the core beam.

If the core beam is thicker (>5 mm), the beams can be drilled in the transverse direction. A possible connection here results from cutting the ends of the beams so that the resulting tabs can be drilled in the transverse direction and then connected with a wooden dowel.

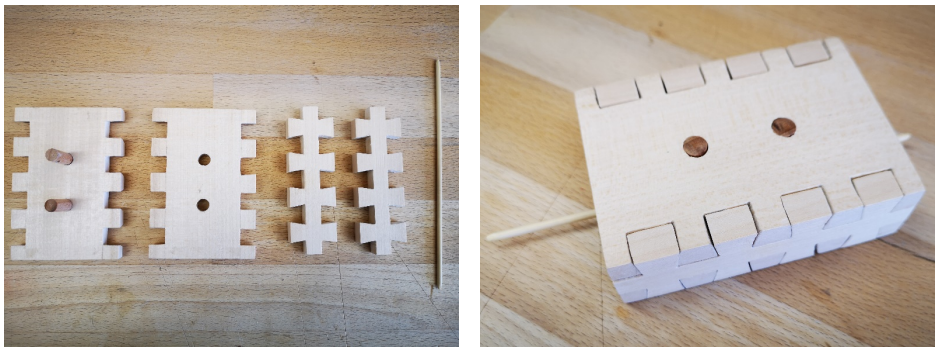

Figure 6. Sleeve enclosing the end faces of core beams <5 mm.

If the core beam is thin (<5 mm), drilling in the transverse direction is not possible. Therefore, at the end face a sleeve is provided with which the end faces are enclosed. This is the case in the built example. Under the influence of bending, the lateral pieces of wood interlock with the upper and lower part of the sleeve. The occurring forces are transferred by pressure and friction between the teeth. The position of the butted beams within the sleeve is secured by two wooden dowels. In the special case of coupling a beam with two cross-sectional layers and a beam with one cross-sectional layer, an additional piece of wood can be used.

Figure 7. Sleeve-joined beams subjected to bending.

3.3.3. Cross connections

This connection must join two intersecting beams in a bending-resistant manner. A gear wheel was used as a reference object so that the angles of the beams can vary. This can realise the desired angles through the toothing and is the basis for the designed shaped piece. The angle is fixed with a wooden dowel. One or more cross-sectional layers can be inserted into the upper part of the shaped piece. This connection only works for bending in the y-direction and attention must be paid to the grain direction of the wood.

Figure 8. Cross connections.

3.3.3. End connections

The developed end connection has two functions. On the one hand, it forms a termination of the end face of the cross-section layers and thus satisfies a design requirement, but at the same time also prevents slipping of beams, should they consist of several cross-section layers. On the other hand, another beam can cross if necessary. The principle is therefore similar to the already described cross connection and is realised with the help of a gear wheel.

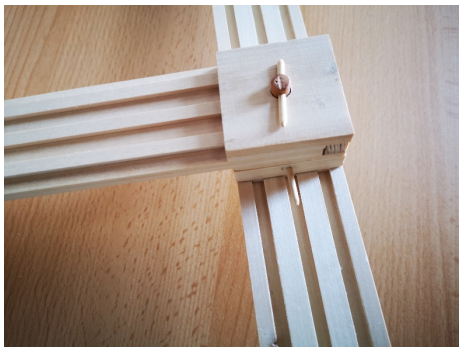

Figure 9. End connection.

3.4. Application of the principle in analytical study

In this section it is examined to what extent the developed principle can be applied to a bending-active structural element. For this purpose, Grasshopper, and the programme Kiwi3D were used. The reference object is the catenary, which represents the optimum shape for a load under its dead weight. The aim of the study was to come as close as possible to this line with the help of short bending-active segments.

First, the given catenary was generated as a curve with a constant cross-section, a length of 9 metres and a span of 4 metres using Grasshopper. Subsequently, a second line with a length of 9 metres was created, the cross-section of which can vary over this length. To realise this, the "Python Script Component" was used. In this way, the previously developed cross-section was modelled in the programme with its dimensions as well as the mechanical properties of the material. The segmented curve is initially arranged flat on the plane and can be brought into its final shape with the help of a movable support at one end of the beam. The Kiwi3D programme then calculates any stresses that occur, resulting in the elastically deformed output geometry.

Due to the different stiffness, the weight of the structure changes from section to section. Since the catenary represents the shape adopted by a freely hanging chain of constant cross-section, the elastica curve using variable stiffnesses will not work in pure compression. Nevertheless, both curves will be approximated to demonstrate the bending capabilities of the variable stiffness structure.

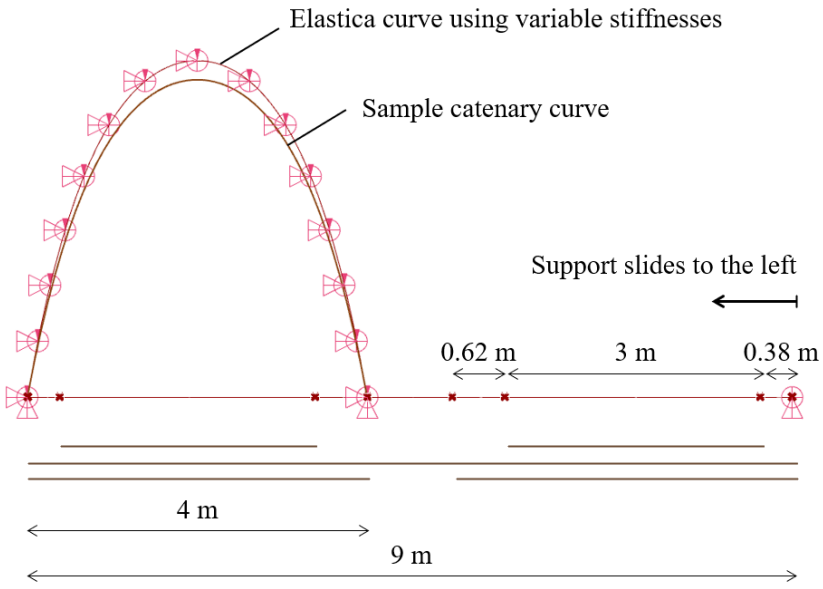

Figure 10. Optimised configuration of modules

To verify the deviations between the sample curve and the bent beam, control points were created at certain distances on both curves, the distances of which were added together. The aim of the optimisation was thus to minimise this sum, whereby lengths, distances, and the number of layers of the segments were adjusted manually.

The manually optimised configuration with its dimensions can be taken from Figure 10. As expected, the stress analysis shows stress concentrations between the segments. These points will be discussed in the following section.

4. Discussion

The study presents interesting results regarding the impact of circular design methods on interlocking systems of bending-active beam elements.

By focusing on design and craftsmanship, the results extend the current state of research on interlocking connections, especially regarding the possibility of interlocking beams along their length in a novel way. The literature studies and analyses of suitable materials and connections show that traditional timber construction provides a wide range of possibilities.

The high level of craftsmanship involved in wood-to-wood connections may increase the perceived value of wood as a material. Despite standardisation, wood looks different and can be processed differently depending on its origin and type of wood. This was also observed during the construction of the demonstrator. Increasing the appreciation of the material could be highly desirable in terms of a circular economy, as it could help to ensure that manufactured components are more likely to be reused and remanufactured at the end of their life than components designed to be discarded. Furthermore, the processed wood shows the labour, carpentry and engineering skills that have been invested in it.

Interlocking connections also make an important contribution to circular construction through their reversibility, but in unmixed timber construction they can also be returned to the biological material cycle as a whole. But it is not only the circularity, but also the possibility of varying forms in connection with bending-active structures that opens new possibilities of use and longer service lives.

Regarding the possibilities of variable design through changeable cross-sections, the present study can only be seen as a first contribution. A comprehensive investigation of the influence of variable stiffnesses on the shape and design of load-bearing structures will follow.

Within the scope of the analyses, European wood species were presented and compared with each other with regard to their mechanical properties and suitability for bending-active structural behaviour. If availability and sustainability reasons are disregarded and non-European tree species are considered, different conclusions could be drawn. Furthermore, different timbers can be chosen for members and joints, which would result in a different load-bearing behaviour.

In the designed cross-section, the different layers are coupled on top of each other to resist bending in the y-direction. Another possibility is to extend the cross-section in the y-direction. Likewise, the proposed stiffness matrix method could be applied. This would have a significant influence on the resistance to impacting bending moments. This is an important aspect that can be explored by further research, particularly due to the bending-active behaviour of the structure and the resulting twisting of the cross-sections.

Due to the fish glue used, the developed system can currently only be used under indoor conditions, as this dissolves on contact with warm water. Conventional component adhesives, however, do not bond components together in a separable way, so that appropriately manufactured components can only circulate in the technical material cycle. The authors therefore welcome research into fully biodegradable glues and can envisage their use in research projects. In addition, the construction method used of glue and wooden nails reaches its mechanical limits due to the shear stresses that occur. As an alternative, the partial cross-sections can also be milled from a solid cross-section. However, the material

consumption for milling the joint is very high. For the cross-section developed in this project, for example, the loss is approximately 25%. For this reason, it must be discussed whether the waste of a biodegradable material can be justified compared to the use of a component adhesive.

In order to allow the beams to slide, tolerances have to be strictly adhered to. By using a CNC milling machine to produce the cross-sections, the accuracy of fit can also be further improved. In addition, creep loads, and the effects of humidity have not been considered and are the subject of further research.

When generating inverted catenaries using variable cross-sections, the individual beams have so far only been optimised manually. Here, a computer-aided optimisation can be developed that calculates the best configuration under given boundary conditions. On the other hand, the stress peaks that occur may require an adjustment of the built cross-sections. The best solution probably lies between the optimum arrangement of individual cross-sections and a construction-based solution. Furthermore, a study of the principle in large-scale systems may also be considered.

5. Conclusion

This study investigated the potential of circular design for bending-active timber structures. Building on the parameters of materials and connections, both experimental and computational studies were used to answer the research questions.

To explore the design scope through variable stiffnesses, small preliminary studies were first carried out, which showed the influence of variable bending stiffnesses on cross-sections, especially over the cross-section length. Under the premise of circular design, suitable materials and connection options for a built system were then analysed. The results from various European wood species showed that hardwoods have good properties for this purpose, so that lime wood was ultimately chosen for the demonstrator. Dovetail joints were chosen for the built example due to the form-fitting nature of the joints. Based on the previous analyses, a modular system was conceptualised and subsequently implemented in the built example. Furthermore, the principle of the stiffness matrix was presented, with which the beam stiffnesses could be successfully varied over the beam length on the prototype. Finally, the developed principle was transferred into a computer model and tested for its design applicability.

The results of the project show that circular design affects the materials, cross-sections and connections of bending-active structures in different ways and is in general possible. The study focused on the design and fabrication of a demonstrator. Possibilities for improvement were identified in the manufacturing methods. In addition, further studies on form finding with variable cross-sections were proposed to further verify the developed principle.

The developed reconfigurable modular system enables a wide range of new design possibilities. Particularly in view of the need for a circular economy in the building industry and the associated reusability and recyclability of materials, the required quality of craftsmanship has a positive effect on the respectful use of materials. The interlocking connections, their reversibility, and the possibility to vary the structural system can lead to a longer acceptance and therefore a longer service life of load-bearing structures. Thus, interlocking connections in bending-active timber structures are an interesting way of contributing to a new design language in architecture and engineering.

Abstract

In previous studies, the authors have presented the concept of building hybrid gridshells as an effective method for spanning large distances with very little material. In this approach, the structure consists of carbon fiber-reinforced polymer (CFRP) strips, which serve as lost formwork in the construction of a concrete gridshell. Preliminary digital simulations and physical tests have shown promising performance gains, but have also raised important questions about the structural behavior of the hybrid cross-sections that require further investigation. Motivated by this challenge, this study aims to investigate the material properties of composite CFRP-concrete cross-sections through physical experiments. A total of eighteen test specimens were produced and divided into six groups, which differed in terms of their internal and external reinforcement and bonding properties between the two materials (full or partial bonding). All specimens were tested in a four-point bending arrangement to evaluate the performance of the proposed CFRP-concrete cross-section. The loading and deflection were recorded and discussed in detail. The results of these tests show that the flexural capacity of gridshell beams, which have a full bond between CFRP and concrete, is more than 300% higher than that of the concrete-only control beams. This confirms that the type of connection between the layers has a significant influence on the load-bearing and bending capacities. Moreover, these test results show that the bending strength and stiffness of the developed hybrid cross-section offer significant improvements over the concrete-only control beams. In conclusion, this study proves that externally bonded CFRP strips not only serve as an effective stay-in-place formwork for the fabrication of concrete gridshells, but also exhibit a beneficial composite effect in the interaction between the two materials of a hybrid cross-section.

Keywords: bending-active formwork, hybrid cross-section, material properties, experimental method, concrete, carbon fiber reinforced polymer, composite structures, hybrid gridshells

1. Introduction

Concrete shell structures are an efficient means of spanning large distances with little material. However, their construction requires a significant amount of labor, which makes the process time-consuming and costly. To address this challenge, researchers have introduced new methods of constructing concrete shells and gridshells using bending-active structures with minimal and easy-to-build formwork. The idea behind bending-active structures is to use large elastic deformations of

originally straight or planar building elements to create structures with complex curved geometries [1]. Moreover, these bending-active structures bring formal design freedom and can be applied to both synclastic (centers of curvature located on the same side of the surface) and anticlastic (centers of curvature located on opposing sides of the surface) geometries [2] [3]. Using this technique, the authors have further demonstrated that it is possible to build elastic gridshells from millimeter-thin carbon fiber reinforced polymer (CFRP) strips, in which the strips can serve both as stay-in-place formwork as well as potential tensile reinforcement in the production of lightweight hybrid gridshells [4]. This concept is beneficial because it addresses one of the biggest challenges in dealing with concrete, namely its low tensile capacity compared to its high compressive strength. While conventional concrete structures counteract this material weakness by adding steel reinforcing bars, which results in thicker cross-sections, the authors investigated the use of CFRP as a material for the stay-in-place formwork and external reinforcement to further reduce the cross-section of the hybrid gridshell. CFRP is a very suitable material in this context and is often chosen for retrofitting or repairing concrete structures, as it is durable, has very high tensile strength, and is available in various forms such as sheets, strips, or rovings [5].

The proposed hybrid concrete and CFRP gridshell takes advantage of the inherent strengths of the two materials while achieving the goal of large spans with low material usage. However, for this hybrid system to be used effectively, a complete understanding of the material's behavior and its limitations is required, both by the engineers who design this innovative system and by the construction workers who handle the material. In addition to the mechanical strength, the modulus of elasticity is one of the most important characteristics in structural design, controlling the stiffness and accordingly deformation and serviceability. A number of studies have investigated the bending behavior of various concrete mix designs and cross-sectional designs, the effect of various amounts of internal reinforcement, the type and amount of external reinforcement (e.g., glass fiber reinforced polymer (GFRP), and CFRP), the percentage of pre-loading, the shear and flexural debonding mechanisms of the fiber reinforced polymer (FRP) layers, and different configurations of the external reinforcement [6]–[12]. However, there are not many studies that focus on the flexural strength in hybrid concrete-CFRP structures, especially in the context of using this material combination for hybrid gridshells based on bending-active formwork. Previous to this work, authors performed a parametric sensitivity analysis for such hybrid concrete and CFRP gridshell structures using digital simulations [13]. As a further step, this study aims to perform a preliminary experimental investigation of the material properties of this hybrid cross-section and to provide some initial design guidelines for its implementation. For this purpose, a series of four-point bending tests were carried out, which will be discussed in more detail in the following sections.

2. Methodology

The tests were conducted at the Civil and Environmental Engineering (CEE) Department at the University of California, Berkeley. The purpose of the tests was to investigate the behavior of hybrid beams made of CFRP strips and concrete. In addition, an analytical study of the proposed hybrid cross-section was performed to compare its results with the experimental results and confirm the reliability of the obtained experimental data.

2.1. Experimental study

A total of eighteen specimens were fabricated and divided into six groups (3 specimens each), including: (i) concrete (C), (ii) concrete with internal GFRP mesh (C Mesh), (iii) concrete-CFRP bonded together by nail connectors (C-CFRP Nail), (iv) concrete (with internal GFRP mesh) and external CFRP, interconnected by nail connectors (C-CFRP Nail Mesh), (v) concrete-CFRP interconnected by epoxy resin (C-CFRP Epoxy), and (vi) concrete (with internal GFRP mesh) and external CFRP interconnected by epoxy (C-CFRP Epoxy Mesh). Finally, three concrete cylinders were fabricated on which compression tests were performed.

2.1.1. Test specimens and material

All beams were 30.4 cm long, 5.08 cm wide, and 1.4 cm deep (referring to the concrete layer). The concrete cylinders were 20.32 cm high and 10.16 cm in diameter. Figure 1 shows the dimensions and connection details of the tested beams in this study. All beam and cylinder specimens were cast from the same batch of Sikacrete®-752 3D concrete with a water-cement ratio of 17% and cured in the fog chamber for 28 days. In addition, nine of the beams were reinforced with an embedded GFRP grid at the midplane of their cross-sectional height. Six of the eighteen test specimens connect the CFRP strip to the concrete through nails. This was achieved by attaching the nails to the CFRP strips with epoxy and later pouring the concrete onto them. The 10 nails are distributed in two parallel rows along the length of the beams, spaced 6 cm apart and 3.2 cm from the short edge. The CFRP strip used for 12 of the specimens has a thickness of 0.2 cm.

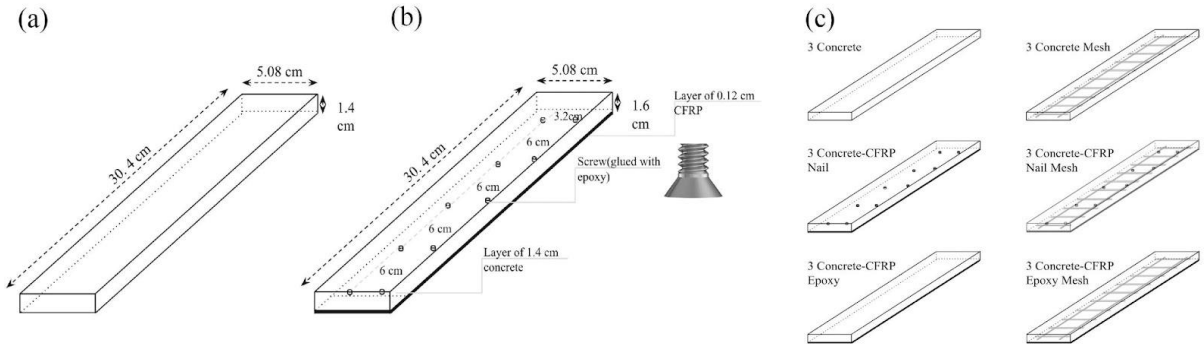

Figure 1. (a) Dimensions of specimens without CFRP (b) Specimens with CFRP and nail connector arrangement for C-CFRP Nail beams (c) Configuration details of the individual beam categories.

2.2. Compression test

28 days after casting, three concrete cylinders were tested for compression using the ASTM C39 procedure and the Forney Compression Machine (700K capacity), as shown in Figure 2.

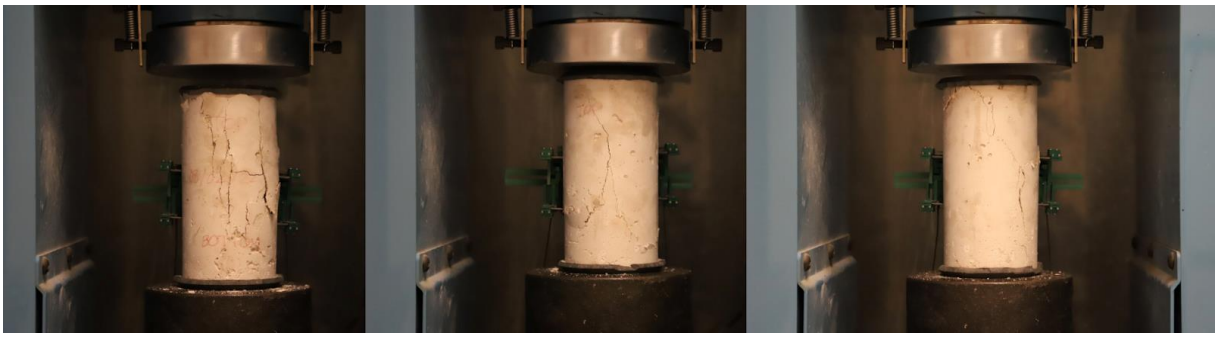

Figure 2. Three concrete cylinder specimens after performing the compression test.

We determined the compressive strength of the concrete using Equation 1 [14] and the failure loads obtained from the compression tests.

$$f_c = \frac{F}{A_c} \tag{1}$$

in which:

F: failure load (N)

A_c: area of the specimen on which the load was applied (mm^2)

The mean strength values, f_c of concrete cylinder, obtained was 31.55 MPa (N/mm^2).

2.2.1. Young's Modulus calculation from the compression test

The static pressure modulus of elasticity is the ratio between a compressive stress difference and the corresponding so-called elastic deformation per unit length [15]. The modulus of elasticity is calculated using the stresses (σ_o and σ_i) and strains (ε_o and ε_i) at points $0.33f_c$ and 0.5 N/mm², respectively, and the associated measuring length l_o of the extensometer (used for calculating the strain values from the displacement measurements), from Equation 2: The mean value for the concrete's longitudinal modulus of elasticity, E, was 33,718 N/mm².

$$E = \frac{\Delta\sigma}{\Delta\varepsilon} = \frac{\sigma_o - \sigma_i}{\varepsilon_o - \varepsilon_i} \tag{2}$$

with:

E: Modulus of elasticity [N/mm²]

σ_o: Test stress at $0.33f_c$ [N/mm²]

σ_i: Test stress of 0.5 N/mm²

ε_o: Strain measured at σ_o

ε_i: Strain measured at the stress of 0.5 N/mm²

2.3. Four-point bending test

The beams were externally instrumented and tested under four-point bending. Two vertical loads were applied symmetrically with respect to the mid-span of the beams with a constant bending moment region of 7.62 cm. All the beams were simply supported and had an effective span of 22.86 cm. Figure 3 shows the experimental setup in detail, along with the dimensions. The applied load and vertical displacements were monitored throughout the tests. Displacement was measured at mid-span using linear variable differential transformers (LVDTs). The applied two concentrated loads to the beam were monitored using load cells. All data obtained from the load cells and the LVDTs were recorded using a data acquisition system.

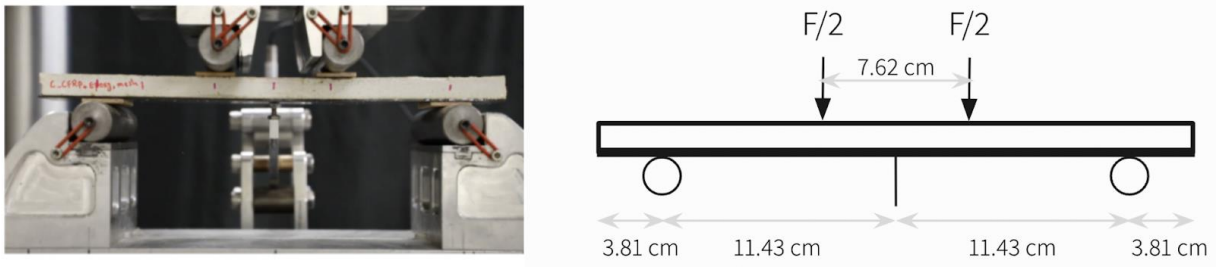

Figure 3. Left: Experimental setup. Right: Dimensions, loading, and support conditions

2.4. Analytical study

The transformed properties of the hybrid cross-section are calculated via the modular ratio n, which is described as shown below and used to obtain the transformed concrete section from the composite section (Equations 3-9). This value determines the reduced cross-section values of the lower (CFRP) layer. The original C-CFRP and transformed calculated concrete cross-sections are shown in Figure 4.

$$n = \frac{E_{CFRP}}{E_c} \tag{3}$$

$$A_{CFRP,tr} = A_{CFRP}.n \tag{4}$$

$$I_{CFRP,tr} = I_{CFRP}.n \tag{5}$$

$$A_i = A_{CFRP,tr} + A_C \tag{6}$$

$$Z_i = \frac{A_{CFRP,tr}.Z_{CFRP,tr}+A_C.Z_C}{A_i} \quad (7)$$

$$I_i = I_{CFRP,tr} + A_{CFRP,tr}.\Delta Z_{CFRP,tr}{}^2 + I_C + A_C.\Delta Z_C{}^2 \quad (8)$$

$$W_i = \frac{I_i}{Z_i} \quad (9)$$

With:

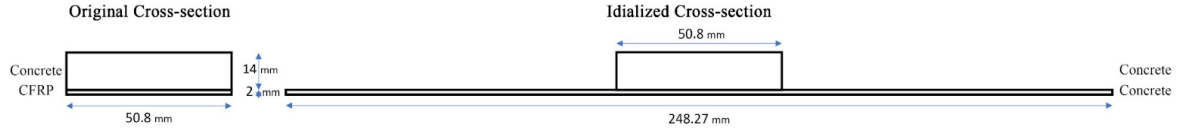

Figure 4. Left: Original concrete-CFRP cross-section. Right: Transformed concrete cross-section.

The cracking moment is calculated using the mean concrete tensile strength f_{ctm}. This is according to Equations 10 and 11, calculated from the concrete's compressive strength. The calculated transformed concrete cross-section and the cracking moment, force, and its associated displacement are presented in Tables 1 and 2.

$$f_{ctm} = 0.3.(f_{ck})^{\frac{2}{3}} [N/mm^2] \quad (20)$$

$$M_{cr} = W_i.f_{ct,eff} \quad (31)$$

3. Discussion

Figure 5 shows the load-displacement diagrams for each of the specimens in the four-point bending test. The plots represent the sum of the loads from the two load cells versus the measured deflection of the beam at mid-span. Figure 6 shows the load-deflection diagram of the C-CFRP Epoxy and C-CFRP Epoxy Mesh specimens compared to the calculated stiffnesses up to the cracking moment M_{cr}, where the cracking moment is calculated using Equation 11. Figure 7 shows the test setup for the four-point bending test and the appearance of the specimens after testing.

In Figure 5a, which shows the concrete-only specimens, i.e. control specimens, an almost linear behavior is observed until the ultimate load is reached, after which the load suddenly drops to zero since the specimens are brittle and have no reinforcement. The calculated modulus of elasticity of these concrete beams from the four-point bending test (32,875 N/mm²) is compatible with the calculated modulus of

elasticity from the compression test of the concrete cylinder (33,718 N/mm²). The maximum load capacity of specimens C_1 and C_2 is lower than that of specimen C_3 because they had some preliminary damage at the edges of their cross-sections.

For the concrete mesh specimens (Figure 5b), after the crack initiation at about 200-267 N, some strength gain is observed due to the internal GFRP mesh reinforcement, which also increases the ultimate load capacity by up to 30%.

Figure 5c shows that the C-CFRP Nail beams experience an initial steep strength drop related to the delamination of the CFRP layer and a second drop due to the brittle failure of the concrete layer.

Figure 5d shows the C-CFRP Nail Mesh beams initially experiencing delamination of the CFRP layer, followed by cracking within the concrete layer and some strength gain due to the internal GFRP mesh reinforcement.

Figures 5e and 5f show that the initial stiffness of the C-CFRP Epoxy specimens with and without internal reinforcement decreases sharply as a result of the delamination of the CFRP layer and subsequent failure of the concrete layer. However, the ultimate strength of these two groups are much higher than the other 4 groups (about 300% higher, load capacity of 1,200 N compared to only 300 N).

In the C-CFRP Epoxy Mesh category, one specimen was completely broken when removed from the casting formwork, while another specimen showed minor cracking. The calculated flexural stiffness (EI) values for C-CFRP Epoxy Mesh specimens 1 and 2 were determined to be about 1,350,000 (KN.mm²) and 202,000 (KN.mm²), respectively. However, due to the large difference between the results of these two specimens and to ensure the validity and generality of the results, it is planned to repeat a four-point bending test on this particular category of specimens. This set of specimens display a significant improvement in their ultimate load capacity compared to the concrete control beams.

The analytical calculations for the C-CFRP Epoxy specimens with and without reinforcement mesh suggest that the first crack should occur at approximately 516 N, as shown in Figure 6. However, the onset of cracking took place at about 800 N, possibly due to the epoxy preventing crack development up to a higher load.

Finally, the flexural strength (EI) of each specimen is calculated using Equation 12, and the average flexural stiffness of the three specimens in each category is shown in Table 3.

$$EI = \frac{Fa(3L^2-4a^2)}{24\Delta max} \tag{42}$$

Where:

EI = flexural stiffness (N.mm^2)

P = total point load (N)

a = distance from support to the point load (mm)

L = length of the span under consideration (mm)

Δ_{max} = mid-span deflection (m)

Table 3. Average flexural strength (EI) of each category of beams.

Specimen Category	**C**	**C Mesh**	**C-CFRP Nail**	**C-CFRP Nail Mesh**	**C-CFRP Epoxy**
Average EI (N.mm^2) (uncracked)	570,051,659	582,398,188	611,749,422	648,362,988	632,864,071

4. Summary and conclusion

This study investigates the flexural behavior of eighteen beam specimens, six of which were reinforced with CFRP strips via an epoxy adhesive or nail shear connectors. The test variables studied in the experimental program were the internal GFRP mesh reinforcement, the external CFRP layer, and the type of connection between the external CFRP and the concrete. All specimens were tested under four-point bending, and three concrete control specimens were used for the comparative strength. In addition, to the experimental tests, simplified transformed section analyses were conducted.

Based on the experimental and analytical studies, the following observations and conclusions were made:

- All hybrid beams failed due to delamination of the CFRP strips, confirming the importance of proper shear connections between the two layers.
- For the hybrid specimens with nails, it is observed that the composite behavior does not fully develop, which may be due to the weak connection between the nails and the CFRP layer and the small force transfer area between the nails and the CFRP layer.
- For the hybrid specimens with epoxy resin, the composite properties have a significant influence on the performance of the cross-sections. These specimens have a higher ultimate flexural capacity (up to 320% more compared to the control beams), and a significant decrease in flexural stiffness is observed after delamination of the CFRP layer.
- For the specimens without CFRP layer, the internal mesh reinforcement contributes to the increase of the ultimate flexural capacity of the specimens (to about 30% of the original crack load of the specimen). However, for hybrid cross-sections, the ultimate load-bearing capacity depends more on the composite action of the hybrid cross-section rather than by the presence of the internal mesh.
- In the case of hybrid cross sections, the addition of the mesh also helps to restore the stiffness lost due to cracking in the concrete. It can also be seen that the delamination of the CFRP layer greatly reduces the stiffness of the cross-section.
- The first crack in most specimens occurs at a force of about 220-300N (about 25% of the ultimate load of the specimens with epoxy). For the C-CFRP Epoxy specimens, the experimental cracking moment is higher than the calculated cracking moment, which could be attributed to the crack-preventing effect of the epoxy.

Acknowledgements

The authors would like to thank the Department of Civil and Environmental Engineering (CEE) and the Department of Architecture at UC Berkeley's College of Environmental Design (CED) for accommodating this study. Special thanks are also due to the Al Falah Fellowship, Hellman Fellowship, and Bakar Fellowship for their generous financial and intellectual support of the authors. We also wish to acknowledge the support provided for this research by Dr. Cruz Carlos, CEE concrete lab manager, for his guidance and discussion on conducting physical testing and analysis, and all the laboratory technical staff members. Finally, we would like to extend our thanks to this project's undergraduate student assistants, Seoyoung Oh, and Zaina Mosalam for their excellent work and assistance during this study.

Abstract

Kerf bending (KB) is a technique to reduce bending stiffness and enabling curvature by providing openings or cutouts in inflexible flat materials. This study focuses on the application of the KB technique for unidirectional bending and proposes a shape control method for active bending arch structures to attain target shapes. The efficiency of this approach is validated through experimental and analytical examinations. There are a multitude of slit patterns utilized in KB, in this study a simple pattern of parallel lines in the orthogonal direction to the span was employed. By manipulating the distribution of two design parameters, "slit spacing" and "slit ratio", the bending stiffness of rigid plane material is altered and the deformed shapes can be controlled. Four distinct geometric shapes were set as target shape: semi-circle, sine wave, parabola, and catenary. Since bending deformation is solely generated through the movement of pin-supported points, the bending moment distribution $M(x)$ on attainment of the target shape can be easily calculated from the support reaction force P and the point height y, and the required stiffness distribution can be obtained through $M(x)$ and the curvature distribution κ of the target shape. By combining information about the required curvature distribution and the slit arrangement - stiffness reduction relationship, the optimal slit arrangement can be determined.

Keywords: active bending, arch, kerf bending, shape control, slit pattern, laser cutter, stiffness reduction

1. Introduction

In recent years, as digital processing technology has become more common, there have been cases where materials have been given properties that were not originally available. One example is "kerf bending (KB)," a technique that reduces bending rigidity by inserting slits or openings in a rigid plane material to make it easier to bend. This technique does not require any special equipment other than a cutting machine, and is expected to be applicable to a wide range of fields from product design to architecture, as it can be easily and quickly bent into various materials.

T. Oshima et al. proposed an analytical model for elastic materials with 2D repetitive slit patterns[1]. They modeled the relationship between the local geometry and resultant global elasticic modulus. O. Z. Güzelci et al. studied cut patterns that can be manually and freely formed on 3D surfaces[2]. S. Zarrinmehr et al. presented a relief cutting method to turn rigid planar surfaces into flexible ones using meander pat- terns that consist of interlocked Archimedean spirals[3]. A. Kalama et al. study kerf bending, where material is removed at strategic locations on the surface of a plate to locally weaken it and make it easier to bend aiming to understand the interrelationship between cutting patterns and properties such as bending curvature and material resistance to load[4]. D. Mitov et al. studied a method for designing cutting patterns based on geometry and material processing for the production of double curved architectural panels for materials widused for interior wall finishes, such as wood and

plasterboard[5]. M. Capone et al. proposed a method to make ruled double curved surfaces by making used of kerf bending[6]. R. Chen et al. studied kerf cut patterns for designing complex free-form shapes[7]. Two types of cut patterns, square and hexagonal, were assumed and the relationship between different cutting densities and kerf patterns for elongation, bending and torsional deformation was considered. B. R. Lorenzoni focused on the geometric accuracy of MDF kerf bending and examined the design, cutting, bending, 3D scanning and analysis of target geometries to form accurate cylindrical shapes[8].

Although a certain number of papers have studied the relationship between kerf cut pattern and bending stiffness, machining accuracy to obtain an accurate shape, etc., there have been no studies that have proposed a method to actively control the shape formed by varying the cut pattern. This study focuses on KB technology for unidirectional bending of wood board materials such as MDF boards. By applying it, it is aimed to propose a method to control the shape of the arch structure formed by the active bending to achieve an arbitrary target shape, and to verify its effectiveness.

2. Calculation of stiffness distribution

To control the shape of active bending arch structures, it is necessary to determine the stiffness distribution along the length of the material that can achieve the target shape. The stiffness distribution can be expressed as a distribution of reduction ratio when the stiffness of a member without slits is set to 1. This reduction ratio distribution is called $C(x)$ here, and the calculation of $C(x)$ is shown in the following section.

2.1. Basic theory

Consider a beam-like member supported by a left-end pin and a right-end pin roller like shown in Figure 1. If the member is transformed into an arch shape only by applying a leftward pushing force P at the right end, the moment distribution $M(x)$ can be simply expressed as follows using the deformation $f(x)$ in the y direction.

$$M(x) = P \cdot f(x) \tag{1}$$

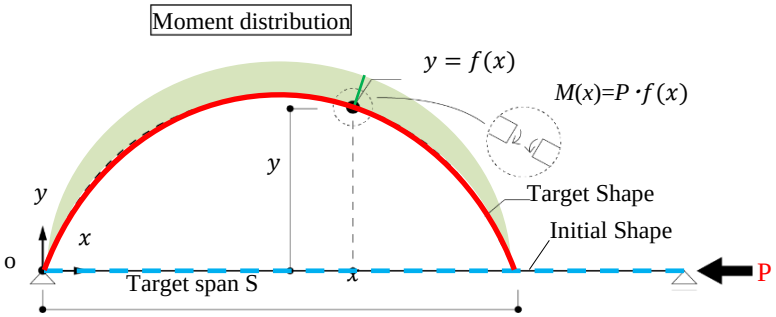

Figure 1. Moment distribution of active bending arch structure

If $f(x)$ matches the target shape and the effect of self load can be ignored, the stiffness distribution $K(x)$ required to achieve the shape can be expressed as follows using $M(x)$ and the curvature distribution $\kappa(x)$ of the target shape.

$$K(x) = \frac{M(x)}{\kappa(x)} \tag{2}$$

The curvature of a beam that produces a large deformation is expressed by the following equation

$$\kappa(x) = \frac{f''(x)}{(1+f'(x)^2)^{1.5}} \tag{3}$$

The stiffness distribution $K(x)$ of the plate material with slits is defined as follows using the distribution of reduction ratio in stiffness due to slitting: $C(x)$, Young's modulus of the material: E, and sectional secondary moment: I.

$$K(x) = C(x) \cdot EI\,, \quad (0 < C \leq 1) \tag{4}$$

From equations (1)-(4), the distribution of the reduction rate of stiffness $C(x)$ required to achieve the target shape can be expressed as follows

$$C(x) = \frac{f(x) \cdot (1 + f'(x)^2)^{1.5} \cdot P}{f''(x) \cdot EI} \tag{5}$$

2.2. Target shape formation method and design

In this section, the stiffness distribution is obtained for each target shape. The model assumed is a 400mm length, 100mm width, 2.5mm thick MDF board. The magnitude of forced displacement will be unified as δ = 145.35mm, which is a semicircular arch when the target shape is a circular arc. Hence, the span (L-δ) after forced displacement for both models is 254.65 mm, and the radius r for the semicircular arch is 127.325 mm (Figure 2).

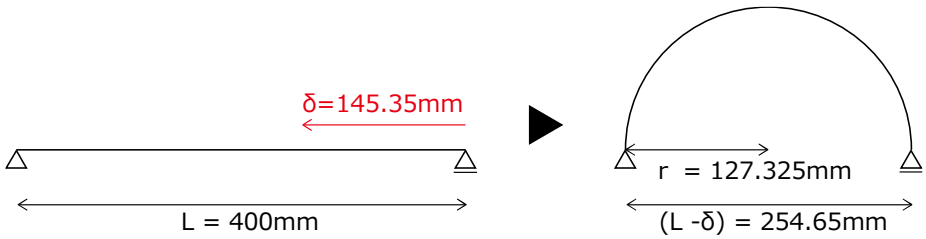

Figure 2. Overview of arch shape generation method

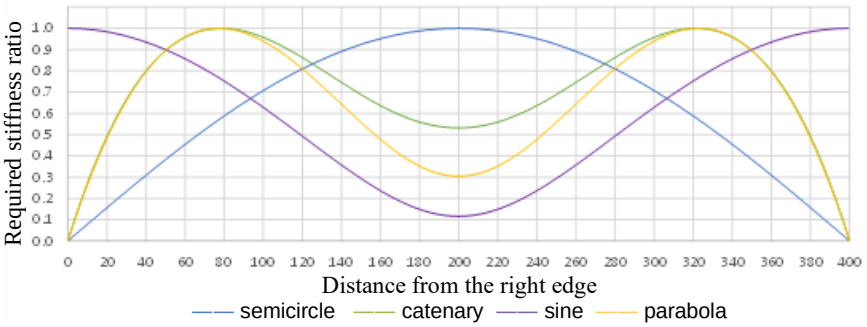
Figure 3 shows the required stiffness ratio distribution for the four target shapes (semicircle, catenary, sine, and parabola) obtained by using the procedure shown in 2.1. The horizontal axis is expressed the distance from right edge in the arch length direction, and the vertical axis is expressed the required stiffness ratio by standardizing the maximum value as 1.



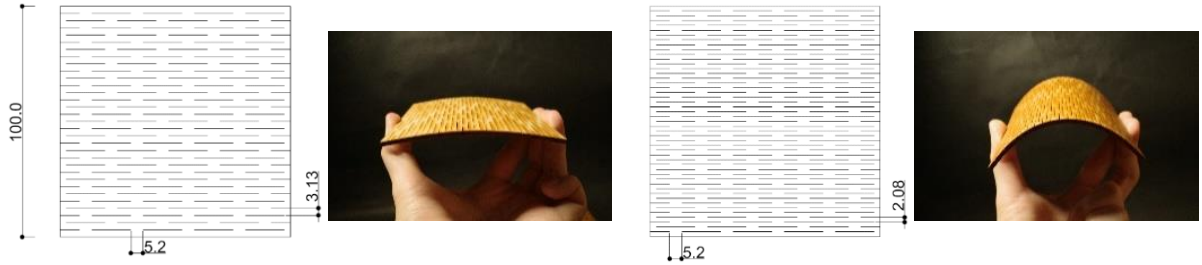


Figure 3. Distribution of required stiffness ratio

3. Design for slit arrangement

3.1. Slit setting

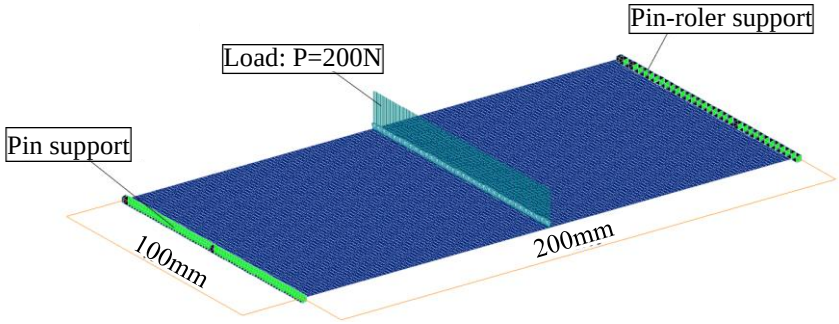
There are various patterns of slit shapes used in KB technique, however in this study the simple pattern with a series of horizontal parallel lines as shown in Figure 4 is used. This pattern is most commonly used in KB with a single curvature and is considered to have an excellent balance of strength and flexibility [2]. It has also been shown that the narrower the slit spacing and the larger the proportion of slits in the width direction, the easier it tends to bend. In this study, two variables, "slit spacing" and "slit ratio," are set as the design parameters for design. Here, "slit ratio" Indicates the percentage of openings by slits in the width direction. The distribution of these variables is manipulated to vary the stiffness of the face material and control the deformation shape. The slits are arranged so that the center positions of adjacent slits are mutually different from each other.

(a) When the slit spacing is wide (b) When the slit spacing is narrow

Figure 4. Slit arrangement and bending flexibility

3.2. Evaluation of bending stiffness by FEM analysis

To verify the relationship between cut pattern and bending stiffness, FEM analysis using a plate element model is performed. An overview of the model is shown in Figure 5. Midas/iGen is used as the analysis program. The models are MDF plates of 200 mm length, 100 mm width and 2.5 mm thick with various slit arrangement. The material properties are set to Young's modulus E = 4000 N/mm^2 and Poisson's ratio: 0.2. Linear analysis were performed under the condition that a centralized loads were applied to a simple beam(Figure 5). The load condition is set so that the total load is about 200 N in the center of the plate beam, and the self weight is not considered.



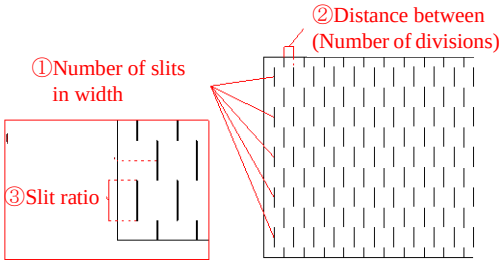


Figure 5. Analysis model

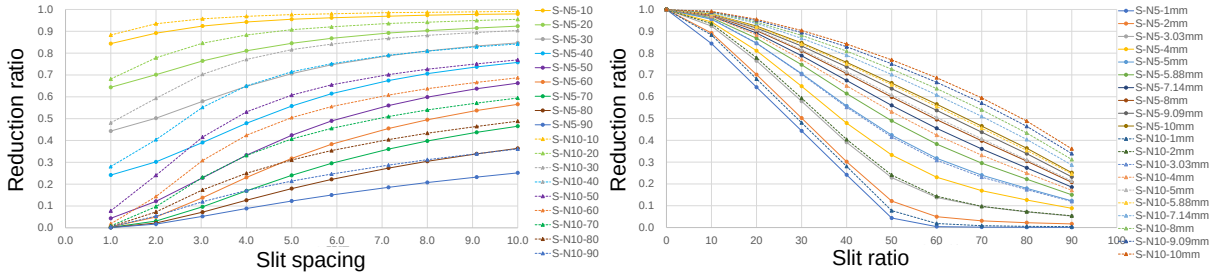
3.3. Analysis parameters

The analytical parameters are shown in Table 1. As shown in the figure in the table, when the number of slits is 5 and the slit ratio is 50%, the length of one slit is 10 mm.

Table 1. Analysis Parameters

Example of notation) S-N5-4mm-50% ① ② ③		
①Number of Slit N	②Slit spacing w[mm]	③Slit ratio c(%)
5 10	1 (200) 2 (100) 3.03 (66) 4 (50) 5 (40) 5.88 (34) 7.14 (28) 8 (25) 9.09 (22) 10 (20)	10 20 30 40 50 60 70 80 90



3.4. Analysis overview and bending stiffness evaluation method

Using the deflection δ obtained from the analysis results, the rate of reduction is back-calculated from the deflection theoretical equation for a simple beam loaded with a centralized load.

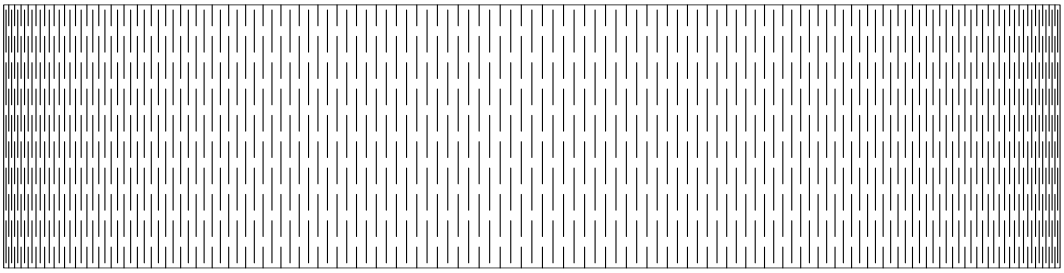
$$C = \frac{PL^3}{48EI\delta}$$

where P is the center concentration load (here P=200N), L is the length (L=200mm) and I is the sectional secondary moment(I=100×2.5^3/12=130.208mm^4).

The analytical results are shown in Figure 6. The relationship between slit spacing and slit ratio and stiffness was confirmed.

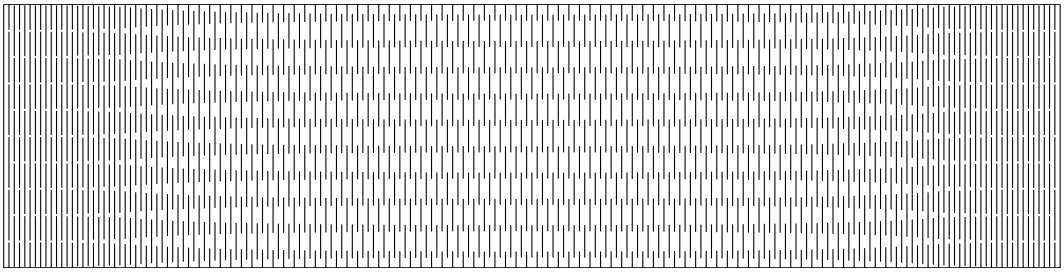
(a) Slit spacing - Stiffness ratio (b) Slit ratio - Stiffness ratio

Figure 6. Each parameter - Stiffness reduction ratio relationship



3.5. Slit pattern design

By combining the required stiffness distribution shown in Figure 3 and the relationship between slit pattern - stiffness ratio shown in Figure 6, the slit arrangement that can achieve the target shape by active bending can be determined. As indicated in 3.4, there are two design methods for slit arrangement.

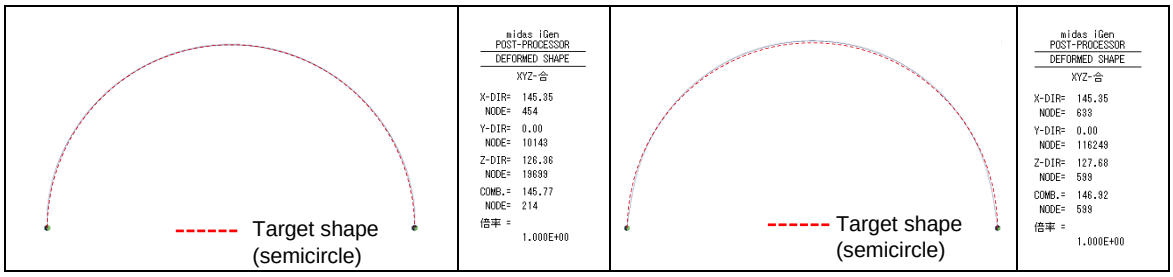


(1) Slit spacing method

(2) Slit ratio method

Figure 10 shows the slit patterns determined by each method for semicircle shape.

(a) Slit arrangement by slit spacing method



(b) Slit arrangement by slit ratio method

Figure 7: Slit pattern for semicircle shape

3.6. Confirmation by geometric nonlinear analysis

The designed slit pattern models are modelled by Midas/iGen, and a geometric nonlinear analysis considering large deformation is performed to confirm if the target shape can be formed. The arch shapes are formed by applying leftward forced displacement at the right edge of the models. In order to generate rise deformation stably, an initial irregularity of 1/800 with respect to the length was added to the center of each model. Figure 8 shows the analysis results of a semicircle as an example. From the analysis results, it can be confirmed that the shape is almost equal to the target shape.

(a) Designed by slit spacing method (b) Designed by slit ratio method

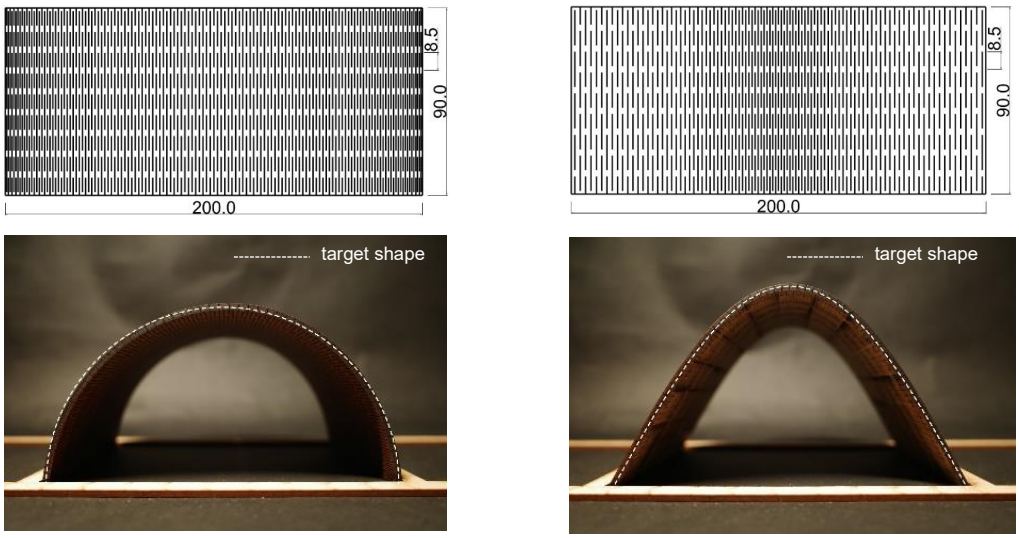


Figure 8: Analysis results for semicircle shape models

4. Experiments with scaled models

To confirm the effectiveness of the proposed method, scaled models was actually produced and the arch shape were formed by active bending. This chapter presents a summary of the results. A Trotec Laser laser processing machine Speedy 4002 was used to prepare the specimens. Slit widths ranged from 0.2 to 0.4 mm, with an average of 0.3 mm.

4.1. Simple experiment

A simple experiment using a small-scale model of 90 mm x 200 mm x 2.5 mm is shown in Figure 9. The cut pattern was designed using the method of changing the slit spacing. It was confirmed that the target shape was achieved for both targeted shape of the semicircle and the sine curve.

(a) Semi-circle (b) Sine curve

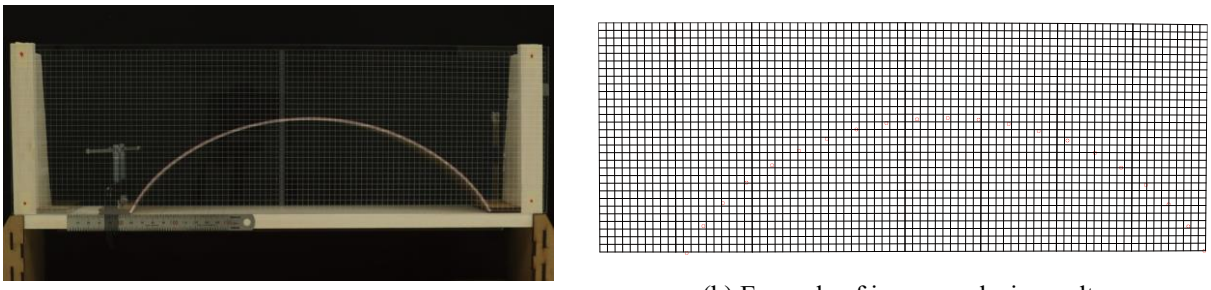

Figure 9. Shape control by varying slit spacing

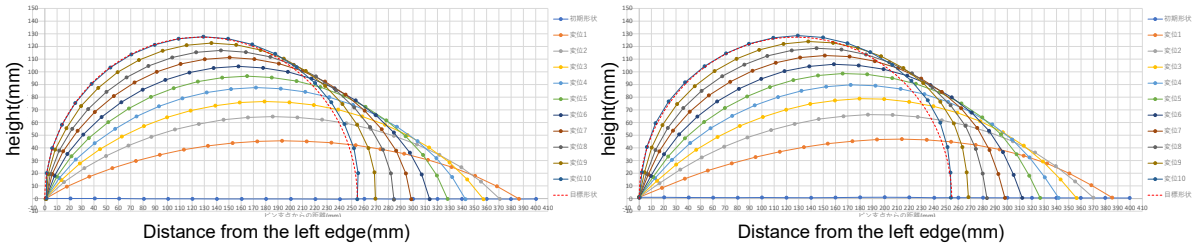
4.2. Detailed experiment

More detailed experiments were carried out and are reported here.

The test specimen preparation conditions are the same as in 2.2. The specimen were made by 2.5mm thick MDF board with 400mm length and 100mm width and were machined with slits in the pattern shown in Figure 7. A Trotec Speedy 400 laser cutter was used for the slitting process.



A forced displacement of up to 145.35 mm on the left side was applied in 10 steps to the right supporting point, forming a final semi-circular arch. The overview of experiments is shown in Figure 10. Measurement points are marked on the test specimen beforehand at intervals of 20 mm along the length direction. An acrylic plate with grids marked at 5 mm intervals is placed in front of the test specimen and the co-ordinates of the measuring points at each step are measured by image analysis using still images.

(a) Test specimen and test equipment (b) Example of image analysis results

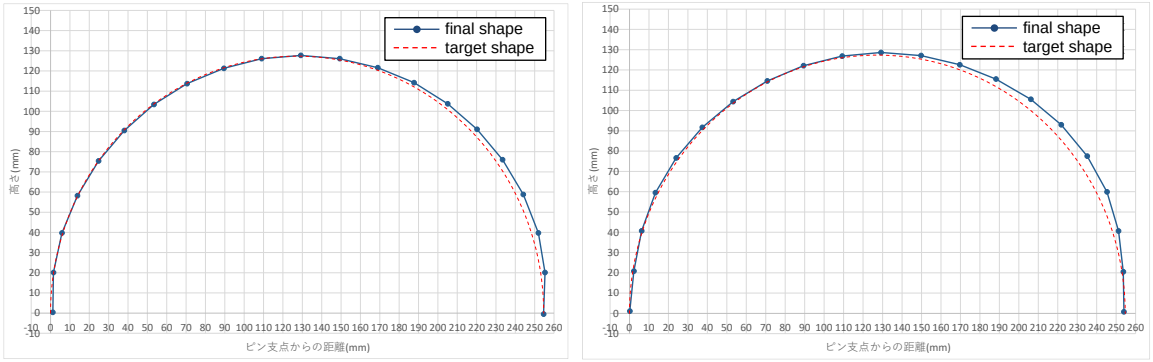


Figure 10. Overview of detailed experiments

Figure 11 shows a progress of deformation at each step and final shape of the specimen forming a semicircle. The final shape formed by each specimen is shown in Figure 12. The test results showed a maximum error of about 2% with respect to the span. Despite some errors, the shape was generally equal to the target shape. The error is thought to be due to the effects of gravity and the initial bias in the stiffness of the material, and partly due to the effects of material non-linearity.

Figure 12: Comparison of final and target shape

5. Conclusion

This study proposed a shape control method for active bending arch structures by combining with kerf bending technique. In this study a simple slit pattern of parallel lines in the orthogonal direction to the span was employed. It is possible to vary the stiffness of inflexible plane board by adjusting the length and spacing of the slits to achieve the target arch shape.

In this study, four distinct geometric shapes were set as target shape: semi-circle, sine wave, parabola, and catenary. The required stiffness distribution can be obtained through $M(x)$ and the curvature distribution κ of the target shape. By combining information about the required curvature distribution and the slit arrangement-stiffness reduction relationship, the optimal slit arrangement can be determined. Simple experiments and geometric nonlinear analysis have demonstrated the effectiveness of the method.

If the span is large in relation to the stiffness, the effect of gravity may be greater. Correction methods that take into account the effect of gravity are still under investigation.

Abstract

Globally, concrete is the second most used material after water. On average, three tons of concrete is consumed per person per year, while each ton of concrete added to the atmosphere contributes one ton of greenhouse gases. Because of this negative environmental impact, research institutions, architects, and construction professionals seek to reduce concrete usage in the built environment. Material-optimized structures offer one approach; however, such structures often require custom-made formworks that are disposed of after a single use and are thus expensive and waste-generating. Recently, several unconventional solutions for formwork have emerged that produce material-optimized structures without generating significant waste, including the examples of lost-, stay-in-place, and dynamic-formworks. This paper examines 4D-printing technology, which is tested in terms of scalability to produce a building component through fiber-reinforced concrete (FRC) spraying. With an empirical study, we evaluate two different 4D-printing techniques: 1) textile 4D-printing and 2) thermoplastic 4D-printing, both enabling the production of self-shaping, lightweight textile formworks. Furthermore, we present the first prototypical results and discuss the challenges and next steps for 4D-printed formworks that promise a more sustainable use of concrete.

Keywords: 4D-printing, concrete spraying, formwork, digital fabrication, architecture

1. Introduction

Concrete is the second most used construction material after water [1], and it is one of the most significant sources of CO_2 emissions worldwide [2]. Even though efforts are made to find new ways to mix concrete using less CO_2, current incentives are not sufficient to reduce emissions. Additionally, using less bulk material overall is necessary, which is possible by casting materially optimized structures. However, custom formworks are required to cast such forms, which are used only once, and they generate a significant amount of waste [3] as well as increase construction costs by up to 70% compared to the standard [4]. Therefore, making technological improvements to formwork systems is critical to move towards a more sustainable way of building [5].

Innovation in formworks is driven by several goals: decreasing production time, reducing costs, advancing geometric complexity, increasing material efficiency, or reducing environmental impacts. Since the early 2000s, researchers have explored concrete 3D printing [6] and 3D printed thin formworks [7]. This paper explores the architectural potentials and fabrication principles for creating self-shaping lightweight, 4D-printed formworks. Such formworks could enable new design possibilities, as they are lightweight, self-shaping, applicable at a large scale, and compatible with various concrete

mixtures.

4D-printed objects are actuated or activated by environmental changes, such as heat, humidity, or tension. [8]. Although such 4D-printing has the potential to function as a flexible system at an architectural scale, the current state-of-the-art in 4D-printing only allows to produce small-scale elements (smaller than 100 mm in size). The study presented in this paper, however, scales the existing 4D-printing technologies to realize architectural and structural applications. To achieve this, a workflow is developed that is applicable to different 4D-printing techniques as shown in Figure 1. This workflow comprises the following steps: (A) Firstly, the object is 3D-printed using a specific print path. Secondly, (B) the object is activated and geometrically transformed. Thirdly, (C) the transformed object, which consists of plastic and textile, is sprayed with a custom mortar mix with a thickness of less than 1 mm on average and the transformation is stabilized. Finally, (D) the result, the bespoke 4d formwork, is sprayed with concrete.

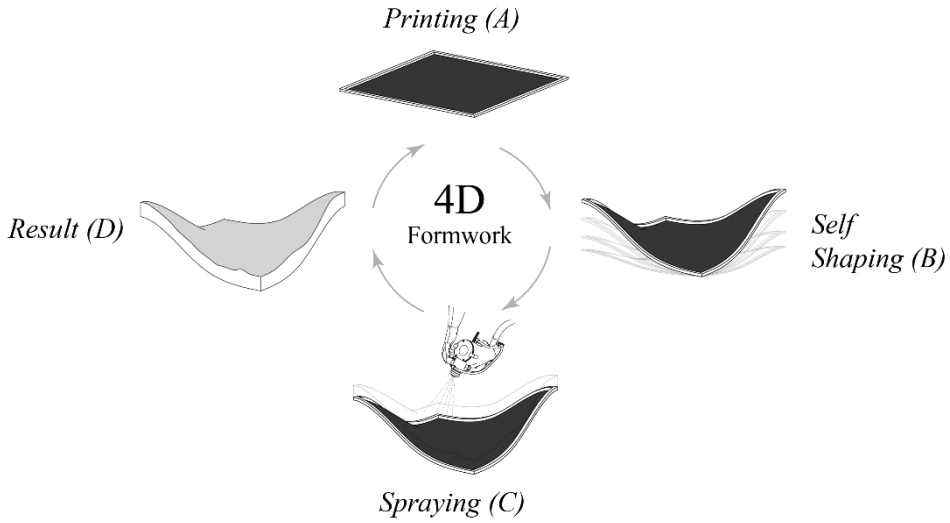

Figure 1. 4D formwork fabrication steps.

2. Relevant Work

2.1. Textile formworks

The concept of using thin textile formworks for concrete has been explored for centuries. It was first used in the Roman period, for which one example is the concrete vault under the Villa Medici in Rome [9]. The textile formworks were revisited later in history by Gustav Lilienthal in the early Industrial Revolution era and then by others throughout the 20th century [9]. More recently, Mark West, founder of the Center for Architectural Structures and Technology (CAST) at the University of Manitoba, re-introduced the concept of thin textile formwork [10]. Their work initially experimented with a method using fabric as formwork to create expressive columns (Figure 2, (A)) and as well as material-optimized beams. Despite offering considerable design freedom, these explorations have yet to make it into architectural structures, mainly due to their unpredictability, which makes it difficult to use them in interfacing with other systems, such as tension cables, foundations, and reinforcement. Another project, Knit Candela, by Mariana Popescu [11], aims to use knitted textiles as lost formworks to precisely fabricate double-curved structurally optimized shell structures. This research uses computational

methods to generate knitted patterns and fabricate textiles suspended on wooden scaffolding systems (Figure 2, (B)), which is more precise and predictable than the CAST method. It demonstrated a fabric-knitted formwork used to fabricate a double-curved shell structure, which was produced and exhibited in architectural scale. The knitted formwork is tensioned and sustained by a secondary timber structure and scaffolding, allowing the textile to stay in place while a layer of concrete is applied. The resulting shell expresses the freedom and flexibility allowed by such fabric formwork. However, despite being a very promising process, the heavy scaffolding structure used to create this pavilion does not fulfill the goal of allowing geometrical freedom using a light and self-standing formwork without extra structural material.

2.2. 4D-printing

To the author's knowledge, the general definition and theory of 4D-printing was first introduced in 2013 by the Self-Assembly Lab at MIT [12]. This definition describes 4D-printing as an additive manufacturing strategy in which an additional factor, an environmental "stimulus" such as light, humidity, heat, or speed, is used to activate a controlled transformation of the material [13]. Among various existing 4D-printing techniques, two are directly related to the study presented in this paper: Thermoplastic 4D-printing and textile 4D-printing. This study compares the potential and limitations of these two 4D-printing techniques for developing *4D formwork,* a term that is coined in this paper.

2.2.1. Thermoplastic 4D-printing

The thermoplastic 4D-printing technique enables the transformation of FDM 3D-printed objects into 4D objects, relying on the residual stress in an FDM 3D-printed object. These objects can be actuated and transformed into 4D objects by heating them above the glass transition phase, using specific print paths. Research has shown that the bending angle and deformation shape of the element are affected by

changing the overall length of the actuator and the proportions of the two sections, as well as the printing layer height and velocity. Research from CMU [14] demonstrates the design potential of this method and its high level of controllability (Figure 2, (D)). However, the prototypes have so far been small - limited to 100-150 mm - and use only PLA. The possibility of scaling up this technique to further architectural applications thus remains an untapped area.

2.2.2. Textile 4D-printing

Textile 4D-printing technique emerged when 3D-printing technology became easily accessible and allowed printing to be carried out on various supports or beds, including textiles [15]. As this method produces roughly predictable transformations, it can be used to design self-shaping objects, such as shoes or fashion garments. One example is the Active Shoe (Figure 2, (C)) project developed at MIT [16]. Other research, such as the work of Lotte Scheder Bieschin on membrane-actuated stiffness gradient composites (MASGC) [17], or similar research conducted at URJC Madrid in collaboration with Disney Research on the computational design and automated fabrication of Kirchhoff-Plateau surfaces [18] demonstrate that the results of a self-shaped membrane can be predicted and classified or simulated with a dedicated optimization algorithm. Such research presents that the design rules guiding the self-shaping deformation are known to depend on the tension applied to the textile, the print path geometry, the printing material properties, and the time allowed for the deformation. However, neither has demonstrated architectural scale applications.

This paper uses existing knowledge of both thermoplastic 4D-printing and textile 4D-printing, substantially upscaling both 4D-printing technologies and combining them with an existing concrete spraying technology, Glass Fiber Reinforced Concrete spraying (GFRC).

3. Material and Methods

To assess the feasibility of the 4D formwork for concrete structures, custom digital design tools were developed, and a series of experiments were conducted to test and validate the proposed formwork. The experimental setup, which allows for an iterative design process, uses the developed set of digital design and fabrication tools, which are explained in the following section. The iterative design and fabrication process follows four steps: design generation, printing, activation of the reaction, and 3D scanning.

3.1. Fabrication setup

The printing setup uses the same base technology for both 4D-printing techniques. As shown in Figure 3, the textile 4D-printing relies on (A) a *UR10* robotic arm with (B) a custom-made filament extruder end-effector, with a 1200 mm square print bed. The thermoplastic 4D-printing uses (C) a *BigRep One* printer with a 1000 mm print bed. On the *UR10* robotic arm, (D) an *Intel RealSense Depth Camera D435i* is mounted to scan and compare the physical result to the digital model in Rhino. For logistic reasons, all prototypes are scanned with the *UR1*0 setup.

All prototypes are printed using PLA NX2 filament [19]. To activate the prints, two different activation platforms are used as shown in Figure 3. The textile 4D-printing results are activated on (E) a platform by cutting the textile around the print without moving it from the print bed. For thermoplastic 4D-printing, the printed elements are placed in (F) a water tank. To activate the deformation, the water temperature is raised to 65°C using an array of water heating resistance.

Once deformed, prototypes are moved to the spraying setup and minimally fixed to a horizontal surface. Prototypes are first sprayed vertically with a 1 mm-thin layer of mortar using (G) a *PFT Swing L FC Airless pump*. This thin-layer locks in the final shape of the transformed print when it hardens and

supplies enough rigidity to support the next layer. After curing for 24 hours, the prototypes are sprayed with GFRC using the setup from *Aerocrete*, a project that introduces a novel spraying technology for the production of slender, bespoke concrete elements [20]. Within the scope of this paper, this setup includes (H) an *MK3 Powertex Facing Coat Spray Gun* that chops glass fibers into 20 mm lengths and then pushes the material with the fibers through (I) a nozzle using pressured air.

3.2. Digital design tools

Digital design tools rely on existing software to generate a print path based on a target geometry. The print path is designed and visualized in Rhino [21] Grasshopper [22]. Both 4D-printing techniques rely on custom Python components developed within the open-source, python-based framework COMPAS, specifically, the COMPAS Slicer library [23]. The input geometries and parameters are converted to *.json* files or *.gcode* and sent to the fabrication setup for printing. The design tool also includes software components that convert the parameters into boundary representation (Brep) to visualize the print volume in Rhino, which serves as a visual interface.

3.2.1. Thermoplastic 4D-printing tool

For thermoplastic 4D-printing, the user can draw the targeted geometry directly in Rhino. As shown in

Figure 4, during the curvature analysis process, the tool first takes the curvature value (k) of uniformly distributed points on the input curve. Then by evaluating the product of *k* between two adjacent points, the input curve is divided into concave and convex segments. The k product of two adjacent points at the concave and convex transition area is *(kn × kn + 1 < 0)*. At the other locations, the k product is *(kn × kn + 1 > 0)*. When the k product equals 0, then *(kn × kn + 1 = 0)*, which indicates that the input is a line. For *(kn < 0),* the curve is convex; for *(k > 0)*, the curve is concave; for *(kn × kn + 1 = 0),* the curve is straight. Based on the results of these calculations, a custom print path is generated. Finally, based on the segmentation of the curve, the tool helps to arrange the actuator and constraint sections and their corresponding print path. This computational process aims to ensure that the shape of the physical specimen after the transformation is consistent with its original digital input.

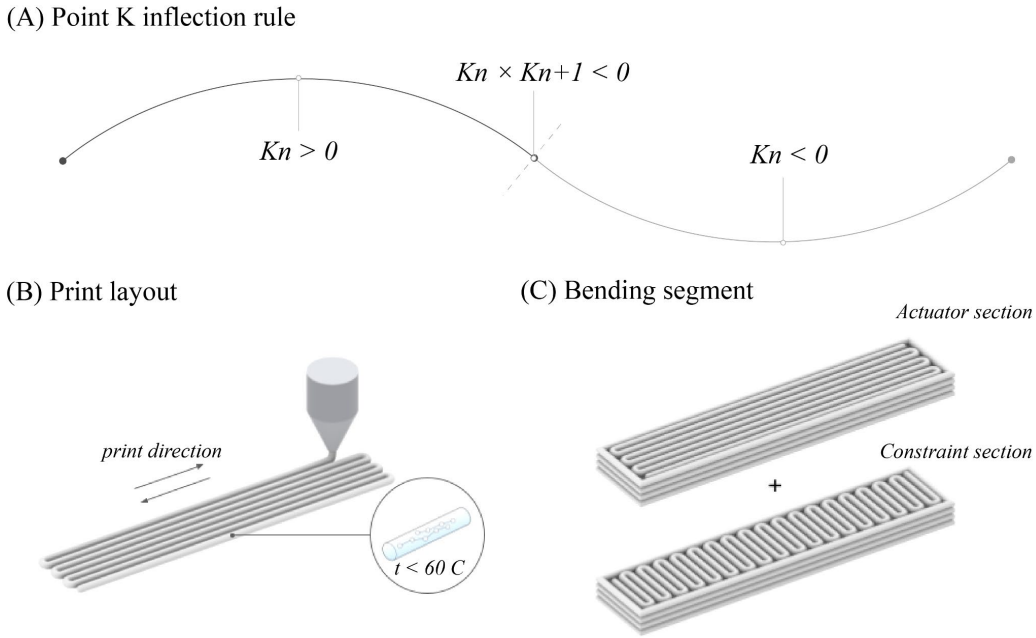

Figure 4. Thermoplastic 4D-printing actuator design rules. (A) Geometric rules defining the curve inflection. (B) Print direction. (C) Combination of the actuator and the constraint sections.

3.2.2 Textile 4D-printing tool

As introduced in Section 3.1, the textile 4D-printing consists of an FDM 3D-printing process on a pre-tensioned fabric covering the printing bed. The textile tension and the printed pattern allow for a three-dimensional deformation of the element once the tension is released (Figure 5). The digital design tools developed for textile 4D-printing are used to determine the print path, the layer height, the layer width, the number of layers, and the print speed. The layer height and width are the parameters that inform the beam cross-section based on empirical observation of each printed result. Print paths are generated using COMPAS Slicer library, and the resulting 3D print is visualized and validated in Rhino Grasshopper before sending it to the fabrication setup. This visualization includes the print path simulation, waiting time at each print point, and extrusion rate, all of which ensure successful print results.

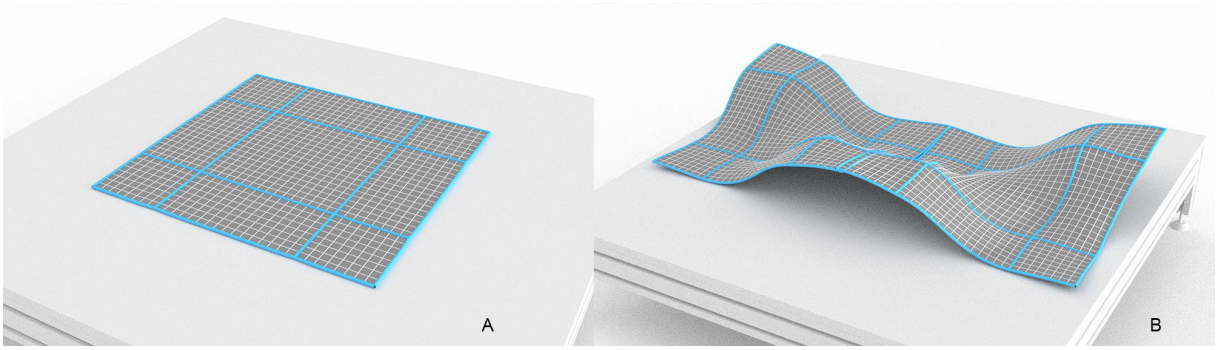

Figure 5. Textile 4D-printing: (A) Print before the tension is released, and (B) after the tension is released.

4. Experiments, results and discussion

This section explains the testing procedure to evaluate the feasibility of a large-scale 4D-printed concrete formwork. The first part focuses on the development of thermoplastic 4D-printing as a substructure for the formworks. The second part focuses on the steps involved in textile 4D-printing, ranging from the initial understanding of this technique to the prototypes. The third part details the testing and emergence of hybrid methods embedding the textile 4D-printing and the thermoplastic 4D-printed frame in one solution, which were then used in the production of the Open Column.

4.1. Thermoplastic 4D-printing experiments

Thermoplastic 4D-printing relied on the shrinking behavior of the shape memory polymer in a preheated water tank (Figure 6). During the printing process, polymer chains in the material were aligned along the extrusion direction and locked in a stretched position. When the material was reheated to above its glass transition temperature, the tension started to release, and the part tended to decrease in length along the direction of the printing path. Meaning, once reheated, the actuator section tended to shrink, and the constraint section (as introduced in Section 3.2.1) maintained its length, which caused the element to bend. The amount of shrinkage could be influenced by many factors, such as printing parameters, triggering temperatures, and material properties. Therefore, experiments compared and evaluated the feasibility of various material properties and fabrication parameters, and bending methods, as well as aimed to conduct material mechanism tests.

Most significantly, experiments confirmed previous findings; the bending angle could be controlled through the arrangement of the actuator and constraint layer. However, the thermoplastic 4D-printing result - the thermoplastic-activated mesh - was not viable as formwork for two reasons. First, the sprayed concrete did not fill the cells equally, resulting in an irregular surface. Secondly, the reaction of cement with the PLA frame created breakage because of the chemical reaction between the plastic mesh and the cementitious material. Those results guided us to protect the mesh from the concrete with a textile.

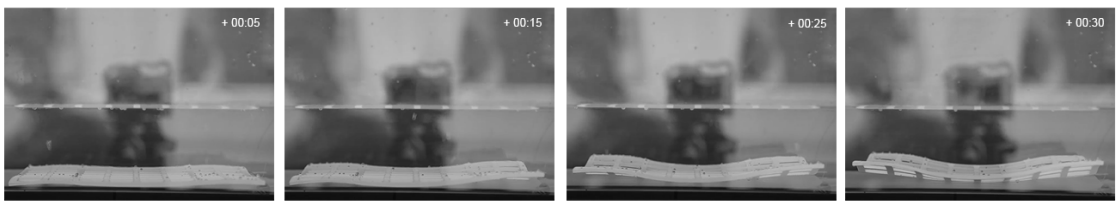

Figure 6. Thermoplastic 4D-printed prototype transformation in 65°C water tank.

4.2. Textile 4D-printing experiments

The initial experiments aimed to find an equilibrium between the tension of the pre-stretched textile and the compression resistance of the print path. The hierarchy between the inner print path and the outer print border governed the global shape of the printed textile. Meaning, the infill, referred to as a sub-pattern, controlled the local transformation and aimed to reinforce the global shape (Figure 7). These experiments helped to establish procedures for adjusting the thickness of the printed lines on the textile and controlling the connection between corners and parallel printed lines of a single pattern. Also, they enabled the calibration of the line thickness, the print speed, and the selection of a suitable textile for the process.

Figure 7. Transformation variations of textile 4D-printed prototypes with different sub-patterns.

To operate a robust print setup, wait times were derived from the point-to-point angle of the toolpath, while the print speed remained constant for the rest of the print path. The more advanced testing phase consisted of applying the parameters to a large variety of printable patterns (Figure 8) to explore the possibilities offered by such a 4D-printing strategy as well as to narrow the research scope down to a pattern that can support the GFRC spraying process.

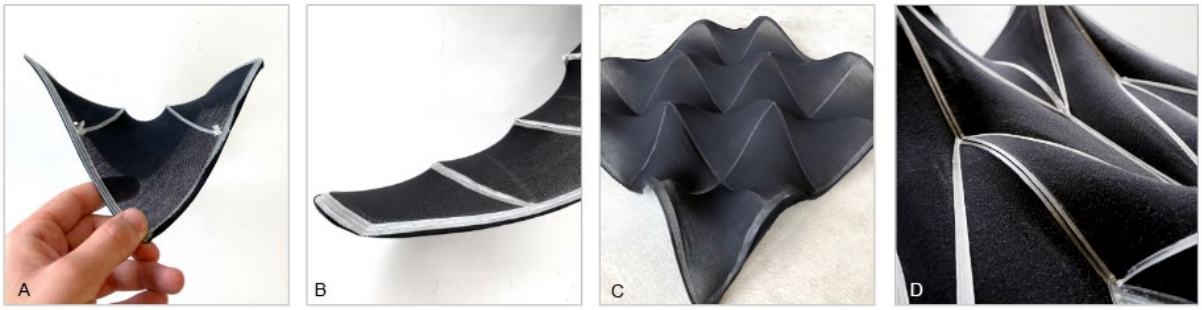

Figure 8. (A) Square with linear pattern, (B) Rectangle with linear pattern, (C) Square grid, (D) Diamond pattern.

For testing the spraying, the first series of experiments aimed to evaluate the capabilities of textile 4D-printing for medium-scale, modular building panels (Figure 9). Each design geometry was 750 mm by 750 mm, and the results created the final 1500 mm x 750 mm x 350mm (W x L x H) prototype panels. To stabilize the formwork, a custom mortar mix with a thickness of less than 1 mm on average was sprayed prior to the GFRC layer. The prototypes were then each sprayed with a GFRC layer and a finishing concrete layer and had an average thickness ranging between 5mm and 8mm.

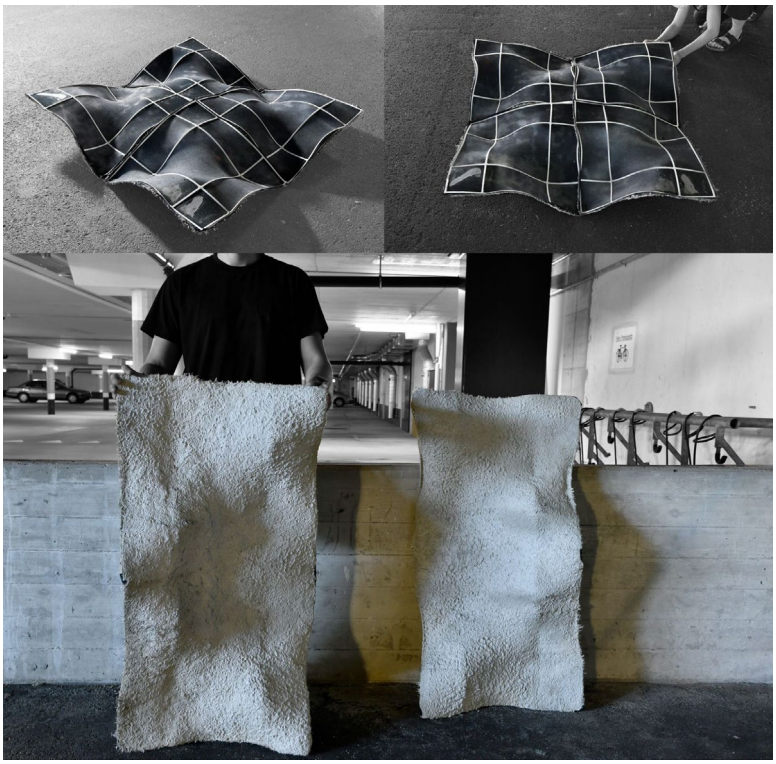

Figure 9. Textile 4D-printed modular panels and GFRC spraying.

4.3. Open Column

The Open Column (Figure 10) incorporates the two techniques presented in Sections 4.1 and 4.2. The goal was to take advantage of those complementary approaches and create a large-scale, doubly curved self-standing demonstrator, which was designed as a 2400 mm high vertical element. The Open Column structure was not optimized however, this particular form was chosen to express the design potentials of this 4D formwork fabrication technique while complying with the limitations described in Sections 4.1 and 4.2. In addition, it aimed to show two different surfaces of the 4D formwork, where the outside surface displayed the sprayed texture, and the inside surface showcased the textile as well as the thermoplastic frames. This demonstrator was composed of six custom-shaped thermoplastic 4D-printed frames. Each thermoplastic frame measured 750 by 840 mm with 25 mm beam edges. The frames were individually triggered at 65°C in a 200 L water tank. First assembled horizontally, the frames were glued together to receive the 2500 mm by 1500 mm textile reinforced with 3D printed ribs. The textile ribs were spaced 100 mm apart to ensure continuous tension and reinforce the textile between the frames. The frames and the textile were welded and sealed together using a hot blade to avoid using additional chemicals. To ensure the stability of the shape, 8 mm steel bar reinforcements were tied to the structure in both directions. This larger-scale demonstrator shows how concrete mass and time impacted and increased the deviation between the targeted shape and the actual result. Nevertheless, this was the first architectural scale 4D-printed formwork of its kind.

Figure 10. 2700 mm high open-column produced with 4D formwork, resulting from the combination of the two 4D-printing techniques and GFRC spraying.

5. Conclusions and outlook

The large-scale prototyping in this research demonstrates the potential of 4D-printing scalability and the use of it as 4D formwork for concrete structures. This research provides the first steps towards a formwork that can be lighter, thinner, and less labor-intensive to produce. The possibility to computationally pre-program a given 3D geometry and transfer it in a flat shape opens up the possibility of efficiently transporting large-scale formworks. This technology works thanks to physical reactions and material compatibility, using widely available materials – PLA, warm water, concrete, and textiles. In addition, the technology will be accessible and easily replicable for research and industry, thanks to the use of the open-source COMPAS framework.

Looking forward, further studies will have various options to optimize this process, for example, water tanks could be heated using natural and sustainable energies like sunlight. Also, building at a larger scale is very likely to lead to simpler and more standardized processes, so further research could investigate the behavior of much larger textile 4D-printed and thermoplastic 4D-printed prototypes.

Finally, improving the precision of these formworks will remain essential to their further development. Current prototypes presented in this research show a gap of 2 to 8mm between the physical and the 3D model in the central parts of the membranes, but we observe a 40 to 80 mm deviation at the edge. These inaccuracies in the final results demonstrate the need to investigate this technique further to reach a more stable and precise process. However, the demonstrators still confirm the potential of 4D-printing as a novel formwork production, taking the first steps for technological improvements to move toward a more sustainable way of building. They provide a perspective on how advanced digital techniques and non-standard formwork production could help to meet the sustainability goals of the near future.

Acknowledgments

This research was partially supported by the Swiss Innovation Agency and the Innosuisse program (Project no. 41139.1 IP-ENG). The authors acknowledge the guidance of Prof. Fabio Gramazio and Prof. Matthias Kohler and the support of MAS ETH in the Architecture and Digital Fabrication program. The authors would like to thank Nizar Taha, Theo Buergins, and Joris Burger for providing support, with the spraying process and the 3D-printing setup, respectively. Buergins Creations is acknowledged for its logistic and technical support and sponsorship.

Abstract

Bioresources like wood, its lignocellulosic constituents or other abundant biopolymers are of returning, enormous interest for our society. This includes their use as construction materials which is due, among others, to their great potential for lowering the carbon footprint of this industry sector. This advantage can be amplified by implementation of smart solutions allowing for multiple reuse of biopolymer based construction elements. Based on a recent study revealing the unique bonding/debonding capabilities of hot-pressed mixtures of equal quantities of corn starch and sodium lignosulfonate ("*BIOMIX*", [1]), this paper presents a novel technological approach targeting the additive manufacture of recyclable bio-based wall elements [1]. It is based on dry blending of wood particles with *BIOMIX* in a weigth ratio of 1:1 (referred to as "*BIOMIX-w*"), subsequent adjustment of a certain surface moisture, extrusion through a printing nozzle and final application of heat and pressure to facilitate bonding within and between the printed layers. Different from conventional adhesives, the bonds between the individual constituents can be re-opened by joint exposure to steam and gentle shear force, allowing for lossless reprocessing and recycling of all constituents.

Keywords: additive manufacturing, 3D printing of renewables, biobased construction materials, structural optimisation, sustainable building construction

1. Introduction

Global warming driven by the ever-increasing emission of greenhouse gases and the impending shortage of fossil resources have recently amplified global efforts towards a more biobased, circular economy. This development has also reached the building industry where sustainability is increasingly considered a key pillar that carries ecological, economical and societal responsibility [2]. This development is of particular importance as the construction industry is among those business segments that consume the most energy and raw materials, and simultaneously release large quantities of air pollutants [3]. Timber constructions are more favourable in this regard, but still far from being a showpiece considering sustainability. In Austria, almost 40% of all processed trees end up as by-products like saw dust, bark or wood chips [4], with the majority being thermally utilized releasing approximately 1.8 kg of carbon dioxide per kilogram of combusted material into the atmosphere. These numbers illustrate, that the wood construction sector only insufficiently takes advantage of the great ecologic potential of wood as one of the most valuable gifts of nature. This obstacle of low efficiency can be overcome by structural

optimization of buildings, co-utilization of by-products in material applications, and efforts to promote the transition towards implementation of circularity in wood product utilization [5].

Besides inefficient material usage, it is to note that the construction sector is increasingly lacking skilled craftsmen and craftswomen, especially in industrialized countries. This is of particular significance as the construction rates continue to mismatch the pace of rising demand for living space nourished by population growth and rising prosperity.

These diverging developments in the construction sector can be counteracted by implementation of fully automated design and construction processes. This paper proposes a newly developed approach for additive manufacturing of fully recyclable walls solely made from renewable resources, covering the entire lifecycle of a sustainable building construction, i.e. manufacture, multiple re-utilization and final composting.

Based on the unique properties of hydrophilic polysaccharides and the amphiphilicity of lignin, both providing excellent compatibility with wood, a novel "*BIOMIX*" blend has been recently developed that demonstrates intriguing adhesive properties for a broad variety of materials, including wood and concrete [6]. This fundamental work – targeting optimization of the blend and hot-press conditions as well as indicative tests of hydrolytic bond line cleavage – was the starting point for the advanced concept of up-scaled additive manufacturing presented here, which additionally includes wood particles as ternary filler (like stones in concrete) for *BIOMIX* (referred to as "*BIOMIX-w*") as well as hydrolytic disintegration under application of gentle shear force [1]. Thus, the novel 3D-printing approach comprises all of the above key aspects of sustainability in the construction sector.

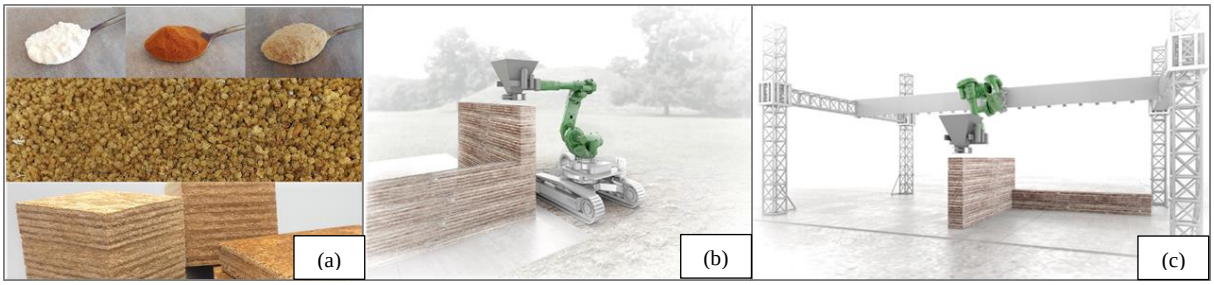

Figure 1: *BIOWALL* printing strategies

Using the example of spruce sawdust mixed with the components of *BIOMIX* in a 2:1:1 weight ratio, it had been demonstrated that an apparently dry blend of "*BIOMIX-w*", adjusted to a certain moisture content, can be processed semi-automatically either as fully-integrated alternative or via a granulate-based approach (Figure 1(a)). For full automation an industrial robot for either prefabrication or onsite 3D-printing could be a viable solution. As the printing head is an independent module, the carrier system can be alternatively connected e.g. to a portal system, as presented in Figure 1 (b)+(c). The produced *BIOWALL* specimens were furthermore confirmed to feature excellent recyclability by shear-aided moistening which provides a maximum of flexibility with regard to reshaping by printing. Since disintegration of *BIOWALL* succeeds at mild conditions, this process step is virtually lossless and preserves the chemical integrity of the individual components to full extent, the material can be reused in multiple cycles.

2. Preliminary data of semi-automated wall printing and environmental impact

Processing of *BIOMIX-w* can be accomplished following two different routes (Figure 2). The first approach, referred to as the fully-integrated concept, comprises of dry mixing three components, i.e. starch, lignosulfonate and wood particles, inside the printing head and offers the possibility of tribo-electric charging for the generation of additional porosity aiding sorption of moisture during subsequent processing (Figure 2a). The second approach includes the production of a granular *BIOMIX-w* blend for improved moisture uptake by capillarity as an intermediate step before printing (Figure 2b; [1]).

First tests exploring the potential of the above-mentioned approaches were conducted using solely *BIOMIX-w* at the standard wood-to-starch-to-lignin ratio of 2:1:1 (reference). Further tests included blends of *BIOMIX-w* with additives like sodium chloride powder or ash from beech bark, as well as processing of granular *BIOMIX-w* pre-manufactured by mixing the wood, starch and lignin in a ratio 2:1:1 under rotation using either spruce or oak sawdust as wood component.

Processing of these mixtures into small-scale *BIOWALL* specimens was accomplished employing the four-stage semi-automatic scheme outlined recently [1]. In brief, the respective *BIOMIX-w* blends – generated by dry mixing of the components (Figure 2(a)) or using pre-manufactured granules (Figure 2(b)) – were extruded through the discharge nozzle. Then, water in liquid phase was sprayed onto both sides of the thin layers to ensure partial solubilization of the adhesive components starch and lignin. Subsequently, the extruded layers were individually transferred manually into a heated hydraulic press to facilitate bonding within and between the layers. Once the desired height of the specimen was reached (typically more than 10 layers), they were equilibrated at standard climatic conditions (20°C, 65% rel. humidity) for one week and subsequently cut to obtain the size desired for the flexural (160 mm x 40 mm x 40 mm) and compressive testing (40 mm x 40 mm x 40 mm).

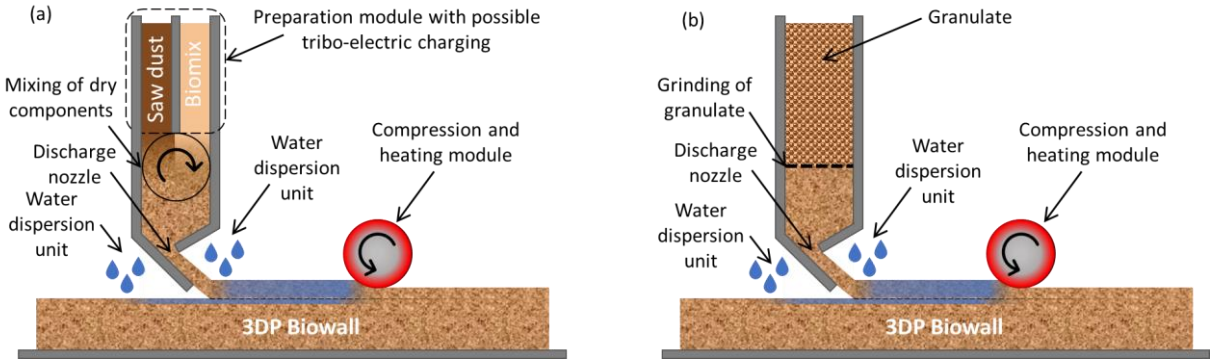

Figure 2: Schematic of the research printing approaches: (a) fully-integrated ; (b) granulate-based [1].

The results, shown in Figure 3, clearly confirm that both compressive and flexural strength of the layer-by-layer *BIOWALL* #1-3 assemblies prepared by the fully-integrated approach with *BIOMIX-w* strongly depend on their apparent density and, hence, by the used process conditions. Using *BIOWALL* #3 as reference the data furthermore reveal, that the addition of either powdered NaCl or ash from beech bark at mass ratio of approx. 30% relative to *BIOMIX-w* has only a marginal impact on the mechanical properties, despite their significant contributions to the bulk density of the specimens prepared. Processing of these blend types at harsher hot-press conditions is subject of ongoing work.

The usefulness of pre-manufacturing granular *BIOMIX-w* is not evident at first glance from the data of Figure 3, since the density-normalized mechanical performance of the respective assemblies does not exceed that of variant *BIOWALL* #3, no matter whether spruce (44,79wt% water) or oak (16,81wt% water) sawdust was used. However, due to the better options for controlling homogenous moistening and considering the shorter pressing times required (120 vs. 180 seconds), the granulate based approach will be further pursued.

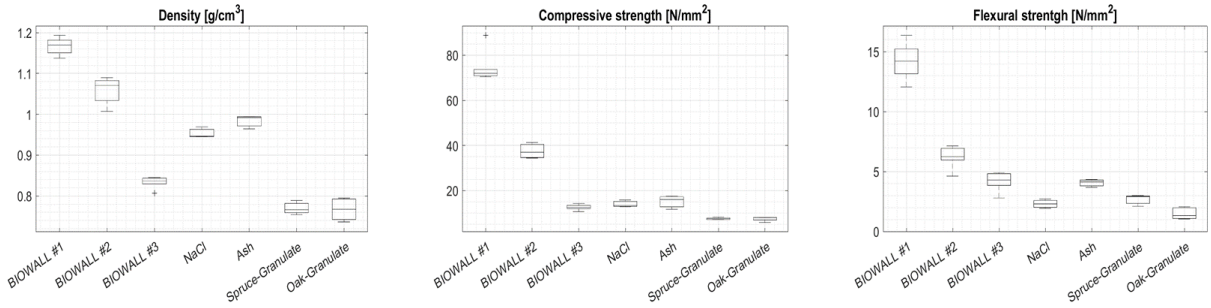

Figure 3: Mechanical properties of first test series

Besides mechanical testing, a preliminary life cycle assessment (LCA) was conducted evaluating the environmental impact of the additive Biowall production steps A1-A3, which comprises raw material supply, transport, and processing. Besides energy consumption (renewable and non-renewable resources), the potentials for global warming, ozon depletion (reference trichloofluoromethane; CFC-11), acidification and eutrophication were roughly estimated (Figure 4). Distinction is made between primary and secondary resources, where primary describes a material that is specifically produced for an application while secondary resources refer to by-products or even waste materials. The LCA results confirm that starch has the highest environmental impact, followed by lignosulfonate. Therefore, this project also envisages testing of secondary resources for potential replacement of one or even both primary resources.

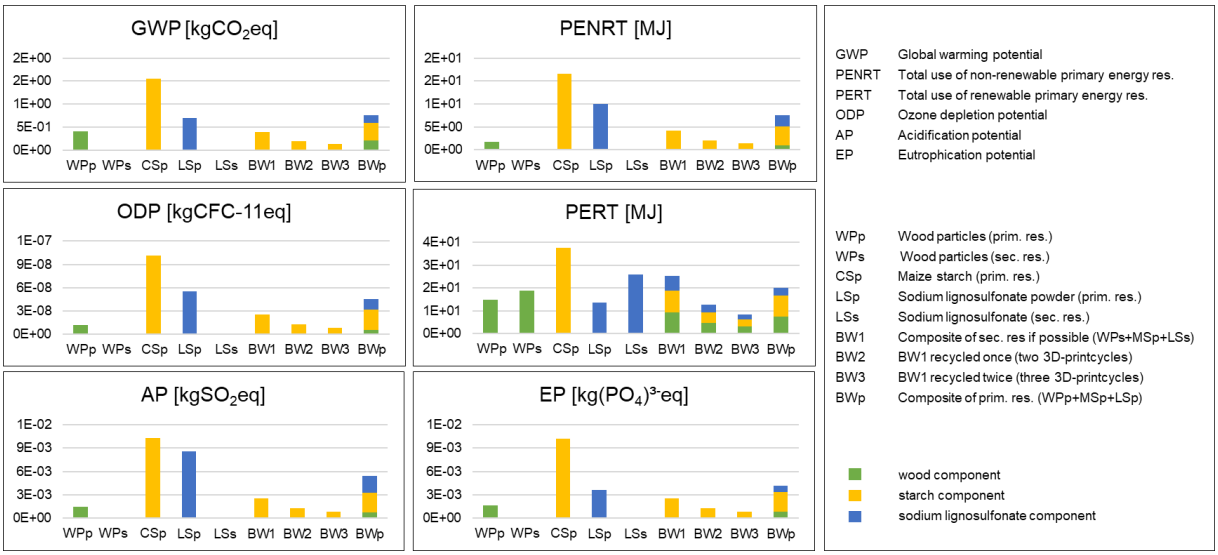

Figure 4: LCA of the *BIOWALL* material [1]

3. Fully automated production process

The independent development of printing head and carrier system as a key element of this project ensures a maximum of flexibility with regard to production techniques or even the site where the *BIOWALL* is printed. Depending on factors, such as climatic or weather conditions, manpower or accessibility of the construction area, the modular concept allows for either offsite prefabrication on an industrial robot system maintaining constant conditions, transport of respective blends to the construction site using a mobile portal system or its onsite prefabrication and feeding into the printing head using a mobile carrier system, as shown in Figure 1 (b)+(c).

Currently three main technologies are available for 3D-printing: 1) Extrusion of highly viscous pastes like melted thermoplastics which solidify upon cooling or cement paste that requires subsequent drying,

2) application of liquid layers hardening by physical or chemical crosslinking like photo-polymerisation and 3) melt-bonding of fine-grained powder similar as accomplished by direct selective laser sintering of metals [7]. Different from all aforementioned approaches, this paper introduces a novel technology targeting additive manufacturing of wood providing the strong asset of multiple recyclability and re-printing at zero synthetic adhesive requirement.

The sequence of final steps currently taking place in the printing head are 1) dry extrusion of *BIOMIX-w*, 2) double-sided moistening of the layer formed and 3) simultaneous application of pressure and heat (*cf.* Figure 2). While automated discarding and moistening has been satisfyingly implemented, further optimization in terms of heating temperature and rate as well as pressure regime is required for the final hot-press stage. This is necessary to shorten the current impracticably long heating times of 2-3 minutes, required to remove the excess of moisture for each of the most recently printed *BIOMIX-w* layers, to a reasonably short time period in the seconds range.

In particular the replacement of the current spray-moistening by steam is promising due to its higher wetting surface, faster penetration of small pores, and formation of thinner and more homogeneous moisture layers, thus supposedly promoting homogeneous solubilization, gelatinization and plasticization of *BIOMIX-w* components. Success provided, significantly less water and, hence, energy for its removal would be needed. Alternatively, it is to be tested to what extent the addition of water can be entirely omitted when *BIOMIX* is blended with fresh sawdust, which typically contains 12-50% wt.% water, instead of only up to 11wt.% in the case of dry sawdust used within the initial experiments (*cf.* Figure 3). This measure, implemented by a upstream process stage producing a granular *BIOMIX-w* blend, would clearly reduce technical complexity, energy and water consumption, at simultaneously improved process reliability with a more even moisture distribution.

In order to provide proof of concept for both alternative approaches, test specimens were produced analogous to those of the preliminary tests. Suitable compression rates and hot-press conditions (15-30 sec, temperatures higher than 150°C) were determined to ensure uniform apparent bulk density (ca. 1.0 g cm^{-3}) as a prerequisite for comparing their mechanical performance. Intriguingly, a significant reduction of pressing time could be achieved compared to the initial experiments. While it was still 30 seconds during steam moistening, the pressing was reduced to 15 seconds when fresh sawdust was used to prepare granular *BIOMIX-w* in the additionally implemented upstream process stage. Mechanical performance of the obtained samples (Figure 5(a)) was assessed after equilibrating them at 65%RH and 20°C for one week.

The behavior of the specimens under compression can be seen in Figure 5(c). The dry and moistened specimens are compared to the *BIOWALL* #2 specimens from the previous tests as they are all in a region of similiar density. For this density the moistened granulate-based approach shows the highest compressive strength (Figure 5(c) middle) together with a higher compression rate than that of the dry granulate-based approach (Figure 5(b)). Thus looking at the modulus of elasticity the values for the specimens produced without water addition are the highest. Although needing six or even twelve times the pressing time, the *BIOWALL* #2 specimens cannot exceed the characteristics of the specimens made from granulate.

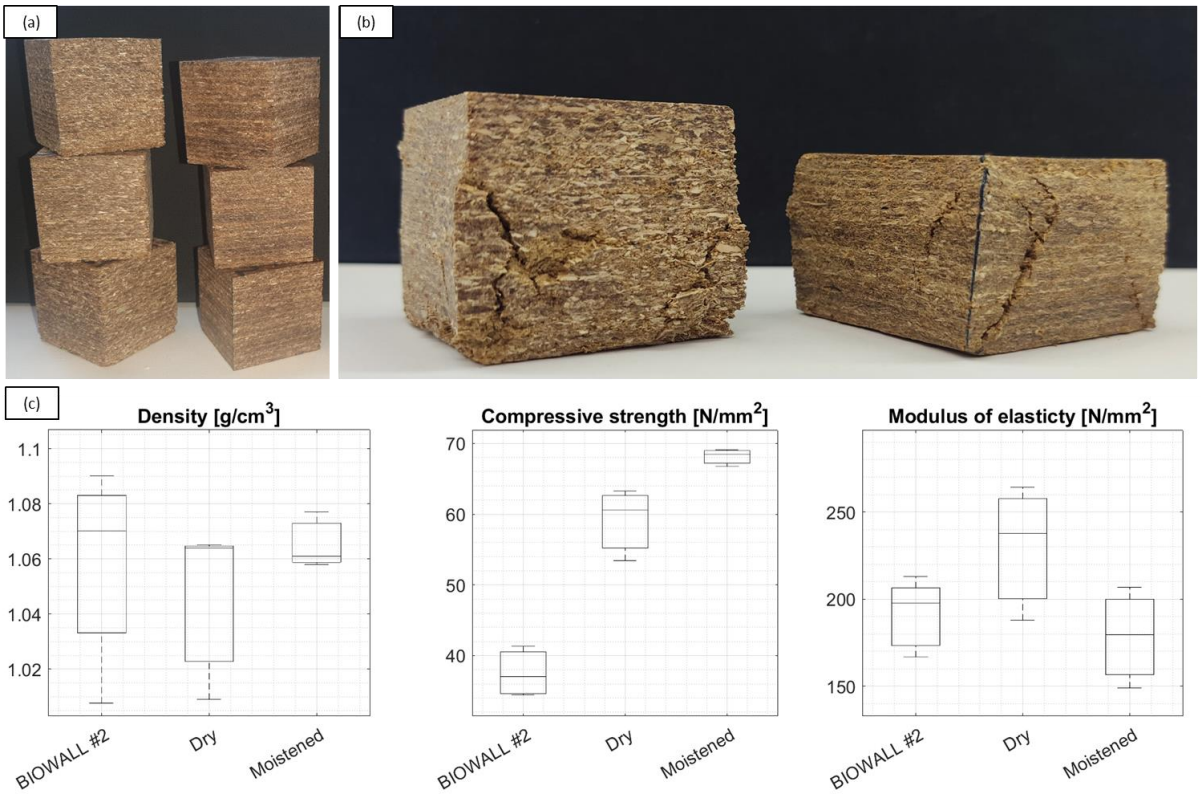

Figure 5: Compression tests of granulate-based small-scale specimens: (a) dry specimens (left) and moistened specimens (right); (b) test specimens after compression test; (c) mechanical properties

The first fully automated tests using a robot system relied on a combination of both steam moistening of the granular material prior and post discharging to promote intra- and inter-layer bonding. Removal of excess water was accomplished by connecting the discharging nozzle with a module consisting of a heated rotating cylinder to apply pressure and a heated plate to extend the time of heat input as the contact area between solely the cylinder and material bed would be too small. This first prototype of the modified printing head was mounted on an IRB 7600-325/3.1 industrial robot system at the robot laboratory of the Institute of Green Civil Engineering (ABB Group; Figure 6(a)), operated at a printing speed of 1 m min^{-1}.

However, despite maintaining a heating temperature over 200°C, three heating passages per layer were required for sufficient drying, as areas with high water content still present after the first and second repetition (dark regions in Figure 6(b)). The first three layers – each being 1,5 mm thick – of a *BIOWALL* assembly printed with the industrial robot system are shown in Figure 6(c)+(d). After removing the assembly from the printing bed and subsequent cooling, thermomechanical warping was observed (Figure 6 (d)) as known from FDM 3D-printing technologies.

While these tests can be regarded as proof of concept, further technology and material development is required since the mechanical performance of the samples did not yet reach that of the preliminary batch tests due to insufficient ensemble of material characteristics and production management.

4. Conclusion

The results of this work confirm that fully automated 3D-printing of wood particles, embedded into a fully biobased adhesive system, is feasible. Improvement of moisture, heat and pressure management as well as material will be subject of ongoing work to unfold the full potential of the novel bio-blends for additive manufacturing of BIOWALL systems. Based on the results of this optimisation work, the life cycle assessment of this study will be further refined.

Abstract

Connections are essential components of steel structural systems as their properties greatly influence the global response and control the collapse behaviour. The conventional approach for the design and analysis of structural frames offers a narrow range of pre-defined connection types and limited scope for optimising their rigidity and strength, and the fabrication of connections is labour-intensive. The novel and advantageous features of Wire Arc Additive Manufacturing (WAAM) can be exploited to address these challenges and produce connections with superior characteristics. This study aims to investigate the potential application of additively manufactured connections for steel frames by introducing an alternative conceptual design achieved by topology optimisation showing a superior structural performance to that of conventionally designed connections. An extended bi-directional evolutionary structural optimization (BESO) technique based on discrete variables is adopted to deliver optimised connections considering material non-linearities. Numerical simulations are carried out on simple beam-column connections to quantify the structural benefits achievable by topology optimisation compared to a conventional design solution. Moreover, the structural performance of a two-storey steel frame assembled using the optimised connection solutions is compared to that of a frame constructed using conventional welded connections.

Keywords: topology optimisation (TO), bi-directional evolutionary structural optimisation (BESO), additive manufacturing (AM), steel frame, conceptual design, structural connection

1. Introduction

Topology optimisation is recognised as a means of achieving advanced and economically rewarding structural designs [1]. Among the most recent and well-known topology optimisation strategies for continuum structures, the Homogenization Method [2], Solid Isotropic Material with Penalisation (SIMP) Method [3], Level-set Method [4] and Evolutionary Structural Optimisation (ESO) Method [5] are widely referenced in the literature. The ESO method is grounded on the idea of gradually removing material from inefficient parts of a structure to evolve towards an optimum solution. The Bi-directional Evolutionary Structural Optimisation (BESO) which was further developed from the ESO method [6], also enables material to be added simultaneously at efficient locations of the structure. In pursuing a more realistic design, the implementation of material non-linearity in optimisation algorithms has also been investigated [7]. In the context of connection components produced through additive manufacturing (AM), the highly non-linear stress-strain behaviour under large deformations is important as is fabrication-related constraints imposed on the geometry of the optimised topology. Inclusion of minimum feature and cavity sizes that are bound by the resolution of printing and post-treatment machining tools [8] accounting for self-supporting geometric features [9] and anisotropy in mechanical response [10] are examples of such fabrication-related constraints imposed on topology optimisations.

Applications of AM in the construction of metallic structures have been reported by several groups, including Arup's design of an optimised space node using powder-based methods [11], and MX3D's

fully functional steel pedestrian bridge, for which the design capacity was also determined through numerical and experimental investigations [12]. While the early uses of metal additive manufacturing in construction have primarily featured modest-scale components such as façade nodes and small connections, the fabrication of large-scale components are currently being developed using the more recent WAAM technique. Therefore, it is expected that a framework suitable for the optimisation and design of large-scale additively manufactured structural components will be in demand in the near future, as pursued in this paper.

The paper is organised as follows: Section 2 describes the optimisation exercise, performed by integration of a Python-based extended BESO script with the well-established Finite Element (FE) package ABAQUS [13] as the analysis engine. Section 3 presents numerical simulations on a simple connection between a beam and a column, designed through structural optimisation and using conventional structural connections, and subjected to various load cases. Section 3 also compares the structural responses of two-storey frames featuring optimised and conventional structural connections. Section 4 draws conclusions from the study.

2. Structural optimisation methodology

2.1. Bi-directional Structural Optimisation (BESO) for continuum structures

2.1.1. Sensitivity numbers

Structural optimisation problems aim to place the material at the most effective location for a design domain subjected to predefined objectives, constrains, loads and boundary conditions and are generally formulated with the objective to maximise stiffness. In order to maximise the stiffness of the structure while ensuring that the structure can bear loads up to the maximum design load (F^*), the complementary work (W^c) depicted in Figure 1 shall be minimised. The basic problem can be described mathematically as:

$$\textbf{Minimise}: f_1'(x) = W^c = \left[\frac{1}{2}\lim_{n\to\infty} \Delta F^T (U_i + U_{i-1})\right] \tag{1}$$

$$\textbf{Subject to}: K(U)U = F$$

$$R = F - F^{int}(U) = 0$$

$$V^* - \sum_{i=1}^{nelem} x_e v_e = 0$$

where U and F represent the nodal displacement and force vectors, respectively, the stiffness matrix $K(U)$ is a function of U in a non-linear problem sourced from material or geometrical non-linearities, i denotes the increment number in the total of n load increments and V^* is a prescribed target volume fraction for the optimisation task. Since BESO is a discrete optimisation procedure, design variables x are assigned to individual finite elements (e). In a "soft-kill" scheme, these binary variables can be taken either of the following values:

$$x = x_{min} \ \ (\text{void}) \text{ or } 1.0 \ \ (\text{solid}) \tag{2}$$

While the solution for the equilibrium of linear elastic problems can be determined explicitly, when the response of the structure is non-linear, an iterative scheme needs to be adopted [7] which typically reduces the residual error **R** between the external and internal force vectors to 0 to achieve an equilibrium solution.

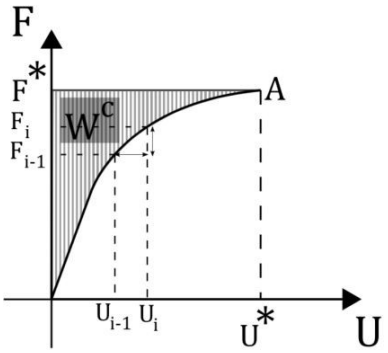

Figure 1. Load-displacement curve for a non-linear continuum structure.

2.1.2. Sensitivity numbers

Considering a non-linear load-displacement behaviour (Fig. 1), the variation of the elemental strain energy with design variable x_e can be derived as [7]:

$$\alpha_e = x_e^{p-1} \lim_{n\to\infty} \sum_{i=1}^{n} \left(E_{e,i} - E_{e,i-1}\right) = x_e^{p-1} E_{e,n} \tag{3}$$

in which $E_{e,n}$ specifies the final elemental strain energy comprised of elastic and plastic components. The smoothed sensitivity number ($\hat{\alpha}_e$) is then calculated to eliminate the mesh-dependence of the solution [14]:

$$\hat{\alpha}_e = \frac{\sum_v (w(r_{v,e})\alpha_e)}{\sum_v w(r_{v,e})} = \sum_v \frac{w(r_{v,e})}{\sum_v w(r_{v,e})} \alpha_e \tag{4}$$

where the weight factor is determined based on the number of *v* elements in the vicinity of element *e* as:

$$w(r_{v,e}) = \max(0, r_{min} - r_{v,e}) \tag{5}$$

where $r_{v,e}$ specifies the Euclidean distance between the centres of elements *v* and *e* and r_{min} specifies the prescribed filter radius, typically taken as ~ 2–3 times the element length (l_e). In order to relax the convergence of the solution, the elemental sensitivities are averaged between the *j*th and *j*-1th iteration yielding the modified elemental sensitivity number as:

$$\hat{\alpha}_e = \frac{\hat{\alpha}_{e,j} + \hat{\alpha}_{e,j-1}}{2} \tag{6}$$

Prior to removal/addition of any elements, the target evolutionary volume for the next iteration needs to be determined:

$$V_{j+1} = V_j(1 \pm ER) \quad (j = 1, 2, 3, \dots) \tag{7}$$

where ER denotes the evolutionary rate, typically taken as 1% or 2%. Depending on whether the objective volume (V^*) has been reached, the target volume may increase or decrease. Once the objective volume has been achieved, it will be kept constant. The elements are then sorted according to their sensitivity numbers ($\hat{\alpha}_e$) and compared to a threshold sensitivity α_{th} aiming to deliver the target volume, retaining elements possessing the highest sensitives and deleting elements with the lowest sensitivities at each iteration [15]. The convergence criterion for the complementary energy is checked at each iteration:

$$\text{error}_j = \frac{\left(\sum_{k=1}^{N} W_{j-k+1}^c\right) - \left(\sum_{k=1}^{N} W_{j-k-N+1}^c\right)}{\sum_{k=1}^{N} W_{j-k+1}^c} \leq \text{tol} \tag{8}$$

where *N* describes the integral number and is usually taken between 2–5 [7].

2.2. Multiple load cases

The optimisation of structural connections needs to consider that the building is subject to multiple load cases (gravity, wind, earthquake, etc.) and combinations thereof over the course of its design life. In order to account for the contribution of each load case in determining the overall performance of the structure, the elemental sensitivity numbers ($\hat{\alpha}_e$) introduced in Eq. (4), are instead calculated using the sum of elemental strain energy values of all different load cases [15] as:

$$\alpha_e = \sum_{m=1}^{M} \alpha_{e,m} \tag{9}$$

Where m denotes the number of load case in the total of M cases considered for the simulation and $\alpha_{i,m}$ represents the ith elemental sensitivity number corresponding to mth load case. Furthermore, the objective function is modified to include:

$$W_j^c = \sum_{m=1}^{M} W_{j,m}^c \tag{10}$$

where $W^c_{j,m}$ indicates the complementary work done at each iteration by each load case m contributing to the overall work done by the structure at each iteration W^c_j.

2.3. Material non-linear model

The connection was assumed to be manufactured from AISI 316L stainless steel, for which, in the elastic range, the isotropic response is defined by a Young's modulus of 190 GPa [16] and Poisson's ratio of 0.3. In the ABAQUS finite element package, they are defined using the *ELASTIC, TYPE = ISOTROPIC for three-dimensional simulations. Moreover, in order to account for plastic deformations beyond the yield point, a two-stage Ramberg-Osgood material model was used to describe the full-range stress-strain relationship [16]:

$$\varepsilon = \frac{\sigma}{E_0} + 0.002\left(\frac{\sigma}{\sigma_{0.2}}\right)^n \qquad for\ \sigma \le \sigma_{0.2} \tag{11}$$

$$\varepsilon = \frac{\sigma-\sigma_{0.2}}{E_{0.2}} + \varepsilon_u\left(\frac{\sigma-\sigma_{0.2}}{\sigma_u-\sigma_{0.2}}\right)^m + \varepsilon_{0.2} \qquad for\ \sigma > \sigma_{0.2} \tag{12}$$

where $\sigma_{0.2}$, E_0 describe the 0.2% proof stress and initial Young's modulus, n and m denote the strain-hardening and degree of hardness components, respectively. The implementation in ABAQUS was completed using the *PLASTIC command and specifying a multi-linear curve (Fig. 2) of true stress against true plastic strain, as obtained from the engineering stress-strain curve (Eqs. (11,12)) also shown in Figure 2.

Table 1. Input parameters for AISI 316L stainless steel [16].

$\sigma_{0.2}$ (MPa)	σ_u (MPa)	ε_u (%)	n	m
316	616	51	5.88	2.2

3. Numerical simulations

3.1. Structural frames and connections

Frame structures are the most widely used systems in the construction of residential and commercial buildings. Connections of such systems are employed to withstand and transfer the combined forces imposed by all connecting structural elements (i.e. beams, columns, lateral bracings, etc.) towards the supporting base. Consequently, it is crucial that they maintain strength and stability while all the connecting elements are in service. In other words, connections must be able to transfer the full capacity of their connecting members. In the context of engineering design, frames must function under a combination of gravitational loads such as permanent (dead) and imposed (live) actions as well as lateral forces such as wind- and earthquake-induced actions. A three-storey commercial frame with a total height of 15 m has been considered for the current study as is shown in Figure 3. The beams and columns in the system have total lengths of 8 meters and 4 meters, respectively, and I-shaped cross-sections with overall depths of 360 mm and 300 mm respectively as is shown in Figure 3.

The assessment of the structural behaviour of the frame system was conducted using the Ultimate Limit State (ULS) provisions of the Australian loading standard AS1170 considering gravity and earthquake loads. An importance level of 2 (ordinary) and a design life of 50 years were assumed in the design. The permanent (dead, G) and imposed (live, Q) actions were determined in accordance with AS1170.1, while the lateral earthquake loads (E) were determined using the provisions of Section 5.4.2 of AS1170.4 for a structure with an overall height less than 15 meters ($F_i = K_s[k_p Z S_p/\mu]W_i$). The combinations of actions considered for the strength assessment were obtained from Section 4.2.2 of AS1170.0, as shown in Table 2, resulting in a total of 9 load cases. A geometric and material non-linear analysis of the frame was undertaken using the material model defined in Table 1.

Table 2. Load combinations for strength.

Item	Name	Combination
1	Gravity	$1.2G + 1.5Q$
2	Earthquake-x	$1.0G + \psi_e Q \pm 1.0E_x \pm 0.3E_y$
3	Earthquake-y	$1.0G + \psi_e Q \pm 0.3E_x \pm 1.0E_y$

NOTES:

1. The reduction factor ψ_e was selected as 0.3 for residential building.

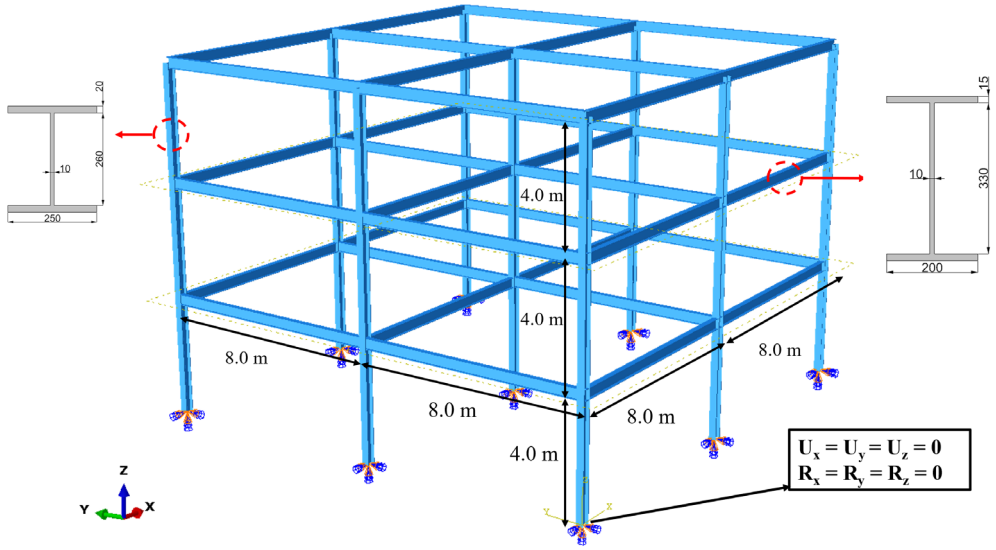

Figure 3. Isometric view of the structural frame and boundary conditions. Sectional dimensions are expressed in millimeters.

3.2. Engineering design

Conventionally, steel members are connected through bolting or welding. The latter is assumed in this study. The conventional welded connection between the beam and column shown in Figure 4 can be designed for strength by providing sufficient capacity to transfer all predicted structural actions from the frame analysis, as summarised in Table 3. The thickness of the fillet weld group can then be determined in accordance with Clause 9.6.3.10 in AS4100.2020 as:

$$v_w^* \leq \phi v_w = \phi \times (0.6 f_{uw} t_t k_r) \tag{13}$$

$$t_t = \frac{v_w^*}{\phi \times (0.6 f_{uw} k_r)} \tag{14}$$

Considering an E55 grade electrode, with a minimum ultimate nominal strength of 620 MPa, the required nominal throat thickness of 6.4 mm will be required.

Table 3. Stress components applied on the weld group considering a unit thickness for the weld group (t_t = 1 mm).

Stress component	**Gravity** (MPa)	**Earthquake-x** (MPa)	**Earthquake-y** (MPa)
$f_a = \frac{N^*}{A}$	20.7	25.7	20.7
$f_{vx} = \frac{V_x^*}{A}$	171.6	172.6	133.4
$f_{bx} = \frac{M_x^* \times (D/2)}{I_{xx}}$	1831.3	1850.4	1429.3
$f_{vy} = \frac{V_y^*}{A}$	0	0	0
$f_{by} = \frac{M_y^* \times (b_1/2)}{I_{yy}}$	0	0	0
$f_r = \sqrt{(f_a + f_{bx} + f_{by})^2 + (f_{xy})^2 + (f_{vy})^2}$	1860.0	1884.0	1454.0

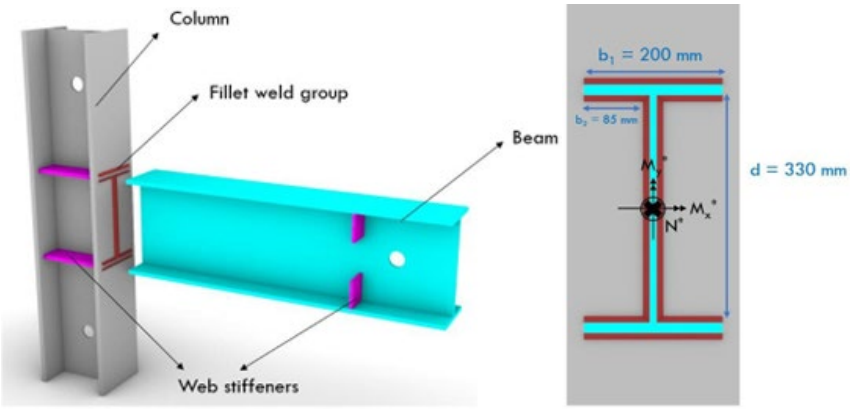

Figure 4. Engineering design: (a) isometric CAD view of the connection components, (b) active structural actions on the group of weld.

3.3. Optimisation of additively manufactured connection

The beam-column joint introduced in Section 3.2 is designed for additive manufacturing using the topology optimisation scheme presented in Section 2. In order to initiate the optimisation, a design domain needs to be defined. A rectangular design domain of 720 × 480 × 250 mm was chosen as shown in Figure 5. In order to generate the design stress flow through the connection, the structural actions obtained from the frame analysis described in Section 3.1 were applied to the top of the column and tip of the beam as tractions while the lower end of the column was fixed (Fig. 5b). The finite element mesh was created using a total of 33612 C3DR8 three-dimensional solid elements in ABAQUS.

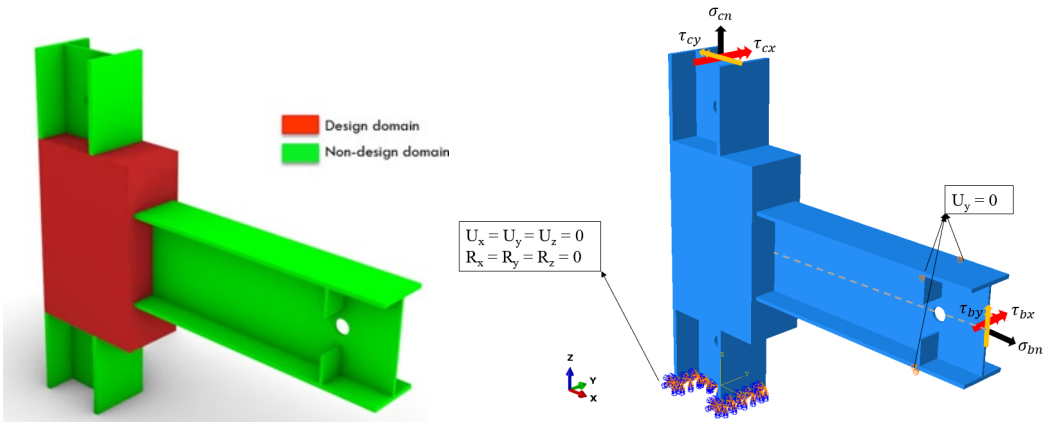

Figure 5. Initial design domain: (a) isometric CAD view, (b) applied boundary conditions in ABAQUS.

The topology of the final design of the optimised joint, presented in Figure 6, is distinctively different from that of the conventional welded joint (Fig. 4). In the optimisation, the target volume fraction was set to match the total mass of the conventional welded connection within a small margin. The mass of the final design was determined as 100.7 kg, which was within 5% of the total weight of the convectional welded connection shown in Figure 4. A total of 77 iterations were completed during the optimisation task after which only 7096 design variables (x_e) in the design domain were forced to be solid. Figure 7 shows the evolution of the topology and the distribution of von Mises stress. The latter demonstrates where the material is least stressed and helps to understand the gradual change of topology. The reinforced areas near the flanges of the beam are apparent, while the less effective central region of the web has gradually been eliminated. Furthermore, the primary compressive stress flow resulting from

the combined axial and bending actions on the column has been redirected through the connection zone to converge towards the flow of compressive stress in the lower flange of the beam.

The final stage of the conceptual design process for an optimised topology involves the smoothening of the finite element model into a manufacturable part and subsequent evaluation of the strength and behaviour of the optimised design. The final smoothed geometry was achieved by applying non-uniform rational B-splines (NURBS) to the boundary nodes of the tessellated FEM mesh. This task could be cumbersome, given the stepwise tessellated faces and existing non-manifold edges. For this purpose, the additive manufacturing CAD software Fusion 360 [17] was implemented to first re-construct the solid geometry from the ABAQUS-generated STL file, then smooth and export the geometry to ABAQUS for FE re-evaluation.

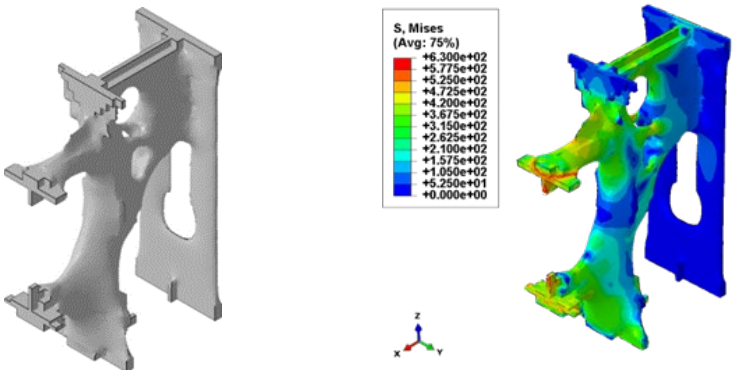

Figure 6. Manufacturable joint: (a) smoothed CAD design for the optimised joint, (b) von Mises stress distribution (MPa).

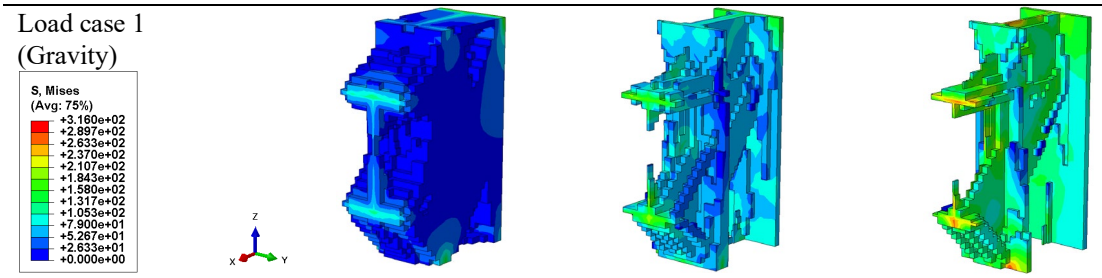

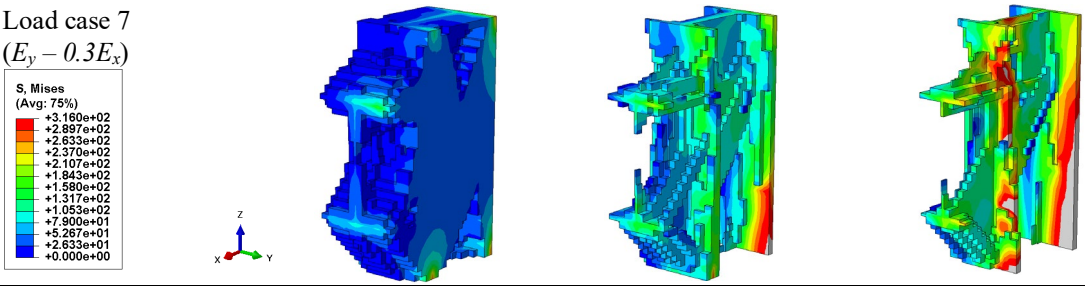

Iteration	**10**	**50**	**70**
Load case 1 (Gravity)			
Load case 7 ($E_y - 0.3E_x$)			
Mean compliance ($N.mm$)	10.34×10^6	12.65×10^6	15.59×10^6
Volume fraction (V/V_0)	0.82	0.36	0.24

Figure 7. Topological evolution with von Mises stress distribution field for the material non-linear stiffness design for various load cases (peak stress of 316 MPa is plotted as red).

The smoothed final geometry was assessed for structural strength and integrity. For this purpose, the moment-rotation curve of the optimised connection was compared to that of the conventional welded

connection presented in Section 3.2. The material properties used for the weld group in the simulation of the conventional welded connection are shown in Table 4. The moment-rotation curves are shown in Figure 8.

Table 4. Input parameters for E5518-C1 H5R electrode [18].

$\sigma_{0.2}$ (MPa)	σ_u (MPa)	ε_u (%)
550	620	26

As can be seen from Figure 8, both the ultimate strength and deformation of the optimised joint are superior to its conventional counterpart. Due to their critical role, connections are generally designed to be the last structural components to fail in structural frameworks. Hence, the ability to sustain large inelastic deformations (ductility) is a desired characteristic of connections. The relative ductility index, defined as the ratio between the ultimate and yield rotation capacities ($\mu = \theta_u/\theta_y$), was used to quantify the difference in the performance of the optimised and conventional connection designs [19]. Table 5 summarises the ultimate moments and ductility indices achieved by the two designs.

Table 5. Applied tractions at the beam and column faces.

Design	**Ultimate moment capacity** M_u (kN.m)	**Yield rotation** θ_y (mRad)	**Yield rotation** θ_u (mRad)	Relative ductility
Optimised connection	423.3	9.7	60.9	6.3
Conventional connection	390.1	6.8	31.1	4.6

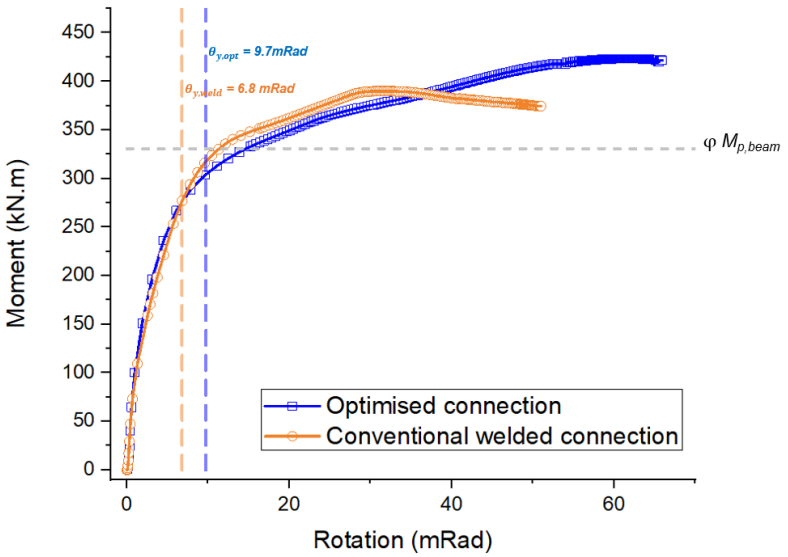

Figure 8. Moment-rotation curves for the two designs.

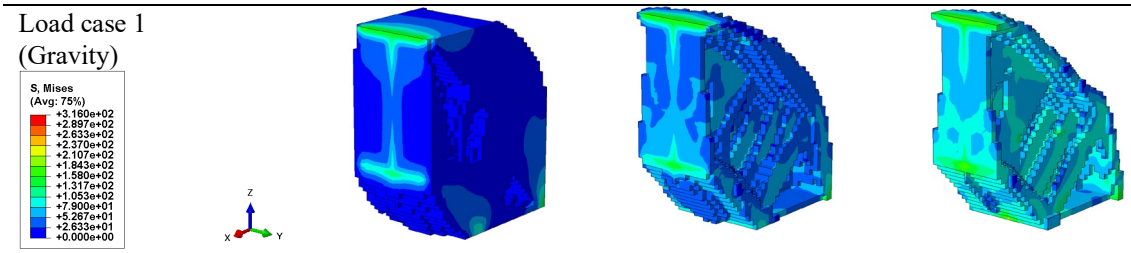
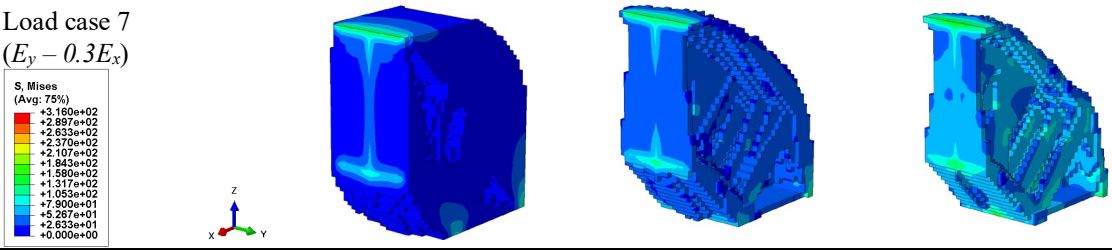
3.4. Optimisation of structural frame with additively manufactured connections

A further assessment on the performance of the optimised joint is made by considering the response of a complete frame. For this purpose, a two-storey steel frame constructed from beams and columns of the same dimensions shown in Figure 3 is chosen for this study (Fig. 10). Initially an optimisation of a "top floor" joint connecting a single beam and column was completed using the same objective function used for the optimisation in Section 3.3. The evolution of the optimised topology is shown in Figure 9,

obtained using 82 iterations to match the weight of the conventional connection counterpart. The performance of the frame has been evaluated for the gravity and earthquake ULS load cases, considering the moments carried by the connections and the members. Figure 11 shows the bending moment distributions for the frames with optimised and conventional connections about the major axis of structural elements. The peak bending moments in the floor beam of the first floor at mid-span and near the connections have been reported in Table 6. It can be seen that by using optimised joints, the mid-span moments are reduced by 12% –13%, whilst the end moments increase by 55% and 89% for the gravity and earthquake load cases, respectively, indicating the optimised joints provided a higher degree of end fixity to the beam at the connections than the conventional connections, while not generating moments larger than the mid-span moments. Moreover, it can be observed that due to the higher stiffness provided by the optimised connections, the bending moments in the columns near the connections increase by 41% and 37% for the gravity and earthquake load cases, respectively.





Iteration	**10**	**50**	**70**
Load case 1 (Gravity)			
Load case 7 ($E_y - 0.3E_x$)			
Mean compliance ($N.mm$)	4.45×10^6	4.90×10^6	5.44×10^6
Volume fraction (V/V_0)	0.82	0.36	0.24

Figure 9. Topological evolution with von Mises stress distribution field for the material non-linear stiffness design for the top joint under various load cases (peak stress of 316 MPa is plotted as red).

Frame type	Gravity case		Earthquake case	
	Mid-span	connection	Mid-span	connection
	kN.m	kN.m	kN.m	kN.m
Optimised connection	471.3	194.7	375.3	194.7
Conventional connection	540.3	125.7	425.7	102.9
Ratio (opt./conv.)	0.87	1.55	0.88	1.89

NOTE: The moments at the connections are taken at a section 280 mm away from the face of the column.

4. Conclusion

The paper describes a framework for investigating the potential application of optimised joints fabricated by advanced manufacturing with a particular focus on the steel framing systems used in commercial and residential buildings. The first part of the paper developed a methodology for the optimisation of a frame structural connection considering multiple load cases. The numerical simulations of the optimised connections showed promising advantages in terms of strength, ductility and stiffness compared to their conventional connection counterparts. In the future, more elaborate connection layouts with multiple connecting members accounting for potential WAAM-related constraints can be developed to enhance the performance of such optimised connections and further demonstrate their advantages over conventional connection designs.

Abstract

Conventional earthen building methods such as cob and adobe are relevant for developing countries but labour-intensive, expensive and slow for developed countries. Automation in construction has been increasingly favourable in developed countries, especially buildings constructed with 3D printed cementitious materials. 3D printed earthen materials demonstrate a better environmental performance compared to 3D printed cementitious materials due to the energy intensive manufacturing of cement. Moreover, conventional earthen methods, such as cob, create earthen buildings with solid sections while 3D printing allows a hollow section and various infill designs using less material. Despite the benefits, the research on the mechanical strength of 3D-printed earthen structures is still limited. The lack of data on the mechanical performance of 3D printed earthen structures, is one of the obstacles preventing the mainstream construction industry from approaching this novel building method. Our research investigates an assembly-oriented novel low-carbon masonry building method with unfired 3D-printed earthen blocks and explores its adaptability to the mainstream construction industry with a critical comparison based on mechanical properties.

Keywords: 3D printing, construction techniques, digital modelling and fabrication, earthen architecture, low carbon construction, automation

1. Introduction

Manufacturing of industrial construction materials contributes up to one-third of all carbon dioxide emitted by the construction industry[1]. Conventional materials like steel and concrete are high embodied energy materials because of the energy required to provide high temperatures necessary for their production [2]. In contrast, unfired earth requires no industrial processing and is generally available at the excavation site or locally. Moreover, earthen buildings can balance humidity and regulate indoor temperatures, eliminating the need for mechanical heating and cooling systems, further reducing the carbon footprint of the building [3].

Nearly a third of the world's population lives in earthen dwellings [4]. Nonetheless, earth is still not considered a conventional building material. Earth is generally perceived as a primitive material only used for dwellings in rural areas or developing countries. Yet, there are numerous contemporary earthen buildings for various architectural purposes built for various economic classes and urban environments in developed and developing countries. Moreover, earth is an excellent material for constructing with the principles of the circular economy [5]. For example, Brussels Cooperation in Belgium creates earthen building elements from 36 million tonnes of earth excavated from the Belgian construction sites, which would otherwise be waste [6]. This approach is promising to create innovative and sustainable future urban habitats within a circular economy.

2. 21st century mud

2.1. Why 3D printing with earth?

During a lecture at the Pratt Institute in 1973, Louis Kahn had his famous conversation with a brick, asking the brick what it wants to be, later added that the same conversation could happen with concrete or marble, emphasising the importance of understanding the nature of each material or "honoring the material" [7]. Today architects and designers take this discourse even further with computational design and digital fabrication. Gramazio and Kohler [8] observe that the advanced design and fabrication techniques blur the boundaries between data and material along with programming and construction, creating a "digital materiality" which "enriches material by information". Additive manufacturing methods such as 3D printing are revolutionising architecture and design by enabling the manufacture of data-driven complex forms created by computational design, which would be hard and expensive for conventional craft and making to realise. By placing the material exactly where its needed, structural stability could be gained with less material. Developed countries are increasingly investing in automation in construction and labour intensive nature of the conventional earthen building methods prevents its uptake by the mainstream construction industry. Population growth combined with the high cost of housing makes access to affordable housing one of the most critical concerns of the 21st century. On-site robotic 3D printing with concrete is a novel construction strategy suggested as a fast and affordable solution for housing. For example, a house in Nantes(France) is the first habitable 3D printed concrete building constructed in 54 printing hours and claimed to be 20% cheaper than conventional concrete construction [9]. This construction system eliminates material waste caused by the use of formwork. However, 3D printed concrete is more carbon intensive than conventional concrete due to plasticiser added to the mix to be able to 3D print. 3D printed earthen buildings are a low-carbon alternative to 3D printed concrete [10], while adapting to the construction industry in developed countries and automating the building process. Without adding chemical stabilisers, the earth from the site or locality could be re-printed until the desired result is achieved. First housing prototypes built with on-site robotic 3D printing with earth, such as Casa Covida [11] by Rael&San Fratello in the USA, Tecla [12] by World`s Advance Saving Project (WASP) and Mario Cucinella Architects in Italy, and Tova [13] by Institute for Advance Architecture of Catalonia (IAAC) in Spain present a natural and low-carbon alternative to 3D printed concrete houses. Since the uptake of steel and concrete after World War II, earth has been neglected as a rural and weak material. The juxtaposition of this humble material with cutting-edge technology also removes this bias and creates a contemporary "21st Century Mud".

2.2 On site vs off-site (prefabricated) 3D printing with earth

On-site additive manufacturing with earth has several environmental and financial benefits. Earth has an advantage for regions where wood and concrete are expensive and require long-distance transport. This process does not need scaffolding and is largely waste-free. However, the construction site must be protected as earthen walls are prone to erosion by rain and strong winds. Strong directional sunlight also creates irregularities in geometry and cracking, if one side of the wall dries much faster than the other side so shading is essential. On the other hand, off-site construction is not weather dependent, making all year fabrication possible in a climate-controlled environment.

Although on-site additive manufacturing offers continuity of the construction, there is only a certain height that can be printed in session, then it is necessary to wait for the walls to dry and gain strength before continuing with the printing. Off-site prefabrication of earthen blocks allows continuous fabrication where blocks can be stacked for drying. The control over the production with expert staff also avoids mistakes caused by craftsmanship on site, ensuring a result without discrepancies, making it more favourable to the mainstream construction industry. Also, prefabrication enables better precision and tolerances for earthen blocks that shrink in volume and weight while drying. The prefabricated rammed earth walls of Ricola Herb Centre by Martin Rauch is a recent example of how a prefabrication approach was welcomed for a contemporary building while using the local earth from the construction area. Experimental research projects such as Terraperforma [14] and Digital Adobe [15] investigates a similar approach with robotic fabrication. Despite several advantages, off-site production also presents challenges, such as transporting and assembling heavy earthen blocks. Building construction hubs close to the site to fabricate earthen blocks combined with fast robotic assembly on site could solve these challenges.

Figure 9-10 : IAAC Terraperforma [27] Image credit: Gabriel Frederick.

3. Prefabricated 3D printed earthen blocks

3.1 Fabrication process

As demonstrated in detail in our research paper for IASS 2022 [15], we have designed and 3D printed eight earthen blocks with KUKA KR 60 high-accuracy robot and a custom-designed extruder at the Welsh School of Architecture, using local clay-rich soil from Cardiff. The goal was to print robust earthen blocks with minimum material using block geometry and infill strategies.

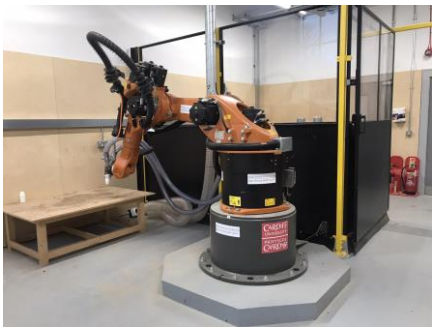

Figure 11,12,13. KUKA KR60 six axis high accuracy industrial robot, the dual extruder [16] and the custom fabricated steel end effector connecting 3D printed nozzle to the pressure hoses.

Blocks were designed with Rhinoceros® Grasshopper® with a parametric design approach, introducing parameters based on wall thickness, number of wall layers, layer height, number of undulations, and width, length control which allowed us to produce and test multiple iterations without the need to design each block from scratch.

During the prototyping process, several blocks were tested while an optimum robot speed at 0.09 m/s, 0.1 m/s extruder speed and soil mix viscosity was defined. The outcomes of the prototyping process confirmed successful data for block parameters such as layer height, number of layers and undulations to finalise the block and infill geometries. Simultaneously, the final earth mix recipe was confirmed as 61% soil, 0.3%straw, 22% sand and %17 water. This recipe was fluid enough to ensure a continuous material flow from the extruder through the pipe and to the nozzle while solid enough to print the blocks without buckling.

Once the prototyping process was finalised, we printed eight blocks that transformed in size, form and infills to create the tapering and slightly rotating wall once assembled. Printing each block took less than 5 minutes, at a rate that demonstrating the potential for fast production.

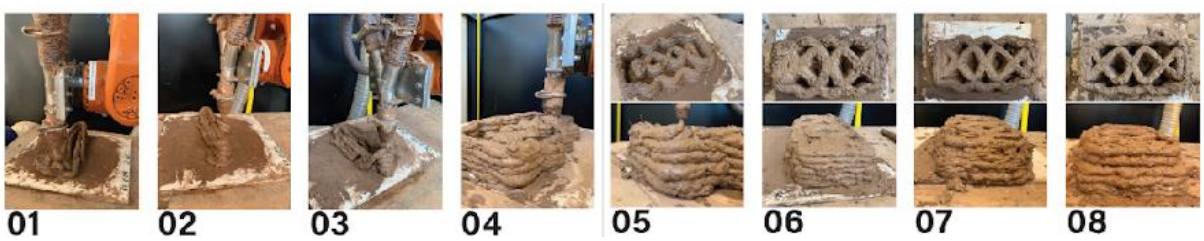

Figure 15. Trials with various robot speeds and layer heights while keeping the extrusion speed at 0.1 m/s and printing with the 25 mm nozzle.

3.2 Drying and assembly of blocks

Printed blocks were left to dry in a heated room for a month. Avoiding the temperature and humidity fluctuations allowed the blocks to dry without significant deformations in form. During the drying period, blocks lost 15% in weight as the water evaporated. Once fully dry, blocks were stacked on each other after being sanded and wetted with the same soil mix used as mortar. The same mortar recipe with adding more water and eliminating the straw can be robotically sprayed on the 3D printed samples to smooth the surface of the blocks, if needed. The assembly process has shown discrepancies between the block design, 3D printed blocks and dried specimens due to the unpredictable nature of the printing and drying process, which presents a challenge for the adaptation to the mainstream construction industry, where predictability and precision are essential. Nonetheless, prefabrication in a controlled environment presents the opportunity to improve the precision of the process by multiple calibrations exempt from weather conditions and accurate prediction of the final geometry after the drying period. This optimisation process to fabricate the blocks is essential to develop various assembly methods and block connections.

Figure 16, 17. Assembled wall and the assembly process.

4. Mechanical properties of 3D printed blocks

4.1 Introduction

As mentioned in the previous sections, 3D printing with earth can enable building robust structures using less material as material scarcity becomes increasingly critical. Cob is a technique of mixing clayey earth and fibres such as straw and then applying them by hand with pushing them to create a monolithic wall. The plastic nature of cob also makes it ideal to use it for 3D printing, with increasing the amount of water to make the mix printable, as previously mentioned. It can be argued that conventional cob is an additive manufacturing method where the mix is gradually added by hand to create walls, while 3D printing cob, automates and accelerates this process. Moreover, conventional earthen methods, such as cob, create earthen buildings with solid sections while 3D printing allows a hollow section and various infill designs using less material. 3D printing also enables the designer to use the gaps in the infill for insulation or ventilation. Despite the benefits of this new approach, the research on the mechanical strength of 3D-printed blocks is still limited. To our knowledge, only three research papers are published on the subject [18] [19] [20]. The lack of data on the mechanical performance of 3D printed earthen structures prevents engineers and contractors from approaching this novel building method. More data and research on the mechanical properties of 3D printed earthen blocks is essential to accelerate the mainstream industry's uptake of this novel building method.

Compressive strength is the main mechanical property when defining the integrity of earthen structures as it shows the loadbearing capacity [21]. Gomaa et al. [18], looked into sixteen research papers, including conventional cob's compressive strength, and found that values fall between 0.4-1.35 MPa. Previous research on the compressive strength of 3D printed earthen specimens is documented as between 1.2 and 1.8 MPa for a cob-like mix using alginate seaweed polymer instead of straw [19], 0.87 MPa for 3D printed cob cylinders [18], and 2.32 Mpa for a 3D printed load-bearing element by WASP [20]. Our compression tests aimed to find out where our specimens fall in this range and compare the compressive strength of each specimen to see if the geometry and the thickness of the block infill affect the compression strength.

4.2 Test specimens

Figure 18,19,20. Test Specimens, Block A, Block B, Block C. Photo Credit: Lina Ahmad.

Three 3D printed blocks, fabricated with the process and material mix explained in section 3 were selected as test specimens. The infill geometry, number of undulations and thickness of the blocks are slightly different for each specimen. The width of specimens are 15 cm at the narrowest and 20 cm at the widest. The heights of the specimens are 7-8 cm and the length of the specimens is 35-36 cm.

4.3 Test preparation, equipment and method

Before the testing, quick-setting dental plaster was applied to the top of the blocks to have a flat surface to ensure uniform load distribution and avoid stress concentrations that could lower the compressive strength values. In addition, prior to dental plaster application, the holes on the blocks were filled temporarily to avoid plaster penetrating inside the block.

Figure 21,22,23. Dental plaster application to flatten the block surface prior to testing.

1MN Servo-hydraulic fatigue testing machine was used for testing to accommodate the size of specimens. First, compression platens were installed and the height of the platens were adjusted according to the block heights. Subsequently, each specimen was subjected to a uniform axial load. Initially, the load was applied at a conservative 0.001418 mm/s to Specimen A and the test took about

50 min. Then, the speed was increased approximately five times to 0.008255 mm/s for specimens B and C, and the test took about 25-30 min for each specimen.

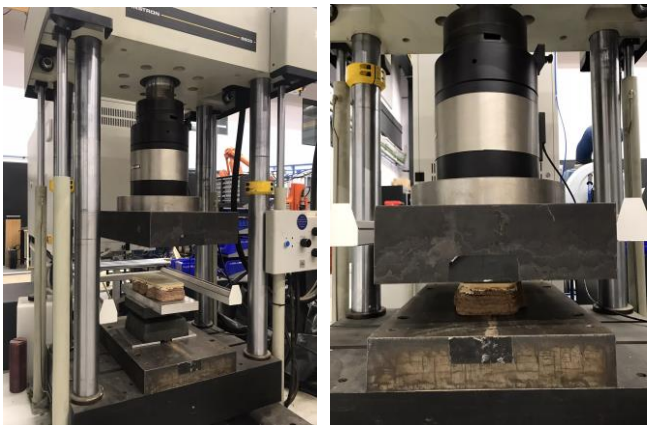

Figure 20. 1MN Servo-hydraulic fatigue testing machine used for the compression tests.

Figure 21. Typical failure at the corners and along the perimeter was observed for all specimens.

4.4 Test Results

The testing machine has generated data for force (kN) vs displacement (mm). The stress was calculated based on $\sigma = P/A$ formula, where P is the applied force and A is the cross-section area of the block. The axial strain was calculated based on the $\varepsilon axial = \Delta/L$ formula, where Δ is the displacement and L is the length of the blocks.

Figure 22. Specimens before and after testing (broken pieces are disposed of).

The irregular infill geometry makes it harder to get an accurate cross-section area with manual dimensioning. Therefore, we extracted each block's accurate cross-section areas from the scanned models of the blocks using Rhinoceros®.

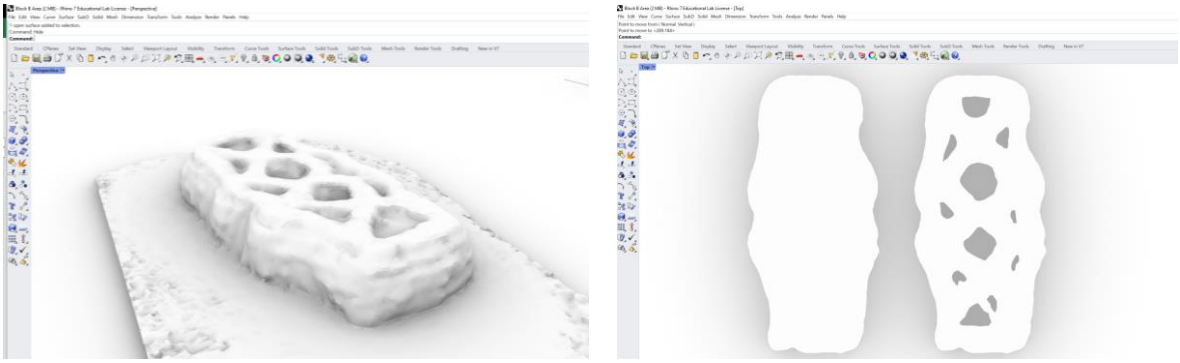

Figure 23. 3D scanned specimen B in Rhinoceros® and cross-section area with and without the gaps in the block.

Table 1. Area and solidity comparison of test specimens

Cross Section Areas (mm^2)	**Specimen A**	**Specimen B**	**Specimen C**
Infill gaps included	54000	48500	56500
Infill gaps excluded	41261	42744	50087
Block Solidity	76.4%	88.1%	88.6%

Based on blocks cross-section areas (gaps excluded) shown above, the compressive strength of Specimen A is 1.7 MPa, Specimen B is 4.4 MPa and Specimen C is 3.1 MPa. When the compressive strength is calculated based on cross-section areas with gaps included, then the compressive strength of Specimen A is 1.3 MPa, Specimen B is 3.8 MPa and Specimen C is 2.8 MPa. All blocks performed well considering the average conventional cob compression strength and previously recorded compression strength of the 3D-printed cob. The stress-strain diagram for each block is shown below.

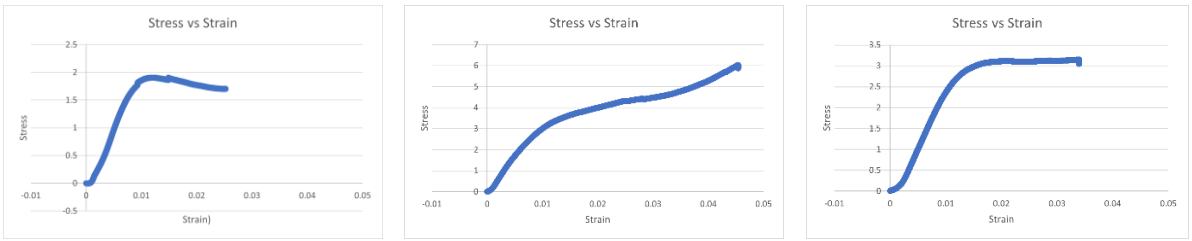

Figure 24. Stress-Strain Diagrams for Specimen A, B and C.

A similar behavior was observed for specimen A and C on these diagrams, where a linear rise ended with the peak and reached a plateu after a small reduction in slope. On the other hand, Block B has shown an irregular behaviour where the linear rise has started again after reaching a plateau. This irregularity might be caused by the dental plaster holding the pieces together and delaying the brittle response. Hence, the first peak before reaching the plateau has been considered for specimen B while calculating maximum compressive strength and the second peak is ignored.

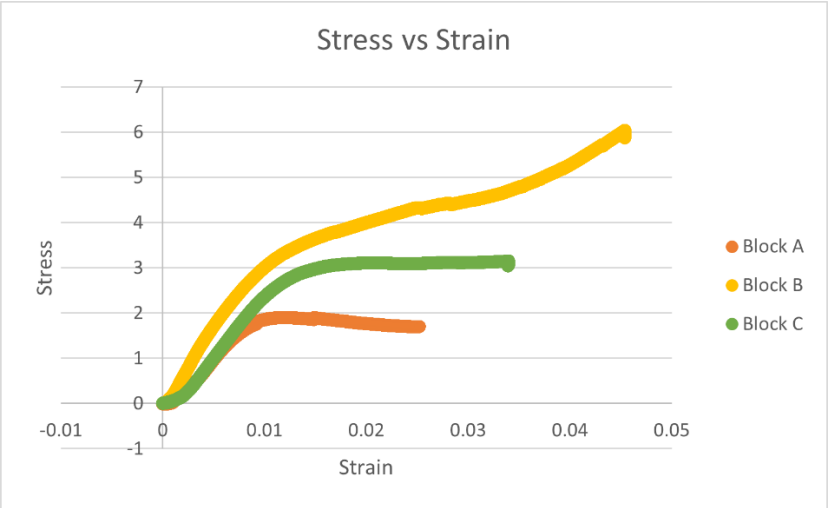

Figure 24. Stress-Strain Diagram, comparison between Block (Specimen) A,B and C.

As mentioned in the previous section, during the prototyping process, the block form was updated with more significant undulations to gain better structural stability and avoid buckling, while 3D printing and interlocking waves were added to the infill geometry to work as buttresses. However, the compression test has shown that while the buttress strategy increases the structural strength of the block, the undulations of blocks on the perimeter have no effect. Additionally, although specimens A and C have similar geometry, specimen C performed much better under axial load due to thicker infill layers. Specimen C also had a stronger buttress connection than Specimen A, which supported its strength too. While dental plaster helped attain a uniform load distribution, it might have held the blocks together longer than usual, preventing an expected brittle behaviour after blocks reached their maximum strength and demonstrating an unusually long plateau in stress-strain diagrams.

5. Conclusion

3D printing enables short supply chains and localised fabrication while providing an opportunity to use less material and ensuring structural stability with geometric optimisation. Prefabrication of the 3D printed earthen blocks has the potential to mitigate the uncertainties about the earthen block fabrication and provide precision in a controlled environment while enabling rapid fabrication for a greater demand. Precision and rapid fabrication can accelerate the adoption of earthen construction by the mainstream construction industry in the developed world. However, the lack of data about the properties of 3D-printed earthen construction creates doubt for construction professionals. Our research explored the mechanical properties and compression strength, in particular, of 3D-printed earthen blocks. As mentioned above, our research has demonstrated that geometry, infill strategies and the infill's thickness affect the compression strength of the 3D printed blocks. Moreover, our specimens performed well compared to the average conventional cob compression strength and previously recorded compression strength of the 3D-printed earthen elements. However, further tests are required to investigate the role of infill geometry on compression strength. In addition, different fibres could be used to explore it`s effect on the strain response of the blocks. This design and fabrication method is promising to allow bespoke block and infill geometries to be created and fabricated using local earth. The increase in the availability and affordability of 3D printing equipment, combined with the increase in the data about the performance of 3D printed earthen structures, will spread it`s use as a novel low-carbon building method in the mainstream construction industry.

Acknowledgements

We would like to acknowledge the diligent work and contributions of Prof Wassim Jabi, Kamal Haddad, and the Welsh School of Architecture, MSc Computational Methods in Architecture students in 2022, Afnan Aldulaijan, Ashley Vias, Dorsa Boroujerdifard, Darshan Chavan, Deval Ambavi, Louai Jaber, Mohammad Omar Eqbal, Sapta Sunusae and Selda Pourali Behzad. We also extend our gratitude to Lina Ahmad who helped us with the scanning, photographing and shipment of the 3D printed earthen blocks. We would like to thank Pieter Dresneck and Phil McLaren for their help during testing. Abstract

The architecture, engineering and construction additive manufacturing field has witnessed rapid development in recent years facilitated by the development of digital fabrication processes and geometrical design workflows. However, there has been limited research on non-planar 3D toolpath optimization tailored for continuous fibre additive manufacturing processes, other than layer-by-layer deposition. This paper addresses a novel design for manufacturing framework for building structural 3D spatial lattices with continuous fibre additive manufacturing processes through an optimisation form-finding method based on stress-lines generation. This fabrication-aware method overcomes the traditional challenges of non-regular topology sequencing, improving material efficiency, weight and structural performance compared to standard 3D lattices. The proposed method produces load-bearing designs for functionally graded lattice cellular topologies that respond to stress distribution and structural requirements. From a structural design perspective, specific non-standard load-based lattice geometries, have the potential to significantly reduce material usage, a major drawback of composite materials in AEC. This research presents a framework to manufacture a globally continuous 3D spatial lattices toolpath for 2.5D structural designs, which takes advantage of the benefits of continuous fibre placement as structural reinforcement for composite elements.

1. Introduction

Nowadays the major constraint for the integration of high-performance materials and additive manufacturing (AM) techniques in construction, is the cost of the material supplied [1]. 3D printing should be used for what it does best [2], which includes optimizing workflows. Conventional methods of additive manufacturing are affected both by gravity and the printing method. As well, layer-by-layer AM is either constrained by material usage or limited geometrically by the inherent overhang capabilities of the material in deposition. For composite AM to be able to reach 'volume' construction on the construction market, it must form part of an integrated, digital continuum in which the performative impact performance-wise on deployment cost and structural improvement/proficiency-outweighs aesthetics alone.

Architects with their role as designers typically prioritize aesthetics while structural engineers focus on the practicalities of building techniques. The integration of advanced computational tools and fabrication techniques has enabled architects to push the boundaries of traditional design, integrating in the design practice, "the architecture of the parametric and data" as part of the design process. This evolution of design has allowed architects to create structures that are not only visually stunning but also highly functional and sustainable.

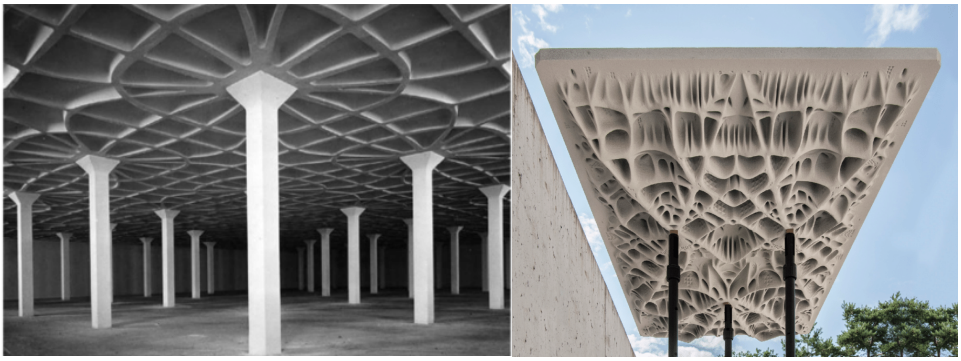

Figure 1.1 (Left) Gatti Wool Factory. Image credit: Ma, Jiaming et al. 2022, Figure 1.2. (Right) -Topology optimization of a slab with three supports. Image credit: DBT ETH

One of the earliest recorded examples of this approach can be found in the work of Vitruvius, a famous Roman architect and engineer who proposed that a building should embody three fundamental principles: firmitas, utilitas, and vetustas [3]. Firmitas, or strength, refers to the structural integrity of the building, while utilitas, or utility, is concerned with its functional purpose and how it can best serve its intended users. Finally, vetustas, or beauty, speaks to the aesthetic and visual appeal of the building. This cross-disciplinary application of fields such as engineering in the modern architectural practice developed the concept of "strength through geometry", terminology coined by Philippe Block for the definition of structures with optimized material usage through its geometrical shape and material manufacturing optimization.[4] or the work developed at the Digital Building Technologies at ETH (Fig 1.2), where they work on computational methods, such as the optimization of size, shape, and topology of material distribution to ensure the efficient distribution of concrete for a given part resulting in high complexity geometries that can achieve significant material reduction at the cost of problematic and intricate fabrication processes, that is overcome by additive manufacturing technologies [5]. As well, there has been growing interest in using advanced materials from fields such as aerospace and biology in architectural practice. For instance, lightweight, high-strength materials such as composite materials make it possible to design buildings with complex shapes and structures that were previously impossible usually, at the cost of high manufacturing complexity [6] (Fig 1.3 and 1.4).

1.1. Research aim

The presented research outlines the exploration of a niche of architectural possibilities on the combination of continuous fibre with AM such as continuous fibre-reinforced plastic (CFRP) technology for the fabrication of structurally optimized spatial lattices, that structurally benefits from the material-load capabilities through advanced composite AM fabrication techniques. The experimental case study for this research on a computational workflow is the Messerschmidt- Bölkow-Blohm (MMB) beam problem for a distributed load. This case study has been partially AM robotically fabricated as a proof-of-concept prototype of the accounted methodology. (Fig.1.5)

Figure 1.5. Photocollage above is the combination of the partially 3D printed spatial lattice prototype explained in this paper and the full digital model of the calculated scenario.

2. Additive manufacturing and spatial lattices

2.1. 3D printed spatial lattices

Several academic institutions accounted as Digital Structures Group and MediaLab at MIT, ICD ITKE, Gramazio Kohler research group (Fig 2.4) and Laboratory of Composite Materials and Adaptive Structures at ETH, among others, have researched the geometrical capabilities of lattices structures with additive manufacturing or sequential assembly and its high load-bearing capabilities to material per weight. [18] Prior examples of space lattice make use of a repetitive unit's arrangement in a regular topology syntax, conforming rows or grids that are added to each other. The uniform topologies sometimes with variable cell sizing ensure reduced path planning complexity and sequencing even when applied on twisted forms or ruled surfaces. The usage of material efficiently is done by the variations of

the distance between the inner and outer cells, a span of the individual cross-section of the node's members or grid geometry/topology [7]. These regular and variable topologies offer limited structural optimization and geometric freedom (Fig 2.2).

In conclusion, the load paths for a structurally loaded regular spatial lattice in a conventional space frame exhibit directional discontinuities due to the members not necessarily aligning with the overall force flow in the structure. As a result, there is less than optimal utilization of materials. However, recent advances in geometrical path-planning techniques have led to the development of irregular lattices that are even more optimized for strength-to-weight ratios. In this regard, new manufacturing technologies and methods could enhance the application of these lightweight structures with lightweight materials in construction.

2.1. Continuous fibre additive manufacturing

One of the major updates, when we analyze the current technologies under development for highly resistant and lightweight materials available for additive manufacturing, is the introduction and enlargement of continuous fibre manufacturing processes (CFAM). The current research on this topic exists in the engineering and material scientist fields [8], [9] and has been focused on the underlying mechanics [10] chemistry [11], [12], and performance of the physical output [13], [14], as well as material behaviour properties [15],[16] (Fig.2.5).

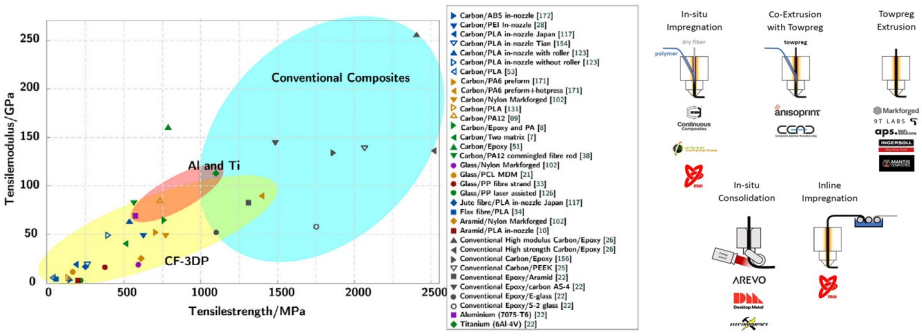

Figure 2.5. (Left) - Tensile strength / Tensile modulus material comparison chart of multiple academic publications on CF-3DP. Image Credit: [18] P. Zhuo et al, 2021. Figure 2.6. (Right) - Concepts for direct fibre integration. Image Credit: Alexander Matschinski, Virtual Symposium on AFP and AM, TU Munich, Chair of Carbon Composites (LCC), Sep. 2020

The development of CFAM techniques is driven by the industry's demand for highly engineered parts (Fig 2.6). Various companies develop these processes, starting with Anisoprint, which uses Composite fibre Co-extrusion (CFC), Markforged and Desktop Metal, which use Continuous Fiber Reinforcement (CFR) technology to create technical parts on desktop and industrial 3D printers and newer companies, such as 9T Labs, Arevo, Mantis Composites, AREVO and CEAD's that can achieve true 3D paths and z-direction reinforcement, allowing those companies to fabricate fully freeform shapes at large scale. With the development of additive manufacturing deposition techniques and material implementation processes for continuous fibre 3D printing, the possibility of more structurally efficient lightweight architectures bears high potential as newer techniques enhance design freedom and flexibility in geometry design [17]. The introduction of continuous fibre in 3d printing is the next step of additive manufacturing. In that way, there is potential to create new fabrication routes for composite-made architectures such as lattice structures.[19]

2.2.1. Hardware

During this research, an end-effector extruder for continuous fibre-reinforced plastic was used (Fig 2.7). This one integrates several continuous PLA plastic filaments combining them with glass fibre yarns in a pull-extrusion integrative method (CFRP), it was ad-hoc designed based on other academic research's [16][20][21][25]. The mechanical platform was an existing 6-axis robotic arm ABB IRB140, connected to a positive air pressure system and electronically controlled with an Arduino-based programmable controller PLC. Both pneumatic and PLC systems are digitally controlled by the robotic arm controller box to proceed with the on/off operation, pressure and speed control, on-the-fly based on the different toolpaths operations.

3. Design for manufacturing & computational methodology

3.1. Stress lines form-finding

There has been limited research on computational design techniques that account for high anisotropy behaviour such as continuous fibre 3d printing, and spatial lattices topologies [19],[23]. In which the material works anisotropically at compression and tension. On the other hand, it has been found correlation between complex lattice patterns found in biological forms and the structural properties of principal stress trajectories [22]**.** Principal stress lines are a representation of the directions of purely axial stress in space (Fig 3.1.). By aligning bar-type elements with the carried load, the material can be directly oriented to meet stress constraints, which can be especially advantageous in situations where little material is required. There is existing research on the generation of fabrication-ready geometries based on stress lines for additive manufacturing (SLAM) [23].

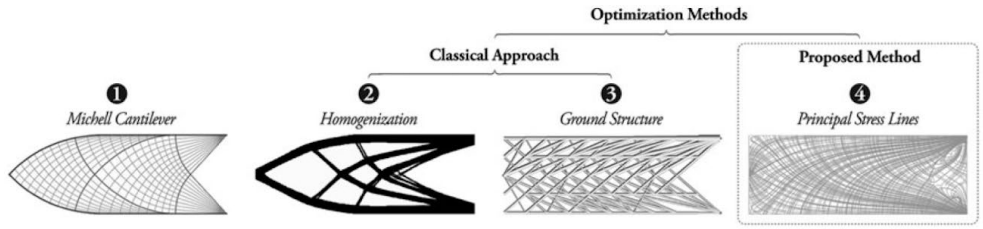

FIG. 5. Convergence of optimization results obtained from **(2–3)** classical optimization methods and both the **(1)** Michell structures and the **(4)** principal stress lines of the corresponding design domain.

Figure 3.1. Additive manufacturing along Principal Stress Lines. Image credit: Tam, K.-M.M. and Mueller, C.T. (2017)

The generative method proposed creates printable paths that follow the stress forces along the materials on a surface it is explained through the presentation of several recursivity algorithms that iteratively start a vector-finding process among the constituent finite element nodal stresses on an initial F.E.M calculation for a specific case study. The algorithmic approach for continuous stress line form-finding not only matches the mechanical characteristics of the fibre composites, which need to have a continuity among the fibre direction to be able to maximize the stiffness and stress capabilities of the materials but also the problems inherent in continuous fibre AM composites. In CFAM is mandatory to have a toolpath with the least number of discontinuities, as the deposition process needs to prioritize the continuity of fibre among its structure to reduce the need for external intervention to section the fibres or an end-effector with cutting capabilities and increase the structural behaviour.

3.2. Stress lines to continuous lattice formation

For the lattice formation, we can distinguish two-level hierarchical structured components obtained across the geometrical lattice. At the first level of resolution, the load paths follow the placement of the main overall force-flow calculated in the SLAM method, at the second level of resolution, the bi-dimensional polygonised matrices are interconnected by the parallel projection of their crossing vertices, followed by reconstruction of the planar defined geometries in a 3-dimensional formation. The projection level of the vertices is constrained by the end-effector capabilities and its conical nozzle point design, stated at a 50mm distance between the first level stage resolution.

Specifically, the final design is not initially modelled in 3D; rather, becomes a 3-dimensional model by the composition of bidimensional matrices that are interconnected with the 3D versions of the same. (Fig.3.2) Cell sizing is informed and driven by the manufacturing criterion of maximum and minimum spacing in their generation of stress lines.

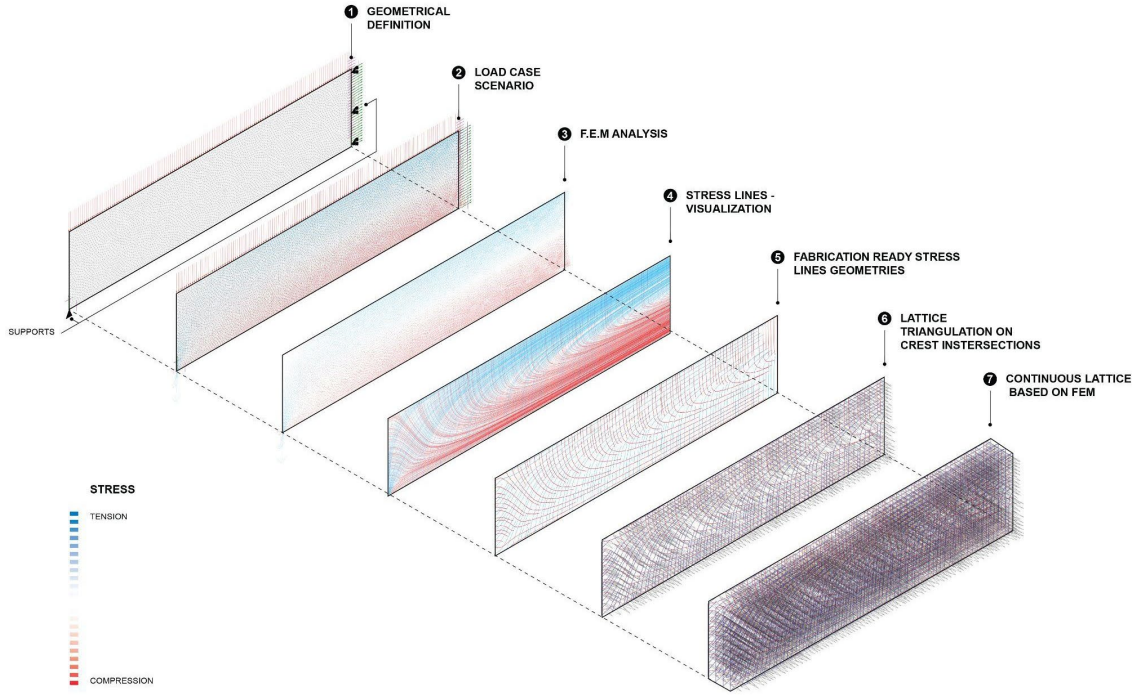

Figure 3.2. Description of the generative method: (1) geometrical definition and boundary constraints, (2) load-case structural scenario, (3) finite element vector result from the load-case scenario, (4) stress-lines interpolation from structural programs, (5) stress-line fabrication aware tracing, (6) stress-line crossing interpolation for crest generation, (7) stacking of bidimensional layers on the 3-dimensional design domain.

Manufacturing-wise, hierarchies follow primarily the two-dimensional substrate resulting from the SLAM followed thoroughly by the vertical interconnecting members. Giving as result a planar-triangulation-planar (P-T-P) lattice formation, that is evenly repeated until the initial volume is filled. The inner and outer layers of it have an identical topology, with a connecting topology between each pair of corresponding nodes, acting as a bracing element for stability. By utilizing carefully-oriented multi bar-type elements, the material continuity can be directly kept by sequencing the polylines on a cartesian space based on the averaged distance to the design space origin, splitting the sequence in stress polylines sequence, continued by the compression ones, allows for continuity of the different elements by force classification, closing the cell lattice between the elements as the material keeps continuity during the print reduce fibre cutting operations, as seen in figure 3.4.

For each individual resulting cell the triangulation topology is constructed by establishing the valleys of it the mid-point of the individual member of each major stress line and the crest at the intersection of these, creating edges on the inner and outer layer, of two possible diagonals for each intersecting set of lines (Fig 3.6). However, the limitation of this strategy is the presence of gaps between the non-reaching boundary lines resulting in non-uniform spacing, resulting in crossing elements that have no structural focus (Fig 3.3).

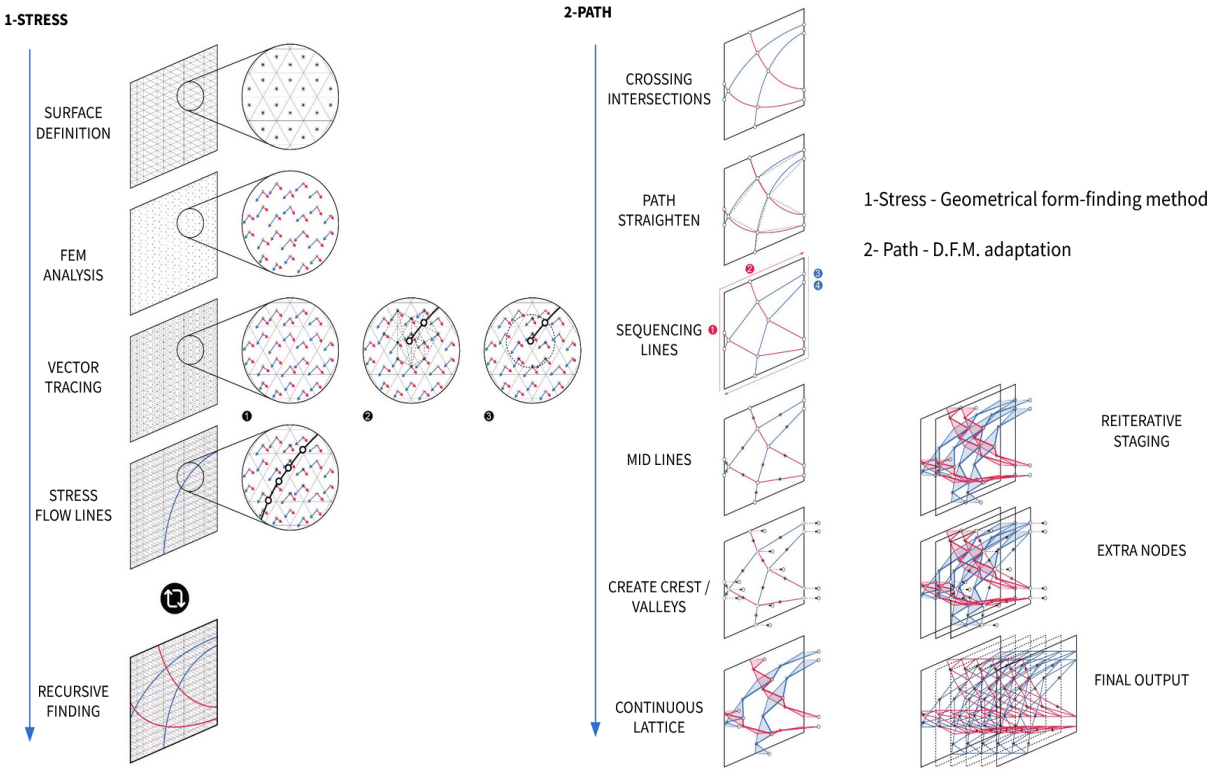

Figure 3.3. Description of the generative method: (1) geometrical definition of stress lines (2) path for manufacturing adaptation and lattice formation.

To effectively incorporate CFAM and topological spatial lattices into fabrication-aware design processes. Continuously arranging the fibres along the lattice-like linear elements of the structure allows for the optimization of material usage and reduces weight while maintaining its structural integrity. This process is more critical when the manufacturing process of continuous fibre deposition relies on the continuity of the fibre for maximum strength and minimizing cutting fibre operations.[21] (Fig 3.7). A continuous print path planning strategy greatly improves the deposition sequence and simultaneously reduced the collision checking operations. The external collision objects have been reduced to a variety of points conforming to the spatial lattice geometry. Instead of using collision checking among mesh to mesh, the points conforming to the spatial lattice are tested to be in the interior of the end-effector basic geometries which greatly improves the calculation time and keeps good detection of possible collisions. This process in the case of lattice additive manufacturing techniques serves as a close match as the material deposited in the workspace is of reduced size and dimension compared to its linear topology.

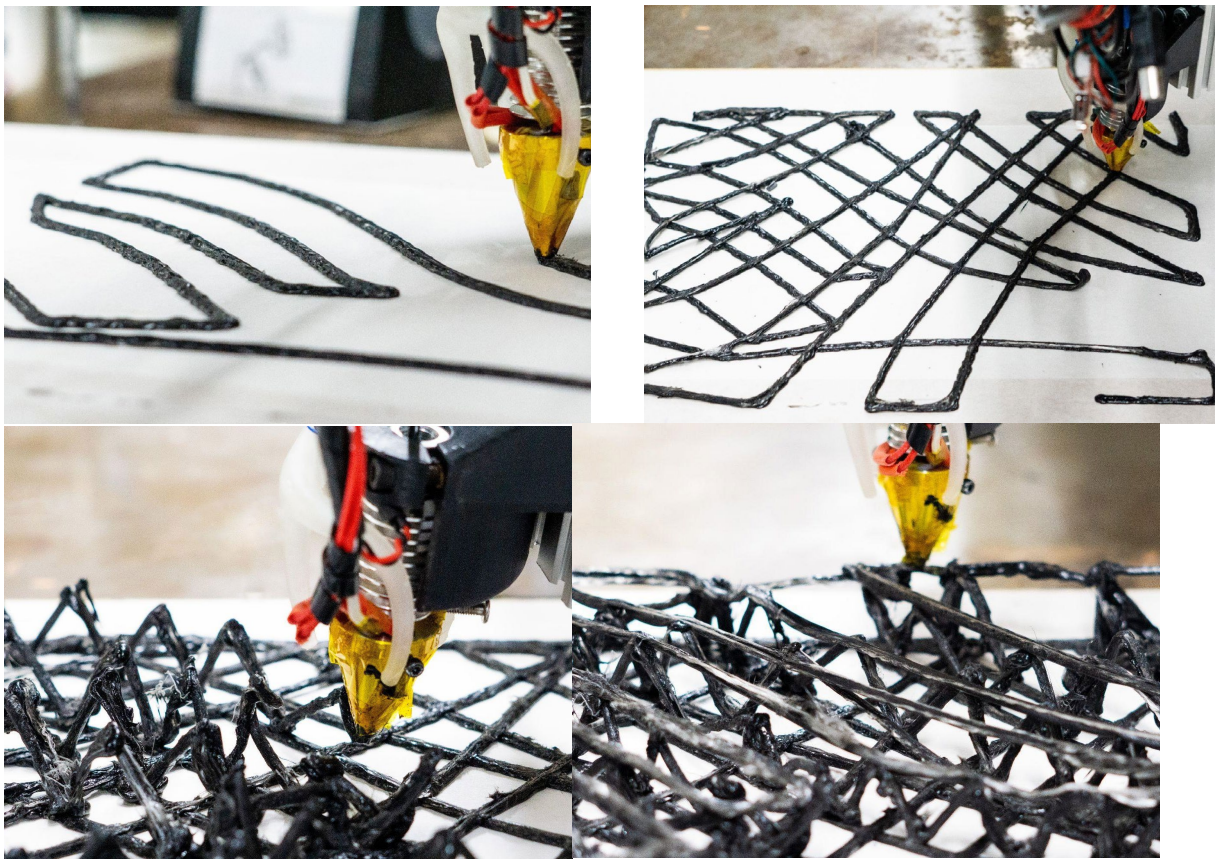

Figure 3.4. (Top-Left) - Continuity path between among the lines with the same force-flow. Figure 3.5. (Top-Right) - Secondary set of compression element continuity. Figure 3.6. (Bottom-Left) - Stress triangulation. Figure 3.7. (Bottom-Right) - Secondary in air stress print layer.

The methodology used for the fabrication sequencing was developed through a series of preliminary material tests, searching for the adequate parameters regarding, material setting time, cantilever maximum spans, geometrical deviation, extruding, horizontal and vertical deposition speed as well as necessary cooling or set time of the material to reach its solid-state mechanical properties.

3.3. Structural re-analysis

In this design for manufacturing workflow which is structurally driven the total supported load relative to the self-weight of the generated case study digital model was reanalysed for its verification as the mechanical performance is a critical aspect for its validation. The spatial lattice line simplified line model was analyzed in KARAMBA 3D, which is a finite element analysis (FEA) plugin for Rhinoceros 3D and Grasshopper 3D modelling environment. The main materials characteristics used in the FEA scenario, are a Young's Modulus of 5000 kN/cm^2, (50MPA), an In-plane shear modulus of 2000 kN/cm^2, a specific weight of 17.45 kN/m^3, for the in-plane ones and the rest of the anisotropy characteristics of the material were fed, based on the aforementioned researchers stated in chapter 2.1. The cross-section resulting from the AM method used, a 4mm diameter linear element in this case was used. A linear elasticity simulation was run using the initial load and support scenario but in this final validation the whole design element was calculated, not the half Messerschmidt- Bölkow-Blohm (MMB), being the design domain a volume of 0.3 x 0.1 x 3 m and a distributed load of 4kn/m^2.

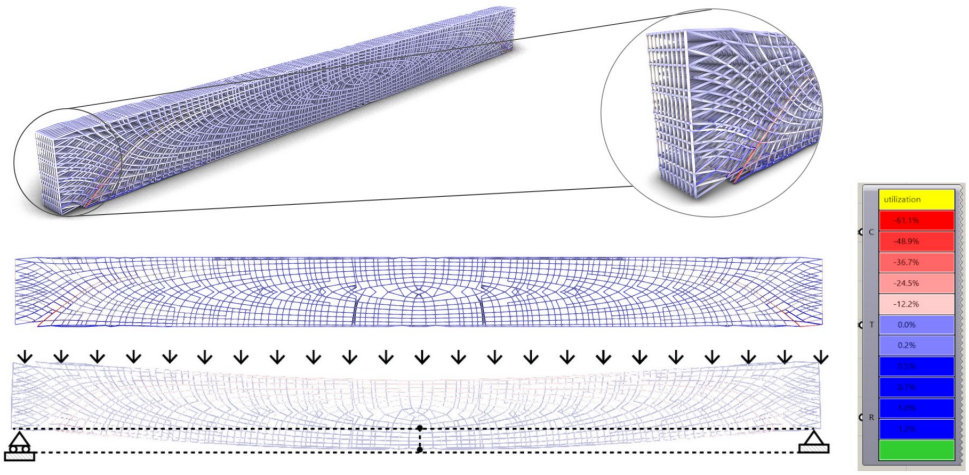

Figure 3.8. Line model analyzed of the structure under a distributed load with PLA+continuous fibreglass material characterization and cylindrical members of 4mm diameter resulting from a CFRP 3D printed extrusion.

The analysis of the resulting structure shows where the principal stresses are driven (red-blue) and the maximum and minimum material utilization on the different lattice elements, being on a visual inspection equally distributed. The diagram in Figure 3.8. is an enhanced image (50x for visualization purposes) of the actual model displacement deformation for this 3m span beam, which is 0.245cm. The total weight for the calculated model is estimated to be 29.88kg.

4. Conclusions and outlook

We have presented a design for manufacturing workflow for continuous fibre lattice additive fabrication and investigated the correlation between continuous path planning and structurally driven stress lines F.E.M. to direct model translation. The characterization of the structural load-bearing capabilities relies on the simple consideration of final structural re-analysis for its validation. Some possible directions for future works are suggested, and the possibility for further optimisation seems achievable. Reiterative stress-line formation and lattice triangulation are mainly driven at the moment by purely manufacturing constraints and the final model can be further lightened by the final output analysis and element reduction as well the possibility of further optimization is therefore inherited in the path-creating process, as the finite element matrix used for calculation occupies the whole initial design domain for the stress line finding algorithm. Reduction of the finite elements used for that process limits the total amount of stress lines created and consequently, material deposited.

Although the proposed method is in its early stages of development, the significance of this research is to confirm that lightweight additively manufactured lattices can be material and topology optimized when coupling structurally driven topology form-finding techniques enhanced with high-performance composite 3d printing techniques. By leveraging the benefits of form-found design and additive manufacturing and considering the multifunctional performance requirements of large-scale structures, this project aims to exploit new opportunities for lightweight architectural design.

Abstract:
In this research, we propose a Multi-Filament Fused Deposit Modelling (MFFMD) printer and a respective generator that can be used to produce structural parts with locally tailored functional properties. 3D-printed structural components can highly benefit from multi-material printing with tuneable functional properties. Currently, multi-material printing is mainly achieved using multiple separate nozzles, leading to discontinuous flow in switching materials. This limitation results in material interface delamination, minimal control in the continuous transition of material properties, and longer production time.To address this, we first design and build an MFFMD printer with a single customized nozzle allowing seamless switching between multiple filaments. We then develop a method that generates a continuous toolpath of a given geometry and differentiates materials based on various stress conditions at particular regions. To illustrate, we fabricate a Pratt truss as an example of a tension-compression structure as a case study. In one go, the MFFMD printer deposits resistant filament, respectively, at tension- or compression-concentrated regions based on local stress conditions. Comparative load tests are conducted to validate the performance enhancement of multi-filament prints against single-filament prints. Our proposed method is a prototypical study conducted at a small scale. While it mainly uses thermal plastic filaments, it can be expanded to other construction materials and scales in the future. The contribution of this paper is multiple. In addition to the prints' structural performance enhancement through the development of the MFFMD printer and slicing tool, the results also provide a tangible visualization of the mechanical and geometrical properties of printed components, facilitating design communications across disciplines.

Keywords: additive manufacturing, multi-material printing, functionally graded material, structural performance, mechanics visualization

1. Introduction

This paper describes a novel method that uses cutting-edge multi-material additive manufacturing technology to continuously print tension-compression structures. The method allows the structure's material properties can be tailored locally based on its' stress patterns through numerical control of material deposition and composition regulation. The method results in the structure's mechanical performance enhancement.

3D printing offers considerable advantages in the design and fabrication of tension-compression structures, enabling greater design freedom, rapid prototyping, material and cost efficiency, and on-demand manufacturing. This technology facilitates the creation of complex geometries, custom components, and the integration of multiple functions while promoting sustainability through reduced material waste and optimized designs. Despite its benefits, when using 3D printing technology to produce structural components for construction purposes, limitations are explicit concerning material properties, printing resolution, and scalability must be considered to ensure its suitability for specific projects.

In the construction of tension-compression structures, taking truss as an example, the utilization of single and homogeneous materials presents numerous challenges, often resulting in suboptimal performance and structural inefficiencies. One such challenge arises from the limited material properties inherent in a single homogeneous material, which may lack the necessary combination of strength, stiffness, ductility, and fatigue resistance required for both tension and compression members [1]. This can lead to inefficient use of the material and compromise the overall structural integrity. Moreover, structures made from a single material are more susceptible to common modes of failure, such as corrosion or fatigue [2]. As a consequence, the entire structure is at an increased risk of degradation, whereas a combination of materials could help diversify the failure modes and enhance the structure's resilience. Additionally, using a single material may result in a heavier structure than necessary, impeding its efficiency and practicality. For example, a truss structure composed entirely of steel could be excessively heavy, whereas a combination of steel and aluminum could provide an optimal balance of strength and weight [3]. Therefore, employing a combination of materials can mitigate these challenges and lead to more effective tension-compression truss structures.

In recent years, various innovative methods have been developed to improve the fabrication and assembly of truss structures. Liu et al. (2018) [4] proposed a continuous carbon fiber reinforced thermoplastic lattice truss, which offers enhanced mechanical properties and manufacturing flexibility. This approach leverages the benefits of carbon fiber reinforcement to create lightweight and high-performance trusses. Another significant development in the field is the large-scale 3D printing of metal structure components, as demonstrated by Assunção et al. (2018) [5]. This technique enables the fabrication of complex geometries and rapid production, making it a promising solution for the construction of truss structures. Furthermore, Foster+Partners [6] explored the potential of 3D printing steel trusses, showing the feasibility of employing advanced manufacturing methods to create robust structural elements. Lastly, Kovacs et al. (2017) [7] introduced a method for 3D printing truss joints, facilitating rapid truss assembly and reducing the overall construction time. These advancements collectively showcase the potential of modern fabrication techniques in revolutionizing the design and manufacturing of truss structures.

Current research on 3D-printed truss structures primarily focuses on utilizing a single homogeneous material for the fabrication of components, neglecting the impact of local load conditions and material properties on overall structural performance. Although some studies [8] have considered local stress lines in the design of 3D printing toolpaths, the primary material employed remains homogeneous. Single homogeneous materials are inefficient in addressing the complex internal load distribution within tension-compression truss structures, especially in slender truss members prone to buckling under compressive forces, compromising structural integrity[9]. We propose the use of multi-material 3D printing to construct truss structures with different materials tailored to specific load requirements, thereby enhancing overall performance and stability. However, current studies on the subject of multi-material additive manufacturing focus less on construction purposes [10], [11], [12].

To tackle the aforementioned challenges, a viable methodology must be developed, enabling the additive manufacturing of tension-compression structures in an integrated manner. This strategy should involve the application of locally tailored material properties, contingent upon the stress distribution and loading conditions of the designed structure.

As a pilot study, this paper is situated from the fabrication perspective and discusses the multi-material printing technique and methodology. We select classic 2d truss structures as a trial to validate the performance enhancement through the proposed method.

In this paper, our primary objectives are twofold: First, we aim to integrate the design-make process of multi-material 3D printed tension-compression structures, leveraging the advantages of additive manufacturing technology to create a seamless workflow from design to fabrication. Second, we strive to enhance the mechanical properties of the resulting structures, enabling more robust and efficient performance compared to traditional single-material approaches. By achieving these objectives, we hope to demonstrate the potential of multi-material 3D printing in revolutionizing the construction of tension-compression structures and addressing the limitations of existing methodologies.

2. Methodology

In truss structures, members predominantly experience axial loads, manifesting as either tensile or compressive forces acting along their longitudinal axes. To ensure stability and load-bearing capacity, the materials employed in these members must exhibit adequate resistance to deformation, specifically elongation or shortening, under the influence of the applied forces. Utilizing fiber-reinforced materials with fibers aligned in the longitudinal direction can enhance the tensile strength and stiffness of the members, making them well-suited for withstanding tensile loads. Conversely, non-fiber-reinforced materials demonstrate fine compressive strength when oriented along their short axial direction, rendering them more appropriate for resisting compressive forces in truss members.

The fabrication of a truss structure as holistic through multi-material additive manufacturing necessitates several critical steps. Firstly, tensile and compressive members within the structure must be identified. Subsequently, the local segment orientation is determined based on the stress distribution. Utilizing the stress condition, a toolpath is designed, and appropriate materials are assigned for each member. The material data is then integrated into the toolpath and converted into G-code, which guides the 3D printer during the manufacturing process. The 3D printer employed, whether a commercial or customized system, must possess the capability to process and deposit multiple materials simultaneously, ensuring accurate and efficient fabrication of the truss structure.

We here use the classic Pratt truss as a case study to demonstrate our approach.

2.1. Identify stress situation for truss member

The Pratt truss is situated in a three-point bending scenario (Figure 1a). The load condition primarily involves vertical loads distributed across the structure through tension in diagonal members, compression in vertical members, and in addition, compression and tension, respectively, in the top and bottom chords. While the two outermost vertical members do not receive force in the three-point bending load case, they are treated as tension members in a typical Pratt truss setup where the bottom points receive a live load. Figure 1b shows a simulation run by Karamba3D.

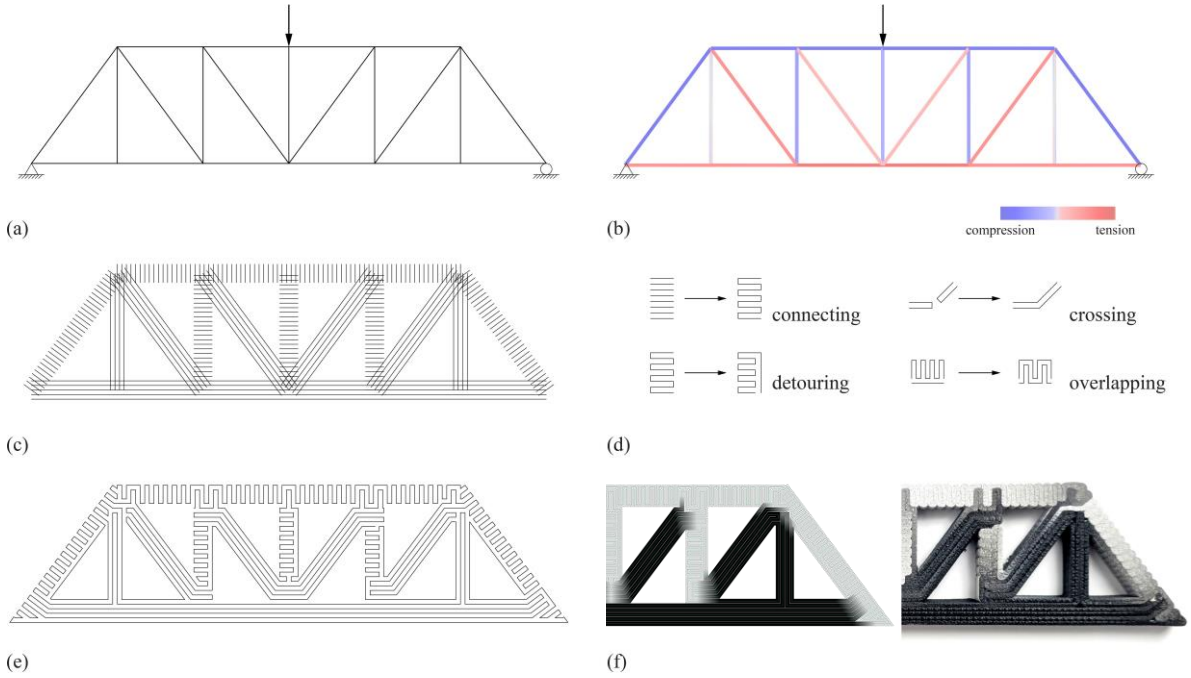

Figure 1. Multi-material printed truss toolpath generation process: (a) Input curves; (b) axial force conditions solved by Karamba3D; (c) raw curves according to the axial forces; (d) post-processing methods to form a continuous toolpath; (e) the final toolpath; (f) left: multi-material visualization of the print, right: multi-material printing

2.2. Translating stress pattern into continuous toolpath design

The mechanical property of a parallel print is similar to that of wood lumbers: the longitudinal direction takes more tensile forces while the tangential direction takes more compression. To utilize such knowledge, the local orientation of the toolpaths is determined by the stress situation (tension or compression). When the rod takes tensile forces its toolpaths are parallel to the rod direction; when it takes compressive forces its toolpaths are vertical. Figure 1c shows this step of generating raw toolpaths as discontinuous lines.

A continuous toolpath for 3D printing significantly saves production time and avoids underfilling and overfilling to enhance the bound [13]. In our case, post-processing (Figure 1d) is introduced to make the toolpath continuous. The curves are connected, primarily in a zig-zag fashion to form several loops. The loops are then merged by crossing and detouring. Finally, at the joints, we modify the toolpaths to create overlapping for better bounding.

The continuous planar toolpath is shown in Figure 1e. Multi-material information is then embedded to print the tensile part using carbon fiber filament and the compressive part using regular PLA filament. Figure 1f shows the visualization of the material-coded toolpath with the printed object.

2.3. Hardware modification

Improving the mechanical performance of structural components through multi-material additive manufacturing involves not only designing toolpaths based on local stress conditions but also utilizing special-

ized equipment for multi-material printing. In this regard, we made minor modifications to a conventional Fused Deposition Modeling (FDM) 3D printer to meet our demands.

Firstly, in terms of hardware, considering the challenges associated with material transition and bonding, we abandoned the use of a multi-nozzle, multi-filament mechanical system for multi-material printing. Although multi-nozzle systems are the most common approach for multi-material 3D printing and can fully facilitate multi-material printing, material transitions mainly rely on nozzle switching. This results in explicit interfaces between materials, which under load conditions, especially tensile forces, can lead to relatively weak bonding adhesion between materials and potentially compromise the overall structural strength.

To address this issue, we developed a detachable single-nozzle multi-filament extruder (Figure 2) to composite the proposed Multi-Filament Fused Deposit Modelling (MFFMD) printer. This extruder comprises a brass 3-in-1-out nozzle connected to three E3D V6 heatsink/heat throat kits. Each kit is connected to a corresponding stepper motor via an individual teflon hose. The brass nozzle is specially designed with three input chambers and one output chamber. The three input chambers merge at the nozzle's center and then connect to the output chamber. We set the output chamber's diameter at 1 millimeter, and the length at 5 millimeters, and the nozzle was fabricated using selective laser sintering. The three stepper motors are responsible for feeding the three filaments, which are then sent through the hoses into the three E3D V6 heatsink/heat throat kits for melting before being extruded through the output.

Meanwhile, the 3-in-1-out nozzle necessitates the addition of two extra stepper motors to the machine's stock configuration. Consequently, it is essential to replace the original printer motherboard, which conventionally supports only four axes (X, Y, Z, and E0). The new motherboard must support the aforementioned four axis as well as two additional feeding stepper motors (E1 and E2). In this study, we employed the BTT Octopus series multi-axis motherboard. This motherboard not only accommodates the standard three linear axes but also provides support for an additional five axes on the extruder, with the potential to integrate three more axes in future developments. At the firmware level, we adopted Marlin 2.1.2 and overwrote certain contents to enable the mixing extruder functionality. This allows for simultaneous adjustments of multiple feeding motor rotational speeds during the printing process.

2.4. Multi-material deposition

The firmware modification facilitates multi-material deposition using a single-nozzle, multi-filament configuration. However, conventional slicing software lacks comprehensive support for multi-material printing with this setup. To address this limitation, we developed a Rhino/Grasshopper-based G-code generator that enables users to input the designed toolpath of the target structure, along with material indications, and generate G-code compatible with the modified single-nozzle, multi-filament printer.

In general, the key steps for generating G-code for single-nozzle multi-material 3D printing involve using M163 and M164 commands to set up and store the configurations for each filament used and then printing the desired toolpaths with the corresponding filaments. Initially, each filament is activated for extrusion, while the others are deactivated, and the setup is stored. This process is repeated for all filaments involved in the printing process. Next, the pre-defined filament setups are called up using the T command sequentially. The corresponding toolpaths are printed by moving the extruder to the specified coordinates while extruding the appropriate amount of the selected filament at a predetermined speed. These steps enable a single-nozzle 3D printer to successfully perform multi-material printing by

or similar matrices of filament, the extruded materials exhibit a highly cohesive bonding. This bonding is essential for achieving reliable, robust, multi-material 3D printing with a single nozzle system. The following pseudocode describes the composition procedure of the G-code used for single-nozzle multi-material printing.

To ensure the overall strength of the printed structural components, we opted to connect all the force-informed toolpaths into a single continuous polyline instead of multiple line segments. This approach ensures the continuity of the printer's extruder movement to result in a continuous extruded filament through a single nozzle. However, this toolpath is mathematically a curve that is composed of multiple segments sharing endpoints. Each segment is assigned a corresponding resistant filament based on the local stress conditions of the structure using the T command in G-code.

In addition, to switch between different filaments, the new material will push out residual material once the new material's corresponding stepper motor begins feeding. Hence, the advancement of material switching is necessary, meaning that the endpoint of each segment needs to move forward for a certain length on the continuous toolpath. For our setup, we use the volume of the output chamber of the nozzle to determine the advancement length.

By using the above method to generate force-informed and multi-material-embedded toolpaths, we successfully 3D printed a three-material Pratt truss (Figure 3) to demonstrate our printability, in where the color distribution is based on Finite element analysis result of a three-point bending simulation. The blue color indicates the stress-concentrated area, and the green color indicates where it withstands less stress.

3. Results

3.1. Experimental setup and testprocedure

To validate the improvement in the mechanical performance of the components fabricated using our proposed method, We prepared two truss samples (Figure 4) to conduct a three-point bending test. Each sample was printed with a layer height of 0.8 mm and an extrusion bandwidth of 2mm. The dimensions of all samples were 250mm in length, 65mm in height, and 16 mm in thickness. The printing time for each sample was approximately one hours. For the experimental specimen, we utilized HATCHBOX white PLA as the compressive material, which was deposited at the compressive members. In contrast, OVERTURE Carbon Fiber reinforced PLA filament was used as the tension-resistant material deposited at the tensile members. For the single material control group specimen, HATCHBOX white PLA was employed as the primary material. All test specimens were printed at a temperature of 200°C and a speed of 30mm/sec. Calculated from toolpath length, the multi-material experimental specimen contains 52.5% of the toolpath that withstands tensional stress while another 47.5% of the toolpath is bearing compression stress. The multi-material experimental specimen is weighted as 166g, while the single-material control group specimen is weighted as 179g.

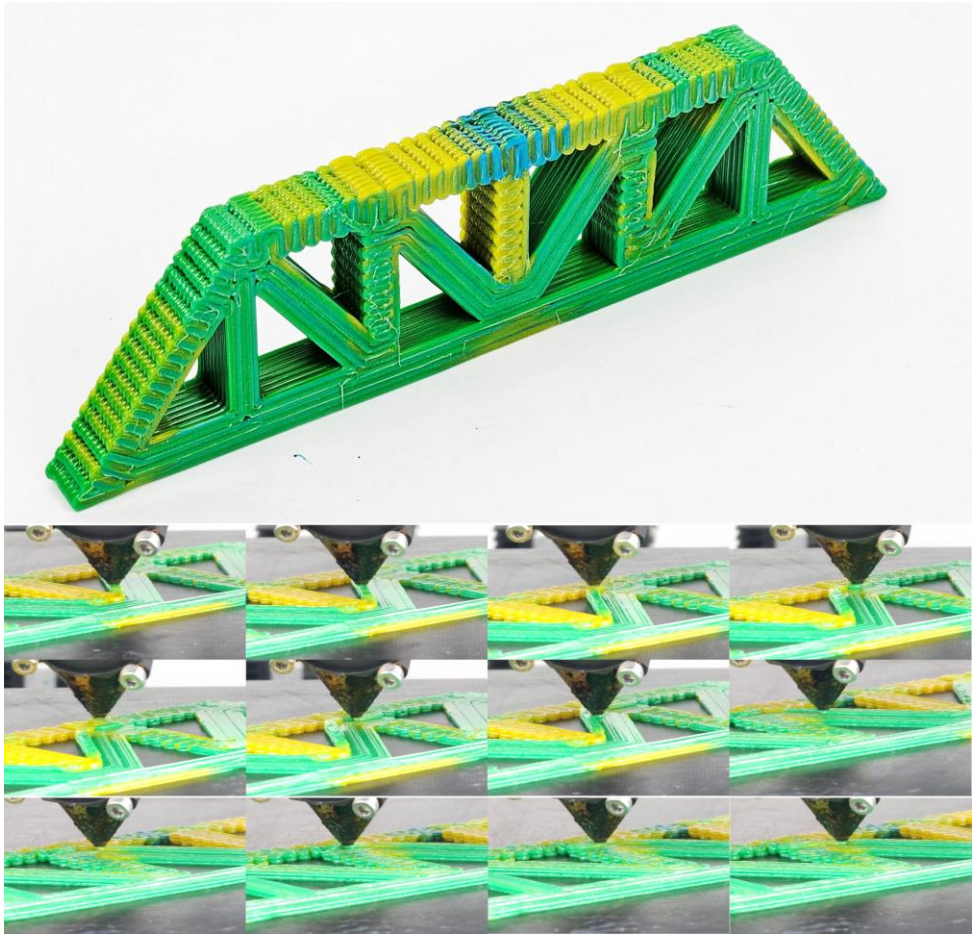

Figure 3. Upper: Printed Pratt truss with three different filaments: yellow PLA Filament, green PLA Filament and blue PLA Filament. Lower: the three-filament continuous printing process.

We utilized an Instron 4206 testing machine to perform the three-point bending tests. Each sample was positioned on the two lower supports of the fixture, and the loading nose was aligned to the center of the top chord of the truss specimen. The span length for the test was set at 220mm.

We first ensured that the loading nose was correctly aligned and centered. We then set the loading rate at 10 mm/min and initiated the test by applying force to the center of the truss using the upper loading nose. Throughout the test, the testing machine continuously recorded the applied force and the resulting displacement of the truss. We continued to apply force until the truss either fractured or yielded and repeated the test for both specimens.

3.2. Results and observations

The three-point bending test as shown in Figure 6 determines the maximum load both specimens can withstand. As shown in Figure 5, the single-material control specimen yielded under a load of 0.83 kN. In contrast, the multi-material experimental specimen reaches the yield point at 1.16 kN, and one of the compressive members begins to buckle, causing overall plastic deformation in the truss. As expected, the multi-material experimental specimen exhibits a higher stiffness than the single-material specimen.

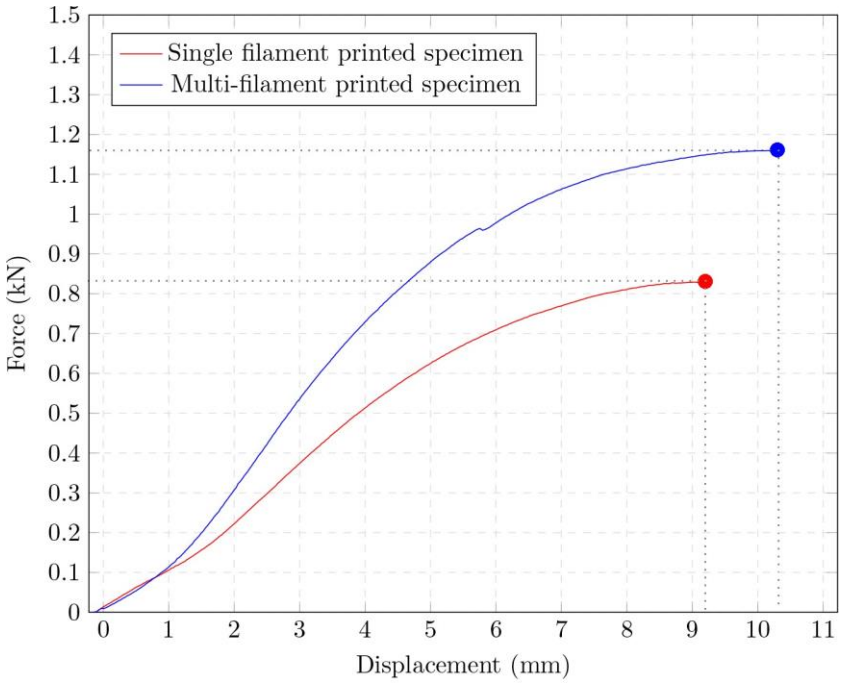

Figure 5. Result of three-point bending test

Figure 5 also presents the load-displacement curves obtained from the three-point bending tests for the different specimens. The load-displacement curves demonstrate that the multi-material specimen possesses substantially higher toughness compared to its single-material counterpart. The toughness is measured by the area under the stress-strain curve up to the fracture point. In our three-point bending test, we employ the trapezoidal rule for numerical integration to calculate this area:

$$\text{Area} \approx \frac{1}{2}\sum_{i=1}^{n-1}(\varepsilon_{i+1} - \varepsilon_i)(\sigma_{i+1} + \sigma_i) \tag{1}$$

where ε_i and σ_i represent the displacement and force values, respectively, for the i-th data point, and n is the total number of data points.

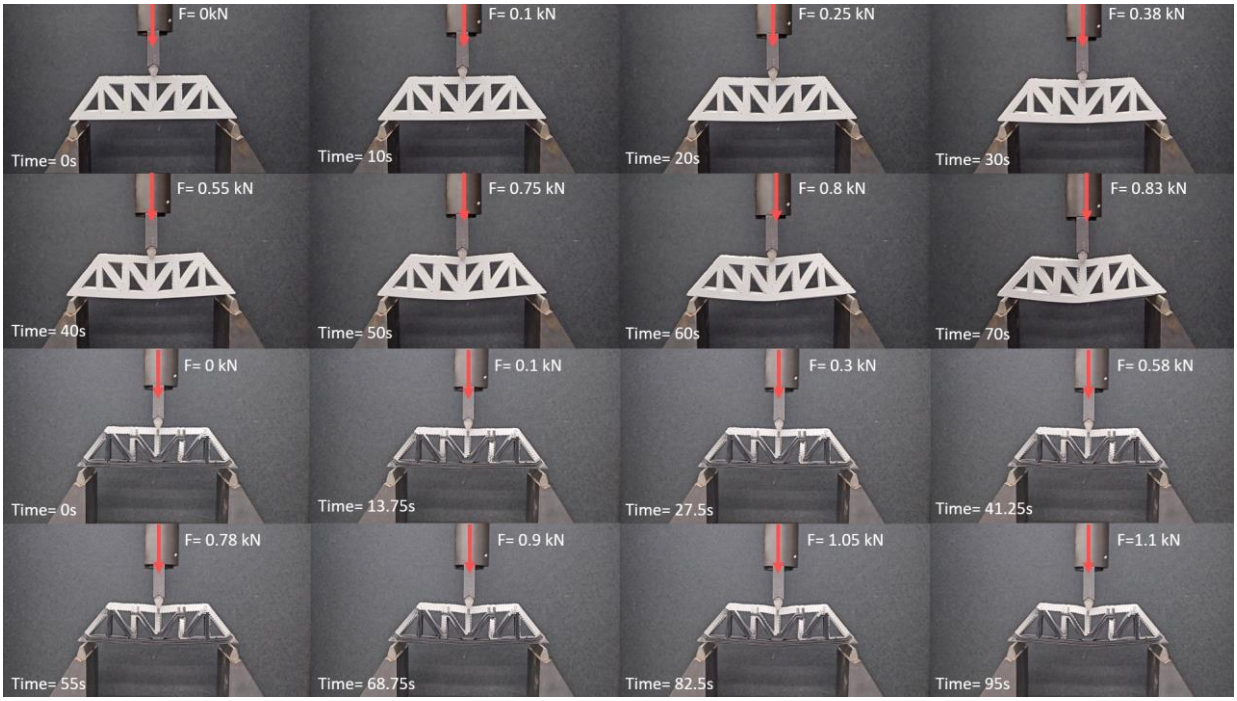

Figure 6. Three-point bending test of two PLA truss specimens. Upper two rows: single material (Regular white PLA) printed controlled sample. Lower two rows: Multi-material (Regular white PLA and carbon fiber enforced black PLA) printed experimental sample.

The numerical analysis revealed that the multi-material sample exhibits approximately 67% higher toughness compared to the single-material counterpart.

Due to the high elastic deformation capacity of PLA filament, we did not observe the behavior of two specimens under fracture conditions after the structure yielded under applied external loads. Therefore, we conducted another test using PETG to examine the fracture behavior of multi-material printed structures when the load was applied. In Figure 7, A subsequent three-point bending test was performed, applying continuous load until fracture to investigate the specimen responses beyond material yield points. The control specimen was fabricated using standard white PETG, while the experimental specimen was composed of carbon-fiber-reinforced black PETG and standard white PETG. The examination of the fractured specimens post-testing revealed no initiation of cracks at the material transition regions, suggesting that the single nozzle configuration effectively mitigates delamination under tensile loading. A comparison between the post-test multi-material and single-material samples demonstrated that one tensile member in the single-material sample experienced failure and disintegration. In contrast, the corresponding tensile element in the multi-material sample remained undamaged. The primary cause of fracture in the multi-material sample can be attributed to the buckling of the adjacent compressive members.

4. Conclusion

This paper presented a groundbreaking method that harnesses the potential of state-of-the-art multi-material additive manufacturing technology to print tension-compression structures in a continuous manner. This innovative technique paves the way for unique opportunities in the development of structures

that possess enhanced mechanical properties. The proposed method enables local customization of the structure's material properties based on stress patterns by accurately controlling material deposition and composition regulation. As a result, this approach not only improves the mechanical performance of the structure but also optimizes material usage and reduces overall material waste. Distinguished from traditional manufacturing techniques and in collaboration with stress-informed toolpath design, the proposed method capitalizes on the versatility of heterogeneous materials to fabricate high-performance tension-compression structures with unprecedented capabilities. The current methodology is constrained by the build volume of the 3D printers, limiting the dimensions of fabricable structures. Additionally, the technique presently accommodates only 2D extrusion, potentially restricting the development of intricate and complex geometries. Furthermore, the existing setup is incompatible with the utilization of construction materials, such as concrete, for additive manufacturing purposes.

Future work should focus on adapting the multi-material extruder for compatibility with robotic systems, thereby enhancing fabrication freedom and scalability. Extending the method to accommodate 3D extrusion is crucial for enabling the creation of more complex structures and designs. Moreover, exploring the integration of construction materials, such as concrete, into the printing process is essential to broaden the range of potential applications in the construction industry.

The wider implications of the proposed multi-material printing system have far-reaching effects that extend well beyond the realm of additive manufacturing. By facilitating local tailoring of components, this pioneering method enables the development of high-performance structures with potential applications in diverse industries, such as aerospace, automotive, and civil engineering.

The system allows for the fabrication of objects with multiple material properties in a singular process, streamlining production workflows, reducing the need for subsequent assembly, and considerably mitigating inefficiencies in manufacturing and construction sectors. Furthermore, the establishment of this groundbreaking technology will offer invaluable insights for researchers across diverse disciplines to construct the single-nozzle multi-cartridge (SNMC) printer for multi-material applications at varying scales.

As a result, the comprehensive ramifications of this innovative system will not only promote the progres-

sion of interdisciplinary research but also contribute to a new era of efficient, sustainable, and advanced manufacturing solutions. By embracing the possibilities offered by multi-material additive manufacturing, we move closer to a future where design and functionality are seamlessly integrated, creating structures and components that redefine our understanding of efficiency and performance.

Abstract

The process of 3D concrete printing (3DCP) and early age material behaviour introduce design constraints related to overall form and toolpath design. These requirements are particularly acute in the case of spanning structures. To avoid printing failure and identify forms that are amenable for 3D printing, a workflow is proposed to optimize forms based on buildability constraints and user preferences. The workflow encompasses four steps: generation of an initial structure based on predefined parametric models and user input, generation of an appropriate toolpath, structural simulation in early and hardened states, and structural optimization of the form and toolpath considering buildability, serviceability, and printability constraints. The workflow was validated by designing and printing a 1.2-meter tall cross-vault. The optimization process focused on studying the scale effect, by comparing how the cross-vault design changes with the area to be enclosed; fabrication process, by evaluating how different construction processes influence the design; and structural performance vs printing quality. Results indicate higher slenderness for larger scale solutions, which is explained by the increased printing time per layer and thus material strength. Additionally, optimization results indicate that increasing printing time per layer through specific fabrication strategies led to material savings up to 50%, and is key to fabricate solutions that are slender, functional, and display better printing quality.

1. Introduction

The world population has experienced exponential growth in the past 100 years because of technological developments that led to the industrial revolution, and advances in medicine and sanitation that allowed disease control. As a result, one of the greatest challenges of our time is to provide affordable housing for millions of people still living in degrading conditions. To solve the shortage of affordable housing, it is necessary to develop innovative construction techniques to overcome the current limitations of the construction industry, while decreasing its ecological footprint. Additive construction is seen as a promising solution because of fast construction rates and use of sustainable printing mixtures, as seen in home construction by Apis Cor, ICON, and Wasp, to name a few cases. Additionally, this technology promotes the use of locally available materials for the mix-design, which has also been an argument for its potential use for lunar and Martian construction. A challenge in the widespread use of additive construction is the fabrication of spanning structures, in particular roof structures. In fact, most recent industry solutions involve printing straight or curved walls and installing the roof with a different technological system, which leads to additional costs and does not exploit the full potential of the technology. Alternatives such as prefabricating discretised parts [1] or large-scale 3D printed formwork for slabs [2] allow the exploration of the architectural freedom that is possible to achieve with this technology, but they require on-site assembly and formwork. Recent work has also explored scaffold-free fabrication [3,4], but this has largely been limited to small-scale spanning structures. Thus, the fabrication of enclosures for additive construction is still an ongoing challenge.

In addition to roof fabrication, design for additive construction presents several challenges. In fact, the current methods to design structures require a multitude of software for different design stages, such as 3D modelling of the basic design, toolpath generation, structural analysis, and in case of using an industrial ABB robotic arm, Rapid code generation. This process is fragmented and time consuming and does not facilitate design optimization. Therefore, there is a need to develop a design optimization framework directed for additive construction.

To overcome the challenges mentioned above, this paper proposes a workflow to optimize printed forms based on printability, buildability, and hardened constraints. The workflow is supported by a design platform developed in Grasshopper that encompasses four main components: (1) shape generator, which generates an initial structure based on predefined parametric models and user input; (2) toolpath and filament generator, which depends on the choice of fabrication process; (3) structural performance simulator, which performs layer by layer structural analysis of the part during printing and in its hardened state; (4) performance-based constrained optimizer. The proposed design optimization workflow facilitates design for additive construction by providing a single platform combining form generation, toolpath generation, structural analysis, and optimization. This work also demonstrates that 3D printing technology is adequate to fabricate small-scale and construction scale roof structures. Additionally, this work studies the influence of scale, layer printing time, and filament design in the structural optimization of roof structures for additive construction.

2. Performance-based design and optimization for additive construction

Design for additive construction involves two inter-related concepts, namely form and toolpath. Many historic structures feature forms and processes that rely on compression as the main structural principle and are, therefore, suitable for printing in concrete without formwork. Previous work [6] identified structures consisting of load-bearing walls and shells, such as pointed vaults and domes, as examples of roof structures suitable for additive construction. The rules for designing these structures can be codified into a shape grammar that can be converted into a parametric model for ease of implementation [7]. Alternatives to parametric modelling include form finding methods such as the force density method [4] and dynamic relaxation [8], which have been adopted in the design and fabrication of funicular shells. Toolpath design follows the overall shape generation and has been a part of research projects that

incorporate shape grammar-based algorithms [7], patch grammars [3], transfinite mapping [9], and a combination of principal stress lines and parametrized control curves [4].

The extension of the overall shape and toolpath generation into a workflow is dependent on analysing early age buildability. A challenge in the study of 3D printed concrete in early age is integrating structural performance indicators into an optimization workflow, which requires simplified models that reduce processing time and are easily automated. Several methods for structural performance for additive construction include limit state equilibrium analysis, discrete element methods, and finite element analysis. Limit state equilibrium has been adopted to evaluate collapse based on the critical angle, as seen in Carneau *et al.* [5], but was limited by not considering the dynamic state of the material caused by the thixotropic behaviour over time. Discrete element modelling has been adopted in 3DCP [1], but this example involved discretised masonry structures. Limit analysis also contains assumptions such as no tensile capacity, infinite compressive strength, and infinite friction coefficient. These assumptions do not represent the early age buildability, in which the material displays a viscoelastic behaviour and a well-defined friction coefficient. Finally, finite element analysis (FEA) has been used to estimate the early-age modes of collapse [11, 12] and has found a good level of agreement between simulations and printing experiments. The work by [3] incorporated a workflow that combined a form finding algorithm with structural stability analysis using FEA, but without considering buildability constraints based on the time-depending material properties. The work by [4] incorporated a design optimization workflow for funicular vaults that optimized a compound function based on the toolpath length and the displacement field of the shell. However, the impact of buildability constraints and respective modes of collapse were not discussed. Both workflow applications described were limited to the context of small-scale shells and did not discuss implications for construction-scale fabrication.

The workflow presented in this paper extends knowledge by allowing the structural optimization of a given structure based on design constraints that depend on buildability, serviceability, and printability. Buildability constraints consider the toolpath solution obtained from a concentric-based toolpath generator, the layer-by-layer performance, variable material properties over time, and the analysis of the modes of collapse: plastic collapse, elastic buckling, and flexural collapse, which were evaluated using a structural simulator developed and validated in a previous publication [12]. Serviceability constraints provide a proxy for excessive deflection and drift for service wind loads. Printability constraints are incorporated as a proxy for printing quality in terms of expected filament geometry. This conference paper shows the application of the workflow to the case study of a cross-vault structure.

3. Methodology

The proposed design optimization workflow and the supporting platform are represented in Figure 2. The platform is comprised of five main components, each corresponding to a step in the workflow: (1) form generator, which generates a 3D model of a shell based on the geometric and printing variables defined by the user; (2) filament analyser, which considers the printing variables and outputs as a proxy for printability a set of constraints based on filament geometry and quality; (3) toolpath generator, which generates a toolpath solution based on the fabrication strategy and printing variables defined by the user; (4) structural simulator, which slices the generated shell model into layers, calculates their ages, assigns the respective material properties based on the toolpath design, and outputs a set of constraints that represent a proxy for buildability and serviceability; and (5) performance-based optimizer, which takes such constraints and the geometric and printing variables, and uses toolpath length, which is proportional to structural mass, as the objective function. The use of the workflow in the of design a cross-vault structure, followed by validation through experimental printing tests, is described below as a way of illustration.

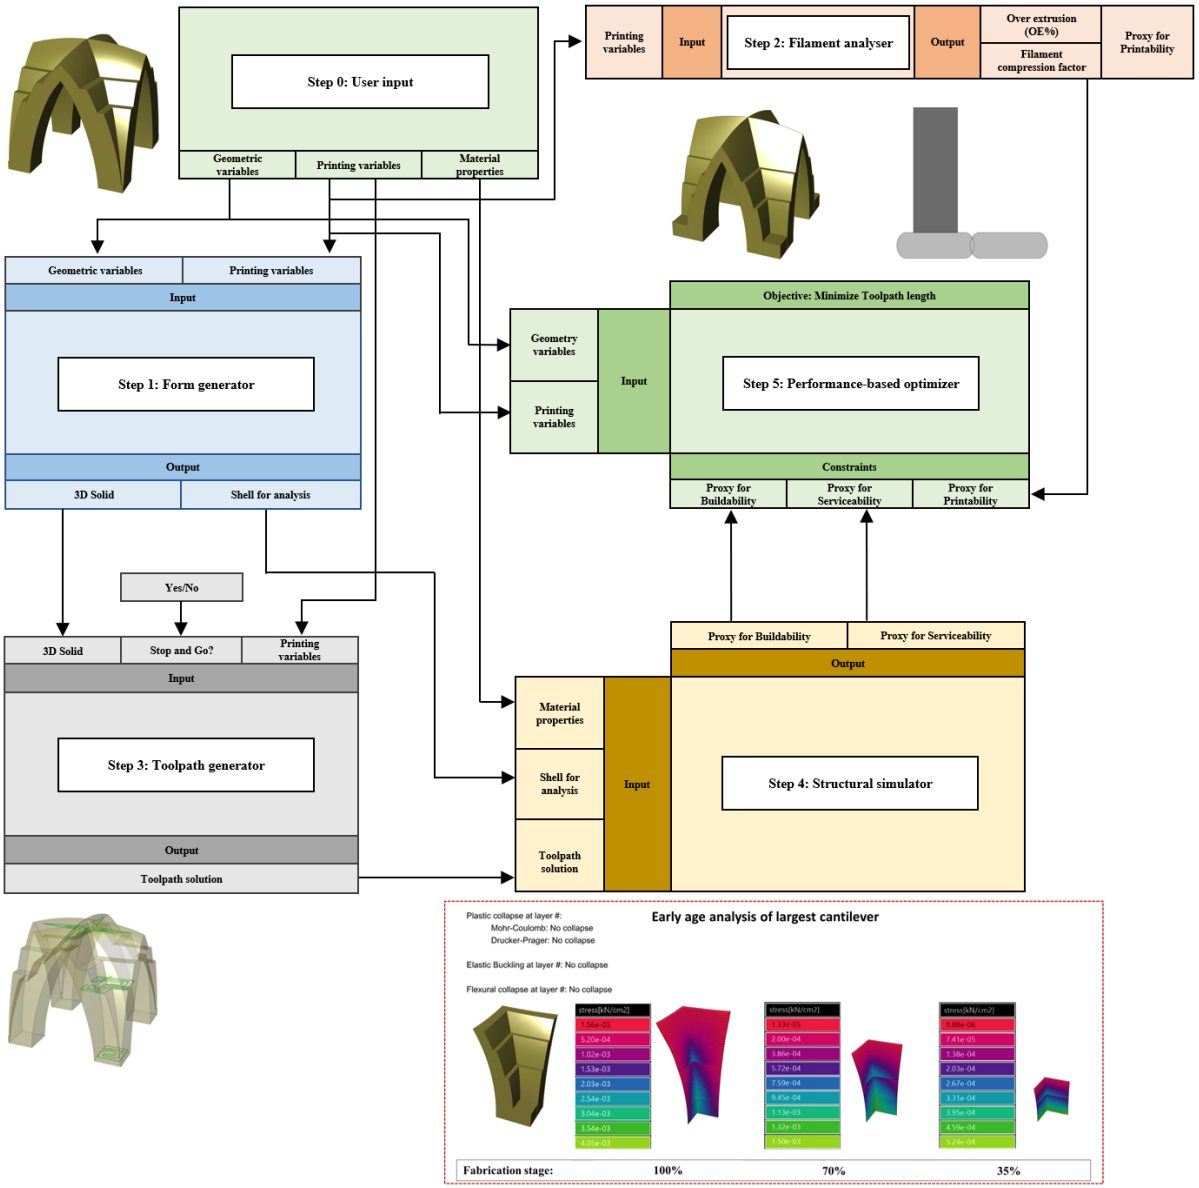

Figure 2. Proposed design optimization workflow.

3.1. Step 1: Form generator

The first step in the workflow is to use a parametric design system to generate an overall form, based on a shape grammar for roof structures. This grammar includes shape rules to generate a variety of roof structures, from vaults (cross-vault, cloister vault, barrel vault) to domes. The representation of a cross-vault solution is presented in Figure 3. The grammar was translated and encoded into a parametric design system that generates the desired 3D designs based on user input, such as the area to be enclosed and the type of vault or dome (Figure 4). The output is a 3D model of the desired structure, which will be input into the toolpath generator, and a shell representation of the same structure, which will be used for structural analysis.

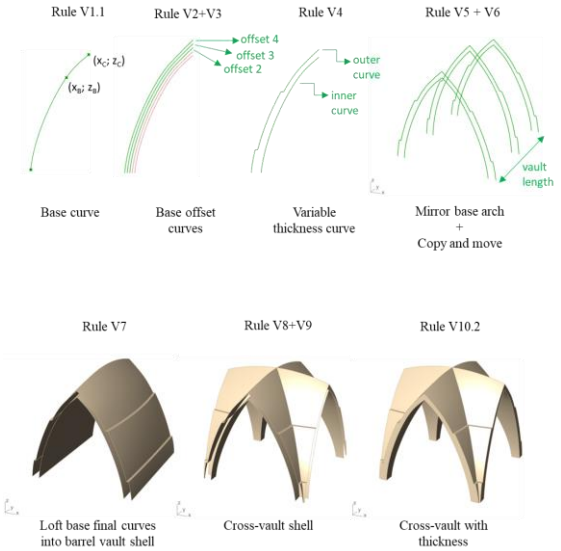

Figure 3. Shape grammar representation for a cross-vault solution.

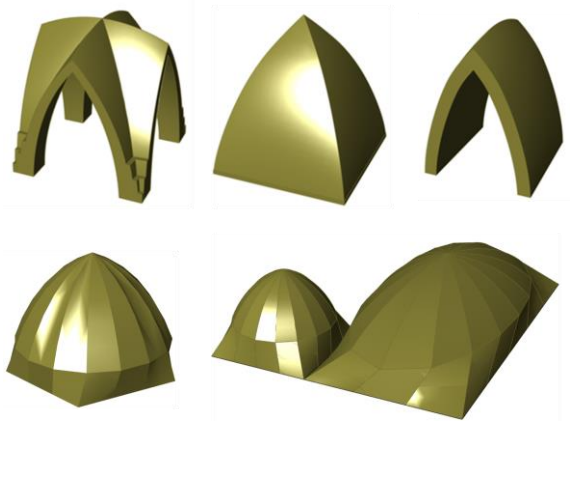

Figure 4. Design generation based on user-defined variables.

3.2. Step 2: Filament analyser

The task of toolpath design requires knowledge of the variables that affect the extruded filament which depend on the geometry of the nozzle as well as the printing settings. The following variables are considered in filament design:

- Φ – nozzle diameter (m)
- h (h_{layer} or $h_{filament}$) – filament height (m)
- Q – extrusion flow rate (m^3/s)
- v_R – robot speed (m/s)
- w – filament width (m)
- $w_{eq,nozzle}$ – filament width for a rectangular section equivalent to the nozzle cross-section (constant extrusion flow rate and robot speed);
- $w_{expected}$ – filament width assuming an equivalent rectangular section (variable extrusion rate and robot speed);
- $w_{toolpath}$ – selected filament width for toolpath design.
- a – radius of the round edge of the filament, which assumes that the edges of the filament have an ellipsoidal shape once $w_{expected}$ exceeds $w_{eq,nozzle}$.
  - If $w_{expected} = w_{eq,nozzle}$: $a = 0$
  - If $w_{expected} \neq w_{eq,nozzle}$ & $w_{expected} > w_{eq,nozzle}$: a = Eq. (4)

The variables presented above are included in mathematical expressions to design filaments for 3D concrete printing (3DCP). Filament design depends on the printing process and should be oriented towards assuring adequate structural performance and printing quality. Figure 5 shows the cross sections of the extruded filament and the nozzle. An equivalent rectangular section for the filament is obtained if the expected filament width $w_{expected}$ is equal to $w_{eq,nozzle}$, with the latter corresponding to a filament cross-section equal to the cross-section of the nozzle (Eq. 1).

$$w_{eq,nozzle} = \frac{\pi \Phi^2}{4h} \text{ (33.78 mm when } \Phi = 25.4 \text{ mm)} \quad (1)$$

Depending on both the extrusion flow and robot speed, the expected filament width $w_{expected}$, might exceed $w_{eq,nozzle}$. The value of $w_{expected}$ can be determined using Eq. 2. This value considers that the

expected cross-section of the filament is rectangular. However, the edges of the section will not be flat because of material behavior. It will be assumed that the edges of the section will be ellipsoidal. As a result, the actual cross-section is a composition of rectangular and ellipsoidal shapes (Fig. 5), where the horizontal axis *a* of the ellipse can be determined by Eq. 3.

$$w_{expected} = \frac{Q}{v_R * h} \quad (2) \qquad a = \left({}^{2 * w_{expected}}/_{\pi}\right) - \left({}^{\Phi^2}/_{2h}\right) \quad (3)$$

In the scenario of adjacent filaments, the prescribed distance between their center lines consists of the toolpath width, $w_{toolpath}$ which can be defined to ensure some overlapping and maximize printing quality. Printing quality stems from two main criteria: dimensional accuracy – the fabricated element has the same dimensions as the 3D model; and filament quality – adjacent filaments are properly bonded, there are no voids (A_{infill}), over extrusion is minimal. The latter criterion is illustrated in Fig. 6. Filament design for printing quality depends on the relation between the area with voids A_{voids}, and over lapping area A_{int}, between adjacent filaments, which will be represented by the over extrusion factor, $OE\%_f$. If *OE%* is greater than 0 there is overextrusion, if it less than 0% there is underextrusion. To optimize printing quality, OE% should be as close as possible to 0% (Eq. 4).

$$OE\%_f = \frac{OE\%_{limit}}{|OE\%|} > 1 \quad \text{Where,} \quad OE\%_{limit} = 5\% \quad (4)$$

$$OE\% = \frac{A_{int} - A_{voids}}{A_{voids}} * 100$$

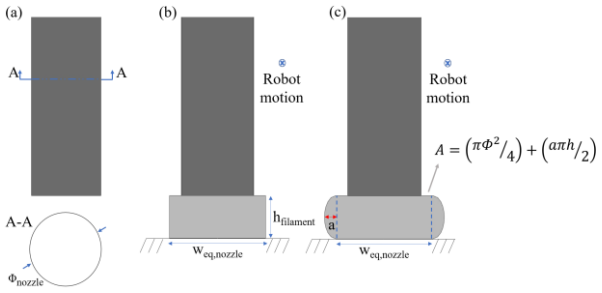

Fig. 5: (a) Nozzle and respective cross-section; (b) equivalent rectangular printed filament; expected printed filament.

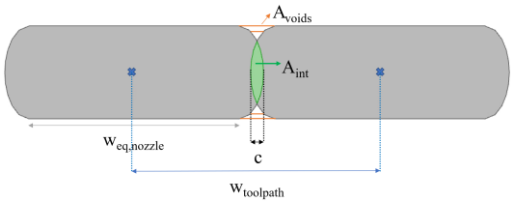

Fig. 6: (a) Overlapping between adjacent filaments spaced by the toolpath width ($w_{toolpath}$), resulting in a overlapping area (A_{int}) and an area with voids (A_{voids}), which will be partially infilled by A_{int}.

Other indicators for printing quality include the nozzle compression factor NC_f, which should be as low as possible but enough to guarantee proper bonding between successive layers (Eq. 5), and the filament yielding factor, S_f, which should be low enough to avoid filament yielding due to excessive tensile stresses generated at the end of the nozzle (Eq. 7).

$$NC_f = \frac{NC}{NC_{limit}} > 1 \quad \text{Where,} \quad NC_{limit} = 0.75 \quad NC = {}^{h_{layer}}/_{\Phi} \quad (5)$$

$$S_f = \frac{S}{S_{limit}} > 1 \quad \text{Where,} \quad S_{limit} = 1.75 \quad S = {}^{w_{expected}}/_{\Phi} \quad (6)$$

3.3. Step 3: Toolpath generator

The next step is to generate the toolpath design for the printing of the 3D roof structure generated in Step 1. The toolpath generator (Figure 7) takes the vault design as input, slices it into layers, identifies the type of surface at each layer (namely closed solid; open hollow; closed hollow; multiple sections), and generates a concentric toolpath based on the specified toolpath width and height. Another available

option concerns the fabrication process, which for layers with multiple surfaces, includes printing a full component (e.g., a complete "leg" of a cross-vault) at a time (fabrication process 1 or FP1), or printing a layer of each member in sequence, thereby introducing travel moves (fabrication process 2 or FP2). The choice of the fabrication process will have a direct impact on structural performance during printing since it impacts the printing time per layer, and therefore material properties.

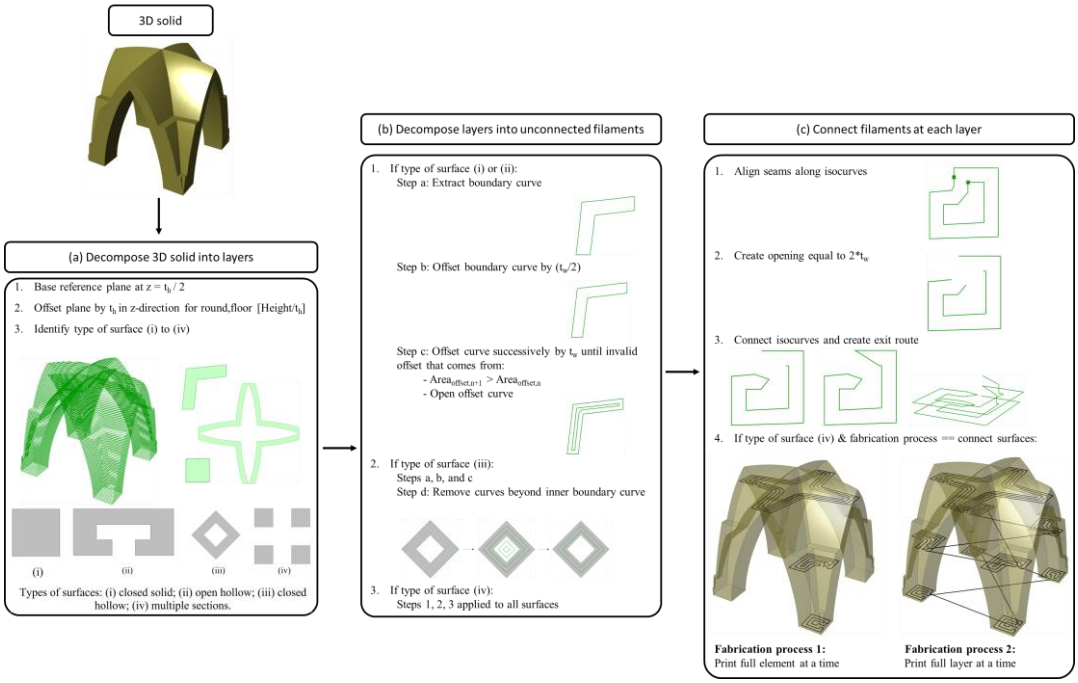

Figure 7. Toolpath generation algorithm

3.4. Step 4: Structural simulator

Step 3 is determining the structural behavior of the structure by performing a finite element analysis using *Karamba3D*, a *Grasshopper* plug-in. The simulation of structural performance includes two separate analyses (Figure 8), namely an early age buildability analysis, and a hardened state serviceability analysis. The simulator performs structural numerical modelling of candidate solutions by taking the shell model and dividing it into layers whose height is equal to the toolpath layer height. It also assigns material properties to each layer as a function of the cumulative printing time at each layer, which is directly calculated from the length of the toolpath solution generated in Step 2. A mesh is then generated for each layer using triangular shell elements.

The early age buildability analysis takes the largest cantilever and analyses the buildability of the element at three different stages, namely, when it is 35%, 70%, and 100% completed, and compares the numerical modelling results with early age criteria for plastic collapse, elastic buckling, and flexural collapse, following the procedure described in [12] with the material properties determined in [13]. Deadload was the only load considered in early age buildability analysis, which represents the weight of the printed layers. The plastic collapse criterion PC_c used is the Mohr-Coulomb criterion, which depends on cohesion C and the angle of friction φ, and compares it with the maximum principal stress at each layer σ_I (Eq. 7). The elastic buckling criterion EB_c is established based on the buckling load factor B_F, which depends on the critical stress σ_{crit}, and is calculated from a linear elastic analysis considering second order effects (Eq. 8). Finally, the flexural collapse criterion FC_c [12] considers the modulus of rupture over time and an adjustment factor α, which accounts for second order effects from layer deformation and compares it with the maximum tensile stress at the top fiber at each layer $\sigma_{t,max}$

(Eq. 9). The three-criterion described constitute a proxy for buildability. The superscript *k,n* in Equation 9 expresses the stress value at layer *k* after printing *n* layers. Therefore, $\sigma_I^{k,n}$ represents the principal stress σ_I at layer *k* after printing *n* layers.

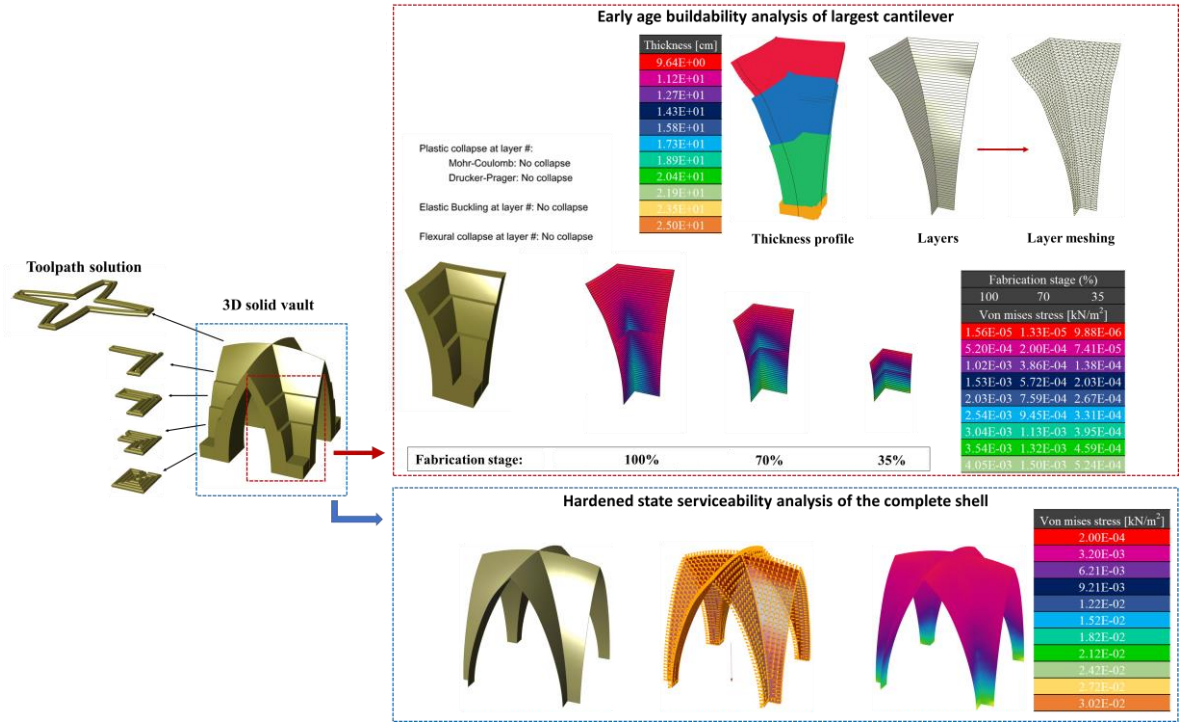

Figure 8. Early age buildability and hardened state serviceability analysis.

Plastic collapse criterion:
$$PC_c = \sigma_I^{k,n} - \left(2C(t)^{k,n} \sqrt{\frac{1+\sin\varphi}{1-\sin\varphi}} + \sigma_{III}^{k,n} \sqrt{\frac{1+\sin\varphi}{1-\sin\varphi}} \right) \leq 0 \quad (7)$$

Elastic buckling criterion:
$$EB_c = B_F = \sigma_{crit}^{n\ layers} / \sigma_{c,max}^{k,n} > 1 \quad (8)$$

Flexural collapse criterion:
$$FC_c = \sigma_{t,max}^{k,n} - \alpha \times 0.50 \times R(t)^{k,n} < 0; \quad \alpha = 0.65 \quad (9)$$

The goal of the hardened state serviceability analysis is to provide a proxy for serviceability that detects excessive displacements, such as excessive deflection δ_v, (Eq. 10) and excessive drift δ_h (Eq. 11), for a wind load scenario applied to the complete shell representation of the vault. The vault length and height are expressed by L and H, respectively.

Deflection criterion:
$$\delta_v - {}^{L}/_{240} < 0 \quad (10)$$

Drift criterion:
$$\delta_h - {}^{H}/_{500} < 0 \quad (11)$$

3.5. Step 5: Performance-based optimizer

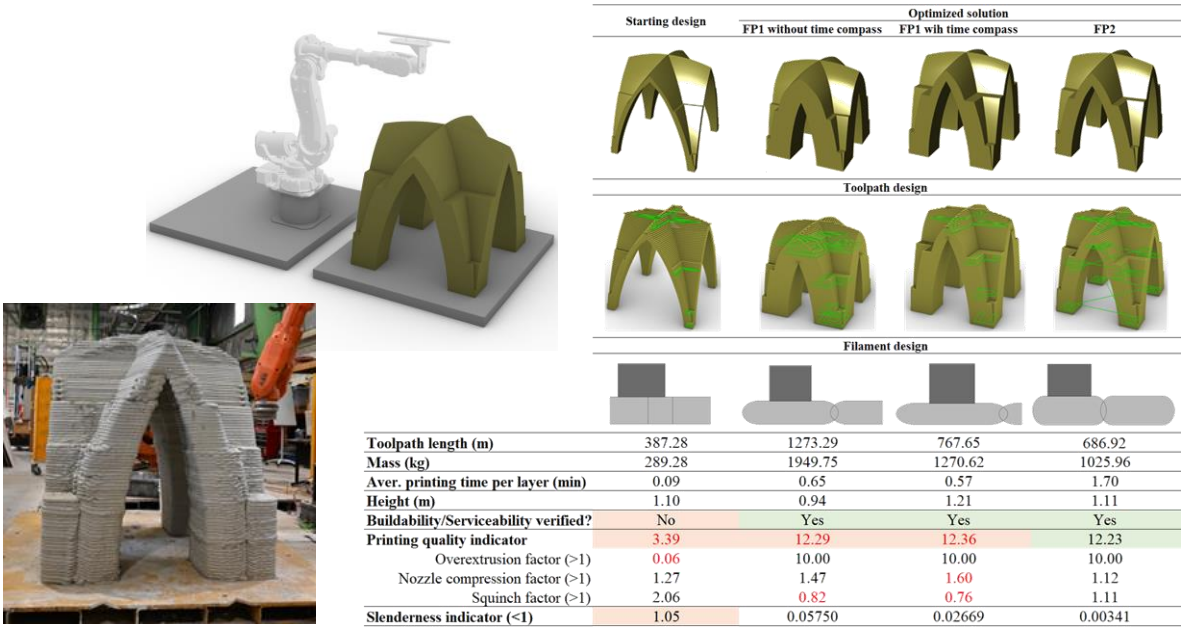
The role of the optimizer is to find the best design, which consists of the solution that minimizes the objective function and respects a set of given constraints. For this study, the objective function is the toolpath length T_L because it is directly related with both the overall printing time and structural mass,

thus being an adequate objective for structural optimization. In addition, three types of constraints were defined, namely, constraints that serve as a proxy for: (i) printability – level of over extrusion (Eq. 4), nozzle compression factor (Eq. 5), and filament yielding factor (Eq. 6); (ii) buildability – plastic collapse (Eq. 7), elastic buckling (Eq. 8), and flexural collapse (Eq. 9); and (iii) serviceability – deflection (Eq. 10) and Drift (Eq. 11). Previous optimization results have identified the need to include the influence of buildability in the objective function due to its large influence on the overall solution. Therefore, the plastic collapse indicator (Eq. 8) was added under a penalty term p into the objective function (Eq. 12). This study proposes penalty-based, constrained gradient-free optimization as a valid method to optimize structures for 3D concrete printing. The proposed optimization strategy employs the gradient free algorithm Linear Cobyla and uses the component Radical from the plugin DSE for Grasshopper.

Objective function:		$T_L + p * PC_c$	(12)
Subjected to constraints:	Printability	Eq (4); Eq (5); Eq (6)	
	Buildability	Eq (7); Eq (8); Eq (9)	
	Serviceability	Eq (10); Eq (11)	

3.5.1. Cross-vault optimization

The case study used to illustrate the use of the proposed framework consists in designing a cross-vault structure to enclose two different areas with a cross-vault, namely a 4 ft x 4 ft (small scale) and a 10 ft x 10 ft (full scale). The optimization process focuses on studying three main aspects: (i) scale effect, by comparing how the cross-vault design changes with the area to be enclosed; (ii) fabrication process, by determining how different construction processes (see Section 3.3) influence the design; and (iii) influence of the boundary conditions. The goals of the small-scale optimization are to study the influence of increasing the printing time of each layer by changing the fabrication process and introducing a waiting time between successive layers. The large-scale optimization focuses on comparing how the fabrication process and boundary conditions impact design solutions.



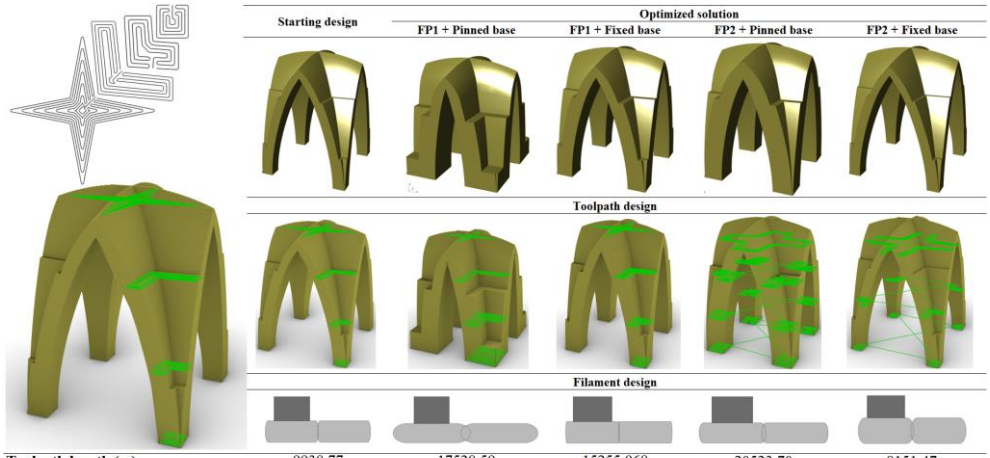
4. Preliminary results and discussion

Preliminary results for both the small-scale and large-scale cross-vault optimization are described below, followed by a discussion of the relevance of optimization in the context of 3DCP. For the optimization, the initial designs were chosen as slender vaults that did not verify the design constraints.

4.1. Small-scale cross-vault optimization

The results of the small-scale cross-vault optimization are depicted in Figure 9, where the optimized solutions verify both buildability and serviceability constraints. However, some of the printability constraints were not met under fabrication process 1 (FP1). Results also illustrate a clear relation between the printing time per layer and toolpath length. The optimization results with FP1 without a waiting time presented the largest mass and toolpath length, which is explained by the need for a larger cross-section to increase the printing time and, therefore, strength to accommodate stresses from deadload and guarantee buildability. In addition, the relevance of printing time in early age buildability was shown by a decrease in toolpath length of 34.83% when incorporating a waiting time Δt that guarantees a printing time per layer of 34 seconds, which has been shown to be de time required for a layer to stop deforming under the weight of subsequent layers for the material used in this study [7]. Finally, when optimizing the cross-vault considering fabrication process 2 (FP2), the average printing time per layer increased from 0.57 min to 1.70 min, which resulted in a solution with a toolpath length 10.5% shorter and 19.26% less material. Therefore, small-scale optimization results indicate how early age buildability depends on the printing time per layer, which is largely influenced by the printing strategy. A small-scale cross-vault was successfully printed using FP1 (Figure 9), which shows that

buildability was respected. However, it did not display high printing quality, which confirms the printability constraints not met when using FP1.



Toolpath length (m)	387.28	1273.29	767.65	686.92
Mass (kg)	289.28	1949.75	1270.62	1025.96
Aver. printing time per layer (min)	0.09	0.65	0.57	1.70

Slenderness indicator (<1)	1.05	0.05750	0.02669	0.00341

Figure 9. Small-scale optimization results and printing validation.

4.2. Large-scale cross-vault optimization

Large scale cross-vault optimization results are presented in Figure 10 and show that to respect design constraints, solutions using a pinned base required double the mass when compared with the initial design, while fixed base solutions show an increment in mass of 42.27% with FP1, and a decrease of 6.09% with FP2. These results are explained by the fact that a fixed base generates lower stresses and in FP2 the same layer of all the legs of the structure is printed before moving on to the next layer, which increases the printing time per layer and, therefore, the layer strength. A similar trend was observed in the toolpath length, where slender solutions resulted in shorter toolpath length. Buildability explains the impact of both boundary conditions and fabrication process on these results. Boundary conditions affect the stresses on the structure, while fabrication process directly influences the cumulative printing time and, therefore, the age of the printed layers (Figure 11) and, therefore, their strength. The impact of the fabrication process is not limited to buildability. In fact, solutions with FP2 present additional benefits: (i) improved printing quality, due to higher average printing time per layer, which increases the strength of the filaments, causing them to deform less under the weight of subsequent layers and therefore have a cross-sectional area smaller, thus displaying better printing quality; (ii) higher slenderness, since solutions are less robust and therefore present a smaller elastic buckling factor because the critical stress is smaller. The slenderness indicator stems as the inverse of the elastic buckling factor; (iii) increased functionality, as the usable area is larger than in solutions with FP1 for same boundary conditions. The described results indicate that increasing printing time per layer either through specific fabrication strategies or by manipulating printing setting such as the robot speed is key to fabricate solutions that are slender, functional, and display better quality. However, it should be noted that excessive time between layers can lead to worsened bonding between layers, which impacts structural performance.

Toolpath length (m)	9938.77	17528.59	15255.968	20523.70	8151.47

5. Conclusions

This paper proposes a design optimization workflow for spanning structures for 3DCP. It is demonstrated by optimizing a cross-vault structure under several conditions and validated by printing of a small-scale cross vault (Figure 9). The optimization considered two alternative fabrication strategies and boundary conditions to determine their impact on the optimized design. The level of fixation to the base was found to influence early age buildability as much as the fabrication strategy, since the former affects the stresses, while the latter directly impacts material strength by changing the printing time per layer and thus the layer age. Differences of minutes in the age of printed layers were shown to largely influence the early age buildability of 3DCP structures at small- and large-scales. Similarly, optimization results indicate a relation between printing quality and printing time per layer. This work proposes a design optimization workflow that enhances design for additive construction by providing a platform that includes shape generation, toolpath generation, structural analysis, and optimization. It adopts

constrained optimization to design both small-scale and construction scale roof structures for 3DCP. Future work will demonstrate the workflow on forms beyond the initial cross-vault example.

Abstract

We present a robotic clay printing technique that uses non-quick-setting paste-based materials and a six-axis robotic arm to quickly fabricate and manufacture complex-shaped surfaces with high hyperbolicity. To analyze the effect of the construction methods on double curvature, the surface prototype is obtained from rotating the cosine-type curve as the generatrix around the y-axis by one turn. This study analyzes the shaping principles and limitations of the primary Contour Craft (CC) and then investigates the complex hyperbolic fabrication technique via multiple sets of improved toolpath planning schemes and associated technological parameters, using paste-based clay as raw material. Employing a customized pneumatic tool to extrude clay, the superior schemes were discovered and extracted over the course of several studies. As the cases are printed and evaluated, craft characteristics parameters that meet the standards for creating high-curvature objects can be deduced, resulting in better-performing Hybrid Craft (HC). It fully preserves and replicates the excellent morphology fitting capabilities of Contour Craft (CC), matching surfaces with target features, while the toolpath arrangement, which is adapted from Lattice Craft (LC), addresses UV bi-directional structural support for hyperbolic surfaces, maintaining the design representation and resolving collision and reachability issues. We create and fabricate hyperbolic digital surfaces over a variety of digital models to illustrate our versatility.

Keywords: high hyperbolic curvature, toolpath planning, hybrid crafts, paste-based material, additive manufacturing

1. Introduction

Sustainable construction has improved using additive manufacturing of earth-based materials. However, the compression and sluggish solidification of these materials under gravity makes it difficult to make construction components of specific shapes, especially curvatures. Some designers have employed drying devices on the robot flange, safe redundant boundaries, and the optimum processing speeds to overcome material property-induced deformation. Other designers have added chemical quick-setting components to earth-based materials to solidify and strengthen quickly to reduce nonlinear depositional distortion between layers. However, these antiquated processes are expensive and hard to copy, and innovation never reaches the method level. It lacks universality for extensive promotion.

In this paper, we explore the mechanism of shaping hyperbolic surfaces of paste-based materials through toolpath planning for clay printing, and the adopted construction method was initially used to develop an early concrete contour craft [1]. It was previously impossible to physically construct complex-shaped clay components, but with the advent and development of robotics and digital fabrication, designers can now control the manufacturing parameters of the clay extrusion process.

Copyright © 2023 by Philip F. YUAN and Lei GONG. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

However, attempts to investigate the complex deformation behavior of clay during extrusion in the context of constructing large curvature components are rarely documented, current research is still restricted to planes or curved surfaces with a small range of curvature, and the goal of producing precise and highly adaptable building components remains elusive. This research, based on previous work on the geometry of the Contour Craft and Lattice Craft toolpath, proposes a Hybrid Craft approach that represents a highly challenging morphology produced in clay and thus presents an appropriate microscopic characteristic. Both the material's vertical deformation caused by gravity and the precise distribution of the UV dimension of the high-curvature surface components must be satisfied.

This work is part of the non-quick-setting material performance research that uses toolpath planning and process parameter management to improve clay 3D printing formation. Hybrid Craft, combining Contour Craft and Lattice Craft, enhances high hyperbolic component printing accuracy while lowering costs, according to the authors. This strategy can enable the use of readily available, environmentally friendly, and even living biomaterials in modern manufacturing technology to achieve more flexible design goals.

2. Related work

2.1. Clay material

Clay, which is a classic green sustainable building material, just like other natural, paste-like materials, offers a potential reduction in the embodied CO2 that the production of buildings using conventional materials emits. In addition, it also has excellent insulation and fire resistance performance. Due to its excellent material properties, clay has a long history of use. Hundreds of years ago, early humans began using the coil technology of clay to create simple vessels[2]. This ancient behavior conforms to the principles of modern extrusion 3D printing in terms of method logic. Clay materials' inability to quickly solidify and form structural strength after extrusion is the most noticeable trait during extrusion printing[3]. Thus, employing clay for printing typically leads to unanticipated results, so a robotic processing technique that matches clay's material behavior is needed. Layer-by-layer clay extrusion in material extrusion additive manufacturing leaves visible traces on 3D-printed surfaces. Clay layers created when wet can sag[4]. This microscopic deformation caused by material characteristics and gravity might abruptly explode, producing local collapse or destabilization. We address material weaknesses and maximize clay's benefits through other means.

Recent improvements in additive manufacturing of paste-based materials show promise for sustainable building construction, despite significant downsides. WASP and the IAAC use robots to extrude and deposit clay along a linear print path. The Big Delta (WASP) and Pylos (IAAC) projects show how clay may be used to build large structures rapidly and cheaply[3].

2.2. Toolpath planning

As toolpath planning plays an essential part in our work, we frame it in a more concrete context of path arrangement problems where a large body of work of high curvature surface-shaping is available in digital fabrication[5]. Contour craft (CC) is a recent layered fabrication technology that has great potential in the automated construction of whole structures, which was initially used to develop the early contour crafting methods for concrete[1]. It can produce a smooth and accurate finish on the outer and top surfaces of each layer, as well as greatly cut costs and construction times, by eliminating the need for formwork used in conventional concrete construction[6].

Lattice Craft is an extreme example of clay 3D printing that makes use of a unique technique created by Alothman[3]. The lattice geometry best exemplifies severe fabrication uncertainty because of its generally delicate form, which is vulnerable to significant deformations during printing and drying .

2.3. Curvature matters

The advent of digital fabrication has enabled the production and manufacturing of many complex customized components that were previously unimaginable. Technological advancements have not only increased productivity, but they have also brought a new paradigm revolution in aesthetics. The primary motivations for contemporary interest in form customization of architectural elements include a qualitative, design-driven desire for new forms. Additive manufacturing technology can relatively quickly produce unique components with complex geometric features, especially hyperbolic surface features, without fixed mold costs[2].

In addition to building complex curvature surfaces to meet certain form requirements, shells are also a typical efficient material structural system that generates their load-bearing capacity through curvature changes. In the past, complex surfaces were mostly made of reinforced concrete supplemented with formwork, with little research on hyperbolic elements made with non-quick-setting material additions. Simply assigning curvature features to structural surfaces does not automatically generate any structural capabilities; On the contrary, the curvature distribution of the surface needs to be carefully designed to establish sound structural principles[7]. Today, the main challenge faced by complex surfaces is, on one hand, the cost of constructing formworks, which is usually occupied by traditional labor-intensive manual masonry costs. On the other hand, its application appearance is limited to regular surface shapes. With the help of extrusion-based methods for complex hyperbolic surfaces, this study aims to solve the dilemma of formwork cost and shape limitation.

3. Method

Under the paradigm of digital manufacturing, the materialization process of high curvature complex shape models that were previously impossible has become practical and implementable. This is mainly attributed to two aspects. This is largely the result of two factors. On the one hand, researchers have modified the material properties to adapt the construction raw materials to the construction requirements of complex shapes. On the other hand, by optimizing and improving the construction process (specifically, path planning and parameter control), new process paths are being explored to investigate the application scenarios of related technologies.

This study will begin with the latter and investigate the application frontiers of non-rapid setting materials within the field of digital construction.

3.1. Curvature extraction

Curvature is a quantity that depicts the degree of curvature of a geometric body, such as how much a surface deviates from a plane or how much a curve deviates from a straight line. Prior to the introduction of digital construction technology, many studies disassembled special-shaped components into basic, developable surface components to facilitate the construction process. However, the manufacturing and processing of complex curvature components are less involved.

3.1.1. Digital prototype

In order to obtain a mathematically analyzable hyperbolic digital prototype, this experiment employs a cosine curve as a generatrix to rotate around the y-axis of the Cartesian coordinate system one cycle to obtain an infinitely extended surface. Then, as shown in Figure 1, a surface centered at the origin and defined within a period is chosen.

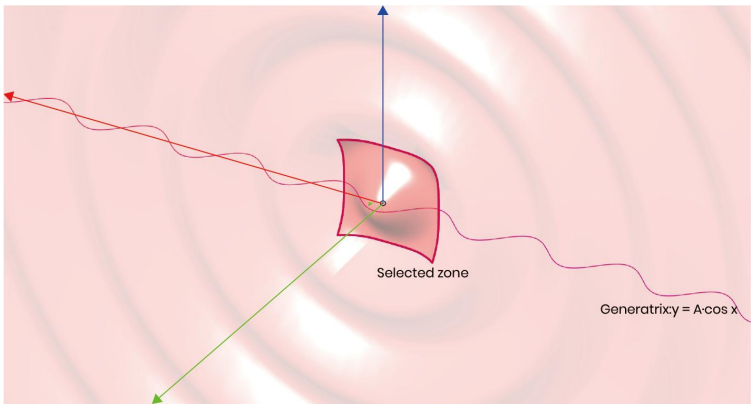

Figure 1. Selected surface and its generatrix

The cosine curve is chosen as the generatrix because, in addition to its mathematical analytical advantages, it has a high degree of operability in comparison to other curves. The curvature of the generatrix can be altered by modulating its amplitude and frequency, thereby altering the curvature distribution of the rotating surface. The following is the standard format for a cosine curve.

$$y = \mathrm{A} \cdot \cos(\omega x \pm t) \#(1)$$

This study attempts to describe as intuitively as possible the distribution of curve curvature. The initial frequency of the curve is therefore set to 1 and the initial phase to 0. The only factor that influences any shift in the curve's curvature is its amplitude. Consequently, the mathematical expression of the generatrix and its distribution of curvature is:

$$\Gamma: \begin{cases} y = \mathrm{A} \cdot \cos x \\ z = 0 \end{cases} \#(2)$$

$$\mathrm{K} = \frac{|A\ \cos x|}{\left(1 + A \sin^2 x\right)^{\frac{3}{2}}} \#(3)$$

The spatial geometric properties of the surface obtained through rotation operations are completely determined by the rotation angle of the generatrix and rotation axis, or by the consideration of control variables. All rotation axes in this study are y-axis, and the rotation angle is 360 °. The mathematical expression of the obtained rotation surface is as follows.

$$r(u, v) = (v \cos u, \cos v, v \sin u)$$

$$u, v \in (-\infty, \infty) \#(4)$$

3.1.2. Normal curvature

Compared to two-dimensional curves, a surface has countless tangents at a point, and normal curvature is the quantity used to describe and characterize the degree of curvature of a surface in a certain direction. From the definition of normal curvature in differential geometry, the ratio of the second fundamental form to the first fundamental form of a surface is a function of the point (u, v) of the surface and the tangent direction du/dv at that point, which is called the normal curvature K_n of the surface along the tangent direction du/dv at that point, namely:

$$k_n = \frac{II}{I} = \frac{L\,du^2 + 2M\,du\,dv + Ndv^2}{Edu^2 + 2F\,du\,dv + Gdv^2} \#(5)$$

where：

$$E = r_u \cdot r_u,\ F = r_u \cdot r_v,\ G = r_v \cdot r_v$$

$$L = r_{uu} \cdot n = -r_u \cdot n_u$$
$$M = r_{uv} \cdot n = -r_u \cdot n_v = -r_v \cdot n_u$$
$$N = r_{vv} \cdot n = -r_v \cdot n_u$$

K_n is only related to the tangent direction (du/ds, dv/ds) of the curve. In fact, we can consider this as a property of the surface, or more precisely, the property of the surface at a certain point and direction. Therefore, normal curvature is more like maintaining the curvature of a curve on a surface.

3.1.3. Principal curvature

In differential geometry, the two principal curvature at a given point on a surface measure how curved a surface at a given point is in different directions at that point. In a nutshell, a surface has the maximum and least normal curvature if it has normal curvature in every direction. The principal curvature is the difference between these two values, and the principal curvature direction is the direction of the tangent to the corresponding curve at this location.

At any point P on surface X, the characteristic direction {e1, e2} of Weingarten mapping becomes the main direction of the surface at point P. The normal curvature {k1, k2} of the surface along the main direction is the characteristic value of the corresponding Weingarten mapping, which is called the principal curvature of the surface at that point, namely:

$$W(dr) = \lambda\, \boldsymbol{dr}$$
$$-(n_u du + n_v dv) = \lambda(\boldsymbol{r_u du + r_v dv})$$
$$\begin{cases} -(n_u du + n_v dv) \cdot r_u = \lambda(\boldsymbol{r_u du + r_v dv}) \cdot r_u \\ -(n_u du + n_v dv) \cdot r_v = \lambda(\boldsymbol{r_u du + r_v dv}) \cdot r_v \end{cases}$$
$$\begin{vmatrix} L - \lambda E & M - \lambda F \\ M - \lambda F & N - \lambda G \end{vmatrix} = 0$$
$$k_1 k_2 = \frac{LN - M^2}{EG - F^2}$$
$$k_1 + k_2 = \frac{LG - 2MF + NE}{EG - F^2} \#(6)$$

As seen in Figure 2, the umbilical point serves as the origin of the surface that was chosen for this study. As a result, the two principal axes of curvature are equal, and any direction might be the main direction. However, this research chooses X direction and Z direction as the selected main directions since the logic of robot design is frequently three-dimensional orthogonal. The surface's major curvature in these two directions is the curvature of the curve projected on the plane spanned by the curve in the principal direction and N, respectively. The surface's normal vector at this point is N.

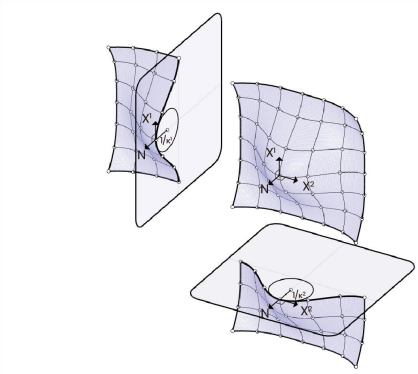

Figure 2. Principal direction and principal curvature

This experiment permits investigating the accurate depiction of the two primary curvature distributions mentioned above in various schemes, which introduces the idea of Gaussian curvature and makes it easier to investigate the impact of the construction method on the surface's curvature.

3.1.4. Principal curvature

In differential geometry, the Gaussian curvature of any point on a surface is the product of the principal curvature k_1 and k_2 of that point. It is an intrinsic measure of curvature, that is, its value only depends on how the distance on the surface is measured, not how the surface is embedded in space.

First, we can simplify the two principal curvature of the hyperboloid into developable surface in the principle direction, and start with a single surface with zero Gaussian curvature, as shown in Figure 3. These two single surfaces are similar in morphology to those obtained by extruding a generatrix along a fixed direction.

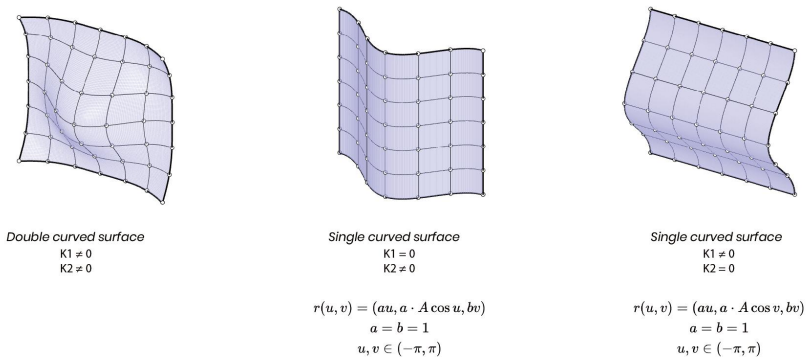

Figure 3. Selected hyperboloid and single surfaces

3.2. Toolpath generation

3.2.1. Primary Contour Craft

The primary contour craft is a method for representing a model's exterior contour that uses continuous material extrusion. This study set four different curvature classifications by varying the amplitude of the generatrix (A=1, A=0.75, A=0.5, A=0.25) in order to investigate how responsive pertinent processes are to various curvatures. Extrusion-based additive construction follows a bottom-up construction philosophy. As a result, if the component's curvature changes significantly when the Z-axis is the primary direction, there will be some overhang. The largest challenge in producing large curvature shapes with non-rapid setting materials is the inability to quickly create structural strength.

As shown in Figure 4, the initial contour process in the early hyperboloid printing experiment has a good effect on the construction of the rotating hyperboloid with A=0.25, but it has a poor effect on the construction of the rotating hyperboloid with A=1, and there is significant deformation in the middle and lower portions of the component.

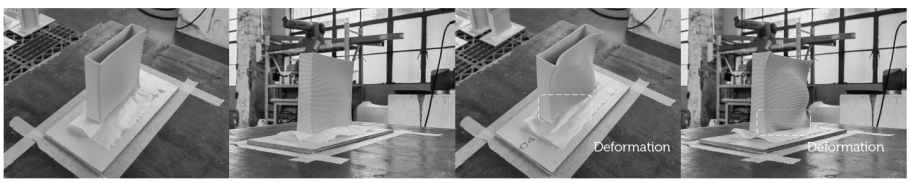

Figure 4. Hyperboloid printing experiments

In the experiment of single curved surface printing, the initial contour craft has a good effect on the construction of single curved surfaces with K_1 of 0 and K_2 of not 0. For single curved surfaces with K_1 being 0 and K_2 not being 0, small curvature surfaces with A=0.25 also exhibit local deformation and cracking, while large curvature surfaces with A=1 exhibit overall instability and the printing process cannot continue, as shown in Figure 5.

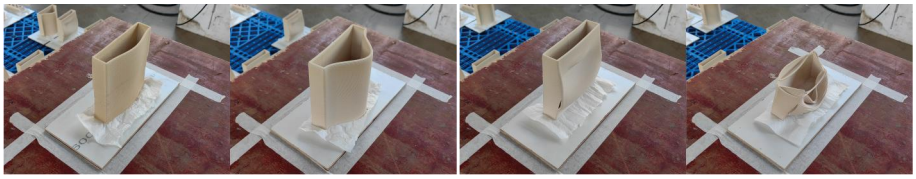

Figure 5. Single curved surface printing experiments

Due to clay's slow rate of solidification, the material's viscosity after extrusion plays a major role in preserving the component's overall stability. The material that is deposited compresses the bottom level of still-fresh clay as the number of printing layers rises. The lower component will be compressed by the rising center of gravity on the upper portion of the component, and the center of gravity will change as a result of the gradually protruding shape, leading to local deformation of the component in the absence of further support. Models with minor curvature changes in the K_1 direction are ideal for non-rapid setting material printing, which is based on the contour technology's forming theory.

3.2.2. Improved Contour Craft

Strip support. According to the two images on the left side of Figure 6, adding a strip support increases the construction stability of a single curved surface's curvature with A=0.5 in the K_1 direction. However, when working with higher curvature components, like A=0.75, strip supports continue to make the components unstable. Although strip support can expand the area of contact between the curved surface and the supporting structure and can keep the component stable by using the material's unidirectional viscosity, it has very little capacity to accommodate significant curvature.

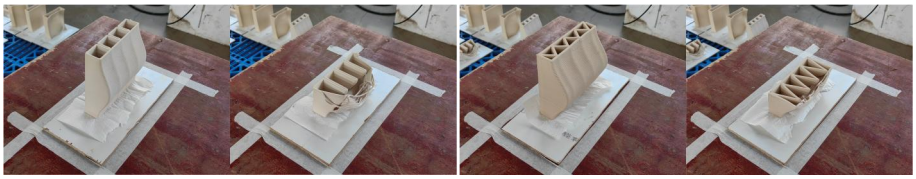

Figure 6. Left: single curved surface with strip supports; Right: single curved surface with folded supports

Folded support. The author also tried a path arrangement based on folded plate support to overcome the aforementioned problem. The folded plate support structure (Figure 7) simultaneously creates a triangular robust load-bearing structure and vertical support through the folded section. According to the printed experimental results (as shown in the right figures of Figure 6), the folded plate support was effective in constructing a single curved surface with an A value of 0.75; however, it failed to do so when the A value was 1.

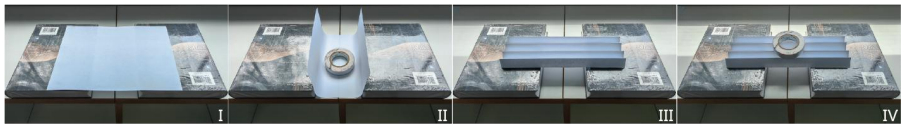

Figure 7. Paper folding plate bearing tests

This is because, regardless of the supporting structure, it can only effectively support the component's bigger overhanging portions along the longitudinal axis. The difficulty to be solved in the following

stage is how to create a support structure that is bidirectional since the two approaches discussed earlier did not create it.

Cross grid support. Due to the difficulty in achieving a strict X-direction support structure for Contour Craft, the author attempts to solve the above problem by diagonally crossing grid paths. In the XZ plane, the support structure of diagonal components can be vectorized into orthogonal supports. From the printing results of a single curved surface with A=1, it can be seen that the diagonal grid support solves the problem of component instability and deformation in the cantilever section. However, the path of this structure itself is cumbersome, resulting in an increase in the weight of the printing material. In the later stage of printing, due to a change in the center of gravity, the component capsizes towards the overhanging direction. However, in the construction experiment of hyperboloid with A=1, the shift of component gravity center was not severe, so the printing task was successfully completed (Figure 8).

Figure 8. Double curved surface with cross grid support

3.2.3. Lattice Craft

Practical engineering relies on component weight. Solving component self-weight is the next research aim to make components viable with bidirectional structural support. Contour Craft is a continuous path arrangement that accurately describes component contours and preserves digital models well. Supporting structures are needed to create a given shape, which increases component self-weight and gravity-induced local deformation and instability. We will focus on the discrete path and use other methods to alleviate the shortcomings in future study. Therefore, we will focus on a special construction method - Lattice Craft, which uses a special process called "spatial print trajectories," developed by the authors[3]. The original continuous path planning method discretized the inter layer printing unit into a certain number of lattice units. The unit path in the printing process is a single path inside the discretization lattice units, and the robot must complete the path inside one lattice unit before moving to the next printing target. Figure 9 shows Lattice Craft creating a spatial grid-like supporting structure inside the component. Compared to Contour Craft, this path planning can significantly lower structure self-weight and shape it.

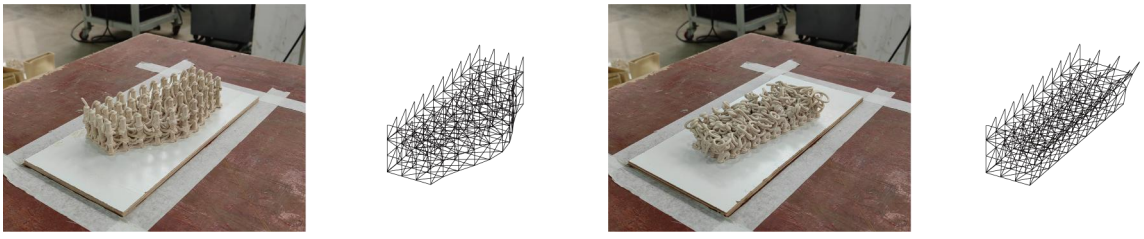

Figure 9. Lattice Craft and its path

For non-quick-setting materials, this approach has various drawbacks: 1. Vertical components in a lattice cell must be vertical to build support strength quickly (Figure 9), hence only single-curved components with K1=0 can be produced; 2. curve, and the lattice cell size cannot be too small, it is

difficult to approximate the original curve after wireless subdivision, which leads to poor surface smoothness and does not achieve high curvature construction in the strict sense (Figure 10); 3. Lattice Craft can only form a spatial structure, not a 3D spatial surface, limiting its application scenario. This method usually yields a constructive spatial structure rather than an expressive one.

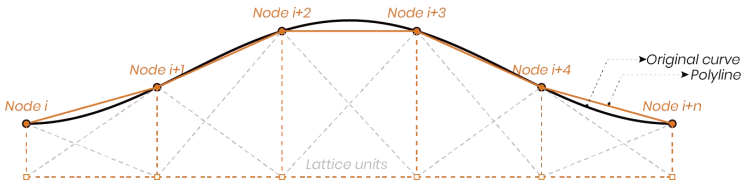

Figure 10. Fitting the original curve with polyline

3.2.4. Hybrid Craft

List all the benefits of Lattice Craft and Contour Craft in detail. The former is better at fitting surfaces, but the supporting structure can make the structure heavier overall. The latter has the advantage of being lighter overall, but is less effective at fitting surfaces. Based on this, this study suggests a Hybrid Craft with benefits that support each other. In particular, the surface of the part is printed layer by layer with Contour Craft to make a smooth surface, while the supporting part of the part is made with individual lattice units with Lattice Craft to make a strong but lightweight structure.

From the real-world printing test (Figure 11), it is clear that Hybrid Craft can make hyperboloid parts well. This method can keep the benefits of the two Crafts we've already talked about while building high hyperbolic surface components that don't distort locally.

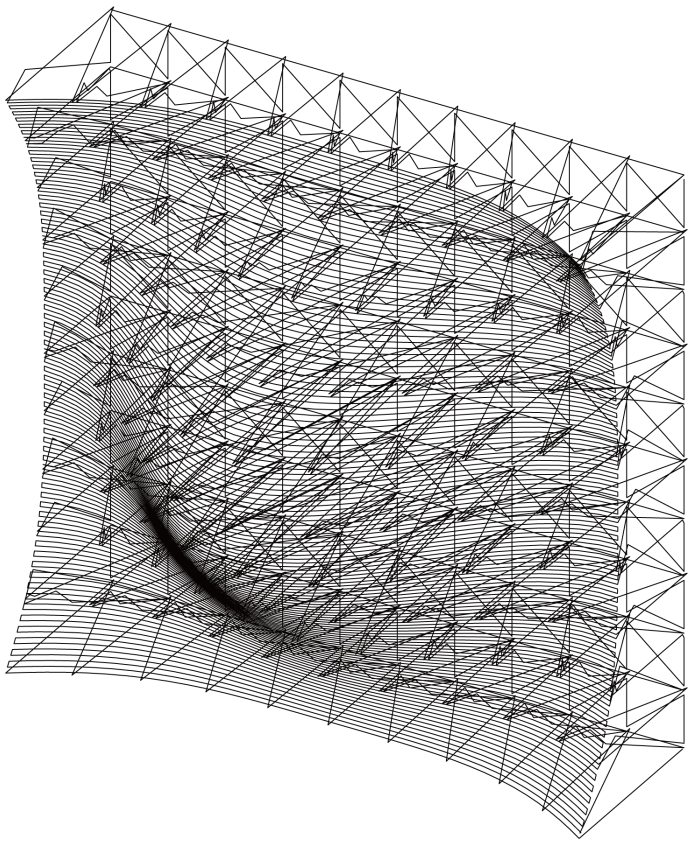

Figure 11. Toolpath for Hybrid Craft

3.3. Parameter debugging

3.3.1. Clay moisture

The amount of water in slurry materials that don't set quickly is a very important sign that has a lot to do with how thick clay materials are. On the one hand, the amount of water in slurry-based materials should stay within a certain range. On the other hand, the amount of water in slurry-based materials should be fairly consistent. Printing is interrupted when stored clay cannot be pushed out during building (Figure 12 left). The author found that unequal clay raw material mixing causes uneven humidity after repeated studies. Low-water mud is hard to extrude and forms a cavity at the pumping end of the tool head, making feeding impossible.

3.3.2. Clay compaction

Printing success depends on humidity and clay slurry compactness. Clay printing is accurate, therefore an air cavity in the slurry will generate cavitation explosion during building and destroy the printing components (Figure 12, right). Clay slurry can be compacted by stirring or vacuum degassing.

Figure 12. Left: Uneven moisture leads to extrusion interruption; Right: Air bubble explosion

3.3.3. Toolpath optimization

Non-rapid setting slurry ingredients make vertical rod printing difficult in Lattice Craft and Hybrid Craft. In order to complete the construction of vertical components, the robot's running speed must be slowed to accumulate mud, which will make the vertical components thicker. The paths of the first and last sections of the vertical components must also be adjusted. In the study (Figure 13), the author tried numerous closure routes and found Obstuse to Act, which prevents the rod from tipping due to tool head collisions and material stickiness.

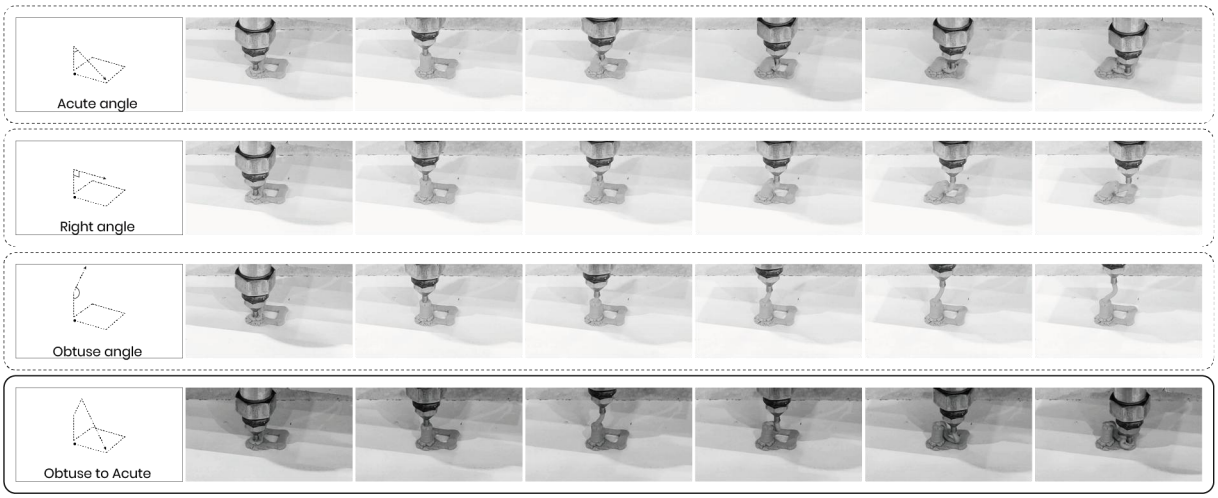

Figure 13. Path optimization

4. Results

4.1. Fabrication setup

The entire experiment was completed through a pneumatic slurry extrusion system that is mounted to an kuka kr30 industrial robot. Standard wet clay is loaded into a pressure Standard wet clay is loaded into a pressure tank attached to the extruder assembly under fixed supply of air pressure at 2.7 bar. The clay is pushed to the extruder assembly, where a motorized augur with controlled RPM regulates and sets the flow of clay. The clay body is prepared using cone 10 stoneware clay and water at 1 kg of clay to 70 g of water.4.2. Fabricated Models. The toolpath for the lattice geometry is generated by FURobot in the Grasshopper3D environment.

4.2. Demonstration

Hybrid Craft takes advantage of both processes. Contour Craft builds complicated surfaces with high precision, while Lattice Craft creates a spatial grid-like support framework for a highly versatile printing process. The challenge with path planning for this process is combining discrete and continuous methods into a single Hybrid method.Continuous path planning emphasizes contour lines between layers and uses "layers" as the unit. After each layer, the print head moves to the next layer's beginning spatial coordinate and prints in the opposite order.

The discrete path planning method is usually based on the "grid" unit, and its design goal is usually an independent path within the grid cells. After each cell path, it restarts the next cell path at its end position and repeats several times until all cell paths within the layer are completed, then moves to the next layer for printing in the opposite direction (Figure 14).

Figure 14. Hyperbolic components of hybrid craft

5. Conclusion

5.1. Forming principle discussion

Through different path planning, Contour Craft can achieve the printing of many complex surfaces. Introducing reinforcement structures such as strip ribs, folded plate ribs, and cross ribs can improve the flexibility of this process in shaping high hyperbolic surfaces.

Lattice Craft discretizes path planning. It divides the surface model into grid voxels. Printing uses a single discretization grid block preset unit path. Tool head must finish a grid block before going to the next printing target. The robot guided extrusion pumping system prints supporting components by maintaining low motion and high extrusion rates in the vertical direction, then prints connecting components by maintaining high motion and low extrusion rates in the horizontal direction. To anchor local nodes using material extrusion, the corner area is paused.

Hybrid Craft uses discrete and continuous construction. Layered technology shapes surfaces and spatial technology completes their supporting structure. The robot builds the model using complicated

speed control and pause point settings under suitable material parameters. The spatial grid-like support system reduces weight and may load forces in two orthogonal directions.

5.2. Future work

The evaluation of deformation in this experiment, which is simply a component of the robot clay technology project, now only considers the extreme deformation that can be seen with the naked eye and the collapse brought on by general instability. Future research will concentrate on 3D structured light scanning camera deformation prediction and route correction in high-precision construction.

Liquid printed reusable dredged-based material for concrete formwork

BoSheng LIU*, Tzu-Hsien LO[a], Cheng-Hsuan YEH[a]

[a,*] Feng Chia University
bsliu@fcu.edu.tw

Abstract

A dredged-based material infused in the additive manufacturing (AM) method using the Rapid Liquid Printing (RLP) technique was applied to fabricate recyclable concrete formwork. The investigation of the printed dredged-based material and AM printing technique demonstrates its potential for custom concrete formwork in mass production. Contrary to the existing concrete formwork casting method, this research RLP additive manufacturing process and its material improve the formwork's adaptability, mobility, and reusability compared to the conventional formwork method. This paper will present the critical findings of Silt Dredged Material (Silt DM) mixed with non-petroleum-based soy-based hydrogenated vegetable glycerides material, and unhydrolyzed beeswax-based esters material printed in water that can instantly harden. The silt DM based material mixture's unconfined compression value is related to RLP extrudability, and workability that coordinate with the printing process. This RLP dredged-based material and technique are predictable, repeatable, and the instant hardened characteristic, making it possible to deliver a higher degree of fabricability suitable for greater design freedom. The material properties allow for a fast-printing process that has great potential to scale up to a sizeable architectural production.

Keywords: rapid liquid printing, dredged-based material, reusable material, 3D printed formwork, reusable concrete formwork

1. Background & introduction

Reinforced concrete (RC) structures are one of the most conventional structural typologies in Taiwan and its neighbouring southeast nations. According to the Ministry of Economic Affairs of Taiwan, more than 90% of existing structures are made of RC, with the remaining percentage split between steel structures and steel-reinforced concrete (SRC) hybrid systems. The conventional RC casting method uses wooden formworks as the primary material to create the casting body for building structures. Each wooden formwork can last for 5 to 9 uses before becoming part of the landfill. Although wood panels are still one of the primary materials for RC structures, plastic and aluminium formworks are gaining popularity within the construction industry due to their longevity, which can last up to 300 uses before recycling. However, the final lifespan of the used formwork is challenging to recycle due to impurity material and other chemical components mixed with the used formwork, resulting in the material mostly ending up in a landfill.

Meanwhile, Taiwan's appetite for premixed concrete and its RC structures has only been increasing yearly, with an average increase of 5.7% from 10.17 million tonnes in 2017 to 13.65 million tonnes in 2022 [1]. This increase translates to a rise in yearly carbon emissions (CO_2) and the total volatile organic compounds (TVOCs) in material processing and construction. This issue is not unique to Taiwan but is happening globally. As a collective body increasing CO_2 and TVOC emissions, it influences the global climate and exacerbates temperature fluctuations. To prevent extreme climate changes, governing bodies have declared Net-Zero Emission by 2050, using the Sustainable Development Goals (SDGs) to

help individual nations determine national contributions (NDCs). In the context of architecture and building construction, researchers and designers have turned to additive manufacturing (AM, also known as 3D printing) as one of the potential solutions because the AM technology is cost-effective in all-scale production while offering an opportunity to use less material for the final product and could satisfy overall requirements.

In the architecture and building construction industries, AM technology is often associated with fusion deposition modelling [2] FDM, also known as layer-by-layer printing) that can extrude a wide range of materials such as metals, polymers, ceramics, composited materials (e.g., premixed concrete), and more. 3D printing concrete [3] (3DCP, i.e., printing premixed or custom-mixed concrete) is the most commonly seen application in the whole building industry, including the most eye-catching companies like ICON Build, Concrenetics, XtreeE, Peri Group, Vicat Group, and more. 3DCP uses the FDM technique, allowing the mixed concrete to pump up to the nozzle and deposit the freshly mixed concrete on top of the designated location via the digitally generated control path, allowing the freshly mixed concrete to fuse with the lower concrete. The process is completed once the concrete is cured and solidified. The 3DCP's FDM process has limitations [4]: (1) The accuracy of the outcome heavily depends on the machine holding the 3DCP extruder. (2) It is not likely to print overhangs (i.e., cantilevers) because the fusing material may not cure fast enough. (3) Adding vertical structural reinforcement is one of the significant challenges using the current 3DCP method. (4) Anisotropic characteristics in the structural performance can be found in the printed concrete structure [5]. (5) The finished printed structure's surface needs post-processing on the exterior due to the layer stacking process, resulting in uneven strands' finish. (6) Printing material performance and consistency during the action or the idol printing process. (7) The challenge of evaluating printed structures lies in the industry's agreed-upon standards.

A variation to the 3DCP method was published by Hank et al., 2020 [6] and Li et al., 2021 [7] integrated Rapid Liquid Printing (RLP) [8] [9] method to create an Injection 3D Concrete Printing (I3DCP) process. The I3DCP method involves extruding the concrete material (M1) into a chemical or natural-based rheological environment (M2, i.e., gel-like material) that supports the deposited M1 material. This I3DCP method can bypass the conventional FDM horizontal strands, providing a solution to the material's anisotropic characteristic. Additionally, the deposited material can be extruded to create overhang forms, providing previously unseen advantages. However, this method has a few drawbacks: (1) The M1 material injects into the M2 environmental volume, which increases the overall volume and subsequently pressures the already deposited material, influencing the final geometric precision. (2) There is uncertainty about the M1 material overlaying or overlapping on the already deposited M1. (3) Concrete creep and shrinkage are difficult to predict and estimate. (4) The reusability and recyclability of the M2 material require further study. (5) When the M1 material is deposited inside the M2 environment, M2 is often not fully visible from the external environment, resulting in the printed outcome having to wait until it is fully cured and solidified to evaluate whether to reprint.

This paper aims to provide an alternative perspective to 3DCP and I3DCP, not by re-engineering the construction process using novel technology but by using custom mixed dredged material (DM) with the RLP fabrication method to improve the existing concrete construction process. Based on the earlier paragraphs about concrete formwork, novel 3DCP, and I3DCP challenges, this paper proposes using dredged material mixed with non-petroleum-based material deposited inside the room temperature water using the RLP method to create customizable 100% reusable concrete formwork. One significant advantage of using dredged material is its abundance as a natural resource that often contains high amounts of clay, silt, sand, and organics. The dredging process is often considered a national interest or national security issue. In Ohio's Lake Erie alone, the US Army Corps of Engineers (USACE) must remove 1.15 million cubic meters (1.5 million cubic yards) of annual sediments from harbors and recreational ports. Some dredged materials are suitable for the built environment, as demonstrated by Liu and Coffman (2016)[10], while once the DM is processed, it can be further used in infrastructure

[11]. However, by law or code, many dredged materials are often categorized as unusable due to the dredging location or by the dredging action and its content's uncertainty (the result in this case).

Previous investigations on fresh dredged material (FDM) printing[12] [13] focused on various methods to create DM vault structures, including conventional tile vaults made from DM compressed stabilized tiles (DM-CST) and 3D printed DM vaults using different locations' dredged material (e.g., Ohio's Lake Erie harbors and one of the coastal ports in southern Louisiana). The 3D printing dredged material investigation focused on the mixture ingredients and their FDM characteristics: extrudability, buildability, workability[3], and durability [14]. While the selected works contribute to the foundation of engineered mixture with dredged material and their applications, deploying outside the research and lab environment has a severe challenge due to the laws or codes in the USA and Taiwan that prohibit DM as the structural building material. As a result, the following research proposes using DM as a substitute for concrete formwork material.

2. Dredged material

2.1. Dredged material source

A diverse landscape of mountains, rivers, and coastlines can characterize Taiwan's national geography. The island is known for its steep slopes that often descend from the mountains to the rivers and the sea. For example, Yu-Shan Mountain, which is 3,952 meters high, is less than 150 kilometres from the nearest west coastline. Taiwan's steep mountain slopes and river valleys create a unique and breathtaking landscape. However, these steep slopes can also lead to hillside erosion and the transport of suspended sediments over long distances. As a result, Taiwan's rivers, streams, and reservoirs contain significant amounts of dredged material.

In this case, the collected DM is from the Jhong-Gang River, which has a typical steep river stream geography in Taiwan (Figure 1). The river is 54 kilometres long, and its upstream is at an elevation of 2616 meters with an average flow velocity of 15 m3/s. The Jhong-Gang River has one Ta-Pu reservoir, which requires dredging to maintain its water storage volume. The dredged material is often processed via soil treatment facilities or sedimentary basins. The washed gravel and sand have significant economic value and are usually sold to concrete mixture or construction companies, while the silt and clay become by-products of the process.

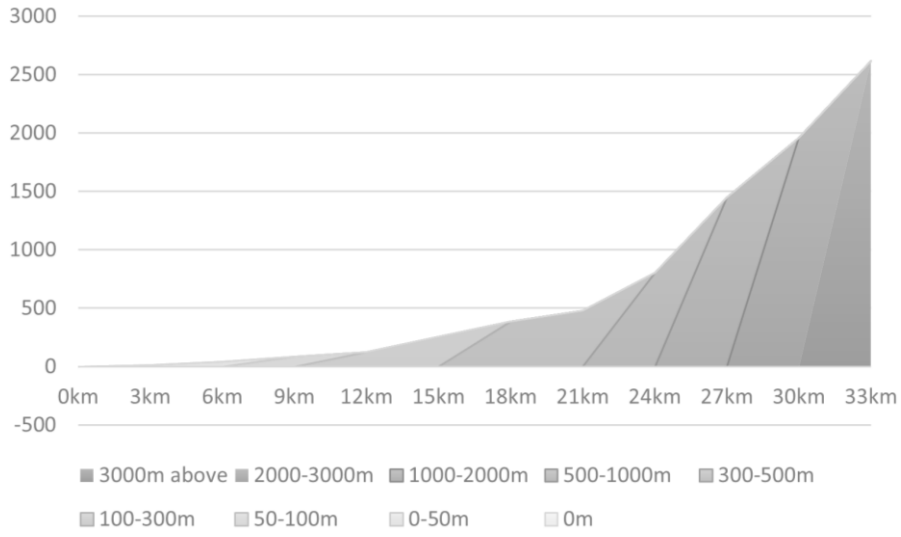

Figure 1. Jhong-Gang River's Elevation Changes from the upstream to the river mouth. The elevation date is pair with the aerial view. Information sourced from Jhong-Gang River ecosystem report and planning [15].

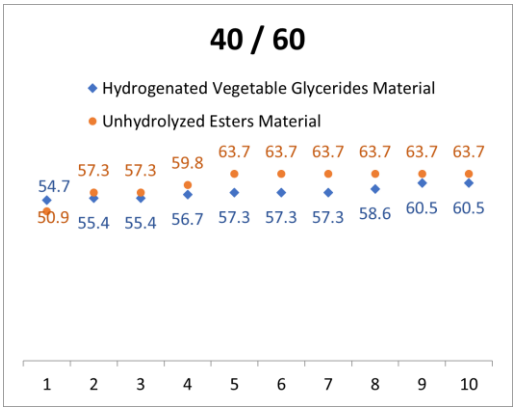
The collected downstream Ta-Pu reservoir's DM has been treated through sedimentary basins (Figure 2), a common practice in Taiwan. The sedimentary basins allow the dredged sediments to be naturally washed down and deposited in various basins. Each basin contains different particle classifications like gravel, sand, silt, and clay. This research first sieves unwanted dredged material through No. 100 mesh to remove unwanted elements and other organic matter. The DM sample selection process follows the ASTM D2487-17 collection process and uses the wet sieve analysis method to wash through No. 400 mesh. The sample resulted in fine silt particles smaller than 0.037 mm. The fine silt sample was later tested via hydrometer, resulting in a consistency of 4% clay and 96% silt, which is classified as silt textural soil classification.

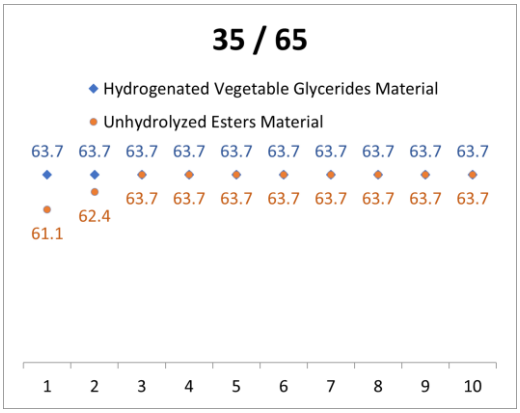
Figure 2. Sedimentary basins next to Jhong-Gang River and the facility is specifically to treat dredged material from the Ta-Pu reservoir.

2.2. DM workability and compression test



Building on the prior DM research [12] [13] [14], the freshly mixed DM material behaves differently in different soil classifications. For example, clayey DM has a more glutinous behaviour than silt-based DM. Additionally, silt-based DM has minimal sticky characteristics, which makes it suitable as the main ingredient for AM extruding processes. Instead of using water as a binding agent or a catalyst to activate the binding agent, the research investigates various non-petroleum-based materials as the binding agent with the silt DM (M1). These materials are injected into room temperature water (M2) to 3D print (RLP) concrete formwork techniques. The two critical binding agents are soy-based hydrogenated vegetable glycerides material and unhydrolyzed beeswax-based esters material. These materials are chosen because they can instantly change from liquid to solid when they come into contact with room temperature water. They are reusable and can be naturally digested and broken down by aerobic bacteria once their lifespan is completed.

An initial material compression test was carried out to investigate the mixture percentage among the binding agent, silt DM, and its mixture solid phase strength. The material workability investigation studied two binding agents: soy-based hydrogenated vegetable glycerides material and unhydrolyzed beeswax-based esters material. The hydrogenated vegetable glycerides material was heat-controlled at 60°C, and the unhydrolyzed esters material was controlled at 70°C. Each binding agent was tested with



six different mixtures ranging from 80% binding agent and 20% silt DM to 20% binding agent and 80% silt DM. The extrudable and workability mixtures are 40% binding agent and 60% silt DM (i.e., 40/60), 35% binding agent and 65% silt DM (i.e., 35/65), and 30% binding agent and 70% silt DM (i.e., 30/70). Due to the glutinous level, a DM percentage of 30/70 or higher is unworkable and not extrudable.

The two binding mixtures noticeably different when it is in liquid and solid forms. The hydrogenated vegetable glycerides material's liquid is denser like syrup consistency while cured harder and the unhydrolyzed esters material is less dense like water while cured softer. Each mixture test sample was randomly selected 10 out of 30 and tested through a compression penetrometer ranging from 0 to 5 MN/m2 (MPa). As a result, the hydrogenated vegetable glycerides-based mixture has a wide range of mixture proportion possibility and the unhydrolyzed esters material has limited mixture combinations (Figure 3 (b and c)). The hydrogenated vegetable glycerides-based mixtures' 40/60 were tested with an average of 57.3 kPA (Figure 3 (a)), and both the 35/65 and the 30/70 withstood 63.7 kPa (Figure 3 (b ~ c)) without failing. Finally, the unhydrolyzed esters-based mixtures' 40/60 were tested with an average of 60.7 kPA (Figure 3 (a)), However the both the 35/65 and the 30/70 barely passed at 63.7 kPa (Figure 3 (b ~ c)) and deformations can be observed at the test samples.

2.3. Injection printing process

In the initial injection printing process (RLP), each M1 mixture was extruded via the compressing chamber, and the pressure buildup was inconsistent, resulting in uneven extrusion (Figure (a)) inside the water environment (M2). Although the extruder equipment is not complete, one important finding was

discovered: when the M2 volume was completely full, as shown in Figure (b), the volumetric pressure of M2 was enough to affect the first printing layer of M1 inside the water tank. As a result, printed objects would detach from the tank's base. However, buildability would be fine when the M2 volume increases along with the M1's layer height (Figure 5), and it is highly possible to print overhangs and cantilevers using this method. When the M1 touches M2 only briefly, the M1 material is workable before it completely hardens. It requires further study to determine the extruding temperature and the hardening time gap to inform the printing speed.

(a) (b)

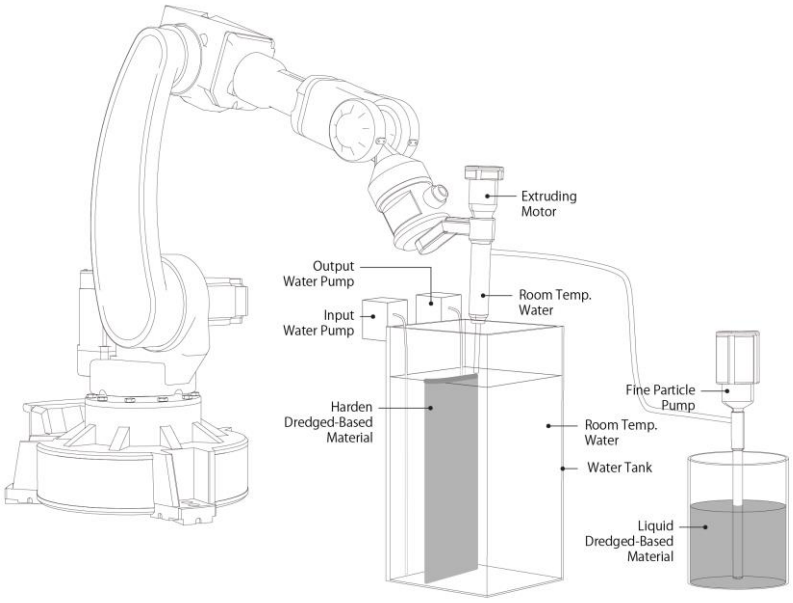

Figure 5. The injection set up including two water pumps to digitally control water height.

4. Conclusion: submission of contributions

The present paper discusses an initial investigation into the DM injection printing (RLP) technology, wherein M1 material is injected into M2 fluid with different rheological properties. The study evaluated

two variations of M1 material, namely silt DM mixed with soy-based hydrogenated vegetable glycerides material and silt DM mixed with unhydrolyzed beeswax-based esters material, using compression tests to determine their strength. Although the two binding mixture performances are different but it still yet enough data to draw a conclusion on which binding agent is better. More of the testing data needs to come from shear stress strength, material buildability, and more.

In the case of printing process, two printing methods were employed: M2 volume fully filled with M1 injection, and M2 volume rising along with M1 injection. It was concluded that the latter method performed better than the former. The results of this material mixture investigation combined with the silt DM injection printing technique satisfied the initial study requirements and suggest that this method is suitable for further research.

Although the research is a proof-of-concept and it has highlighted specific potentials, several challenges, and unknown factors also require further investigation. Firstly, while the solidified material strengths of M1 were studied, its liquid strengths were not, necessitating a shear strength study to understand better the moment M1 extrudes from the nozzle and to determine the design constraints of the printing object. Secondly, the M1 printing consistency and nozzle design must have the ability to maintain or increase their temperature during the printing process. Thirdly, the overlap condition of M1 material deposits is unknown. Lastly, it is still being determined how the printed M1 material will perform during the conventional concrete curing process and whether it will impact concrete strength.

It is important to emphasize that the DM injection printing technique relies on a solid connection between the fabrication process and material parameters. These elements cannot be viewed in isolation. Therefore, to make progress in research, it is essential to have a coordinated effort between material design, structural design, and fabrication process.

Acknowledgements

The authors would like to thank *Taichung Cultural Education Foundation for Architecture* for providing the funding and offer the opportunity to kick-start “Liquid printed reusable dredged-based material for concrete formwork”. I also want to thank student worker Meng-Ze Du for helping material investigation. And special thanks to Professor Cheng-Chia Huang and Li Qin mechanical contractor in Taiwan for assisting me to acquire Ta-Pu reservoir’s dredged material.

Abstract:

This paper presents an optimization method to create self-supporting shell structures for 3D printing (3DP) purposes. Compared to other methods of construction, 3DP can facilitate the fabrication of freeform, complex shell structures. However, for objects printed at the architectural construction scale, the 3DP supports are typically hard to remove, causing considerable material and energy waste and requiring additional postprocessing work. Making the geometry self-supporting is a challenging alternative to neutralize these downsides of 3DP. We propose a post-slicing optimization method to make porous shell structures self-supporting for 3DP by reducing the overhang when necessary. The method is applicable to shell structures that, when printed, only consist of walls without infills or caps. After slicing, we represent the planar wall toolpaths using medial axes and maximal disks. The method then examines the proximity between the medial axes of adjacent layers to build a skeleton model and makes adjustments when the overhang exceeds a limit. Finally, the planar toolpaths are updated through linkage to the medial axes. An example of a Triply Periodic Minimal Surface (TPMS) geometry is illustrated. In this paper, we offer a computational framework for the local optimization process. Instead of imposing limitations at the beginning of the design process, it adjusts a finished design to form self-supporting geometry. It investigates the geometry through an organized series of toolpaths and preserves the shell structure's local thickness and curvature continuity. While recent self-supporting optimization research mainly inspects geometries of fixed vertical sections, our method fully develops 3DP's potential in manufacturing free-form shell structures and can be of vast application on various scales.

Keywords: 3D printing, shell structure, structural optimization, Hangai Prize applicant

1. Introduction

1.1. Self-supporting structures for architectural additive manufacturing

Additive manufacturing, primarily 3D Printing (3DP), has revolutionized the way objects of different scales are designed and manufactured. It gives architects the ability to flexibly create complex functional and exotic geometries that are difficult to achieve with traditional manufacturing methods [1]. How- ever, architectural additive manufacturing, with concrete 3DP as a most prevalent practice, also faces limitations in mass production. While conventional layer-based 3DP utilizes support structures that are printed together with the geometry and removed afterward, at the architectural construction scale they are typically hard to remove and create considerable material and energy waste and require additional post-processing work [2].

Overhanging, hole, and edge features in the print geometry usually require support structures [3]. This paper is situated in the trend of designing self-supported structures and neutralizing the downsides of support structures. Making the geometry self-supporting is a challenging task. Extensive research has been conducted to globally optimize the topology using methods involving moving morphable compo- nents [2, 4, 5]. However, instead of being the *post-processing* to a pre-designed geometry, the *global* topology optimization process incorporating self-supporting constraints is more like the *design process* itself. The principles of topology optimization restrict the freedom of architects in experimenting with novel structural prototypes. Their outcomes are usually limited to multifurcating structures with fixed sections such as the Messerschmitt–Bölkow–Blohm (MBB) beam.

In this paper, we propose an alternative to creating a self-supporting structure by locally optimizing a present geometry that is in general printable but can be vulnerable at certain locations. The main characteristics of a vulnerable region in the print are identified as bridges, overhangs, and angles [6] when the geometry is viewed *as geometry*, or in other words, the mesh or boundary representation as the slicing input. Our method will scrutinize the geometry *as toolpaths* after the conventional slicing is finished. The unprintable characteristics, all referred to as *overhangs* in this paper, will then be manifested as the planar offset between layers of toolpaths. Utilizing a post-slicing skeleton model we will be able to calculate and reduce the overhangs when necessary and thus make the geometry self-supporting.

1.2. 3D printed shell structures

The process of 3DP is essentially linear extrusions. Compared to the traditional casting method, it is advantageous in creating shell structures with holes and multifurcations which then become innovative architectural components such as the wall, column, beam, and dome elements with tailored functions [7–11]. This sustainable approach with minimized material usage to design and fabricate lightweight structures with high structural performance has thus gained more attention.

This paper will look at lightweight porous shell structure components that, when printed in concrete, only consist of walls without infills or caps. Typically, they are prefabricated in the factory and then transported to the site for assembly, as opposed to the other two fashions of 3D printing formworks or an entire building [12]. When combined with structural form-finding, they make efficient discrete systems [13]. Triply Periodic Minimal Surface (TPMS), as one of the lightweight structural prototypes, has been extensively tested and researched. Due to their minimal surface area, TPMS structures possess a high surface area-to-volume ratio. The periodic and continuous nature of TPMS structures also allows the efficient distribution of external loads throughout the material. When a force is applied to one point on the structure, the load is distributed across multiple points, reducing the overall stress experienced by any single point. This distribution results in better overall mechanical stability and resistance to deformation [14]. This paper uses Diamond TPMS as a case study and demonstrates the respective potential of our optimization proposal.

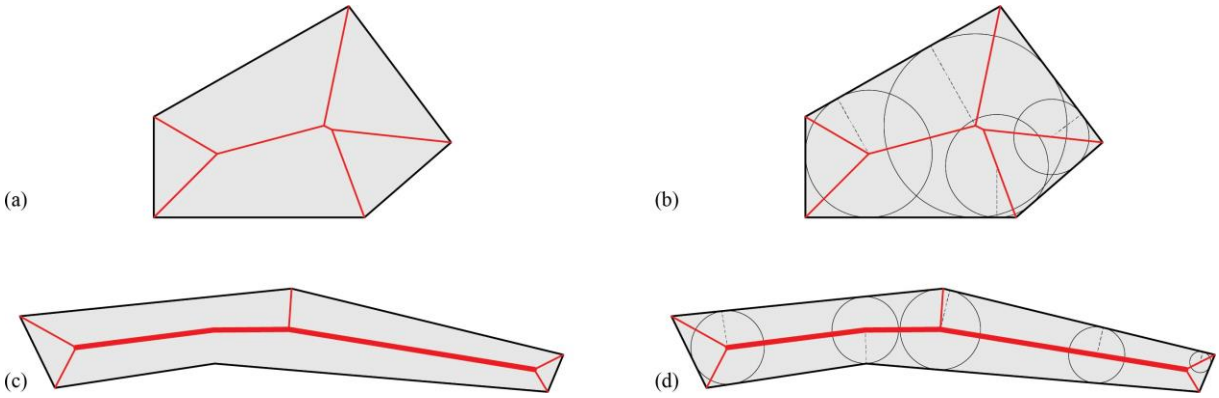

Figure 1. Medial axis (red) and some maximal disks of (a) (b) a regular polygon; and (c) (d) a slender polygon.

1.3. Medial axis and skeleton model

Introduced by Blum [15] in 1967, the *medial axis* is an efficient way to describe a 2D shape. It is essentially the set of points in a shape that have at least two closest points on the shape's boundary (Figure 1a, c). For each point on the medial axis, a unique *maximal disk* can be drawn if we use the distance between that point and the closest points on the boundary as its radius (Figure 1b, d). The points in all the maximal disks are within the original shape and all the points in the original shape are covered by some maximal disks. We call the combination of the medial axis and each point's local radius (of its maximal disk) a *disk representation* of the shape. We can mutually transform between the boundary representation and the disk representation of the original shape. This method is also applicable to planar domains with holes [16] where instead of being a *tree*, the medial axis will incorporate *cycles*.

This paper proposes printing the two sides of shell structures in two parallel curves so that the toolpaths a) are closed contours with seams for better finishing quality and b) can be continuous while accommodating multifurcations in the plane. To do so, the input geometry is a shell with thickness and volume. Given a printing direction (*z*-axis of the printer), it is sliced into one or multiple closed contours in each plane. If the structure is in general printable, the contours enclose slender domains representing the solid part of the shell (gray parts in 4). Figure 1c, d show that for a slender domain, a main axis (thickened) representing the direction and position of the geometry is observed. It offers an efficient representation where the radii of most maximal disks are similar. Thus we transfer the slender domains created into medial axes for optimization. And the disk radii are recorded as vectors to preserve the shell structure's local thickness and curvature continuity in our method.

The precise calculation of medial axes in polygonal or curved shapes is a complex and slow task [17]. We use an approximate method to compute medial axes and then examine the proximity between the medial axes of adjacent layers. Adjustments are made when the overhang exceeds a limit. Finally, the planar toolpaths are updated through vector linkages to the medial axes. This *skeleton* method will be explained in detail in the Methodology section. Note that while the concept skeleton is used by computer scientists as an extension of the medial axis of a 2D geometry, this paper uses it to refer to an entire 3D print geometry organized in a hierarchical data structure.

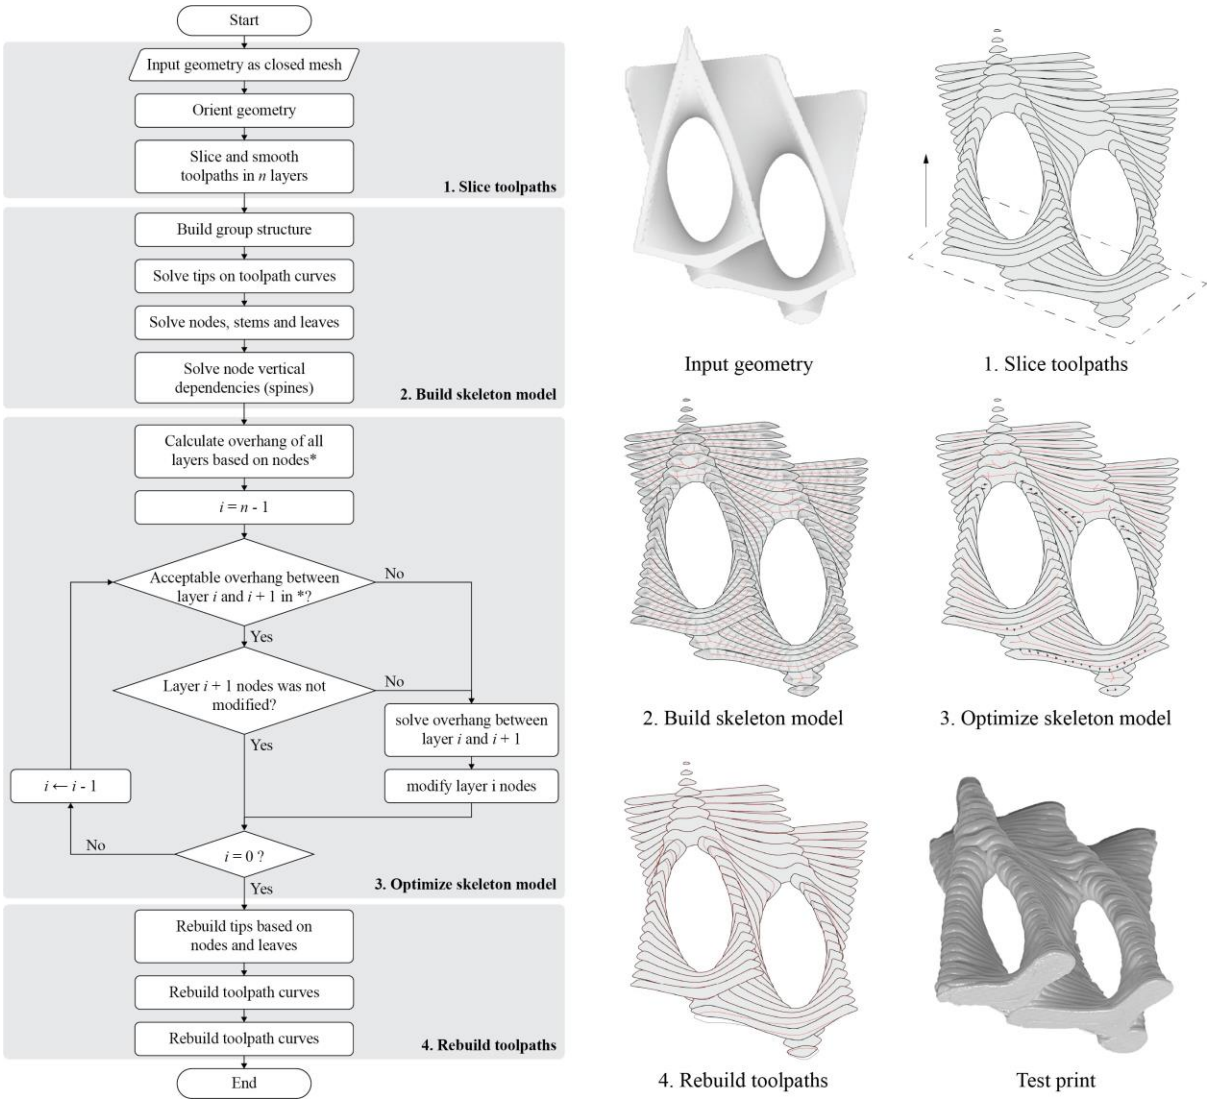

Figure 2. The computational flowchart for reducing the print overhang utilizing the skeleton model method, show- ing the geometry at different stages.

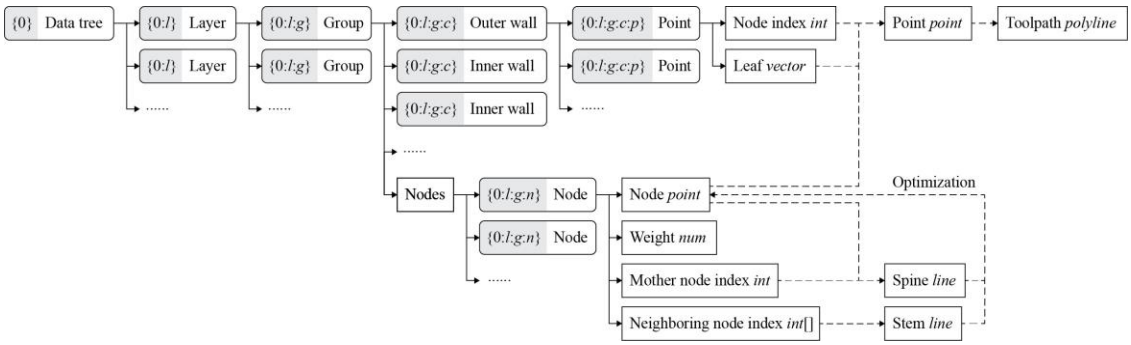

Figure 3. Main data structure of the geometry optimization.

2. Methodology

Figure 2 offers an overview of the optimization framework. It comprises four major steps: slice tool- paths; build the skeleton model; optimize the skeleton model; and finally, rebuild the toolpaths. Figure 3 illustrates the computational data structure where points are stored in relative positions to nodes of the medial axes. A case study of a Triply Periodic Minimal Surface (TPMS) geometry (Figure 2b) generated using the volumetric modeling plugin *Axolotl* [18] for *Grasshopper* is illustrated.

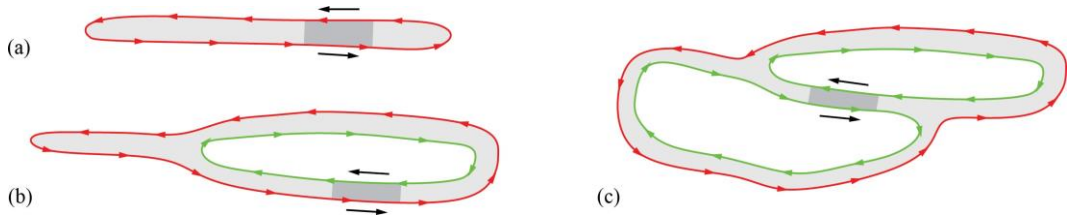

Figure 4. Outer walls (red, counterclockwise) and inner walls (green, clockwise) of groups with (a) no holes; (b) one hole; and (c) multiple holes.

2.1. Slice toolpaths

Our method applies to both parallel and non-parallel slicing of solid geometries. A concrete 3DP geome- try as a structural component usually uses its flat top and bottom faces as contact surfaces for assemblage. The two faces are part of the input of the slicing or can be found using a convex hull analysis. They de- termine the slicing planes in between that intersect the geometry to create closed contour curves.

2.2. Build skeleton model

In each plane or *layer*, the contours are then sorted based on their cross-inclusion relations to form several *groups*. As illustrated by Figure 4, each group indicates a solid domain (shown as gray). A group is formed by one *outer wall* and can have several *inner walls* each indicating a hole. In the data tree, they form a list of curves where the outer wall is the first curve (Figure 3). The printing directions of the walls are also unified to have the parallel layers printed in reversed directions and thus have increased bounding.

Our approach to calculating the medial axis is developed based on the Voronoi diagram approximation method by Brandt and Algazi [19]. (Another application of the method in 3DP is the extrusion rate control to create variable print width [20].) We start by refitting the *toolpath curve* using a compact polyline whose adjacent vertices have a prescribed maximal distance. The vertices are then extracted as a list of *points* (Figure 5a). Based on the discrete points a Voronoi diagram can be solved and purged to show the inner structure of the domain (Figure 5b). The half cells form a redundant, approximate planar skeleton structure. We then merge the adjacent vertices of the Voronoi diagram within a tolerance into *nodes* to make the representation more efficient (Figure 5c). The end nodes (having only one neighbor) too close to the boundary are also purged recursively to extract only the “bones” of the slender geometry. Referring to the original Voronoi diagram, the linkages between nodes are calculated as *stems*. With the node-stem structure formed, each toolpath point is projected to the closest node and regarded as offsetted from it by a *leaf* vector (Figure 5d). Note that here we use nouns describing plants because our geometric structure is similar to plants

such as shameplants and ferns in plane.

To examine the overhang between layers, we solve the vertical dependencies between nodes of adjacent layers. When the supporting condition of a node is examined, the node is referred to as the *daughter node*. For each daughter node, the closest node in the previous layer is found as its *mother node*. The last component of the skeleton mode, the *spines* are then created by connecting the daughter nodes and their mother nodes (Figure 5e).

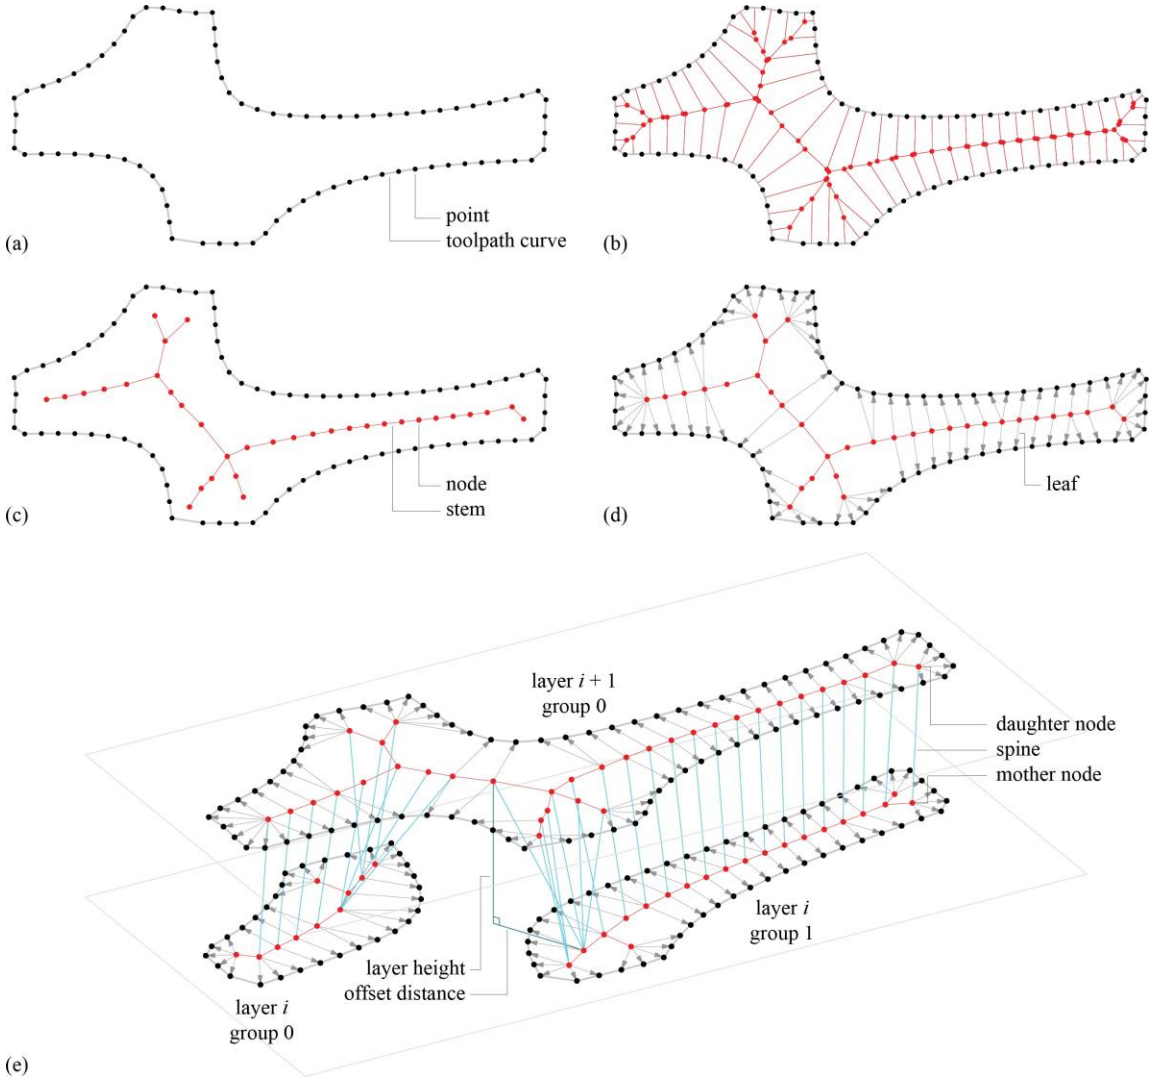

Figure 5. Skeleton model building process: (a) convert the input *toolpath curve* into a compact polyline and extract *points*; (b) solve the Voronoi diagram and the vertices inside the domain; (c) merge the vertices to create *nodes*, purge those too close to the boundary, and create *stem* connections between nodes; (d) find the closest node to each point to create *leaf* vectors; and (e) find each *daughter node* in layer $i + 1$ the closest *mother node* in layer i and connect them to form *spines*.

2.3. Optimize skeleton model

The goal of our local optimization method is to reduce overhang between layers. Ideally, the local overhang distance is defined as the offset distance between the new toolpath and the previous one that supports it (Figure 6). It can be calculated by projecting a point on the new toolpath to the

previous slicing plane and finding its distance to the closest toolpath curve. We use pairs of mother and daughter

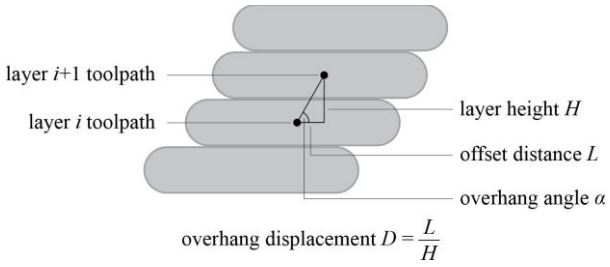

Figure 6. Ideal definition of overhang displacement.

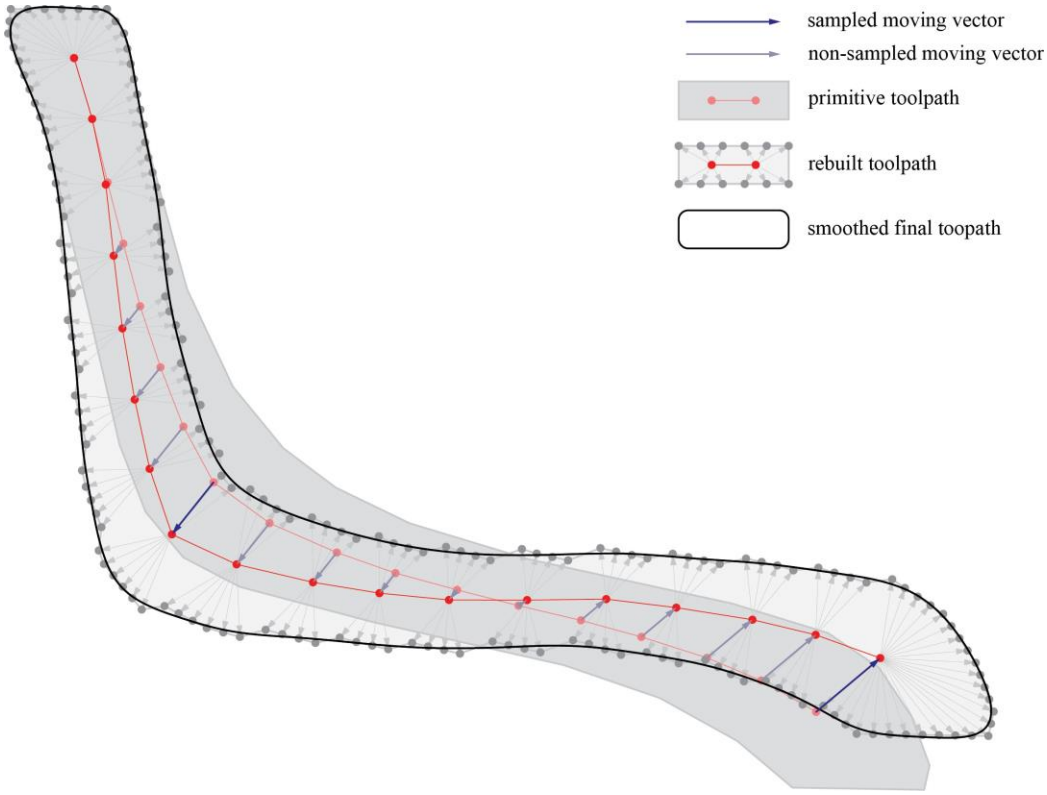

Figure 7. Example of optimizing a group where two nodes are sampled.

nodes, instead of the points to calculate the offset distance and the overhang displacement. The offset distance of all the points that rely on the same daughter node is thus treated as the projected length of the node's spine in the mother layer plane (Figure 5e). Note that the radii of the two nodes also affect the actual offset distance. However, when the radius is significantly larger than half of the shell thickness, it means the surface orientation is largely tilted, and in this extreme case allowing more tolerance in offset by neglecting the change in radii can help maintain the overall shape of the geometry.

Our method requires a predetermined overhang displacement optimization goal (0.9 in the case study). As shown by Figure 2a, after a round of pre-check, the local optimization process examines

each layer in a certain order. Usually, the contact surface of the top and bottom faces should be preserved in their original shapes and the merging regions close to the top are more dangerous than the diverging regions close to the bottom. Therefore, our method follows a top-down order in inspecting layers.

Examining each pair of adjacent payers, we adjust the mother layer (layer i) to better support the daughter layer (layer $i + 1$). Each mother node receives *moving vectors* required by the daughter nodes to reduce their overhang displacement when necessary. One mother node can have multiple daughter nodes. The vector with the largest magnitude is used to move the mother node, which means that at times our method cannot eliminate all excessive overhangs.

A node is *sampled* if it received a moving vector as the mother node. However, its neighbors should also be adjusted to preserve curvature continuity. The moving vectors of the *non-sampled* nodes are calculated based on their distance to the sampled nodes. The distance is the length of the path between the two nodes on the graph formed by nodes and stems. It acts as a variable to linearly reduce the sampled moving vector in solving non-sampled moving vectors. In the example of Figure 7, only two mother nodes are sampled, meaning their overhangs exceed the prescribed limit. When we tune the nodes in a continuous way using both sampled and non-sampled moving vectors, the curvature continuity of the node-stem graph is preserved as in the original geometry.

2.4. Rebuild toolpaths

The rebuilding of toolpaths is straightforward. By adding back the leaf vectors to the new nodes, the points of the new curves are recomputed as shown in Figure 7. The rebuilt toolpath is then smoothed recursively to form the final toolpath. The entire optimization process thus mimics the kinematics of a snake skeleton and the thickness and curvature continuity is preserved in the new shell walls.

3. Results

Our case study features a 35 × 70 × 70mm Diamond TPMS with a 2mm thickness as the input geometry. We use an in-house developed PET-G printer with a 1.65mm diameter nozzle to simulate the concrete 3DP in a 1/10 scale. The print width is 2mm and the layer height is 1mm. 0.9 is set as the optimization threshold. The computation process of slicing and optimizing takes around 60 seconds. The primitive and optimized toolpaths differ mainly in merging regions (Figure 8a). The branches holding the bridge are dragged towards each other to reduce the overhang (Figure 8b, d). Figure 8c shows the cumulative distribution of the overhang. The overhang at each node is weighted by the length of the toolpath projected to it. As a result, the percentage of toolpaths sufficing the requirement of 0.9 raised from 91% to 99%.

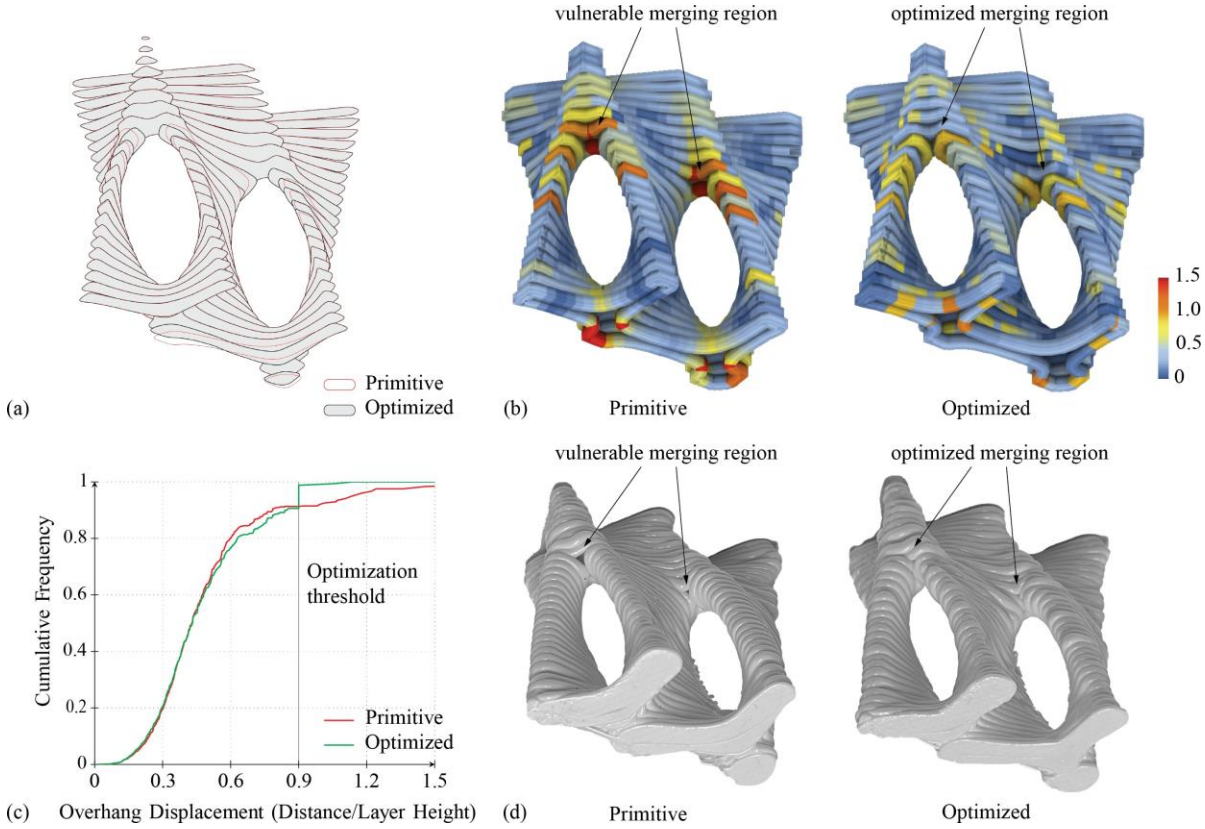

Figure 8. Optimization results of a Diamond TPMS geometry, 0.9 is set as the maximal overhang displacement: (a) toolpaths; (b) volumetric visualization showing overhang displacement; (c) cumulative distribution of printing overhang displacement; and (d) test prints.

4. Conclusion

In this paper, we offer a computational framework for the local optimization process. Instead of imposing limitations at the beginning of the design process, it adjusts a finished design to form self-supporting geometry. It investigates geometry through an organized series of toolpaths. It is a pivot exploration to assist in manufacturing free-form shell structures and can be of vast application on various scales. Meanwhile, it has the following limitations that require future work:

The method is highly resolution-dependent. The resolution and tolerance parameters, especially the overhang threshold, determine the quality of the optimized print. When the method is applied to different scales and diverse geometries, a systematic study of those parameters is required.

While our method features a top-down sequence, the order in which the layers should be organized and optimized is still open to discussion. One possible solution is to relate the overhang message with the Reeb graph structure of the geometry and decide on an optimization sequence accordingly. (An application of the Reeb graph in 3DP is provided by [21].) In addition, a constraint over the geometry's boundary parts is also a feature required by using such prints as structural components.

Finally, our local optimization can change the force flow and thus the structural performance of prints. A comprehensive, comparative study is required to investigate its limits and downsides. Cracking and vibration in the printing process of branching shell structures, discussed by [22], is also another factor affecting the printability and final quality that need to be evaluated in addition to being self-supported.

Abstract

The combination of topology optimization and metal additive manufacturing technology is a new effective approach to realize integration of design and fabrication for nodal joints in spatial structures. The variable density method method was employed to optimize the topology of two typical nodes in cable dome, namely, the inner-ring cable-strut node and the outer-ring upper chord node. Stainless steel additive manufacturing of the two topology nodes was completed by selective laser melting (SLM) technology. In order to study the behavior of metal additive manufacturing nodes under actual 3D loading conditions, two structural models using conventional nodes and two of them replaced by metal additive manufacturing nodes were experimentally studied for a sunflower triple-strut cable dome model with a diameter of 10 m. Construction forming and static loading tests under full-span were carried out on the cable dome model. The results showed that the topology nodes fabricated by SLM technology instead of conventional nodes have little influence on overall behavior of the cable dome, which verified the validity and feasibility of adopting metal additive manufacturing nodes in practical engineering.

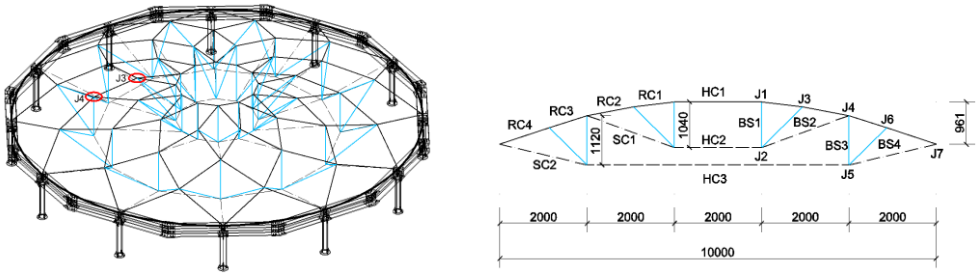
1. Introduction

Topology optimization is an optimization process based on structural conceptual design, that is, the given initial space is taken as the design variable, and the optimal topology shape or material distribution satisfying certain constraints is sought. A reasonable initial form of the structure can be obtained through topology optimization [1-2]. By introducing the process of continuum topology optimization into the design of spatial structure nodes, node forms with reasonable mechanical properties, less material consumption, novel and beautiful shapes and satisfying diversified demands can be obtained [3-4].

However, the nodes obtained by topology optimization usually have irregular and complex geometric shapes, which can hardly be realized by traditional manufacturing technology. In recent years, additive manufacturing technology, an emerging technology with global attention, provides a new and effective way for the manufacture of topology optimization nodes due to its characteristics of fast and free forming [5-6]. Metal additive manufacturing is a manufacturing method based on 3D model data, which mainly uses powder or wire material as raw material, and uses laser, electron beam, electric arc and other high power heat source to melt and solidify materials quickly and then forms products layer by layer [7-8].



In this paper, the topology optimization of two typical nodes for sunflower triple-strut (type I) cable dome structure, inner-ring cable-strut node and the outer-ring upper chord node, is carried out. Stainless steel additive manufacturing of the two topology nodes was completed by the SLM technology. For a cable dome model with a diameter of 10 m, the construction forming and static loading tests were carried

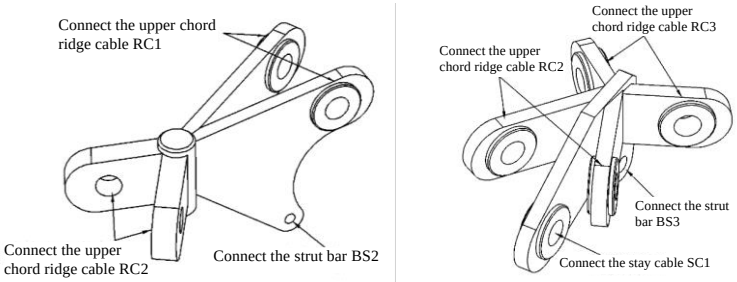
out respectiely on two structural models using conventional nodes and two of them replaced by metal additive manufacturing topology nodes. Then, the mechanical behavior of metal additive manufacturing nodes under actual 3D loading conditions were studied.

2. Cable dome structure model and typical nodes



Sunflower triple-strut cable dome structure is one of a series of new cable dome structure system proposed by Dong in recent years [9]. In this section, the structure design and experimental study of a sunflower triple-struc (Type I) cable dome structure with a diameter of 10 m were carried out. Along the circumferential direction, the model consists of 12 trusses of ridge cable (RC), stay cable (SC), hoop cable (HC), strut bar (BS) and rigid ring beam, with a rise-span ratio of 0.1. The members of the model include 48 ridge cables, 24 stay cables, 72 strut bars and 3 hoop cables, and the total number of nods is 84, among which 12 are connected with rigid ring beam. Fig. 1 shows the three-dimensional diagram and section diagram of the model. High vanadium cable is used in cable dome structure model with elastic modulus of 1.6×10^5 N/mm^2 and tensile strength of 1670 MPa. The strut bars, nodal joints and rigid ring beams are made of Q355B low-alloy high-strength structural steel with elastic modulus of 2.06×10^5 N/mm^2 and yield strength of 355 MPa.

(a) (b)

Figure 1. Cable dome structure model (a) three-dimensional daagram, (b) section diagram.

The nodal joints of the cable dome structure model are usually completed by welding or casting process. The connection between the member and the node is hinged, and the design of the node ensures that all the internal forces of the cable and strut members line converge at a point, and the node will not produce bending moments in the plane. The two ends of the tensile cable or pressure strut are fixed on the pin-plate of the nodal joint through the hinge pin, so that there is no in-plane bending moment at the node, but it has a certain out-of-plane bending stiffness.

(a) (b)

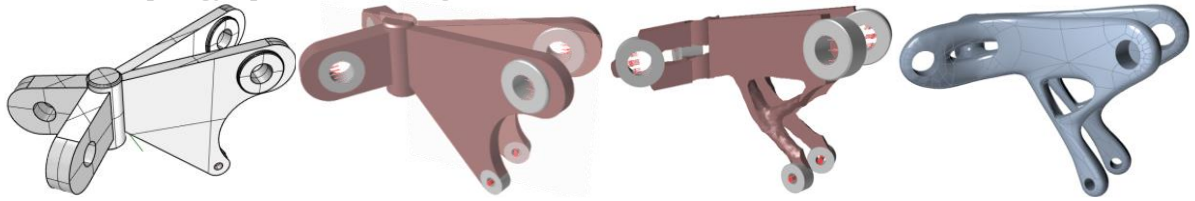


Figure 2. Conventional nodal joints (a) inner-ring cable-strut node J3, (b) outer-ring upper chord J4.

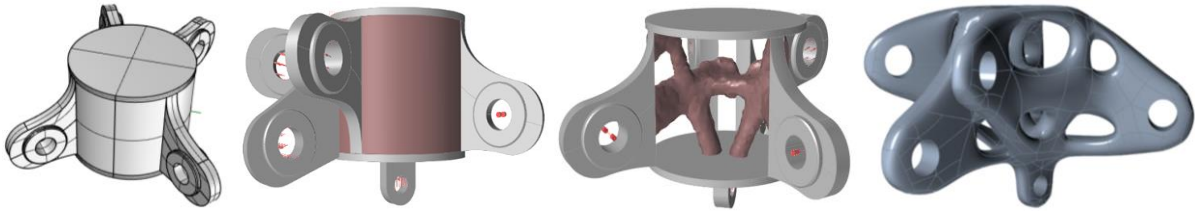
According to different forms, positions and sizes of nodes, the nodes of this model can be divided into 7 types: inner-ring upper chord cable clamp node J1, inner-ring lower chord hoop cable clamp node J2, inner-ring cable-strut node J3, outer-ring upper chord node J4, outer-ring lower chord hoop cable clamp node J5, outer-ring cable-strut node J6 and outer-ring ring-beam node J7. Fig.2 shows the two representative nodes J3 and J4 (hereinafter referred to as conventional nodal joints) designed by conventional methods. In this paper, ANSYS is used to calculate the cable dome structure model to obtain the cable-strut balance design prestress based on strong nodes and weak members under the most

unfavorable loading condition, and take this as the most unfavorable loading condition to optimize the design of two conventional nodal joints.



3. Topology optimization and metal additive manufacturing of typical nodes

Common topology optimization methods of continuum structure include homogenization method, variable density method [10], level set method, bidirectional evolutionary structural optimization method (BESO) [11], etc. Among them, variable density method describing structure topology with constant unit density is the most mature method with high computational efficiency and good computational stability, and has been widely used in ANSYS, ABAQUS, Solidthinking, Hyperworks and other commercial software. BESO method has also been applied to Ameba commercial plug-in developed based on Rhino Grasshopper platform [12]. In this section, variable density method method is used for topology optimization design.

Figure 4. Topology optimization design with minimization of mass for node J4 based on variable density method (a) original Rhino model, (b) original Inspire model, (c) Inspire optimization result, (d) Evolve redesign node.

Firstly, Solidthinking Inspire software is applied to carry out optimization design with minimization of mass as optimization objectives. After completion of optimization, optimization results are imported into Solidthinking Evolve software for redesign. The corresponding optimization result and redesign nodal joints of node J3 and node J4 are shown in Fig.3 and Fig.4 respectively. For the node J3, the mass of the optimization node is 2.45 kg, which is 37.5% less than that of the original node. For the node J4, the mass of the optimization node is 4.21 kg, which is 46.5% less than that of the original node.

(a) (b)

Figure 5. 316L stainless steel nodal joints made by SLM technology (a) inner-ring cable-strut node J3, (b) outer-ring upper chord node J4.

First, the STL file is imported into the Magics software for the pre-processing of model position adjustment and support, and the BP software is used for slicing and related parameters adjustment. The software BLT-MCS is used for printing setup and equipment control, and SLM technology is used for layering and overlay molding. Then the heat treatment of the molding part and the bottom plate is carried

out together to prevent the deformation of the 3D printing node. Then the post-treatments including wire-electrode cutting and support removal are carried out togother, followed by grinding, polishing and sand blasting surface treatment. Finally, vernier caliper is used for precision measurement, and the error between the printing product and the original model is controlled within ±0.2 mm. Two 316L stainless steel nodal joints made by SLM technology are shown in Fig.5.

4. Model test of structure with metal additive manufacturing nodes

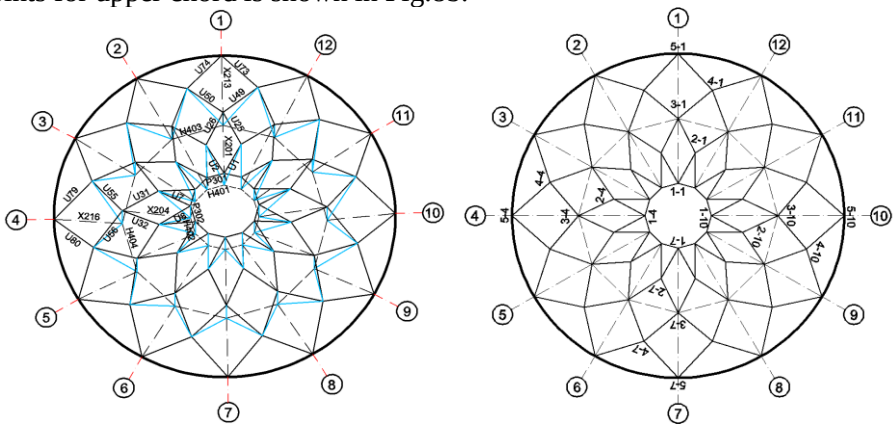
4.1. Tensile forming of the model

It is pointed out in literature [9] that there is only one overall prestressed mode in sunflower triple-strut (type I) cable dome structure. By tensioning the outer-ring stay cable so that its internal force reaches the design prestress, then the internal force in the whole structure member is that the design prestress. The graded batch tension scheme is adopted, which is divided into three levels of tension, that is, the first level of tension is 0.5 times the stay cable force, the second level of tension is 0.75 times the stay cable force, and the third level of tension is 1.0 times the stay cable force. In the process of each level of tension, twelve outer-ring stay cables are divided into three batches of tension, and four symmetrical outer-ring stay cables are tensioned in each batch. The photo of the structure model after tensile forming is shown in Fig.6. The assembly effect of conventional original design node and metal additive manufacturing node by SLM technology for nodes J3 and J4 are shown in Fig.7.

Figure 6. Cable dome structure model after tensile forming

(a) (b) (c) (d)

Figure 7. Assembly effect of conventional original design node and metal additive manufacturing node (a) conventional node J3, (b) additive manufacturing node J3, (c) conventional node J4, (d) additive manufacturing node J4.



Before and after the replacement of the node J3 and node J4, the two structural models are tensioning respectively, and the internal forces of member and the elevations of node are measured in the initial state, and then compared with the ANSYS finite element results. The results show that the internal forces of member and the elevations of node are basically consistent with the ANSYS results, except for the inner-ring diagonal struts and the inner-ring upper chord ridge cables with less designed prestress, which indicate that replacing the node J3 and node J4 with the additive manufacturing nodes has little influence on the initial state of the cable dome structure model.

4.2. Static loading test scheme of the model

Two cable dome structure models using conventional nodes (model 1) and two of them replaced by stainless steel additive manufacturing topology nodes (model 2) are tested respectively. The loading modes is set to full-span loading. Apply a total uniform loading of 0.4 kN/m^2, divided into three levels

of proportional loading. The loading is carried out by the way of lower chord nodes mounting, and the loading object is 20 kg steel weight block of standard mass.

The sunflower triple-strut (Type I) cable dome structure is an axially symmetric structure. Theoretically, the data of the whole structure can be obtained by measuring only one struss of the internal force and node displacement. However, considering the error of the test model and other factors, the actual distribution of internal forces and node displacements may be uneven. Considering the symmetry and the limitation of the number of measuring points, the arrangement scheme of measuring point in the test is as follows: 1) Cable force measuring points of the cables: One cable force sensor is arranged in each of the two trusses of the cables at the position of axis ① and axis ④, which are perpendicular to each other, and two cable force sensors are arranged in each of the three hoop cables. The arrangement of cable force measuring points for cable is shown in Fig.8a. 2) Internal force measuring points of the struts: Strain gauges are arranged in the middle of the two trusses of the struts at the positions of axis ① and axis ④, which are perpendicular to each other. In order to eliminate the error of eccentric force for the struts, a three-way resistance strain gauge is arranged on the positive and negative sides of all the strut measuring points respectively. 3) Node stress measuring points: eight measuring points are arranged at the inner-ring cable-strut node J3 by SLM technology, and nine measuring points are arranged at the outer-ring upper chord node J4 by SLM technology. 4) Node displacement measurement points: Reflective plates are affixed to the upper surface of all nodes, and coordinate acquisition is carried out by total station instrument, so as to obtain node displacement. The arrangement of node displacement measuring points for upper chord is shown in Fig.8b.

(a) (b)

Figure 8. Arrangement diagram of part measuring points (a) cable force measuring points of the cable, (b) node displacement measuring points of upper chord.

4.3. Comparison of test results and FE results

Fig.9 shows the measured internal forces of part cables in the two models under full-span loading and the comparison with the FE results. It can be seen that the variation trend of the measured cable forces is consistent with the FE results, and most of the errors are within 10%. With the increase of loading, the internal forces of outer-ring ridge cables, inner-ring ridge cables and inner-ring upper chord hoop cables first decrease and then increase. With the increase of loading, the internal force of the outer-ring stay cables and inner-ring lower chord hoop cables first increases and then decreases. The internal forces of the cables before and after the replacement of the metal additive manufacturing nodes are both linear change. The node displacements are small, that is, the corresponding overall stiffness is large, indicating that the replacement of the metal additive manufacturing nodes does not influence the overall stiffness of the structure model.

Fig.10 shows the variation curves of internal forces for the outer-ring stay cables X213 and 216 under full-span loading. It can be seen that the measured internal forces of the structure show a linear change trend and are in good agreement with the FE results. The structure is always in the elastic working stage during the whole test process and basically returns to the initial state after unloading. Fig.11 shows the

comparison of the node displacements for one struss of ridge cable in the cable dome structure under the uniform full-span loadings of 0.4 kN/m^2. It can be seen that all nodes of the ridge cable have downward displacement, which is no more than 8 mm. The closer the node is to the support, the smaller the node displacement is, and the curve variation is basically consistent with the FE results.

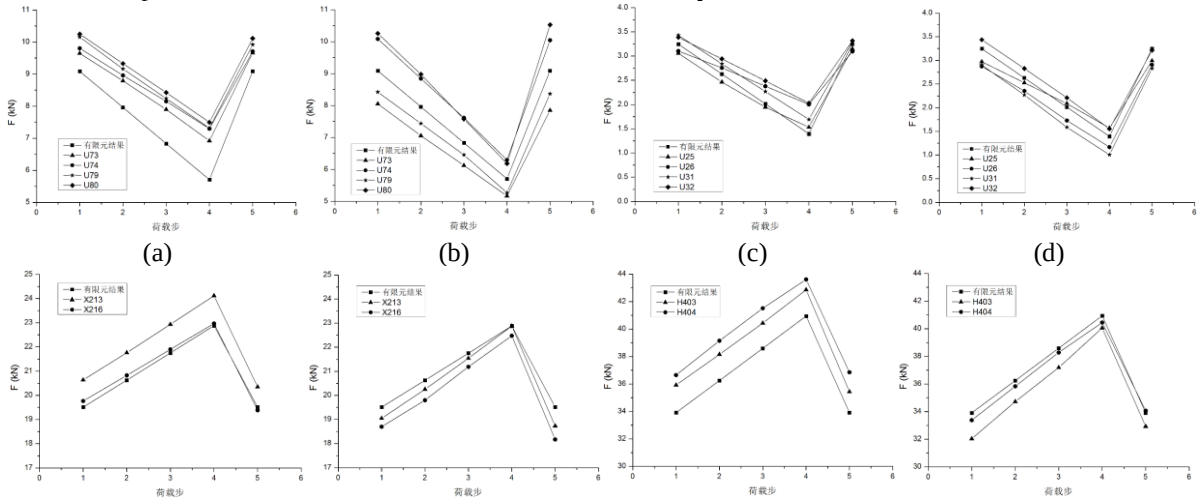


Figure 9. Internal forces of part cables for the two models under full-span loading (a) outer-ring ridge cables for model 1, (b) outer-ring ridge cables for model 2, (c) inner-ring ridge cables for model 1, (d) inner-ring ridge cables for model 2, (e) outer-ring stay cables for model 1, (f) outer-ring stay cables for model 2, (g) inner-ring lower chord hoop cables for model 1, (h) inner-ring lower chord hoop cables for model 2.

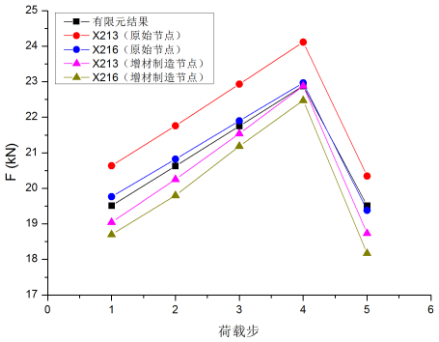

Figure 10. Variation of internal forces for outer-ring stay cables with loading step

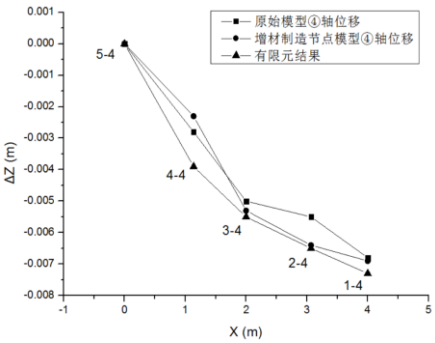

Figure 11. Comparison of node displacements for one struss of ridge cable

It can be seen from the above results that the topology nodes fabricated of metal additive manufacturing instead of conventional design nodes has little influence on the overall behavior of the cable dome structure, which preliminarily verifies the validity and feasibility of adopting metal additive manufacturing nodes in practical engineering. In addition, due to the low loading level of this test, the bearing capacity and failure mechanism of metal additive manufacturing nodes need to be further studied.

5. Conclusion

By using Solidthinking Inspire software based on variable density method, the topological optimization is carried out on two typical nodes of sunflower triple-strut (type I) cable dome structure, namely, inner-ring cable-strut node and outer-ring upper chord node. The SLM technology has been used to fabricate two stainless steel additive manufacturing nodes based on minimization of mass topology optimization. Full-span static loading test is carried out on the two cable dome models, which use all conventional nodes and two nodes are replaced by stainless steel additive topological optimization nodes. With the increase of test loading, the measured internal forces and node elevations showe a linear trend and are

in good agreement with the FE results. The change of node displacements is small, indicating that the structure is always in the elastic working stage in the whole test process, and the overall stiffness is high. Replacing the additive manufacturing node does not influence the overall stiffness of the structure.
Replacing the conventional design nodes with the topology optimization nodes fabricated of metal additive manufacturing has little influence on the overall behavior of the cable dome, which preliminarily verifies the validity and feasibility of adopting metal additive manufacturing nodes in practical engineering. In addition, due to the low loading level of this test, the bearing capacity and failure mechanism of metal additive manufacturing nodes need to be further studied.

Abstract

Additive manufacturing in the construction industry has reformed traditional construction approaches, allowing for the realization of customizable structure design in low cost and low waste manner. This paper explores a new additive construction system, namely additive lamination manufacturing (ALM), to construct large-scale structural components. The ALM utilizes Fibre Reinforced Polymer (FRP) fabric materials and the lamination approach to extrude the formwork structure, along with the robotic technique to achieve the desired fabrication accuracy. The adaption of conventional manual lamination technique into robotic construction enables the technique to build very structural components in mouldless and support-free process. This paper further compares the fabricated components performance with different composite materials, and the optimal materials are then used to fabricate a double curved shell structure.

Keywords: design customization, structural optimization, FRP composite material, freeform formwork construction, Hangai Prize applicant

1. Introduction

1.1. Additive manufacturing in construction industry

The additive manufacturing in construction industry has revolved the construction approaches with high material utilization, low labour cost and easy project management. Well-established additive manufacturing methods, for example contour crafting[1] and concrete printing[2], commonly utilized cementitious materials to construct structures via layer-by-layer material deposition. Those techniques are suitable for the fabrication of structure components in any 2.5-dimensional geometry or 3D geometry with low sloping angle in upright direction. The full-fledged family home[3] (Fig. 1a) and eco-house TECLA[4] (Fig. 1b) are the two examples demonstrating how additive manufacturing can be effectively employed in the construction of residential house.

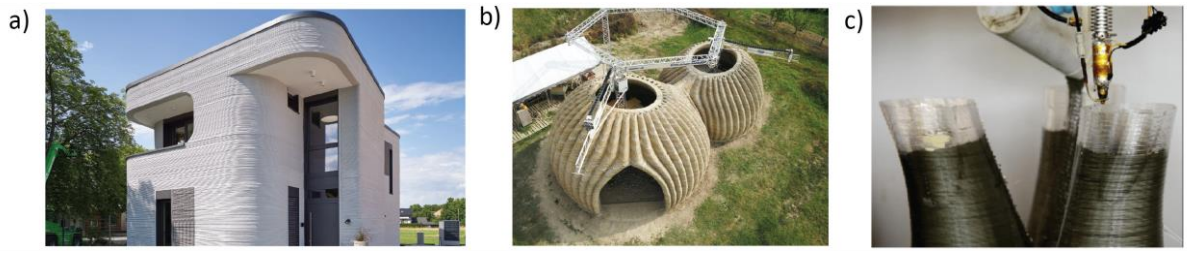

Figure 1. (a) The full-fledged family home[3]. (b) Eco-house TECLA[4]. (c) Egg-shell formwork[5].

In addition to constructing structural components, additive manufacturing can also be utilized to

Copyright © 2023 by Zhuoyang XIN, Guanqi ZHU and Dan LUO. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

fabricate formwork, for example the egg-shell formwork[5] (Fig. 1c). Although this application requires an additional step to cast the material, the resulting component gain more homogeneous material property and eliminates the issue of weak inter-layer bonding capacity in material due to the one-time casting process. This highlights the potential of additive manufacturing in formwork fabrication, as it can improve the overall quality and durability of the final product.

Nevertheless, achieving mass customization while maintaining efficiency, enhanced performance, and sustainability has posed a persistent challenge in the field of architecture design and construction. This challenge is particularly pronounced when dealing with freeform geometries, as existing additive manufacturing techniques are often limited by geometry constraints. As illustrated in Fig. 2a, the current layer-by-layer deposition printing method suffers from the drawback of being unable to achieve large inclined angles without external support for both component and formwork fabrications. This limitation becomes more evident in the case of geometries with significant cantilever angles, where additional material and time may be wasted in printing support elements to ensure proper fabrication.

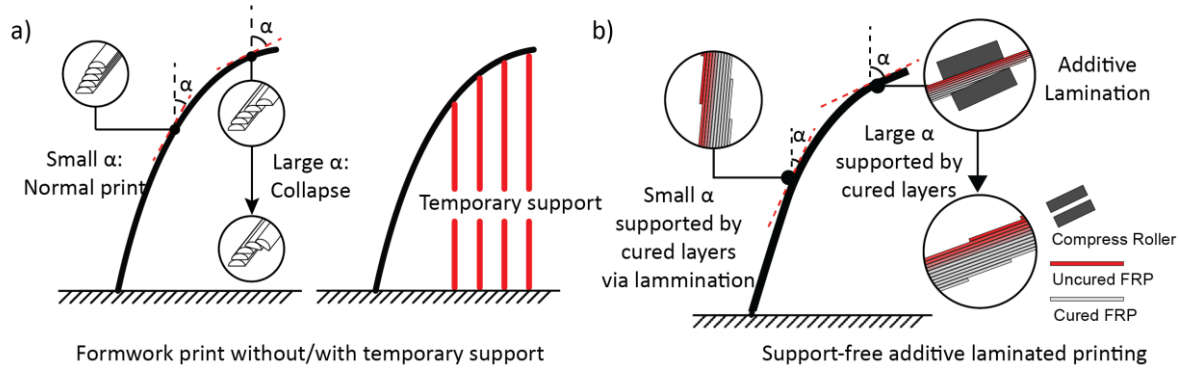

Figure 2. (a) Layer-by-layer deposition 3D printing limitation. (b) FRP lamination 3D printing benefit.

1.2. Reinforcing material in AM

In order to achieve higher performance and more flexible geometries, there is a need for material reinforcement strategies to be integrated into current 3D printing methods. One approach that has shown promise in enhancing the performance of 3D printed products is the incorporation of fiber materials, with MarkForged printer[6] being a typical example. Research has demonstrated improvements in product behaviour through the use of fiber reinforcement, albeit limited to reinforcement within layer[7-9].

Nevertheless, fiber reinforcement also exhibits potential in addressing the weak bonding capacity between layers in 3D printing techniques. This is due to the flexible geometry and superior tensile strength of fiber material[10, 11], which can facilitate effective reinforcement across layers and improve the bonding capacity.

1.3. Motivation

The concept of this paper is inspired from the conventional FRP Fibre Reinforced Polymer (FRP) lamination[12], where layers of fiber material are sequentially laminated and combined with chemical binders to gain achieve desired strength. The lamination approach allows for slight offsets between layers, enabling the product to incrementally grow in length. It is therefore reasonable to adapt 3D printing technologies to FRP lamination, with the aim of achieving a superior interlayer bonding capacity compared to the conventional layer-by-layer deposition method and fabricate the large inclined angle geometry without external support as shown in Fig. 2b.

This paper explores a new design and construction system, namely additive lamination manufacturing (ALM). The ALM utilizes FRP fabric materials and the lamination approach to extrude the formwork

structure, along with the robotic technique to achieve the desired fabrication accuracy, as shown in Fig. 3a.

2. Preliminary design and progress

2.1. Preliminary ALM system development

The system has been preliminarily developed as a proof of concept, namely the 1st generation ALM system (1G ALM SYS). The 1G ALM SYS primarily involves a designated end-effector assembled on the robot arm, as shown in Fig. 3b. The end-effector was composed by a metal framework E and multiple rollers A-D. While the robotic arm ran, the end-effector can passively drive the FRP material to implement the FRP formwork winding process, as shown in Fig. 3c. Two materials utilized in the system are plain-weave glass fiber fabric and lamination epoxy resin, as shown in Fig. 3d.

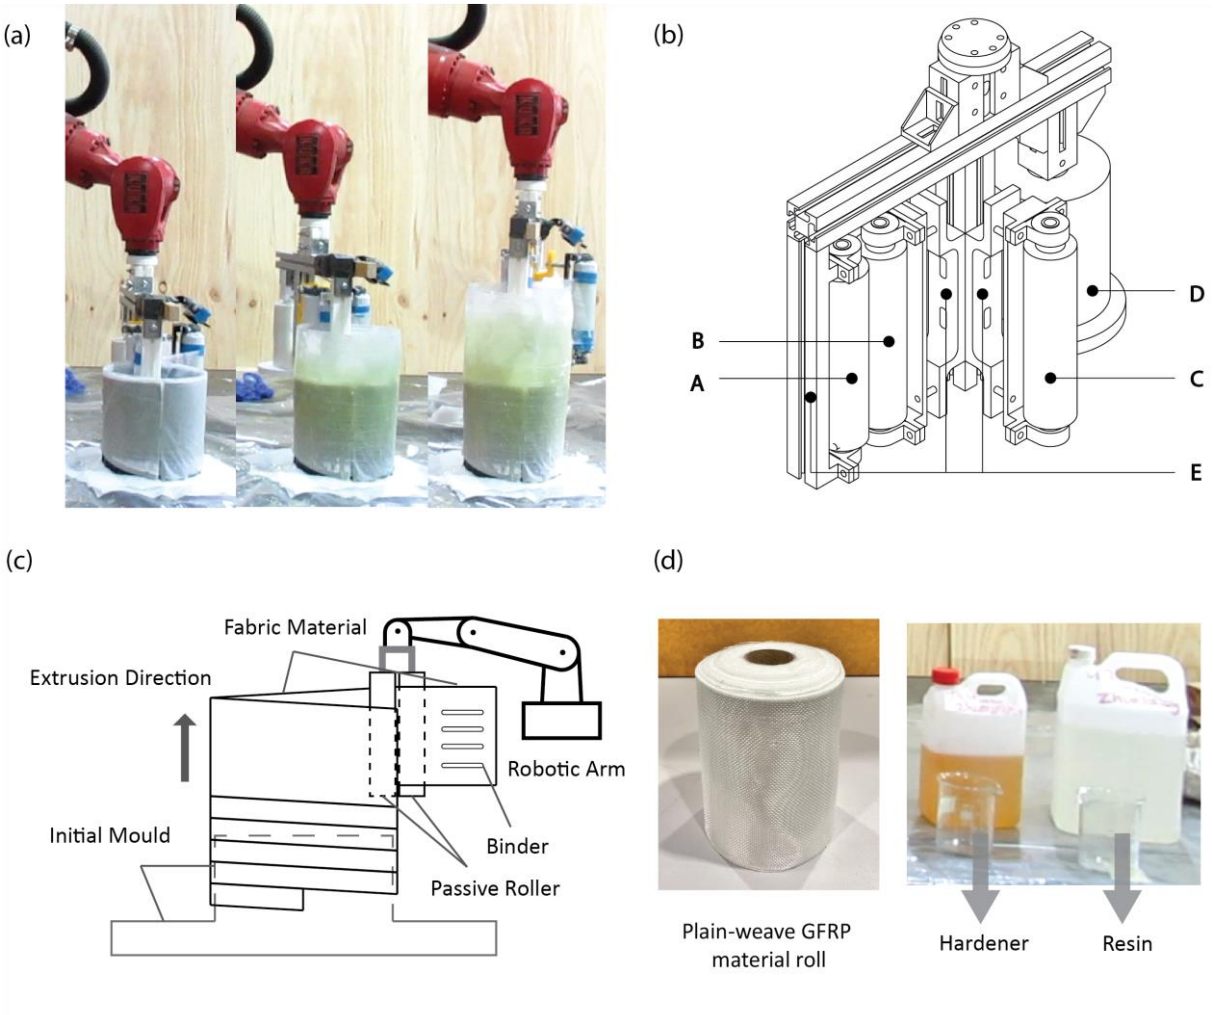

Figure 3. (a) ALM system overview. (b) End-effector sketch. (c) Winding mechanism sketch. (d) Composite material.

The 1G ALM SYS workflow consists of three recurring procedures. The first is the robotic fabric winding to attach the FRP material on the mould. The following is the resin application to manually apply the resin on FRP material and form a composite material. The final is the material curing to solidify the FRP material to provide new moulds for the subsequent robotic fabric winding. All the three procedures will be repeated until the formwork is finished.

Two upright formwork prototypes have been fabricated, one utilizing a standard circular cross section while the other employing a non-standard cross section as shown in Fig. 4a. The findings demonstrate the feasibility of 1G ALM SYS in 2.5 dimensional free-form formwork fabrication.

2.2. Limitation

Some drawbacks have been identified, the first of which is the time consuming. This is due to the utilization of lamination epoxy resin which possesses a short pot-life and long curing time under ambient temperature. To prevent the resin from exceeding its pot-life, the resin mixing process must be carried out in small quantity at a time. As a result, the fabrication requires numerous resin mixing work to continuously apply the resin. Additionally, the FRP composite's intermediate state is significant for formwork winding process as it requires sufficient stiffness to serve as a temporary mould for the subsequent material winding. Consequently, a significant amount of curing time is required during the winding process to attain the desirable material stiffness. Both of these procedures significantly reduce the fabrication efficiency and cause frequent system interruptions.

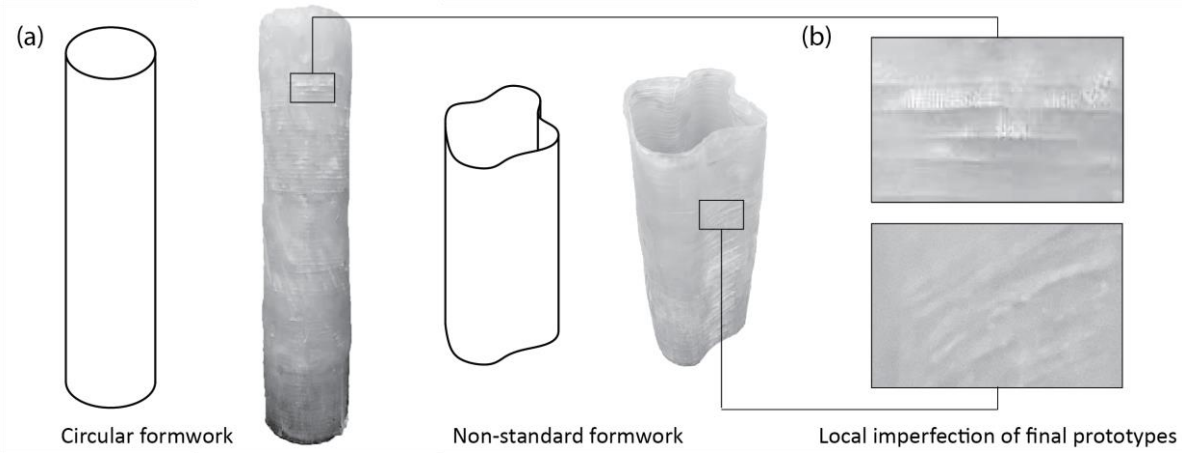

Figure 4. (a) Two upright formwork prototypes. (b) Local imperfection examples.

The second drawback to consider is the geometry imperfection. The 1G ALM SYS employs a plain weave E-glass fiber fabric which possesses remarkable pliability. Despite being mixed with uncured resin, the fabric remains susceptible to deformation. Any external interruption such as the dragging of fiber fabric roll, the sticking from winding roller with the accumulation of excess resin, the manual resin application and the application of heat from heating gun to accelerate the curing process, can result in the local imperfection of fabric material or even affect the cross section geometry. as shown in Fig. 4b.

The use of plain weave E-glass fiber fabric and lamination epoxy resin in 1G ALM SYS was observed to be a challenging fit for this rapid fabrication system. Therefore, extensive research is required to identify suitable material, as the development of appropriate materials is crucial for the successful development of any new 3D printing system[13].

3. Material innovation

The limitations in the 1G ALM SYS were apparently manifested from the preliminary prototyping, highlighting the need for improvement to address its drawbacks, especially regarding to the material. Consequently, efforts have been made to explore alternative materials that could be suitable for use in the ALM system.

3.1. Resin option

The substitution of the lamination epoxy resin is essential for minimizing the time waste and improving fabrication quality. Ultraviolet rays cured resin or UV resin is selected because it can stay in workable

state for a long time and can be cured rapidly once exposed to UV light. There are commonly two types of UV resin in the market, thermoplastic UV acrylic resin and thermoset UV epoxy resin[14]. With the consideration of the exposure to changing environment of fabricated formwork, UV epoxy resin is a preferable material in formwork fabrication to increase the stability of final product.

3.2. Glass fiber options

The plain weaved glass fiber fabric utilized in 1G ALM SYS is highly malleable. While mixing with uncured epoxy resin, it is still prone to deformation even with small, unexpected interruption during robotic winding process. Despite the intended use of UV resin will alleviate such instances by rapidly curing the fiber and making it resistant to interruption, a new material namely self-stick grid glass fiber fabric is still sourced as an alternative option. The self-stick glass fiber fabric has already been pre-impregnated with glue, providing a degree of stiffness while also being malleable.

3.3. Performance of composite material

In order to compare the performance of different composite material, four different combinations were prepared using two kinds of UV resin and two types of glass fiber. A simple flexural stiffness test adapted from ASTM D1388[15] is implemented. As shown in Fig. 5a, the testing set up comprises a sliding platform, a block weight and an angle platform inclined at an angle of 41.5°. The tested samples with a width of 25mm and length of 200mm as shown in Fig. 5b, were placed on the sliding platform and manual slid in 10mm/s, until the sample ends touch the inclined platform and the overhang distance c was measured. If the samples did not touch the inclined platform, they were positioned with 50mm on the sliding platform, left hanging out in the space, and photographed for comparison.

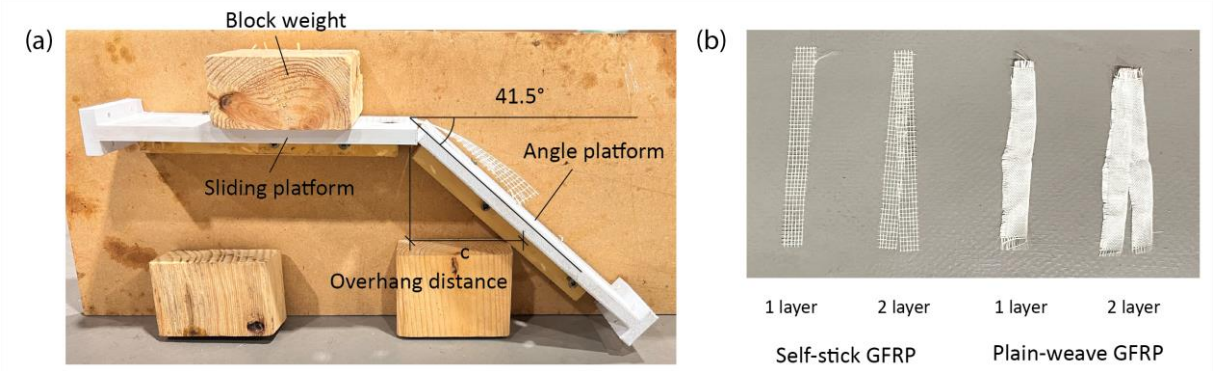

Figure 5. (a) Flexural stiffness test set-up. (b) Tested samples.

As summarized in Table 1, the outcome visually indicates that the stiffness of both types of fabric strips is lower when mixed with UV acrylic resin compared to UV epoxy resin. Additionally, the self-stick GFRP is stiffer than the plain-weave GFRP in the uncured state, but their performance is similar when mixed with the resin, indicating that the composite material stiffness is mainly contributed by the resin rather than the fiber. Furthermore, the minimum curing time of UV acrylic resin is 1 minute, while UV epoxy resin cures in just 10 seconds, making it about six times faster to cure the composite material. In conclusion, UV epoxy resin provides higher flexural stiffness and faster curing time, making it the preferred choice for the later prototyping process.

4. Prototyping comparison

In this section, the fabrication of two prototypes using UV epoxy resin, combined with plain-weaved GFRP and self-stick GFRP, respectively, is described. The performance of the prototypes during fabrication is then compared.

4.1. End-effector development

The end effector in 1G ALM SYS was observed producing large dragging force on the fiber material. As a results, modifications were made to the current 2nd generation ALM system (2G ALM SYS). The first modification involved installing two bearings for the fiber roller holder to reduce the friction during material delivery, as shown in Fig. 6a. Additionally, an extra space was provided to attach one UV torch to cure the material.

Table 1. Flexural stiffness testing results

Overhanging Distance c (N/A for not touch)				
Resin Type		Uncured	UV Acrylic	UV Epoxy
Min Curing Time		0	1 min	10 s
Plain-weave GFRP	Single Layer	53mm	85mm	N/A
				
	Double Layer		N/A	N/A
				
Self-stick GFRP	Single Layer	N/A	110mm	N/A
				
	Double Layer		N/A	N/A
				

4.2. Prototyping progress

The geometry was designed as a curved tube as shown in Fig. 6b to evaluate the performance of ALM fabrication in constructing non-linear extruded formworks. The tube has a length of 400mm and a diameter of 200mm, with a maximum curvature of 0.005mm^{-1}. Both types of fiber material utilized have a width of 75mm, which is the only common dimension available for the two materials. The overlapping number was set at 15.

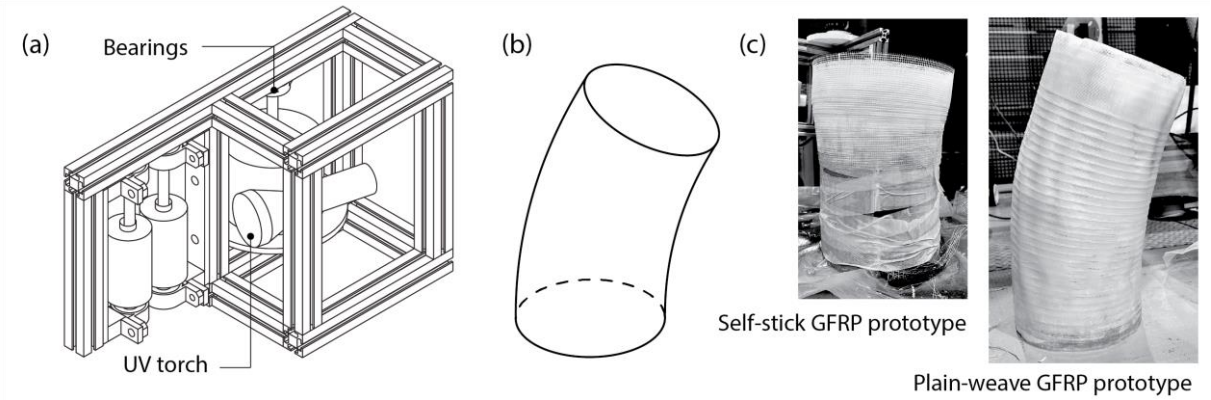

Figure 6. (a) Modified end-effector in 2G ALM SYS. (b) Designed curved tube geometry. (c) Two prototypes with 2G ALM SYS.

The fabrication process is similar to that of the 1G ALM SYS including the robotic winding and resin application. However, curing process is no longer necessary as the UV torch simultaneously cures the UV epoxy resin during lamination. The precedent material can rapidly gain certain stiffness to provide the new mould for the subsequent layer lamination. The final two prototypes are shown in Fig. 6c. The outcome demonstrates that 2G ALM SYS enables rapid fabrication, with a 2-hour production time for a 400mm long component, which is about 3.2 times increase in speed compared to the 1G ALM SYS. The new system also enhances the operability of the process and enables better control of formwork quality.

4.3. Discussion

Some benefits and drawbacks are observed during the two prototyping process. The plain-weave fabric prototype exhibits a high malleability property, rendering it suitable for shaping into any geometry, particularly in the bending section. The material can absorb the resin sufficiently to gain required composite material property and achieve full stiffness. The fabric layers are homogeneous as shown in Fig. 6c while less dragging force to interrupt the formwork geometry. Nevertheless, local imperfections still exist as shown in Fig. 7a. The winding roller with springs is challenging to press the material ideally and once the winding process surpass the initial mould, the fabric wrinkle and formwork delamination will occur.

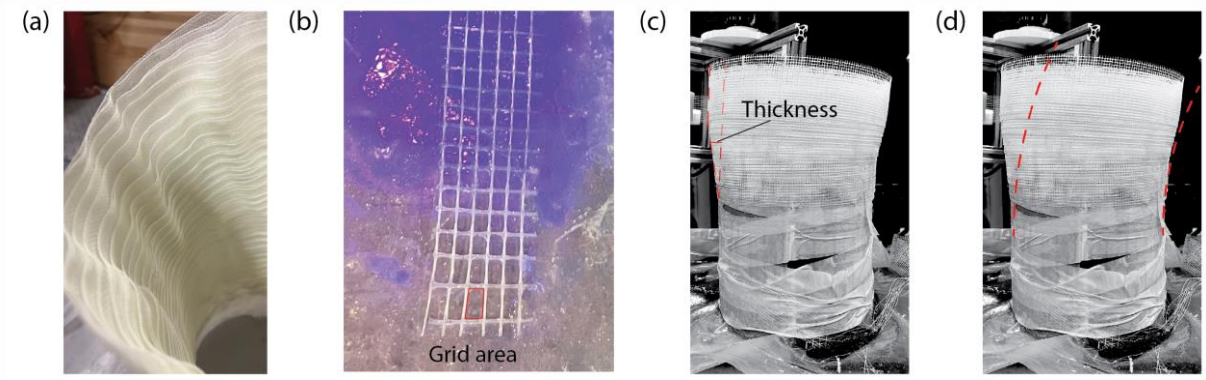

Figure 7. (a) Local imperfection examples in plain-weave fabric prototype. (b) Grid area in self-stick fabric. (c) Accumulating thickness illustration. (d) The profile deviation illustration.

In terms of the self-stick fabric prototype, which has been pre-impregnated, no local fabric wrinkle was observed on the exterior surface, resulting in a smooth and continuous cross section profile for the final prototype, as shown in Fig. 6c. However, the resin absorption capability is lower than that of the plain-weaved fabric as the material has been impregnated and the UV epoxy resin can only fill the grid area instead of penetrating the fiber material, as shown in Fig. 7b. This can lead to a higher likelihood of UV resin filling failure, inducing the composite material to form inadequately and the final prototype to lack sufficient strength. Additionally, the self-stick material has a relatively large thickness. As the formwork continues to extrude, the thickness will accumulate as shown in Fig. 7c, and the prototype will expand outward like a funnel as shown in Fig. 6c, affecting the weaving quality significantly. Furthermore, due to the pre-impregnation of the material, the self-stick fiber has less deformation capability than the plain-weave fiber, and the prototype deviated from the designed profile particularly in the bending location as shown in Fig. 7d.

4.4. Comparison

Thus far, ALM system has been utilized to fabricate several prototypes utilizing different material combinations. In this section, three prototypes with different materials are compared and their advantages and disadvantages will be highlighted in order to select a preferred composite material for the subsequent construction of a double curved shell prototype.

This paper presents three prototypes fabricated with different materials. The first prototype (P_L) utilizes plain-weave fabric and lamination epoxy resin and is produced using the 1G ALM SYS. The second prototype (P_UV) also uses plain-weaved fabric, but the curing process is eliminated by utilizing UV epoxy resin and is fabricated using the 2G ALM SYS. The third prototype (S_UV) is made with self-stick fabric and UV epoxy resin and is also produced using the 2G ALM SYS. Three prototypes are compared in Table 2 in terms of their material winding quality, geometry flexibility, fabrication operability, labour cost and fabrication speed.

P_L prototype exhibits medium winding quality due to the manual interruption and the need for additional resin curing time, leading to local imperfection on the prototype. In contrast, P_UV prototype performs high winding quality due to the fast-curing resin and less manual interruption. S_UV, on the other hand, displays poor winding quality in curved profile due to reduced material deformability. Thus, plain-weave fibers provide high flexibility, while self-stick fibers offer low flexibility. The operability of prototypes that utilize UV epoxy resin is superior to those employing lamination epoxy resin, although not classified as high due to the associated labour costs. The speed of prototypes using UV resin is significantly higher than that of prototypes utilizing lamination epoxy resin. Based on the comparison outcome, the composite material comprising plain-weave glass fiber and UV epoxy resin is the optimal material for use in future prototyping process.

Table 2. Performance comparisons of three fabricated prototypes

PTOTOYPES	**P_L**	**P_UV**	**S_UV**

5. Free-form double curved shell prototype design

Existing prototypes fabricated by ALM are in linear or curved profile with various cross sections and can only serve as column or beam components. Building upon the successful fabrication experience with 2G ALM SYS for free-form linear element geometry, the potential of the ALM system in shell structure fabrication is being explored through the design of a free-form double-curved shell geometry, as shown in Fig. 8a.

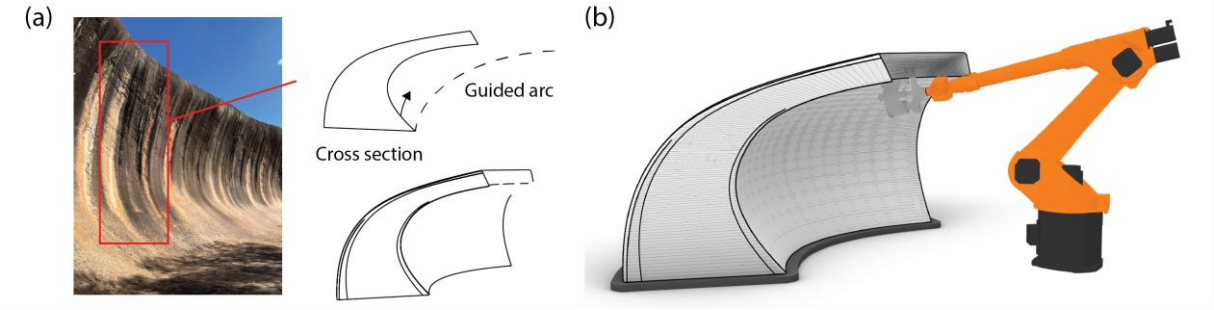

Figure 8. (a) The design progress of double-curved shell geometry. (b) Full-scale shell structure construction rendering.

The shell prototype is inspired from the wave rock in Perth. The generation of the shell begins with a cross section that has a wider foundation and a thinner top, which bends in one direction. Then, the

geometry is swept along an arc to generate a double curved 3D shape. Finally, the four edge corners are filleted to facilitate the fabrication using the ALM system. Although the prototype has not yet been fabricated due to time constraints, a medium-scale version of the shell will be fabricated before the IASS day, and the fabrication of the full-scale version, shown in Fig. 8b, will depend on the availability of time and workspace.

6. Conclusion

This paper has investigated the potential of the additive manufacturing system ALM in the construction of large-scale free-form structures. Several composite materials were evaluated and compared based on their performance with ALM system. As a result, a preferred composite material was selected based on its superior fabrication efficiency, product quality and cost-effectiveness. This material or similar alternatives will be utilized in future system development to further explore the capabilities of the ALM system in the construction industry.

Abstract

As a new trend of architectural system, free-form structure expands the possibilities of architectural form and spatial experience. However, in the real construction process, the lack of connection between the parameters of fabrication morphology and the misalignment of the workflow lead to unsatisfactory results in appearance. The paper proposes a multi-objective progressive optimization method based on fabrication morphology during the process from parametric design to fabrication. The method explores the geometric relationships among free-form surface, component geometry, function, and fabrication feasibility, which could be implemented in 3D modelling. To verify the effectiveness of the method, a project of a lightweight glass canopy structure was executed. The project practiced the fabrication-based optimization method for free-form canopy structures, making a complement for the method with specific digital tools and details in the process. At the same time, the successful implementation of the project demonstrates the effectiveness of the multi-objective progressive optimization method in bridging the gap between design and construction, which allows a good reproduction of the original design while controlling the difficulty of the fabrication and the cost. The working method of revealing the parameters of design and fabrication morphology in the research will help to empower better design and construction of free-form architectural system.

1. Introduction

The free-form structure has become one of the most striking trends in contemporary architecture due to its unique form [1]. The free-form surface was first proposed by the mathematician French mathematician Be´zier and then used for the design of automobile bodies [2]. Nowadays, we can see more and more buildings using free-form structures with complex geometric forms. Some precedents are the Cathedral of Saint Mary in San Francisco and the Philips Pavilion in Brussels [3]. Numerous projects based on free-form structures refresh the perception of architectural geometry, creating an unprecedented spatial experience.

For canopy structures, the application of free-form structures has attracted a wide range of interest from architects and engineers. On the one hand, it brings new forms for architectural design. On the other hand, it poses considerable challenges for fabrication. In other words, there exists an ongoing issue of how to bridge the gap between design and fabrication, so that a desired appearance could be obtained with elements related to fabrication under control [4].

The organization of the architecture itself as a complex system plays an important role in bridging design and fabrication. Due to its large volume and diverse functions, architecture works as a complex system integrated with various elements. The process from design to fabrication is usually a process of rationalizing the virtual model into physical building components. For physical components of the canopy structure, it consists of numerous components in different materials and shapes, such as columns, keels, sub-keels, panels, and auxiliary components that help them work together. These components belong to different subsystems under the whole architectural system, such as the structural system and maintenance system. Thus, when it comes to fabrication, it is a question of how to combine the various subsystems in a self-organized way under a whole building system.

The organization of component systems can be inspired by the research on structural morphology. As one of the most active research areas in architecture, structural morphology aims to bridge the gap between civil engineering and architecture [5]. structural morphology makes architecture a whole in the sense of structure by studying the relationship between the four parameters of form, force, material, and structure in a building system. In this system, the two parameters "form" and "structure" need to be coupled with each other to satisfy the balance of materials and forces [6]. For the architectural design and modelling process, how to express the relationship between the parameters geometrically becomes a key issue.

Studies on architectural geometry have contributed to clarifying the parametric relationship between form and structure [7]. Considerable research has been done by pioneers in order to study the relationship between form and structure. For example, Frei Otto used soap bubbles as a physical model [8] to explore their relationship. A similar approach is Antoni Gaudi's form-finding experiments with hanging chains [9]. With the popularity of computer modelling techniques, some structural form methods based on numerical simulations have been proposed, such as shell structure optimization methods, height adjustment methods, and NURBS-GM methods [10].

Besides, the integration of building functions is an important dimension [11]. For numerous components, they perform different functions, such as supporting, rain protection, drainage, smoke exhaust, and so on. Various types of different parameters are also involved in the whole design process. The way of coupling these parameters has a significant impact on the final completed form of the canopy. In addition, fabrication is another important factor, in which feasibility, difficulty, and cost are taken into consideration [12].

2. Proposal

Based on the research, the paper proposed a multi-objective progressive method for canopy structure based on fabrication morphology, making an explosion to the relationship between parameters involved in the parametric design and fabrication process.

In order to clarify the containing aspect of the method, four main influencing factors are summarized in the process from parametric design to fabrication according to the previous research. They are smooth surface, component geometry, fabrication, and function. And these four factors are respectively oriented to the following issues:

1. For free-form structures, creating smooth surfaces in the design process makes a good beginning for being able to perform rational construction [10]. The aesthetics of the form and construction problems would be brought about by the broken patchwork of free-form surfaces.

2. The way to combine the morphological distribution logic of the keel, secondary keel, panel, or other components to the smooth surface.

3. The problem of how to control the difficulty and cost of the fabrication process by optimizing the geometry of the building components.

4. The method for intervening with functions such as drainage and smoke exhaust based on existing components.

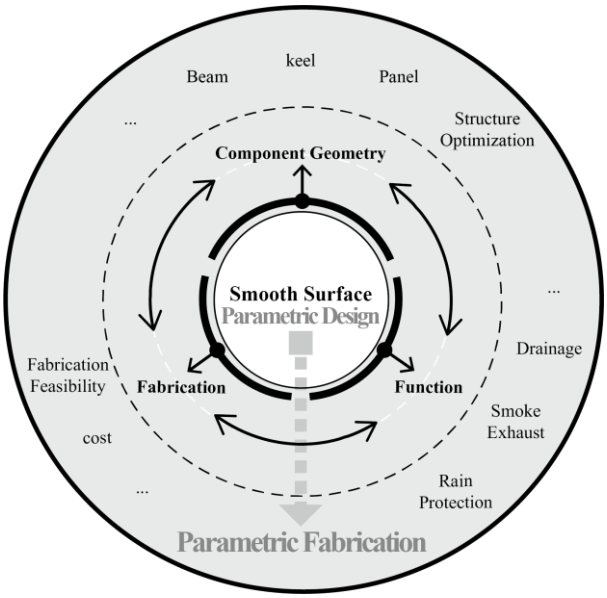

Figure 2. Four main influencing factors in the process from parametric design to construction

For the above problems, the following methods are given in the multi-objective progressive optimization method for free-form canopy based on fabrication morphology:

1. Smooth surfaces are the beginning of the process from parametric design to fabrication. The Non-Uniform Rational B-Splines (NURBS) is an effective method for generating smooth free surfaces. There are two methods of creating NURBS surfaces, one is to create fitted surfaces and the other is to create curves to build surfaces [13]. To judge the smoothness of the surface, curvature visualization is one of the methods [14]. Highlight detection also works.

2. For the component geometry, it's crucial to ensure that the geometry logic aligns with the surface morphology. For example, the positioning line of the keel can be derived from the structure line of the surface. In order for all components to agree on a consistent morphological logic, a positional relationship needs to be established between them. For example, secondary keels have to be positioned according to the main keels.

3. For fabrication, factors such as cost feasibility should be considered, which can be controlled through geometric optimization of the components. One effective method is geometric dimensionality reduction. For example, a double-curved keel can be transformed into a single-curved keel, while a single-curved

secondary keel can be transformed into a straight line, and a curved panel can be transformed into a flat surface. Another way is the standardization of component specifications.

4. When planning functional interventions, such as drainage and smoke extraction, it's important to consider the geometric form of existing components to ensure consistency in their geometric order. The determination of these interventions should be done in conjunction with the existing components' geometric form.

3. Empirical evidence

To validate the above proposal, a real project involving a lightweight free-form canopy structure was implemented using a multi-objective progressive method based on fabrication morphology.

3.1. Basic information

The project is located in Shanghai, China. The sponsors aimed to optimize the geometry of the building to improve its form and appearance while controlling costs. Before optimization, three problems were identified in the initial canopy design:

1. The curved surfaces of the canopy structure were not smooth, resulting in an uneven distribution of keel axis curvature and aesthetic concerns regarding the appearance.

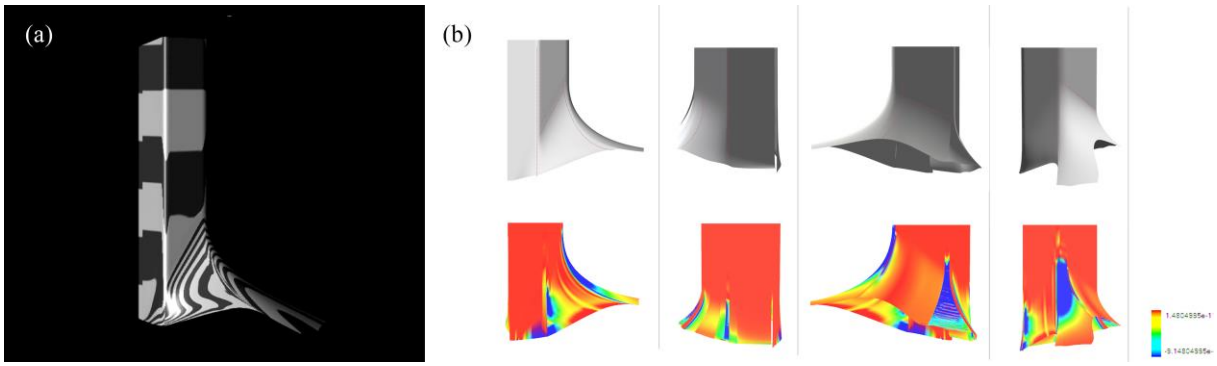

Figure 3. (a) The high light detection results of the original design surface. (b) The visualization of original design curvature on the surface.

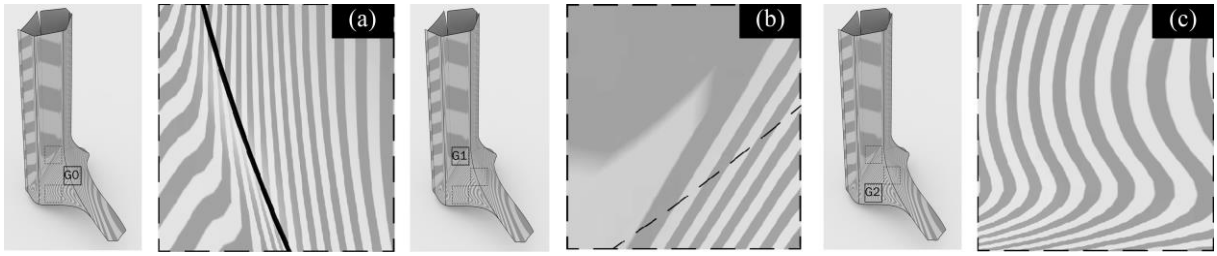

Figure 4. (a) The smoothness of G0 between the two facets. The zebra pattern cannot be connected. (b) The smoothness of G1 inside the facet. The zebra patterns are connected but not smooth. (c) The smoothness of G2 inside the facet. The zebra patterns are relatively smooth.

2. The geometric logic of the components in the canopy was not compatible with the curved surface. The discrepancy between the main keel line and the curved structure line resulted in uneven keel curvature, which had an impact on fabrication. Additionally, the differing orthogonal logic geometry languages of triangular panels and keels reduced the quality of the overall appearance.

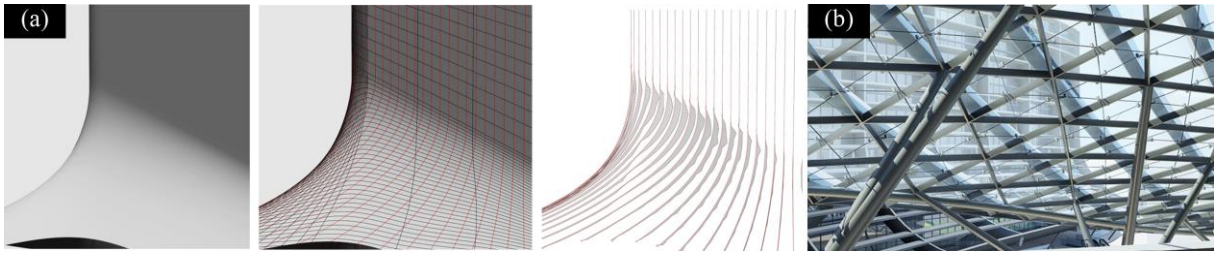

Figure 5. (a) The logic of the structural line and the main keel line in the original design is not consistent, resulting in uneven keel curvature changes. (b) The triangular panels failed to fit into the form logic of the keel.

3. The drainage elements of the canopy were not consistent with the geometric logic of the main structure. The huge drainage ditch had an adverse effect on the appearance of the canopy.

3.2. Smooth surface

In order to enhance the appearance of the original canopy, a multi-objective progressive optimization method based on fabrication morphology was employed. The optimization process began with improving the curved surface design. As a highly versatile method for generating smooth surfaces [12], the sectioning generating method was used, which employs curves in sections to create surfaces.

Figure 6. The process of generating smooth surfaces.

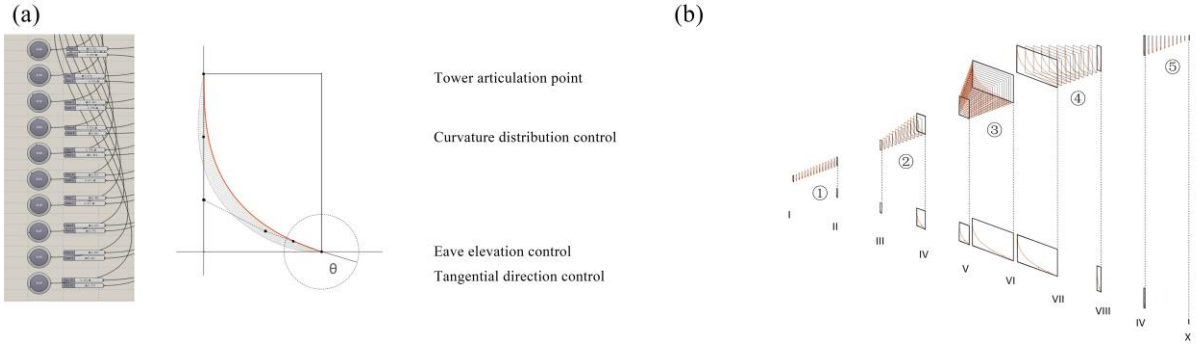

Figure 7. (a) Geometric control mechanism. (b) Generative mechanism of the beam curves.

First, a series of cross-sections were determined based on the overall shape of the building. Next, the curves in the cross-sections are adjusted to control the smoothness of the curve. The project used control at least 3 control points to achieve G2 smoothness at the tower articulation point, and at least 6 control points within the surface to ensure G3 smoothness in the interior of the surface. Then, the section control

curves were then mapped to obtain 5 surfaces. A series of section control curves were generated in excess between the 10 basic section control curves. By connecting the curve control points, section curves were obtained for the articulation between the 5 surfaces to achieve blending between the surfaces. Finally, loft all the section curves to generate the final smooth surface.

3.3. Component geometry

The geometric design of the components aims to achieve two goals. On the one hand, the overall form of all the components needs to be appropriate to the surface form. On the other hand, the geometric logic language between the components is supposed to be consistent.

Keels play a dominant role in the structural form of the entire canopy. In the project, the keels were positioned according to the position of the main structural columns and the form of the reference surface, which transformed the free-form surface into single curved keel curves.

In the process of transforming the keel positioning curve into the geometry of the components, it is necessary to determine the cross-sectional shape and direction of the components. Rectangular shapes were used because of their efficiency. Additionally, the direction of the surface normal vector was used to determine the keel thickness direction, ensuring uniform changes in the cross-section of the member, which had a positive impact on the production and assembly of the components. The position of the horizontal keels was determined based on the vertical keels.

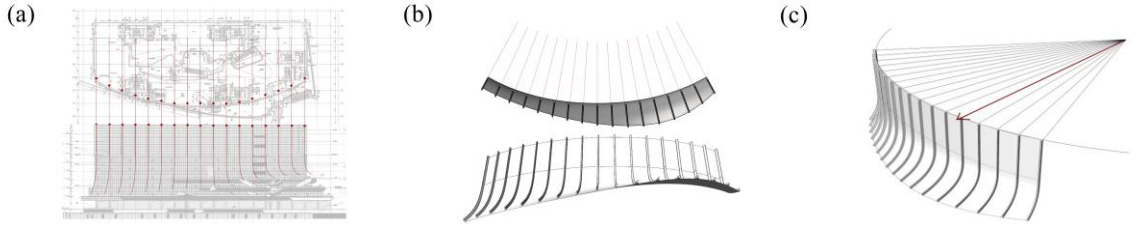

Figure 8. (a) Positioning the vertical keels through the columns. (b) Realizing all vertical keels as a single curve. (c) Determining the section direction of the vertical keels.

The panels should be designed to conform to the shape of the reference surface. In the fabrication process, panels often cannot exist as a single surface. The continuous surface needs to be divided into multiple discrete panels. In this project, the panels were divided twice. The first division was based on the horizontal keel direction. For a better appearance and fabrication ease, the primary division of the panels was positioned optimally according to the spacing of the horizontal keels. Thereafter, the secondary division of the panels was based on the vertical keels.

3.4. Fabrication

During the design-to-fabrication process, geometric optimization for the shape of components based on fabrication feasibility and cost control is important. Standardization of components and reduction of geometric complexity are two effective approaches.

For the single-curve keel in the project, the curvature of the single-curved keels varied across different sections, making it difficult to customize each keel section to the original curvature during fabrication. The curvature of the keels needed to be standardized and optimized. Therefore, a circular arc fitting optimization method was used to optimize the shape of the vertical keels. The algorithm logic can be divided into the following six steps:

1. Given an expected error value.

2. If the chord height < $\triangle x$, optimize directly to a straight line.

3. If the chord height > $\triangle x$: (a) The curve is shifted to both sides by a distance of $\triangle x$. (b) A circular arc tangent to the two new curves is made over the curve endpoints. (c) Then the arc over the curve

endpoints and the radius value between the radii of the above two circles meet the optimization requirements, so a suitable interval of [R-min, R-max] is obtained.

4. Express all the suitable intervals as a vertical line segment.

5. If there exists a horizontal line R can pass through n straight line segments, then the arcs corresponding to these line segments can all be optimized as arcs of radius R.

6. Repeat the above algorithm until all circular arcs are covered.

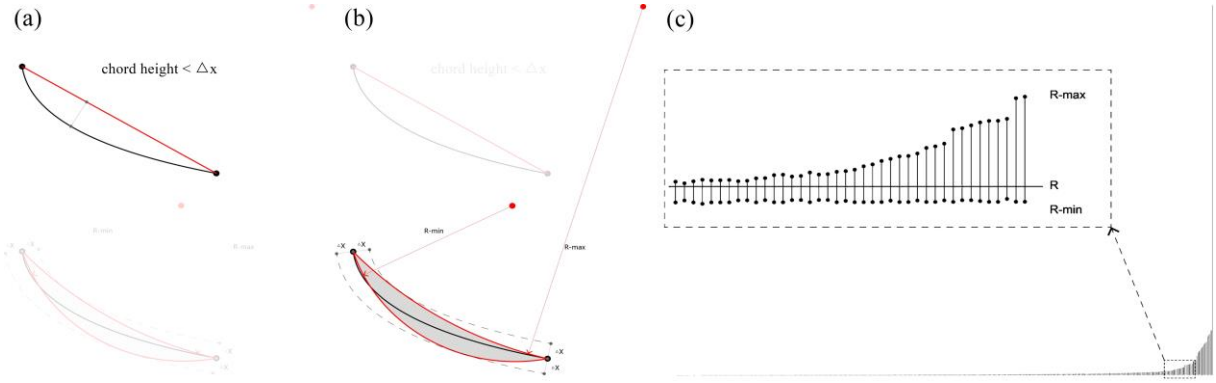

Figure 9. (a) The solution when the chord height < △x. (b) The solution when the chord height > △x. (c) The circular arc fitting optimization method for keels.

Finally, the vertical main keels were divided into 18 types of radius arcs, taking into account the elevation effect. Using an error calculation method, the average error was obtained as 9.5, the maximum error was 43.8, and the median error was 12.0. The overall form was generally consistent with the original design.

In addition, as a consideration for cost control, the geometry dimension of the secondary keels and panels was reduced in the project. The single-curved form of the secondary keels was optimized to a straight line. Similarly, the 3D curved panels were transformed to 2D flat panels.

3.5. Function

After determining the shape and logic of the basic components, the design of component nodes needed to be considered with respect to functional issues, such as ventilation, drainage, and smoke exhaust. In this project, the node design primarily focused on drainage and smoke exhaust concerns.

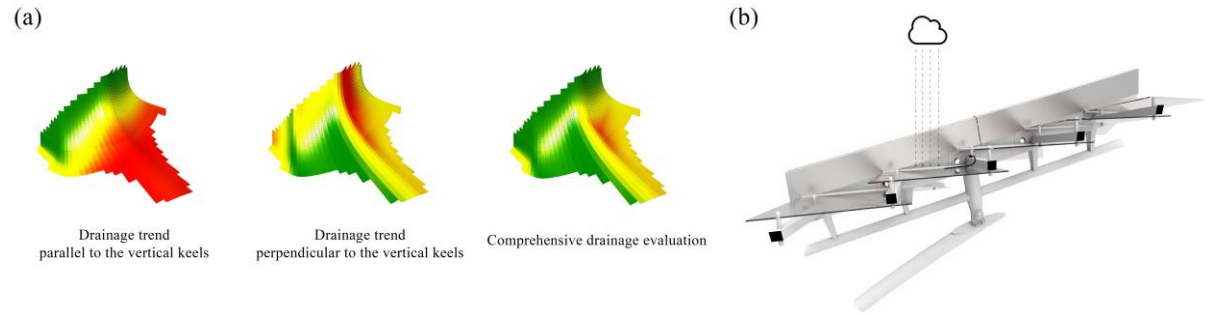

Figure 10. (a) Drainage evaluation. (b) The adaptability of the node to drainage.

For drainage, based on the optimized components, the connection nodes between components were adjusted based on drainage requirements. The drainage measures were carried out in two directions, which were parallel to the vertical keel and perpendicular to the vertical keel. In the direction parallel to the vertical keel, the panels were interlocked. All panels were rotated along the plane parallel to the vertical keel. At the same time, the end of the first panel and the front of the second panel were

overlapped. By placing the horizontal keels in between, on the one hand, the presence of the horizontal keels was hidden, making the surface of the canopy look simpler. On the other hand, the horizontal keels blocked rainwater from leaking into the space under the canopy along the panels. In the direction perpendicular to the vertical keel, the vertical keels opened holes near the panel so that the rainwater could be evacuated along the vertical keel direction. The final rainwater infusion effect is shown in the figure below.

For the adaptability to the function of smoke evacuation, when the two adjacent panels meet, the transverse keel did not completely seal the space between the adjacent panels in the node. Web bars were set between the two panels. This made a gap between adjacent panels, which was conducive to smoke evacuation.

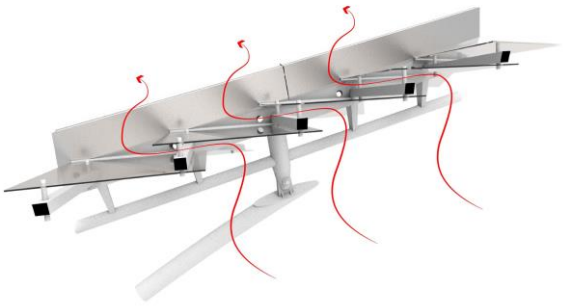

Figure 11. The adaptability of the node to smoke evacuation.

4. Feasibility analysis

The multi-objective progressive optimization method for free-form canopy based on fabrication morphology exhibits exceptional performance in the comparison of the fabrication morphology before and after optimization.

Before optimization, the vertical keel axis curvature variation was significantly uneven, which resulted in an unsmooth surface. This uneven variation was evident in both curvature visualization and highlight inspection, leading to an unfavorable appearance of the finished project.

After optimization, the optimized surface performed better in the highlight inspection. And the vertical keels became uniform in curvature variation based on a smooth surface. Furthermore, components like horizontal keels and panels also showed a better appearance.

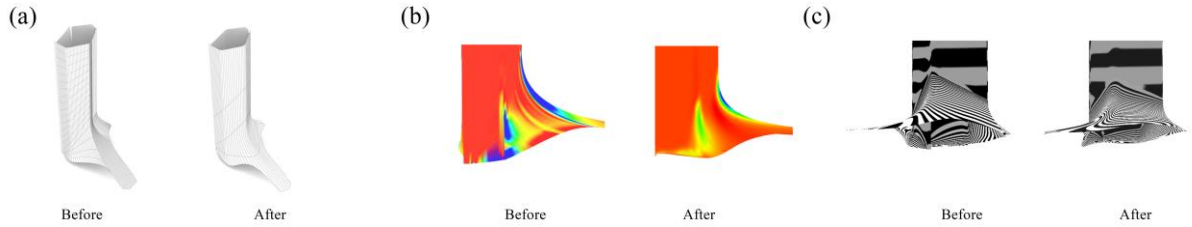

Figure 12. (a) Comparison of curvature quality. (b) Comparison of curvature of curved surfaces. (c) Comparison of highlight detection results.

In addition, for the component geometry, the logic used to generate the keels did not align with the surface morphology before optimization. And the glass panel position distribution of the triangles did not match the position of the keels. After the re-optimization of the logical relationship between the curved surface, keels, and glass panels, the canopy finally exhibited a significant improvement in its appearance.

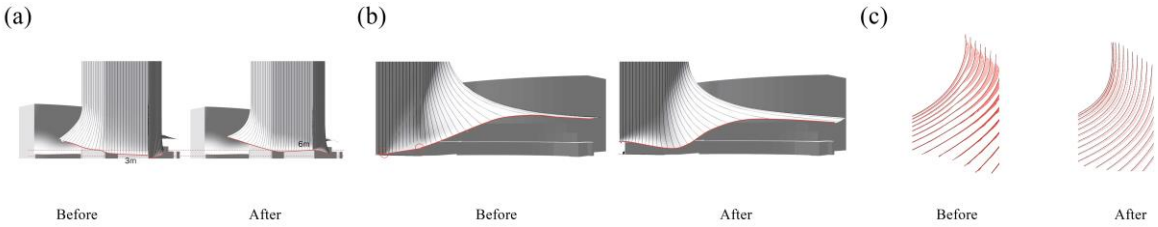

Figure 13. (a) Comparison of elevation appearance. (b) Comparison of elevation appearance. (c) Comparison of curvature of curved surfaces.

In terms of functional organization, interventions of the components required for drainage and smoke exhaust were aligned with the geometric logic of keels and panels.

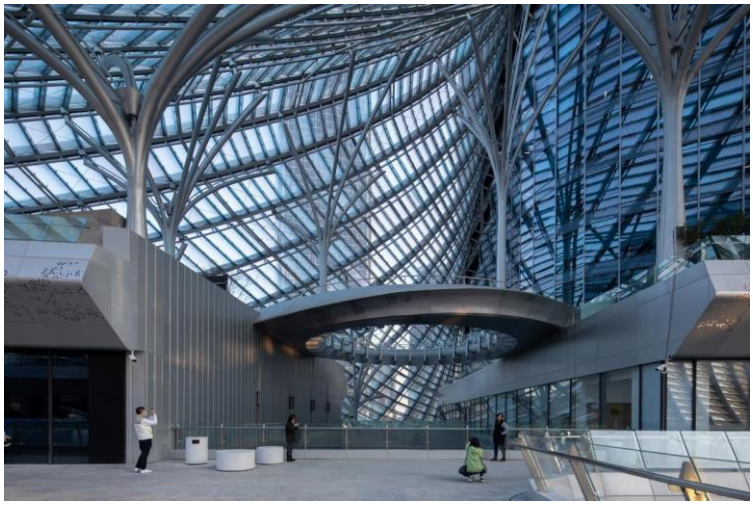

Figure 14. Picture of the interior appearance after optimization.

5. Conclusion

The paper presents a multi-objective progressive optimization method for free-form canopy based on fabrication morphology. The method aims to address four key factors encountered in the process from parametric design to fabrication in building projects. These factors include the smoothness of the design surface, the consistency of the geometric component logic, the fabrication-based component optimization, and functional nodes intervention. The smoothness of the free-form surface can be achieved by using the NURBS surface modelling method. The consistency of the geometric component logic is ensured by extracting geometric component positioning curves from the structural curves of the surface. At the same time, different types of components should be positioned to achieve a consistent geometric order. The geometry optimization based on fabrication can be achieved by component standardization and geometry dimension reduction. Nodes involving other functions need to intervene while maintaining the consistency of the logic ordering different components.

In order to verify the effectiveness of the method, a real project of a lightweight free-form canopy was executed in Shanghai, China. The project complemented the method with a concrete operational approach. The success of the project demonstrates the effectiveness of the multi-objective progressive optimization method in bridging the gap between design and fabrication. It can achieve a good reproduction of the original design while controlling the difficulty and the cost during fabrication.

Overall, the multi-objective progressive optimization method for free-form canopy based on fabrication morphology proposed in the paper aims to establish a parametric link between design and fabrication in the way of architectural geometry, hoping to inspire the design and fabrication of free-form canopy structures.

Acknowledgements

The implementation of the canopy structure project in the paper benefited from the collaborative efforts of all the participants. In the project, Professor Mike Xie from RMIT, Wei Shen, Qiang Zhou, Jin Wang, and Yanning Jiang from Ameba Engineering Structure Optimisation Research Institute made contributions to the structural design. Professor Philip F. YUAN from Tongji University, Li Han from Shanghai Fab-Union Technology Co., Ltd., Tianrui Zhu, Shaoying Lei, and Yuhao Fu from Archi-Union Architects contributed to the architectural geometry optimization.

Designing the West Gate Tunnel portals: Timber gridshells

Andre F. PEREIRA[a,*], Benjamin COOP[a], Dmitry ZELENKIN[a], Richard WHITFIELD[a], Kevin BERRY[a]

[a,*] Taylor Thomson Whitting (TTW)
andre.pereira@ttw.com.au

Abstract

This study presents the architectural geometry and structural engineering work developed by TTW for the West Gate Tunnel Project (WGTP), a 4-kilometre toll road under construction in Melbourne. The portal structures, situated above the tunnel dive structures, feature architectural timber transition elements at the tunnel entrances and exits. Two patterns were examined for the geometric discretisation of the timber structures: diagonal (diamond-shaped) and triangular grid. The diagonal grid scheme employed genetic algorithms to approximate the portal envelope to simple surfaces, subject to constraints such as surface tangent continuity, base support positions, and road vehicle clearance. The diamond-shaped topology was generated using geodesic curves on the simplified envelope and COBYLA optimisation. Furthermore, the number of node connection types was minimised through mesh relaxation and custom form-finding techniques. The triangular grid scheme featured primary parallel hoops and secondary diagonal infill members. The opening angle between primary and secondary timber members was determined through constrained optimisation. A limited number of bracket connections were established for the primary timber members. Both schemes employed in-house structural timber design libraries compliant with AS 1720.1:2010, integrating them into the structural optimisation processes. The combination of optimisation techniques, custom timber design libraries, and automated analysis workflows facilitated cost reduction and improved fabrication while preserving the architectural design integrity.

1. Introduction

The West Gate Tunnel Project is a transformative project that will deliver an essential alternative to the West Gate Bridge, facilitating faster and safer commutes while diverting thousands of trucks from residential streets. The project encompasses three key components: the tunnel structure, an elevated roadway section, and an upgraded section of the West Gate Freeway.

Three primary portal structures are situated at the entrances and exits of the tunnel. Designed by architects Wood Marsh, the portals feature architectural timber transition elements, known as the Eel Nets, leading into the tunnel, and a concrete ventilation structure with a feature clad steel diagrid [1]. The Eel Net timber structures, inspired by the Aboriginal nets and traps used to catch eels by the indigenous inhabitants of the land, serve as a cohesive architectural element, providing a seamless transition between the open and tunnel environments.

The timber structures take the form of structural gridshells constructed out of glue laminated timber. The largest of the structures, the Northern Portal, is located adjacent to Yarraville Gardens on Whitehall Street, with the timber component measuring 116 metres long, 39 metres wide, and 40 metres high (Figure 1). Most of the figures, results and numbers in this paper refer only to the Northern portal.

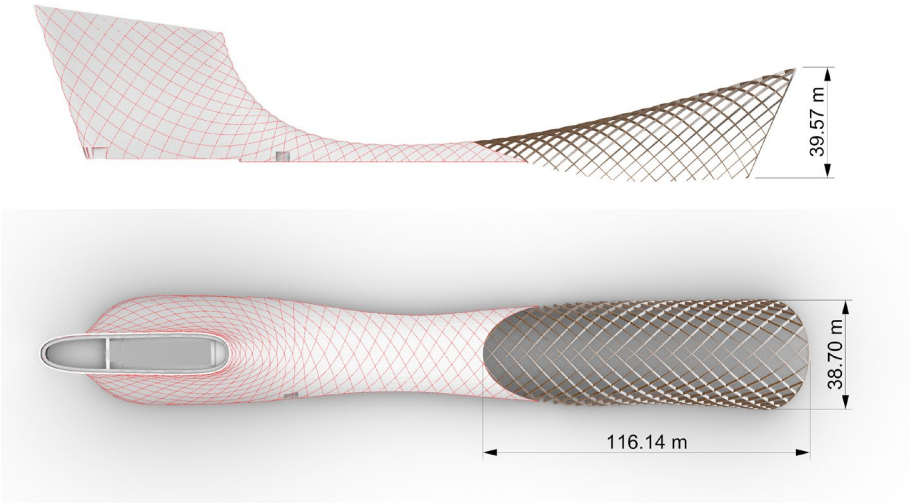

Figure 1. Northern timber portal dimensions and original diagonal gridshell topology.

Taylor Thomson Whitting (TTW) were engaged by the managing contractor for the tunnel project, CPBJH Consortium, to advance the architectural concept design for the timber structures. The concept design aimed to determine the structural feasibility of the architectural scheme, assess the structure's impact on the supporting tunnel structure, and identify potential areas for optimisation to benefit the project as a whole. TTW's work contributed to the successful awarding of a subcontract package.

A constraint led design approach was adopted, considering structural design standards, durability, vehicular impact, transportation, fabrication, erection and maintenance. The scope of this paper, however, is limited to the generation of the geometry (and associated topology) of the timber portals and the structural optimisation work carried out to design the timber members. We utilised computational design and optimisation methods to establish an automated end-to-end process, enabling the effective analysis and validation of numerous design iterations. This approach facilitated the identification of optimal solutions and, ultimately, the delivery of a high-performing and visually striking timber structure.

This paper is organised into three main sections. Sections 2 and 3 describe the geometry work developed for the two different structural gridshell topologies considered – diagonal and triangular. Section 4 addresses the work conducted for the structural design and optimisation of the timber members and connections.

2. Geometry: diagonal gridshell

The initial gridshell design (as proposed by the Architect) featured a two-way diagonal structural grid, as illustrated in Figure 1. The initial design had two primary issues. Firstly, every timber member exhibited curvature in two directions. Secondly, all members and all nodes were unique.

As the timber members' axis traced around the proposed shape, this required members curved about both axes and twisted along their length with the degree of curvature/twist varying non-uniformly along the members. Twisted members reduced or eliminated uniqueness in member types and node connections; however, it considerably limited timber fabrication partners while substantially expanding costs. In addition, very few fabricators can offer twisted timber glulam members. While there are methods to alter the shape to eliminate the twist, the resulting geometrical modifications to the envelope would be substantial and significantly affect the appearance of the timber structures. As such, this approach was not considered feasible. We addressed this with a step change in timber member rotation at the node positions and converting all members to arcs (and therefore planar).

This section outlines the work undertaken by the project team during the first half of 2018. By adjusting the overall shape and topology of structural members, we aimed to enhance structural performance, cost efficiency, and buildability by increasing the repetition of member and node families while preserving the architectural vision.

2.1. Methods

The geometry optimisation process consisted of three primary steps: (1) envelope surface rationalisation, (2) initial topology generation, and (3) topology optimisation. The goal of the first step was to create surface envelopes that rationalised the envelope, laying the foundation for an optimised topology. The second and third steps focused on organising structural members in patterns that enhanced the repeatability of nodes and member radii.

2.1.1. Relevant connection node parameters

The connection node was designed to have a circular steel hollow core and end plates welded to it. The timber members' glued rods were bolted to the end plates (Figure 2). The parameters considered for clustering different families were the three angles shown in Figure 2:

1. Alpha (α): angle between consecutive members on the plane perpendicular to the node;
2. Beta (β): angle between node direction and tangent of the member at the node;
3. Gamma (γ): twist angle between node direction and member plane.

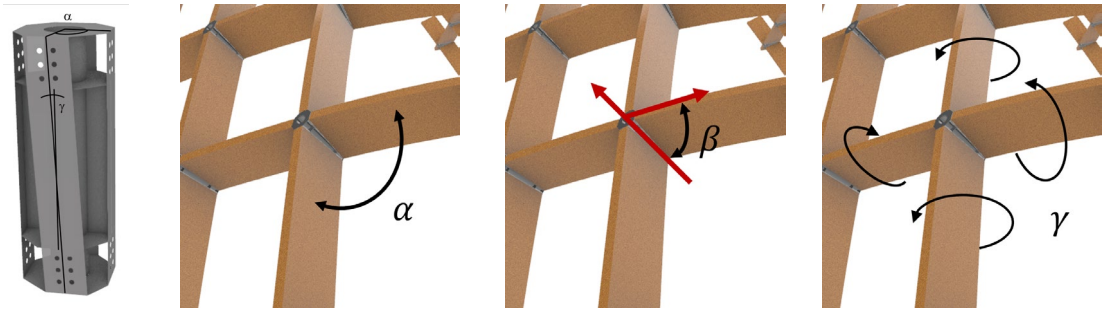

Figure 2. Parameters used for node cluster description: Node normal shown as red arrow, angles α, β and γ were used to describe node cluster family.

The beta angles (β) were considered to be zero for all nodes, as all arcs should meet the node at a 90º angle. Therefore, only alpha and gamma were considered for the clustering exercise.

2.1.2. Envelope rationalisation

We adapted the freeform architectural envelope to simple surface patches, derived from cylindrical and conical patches. Our initial step involved identifying the best-fit cylindrical surface for the envelope's top section, illustrated in yellow in Figure 3. This surface served as a reference for fitting the other surface panels.

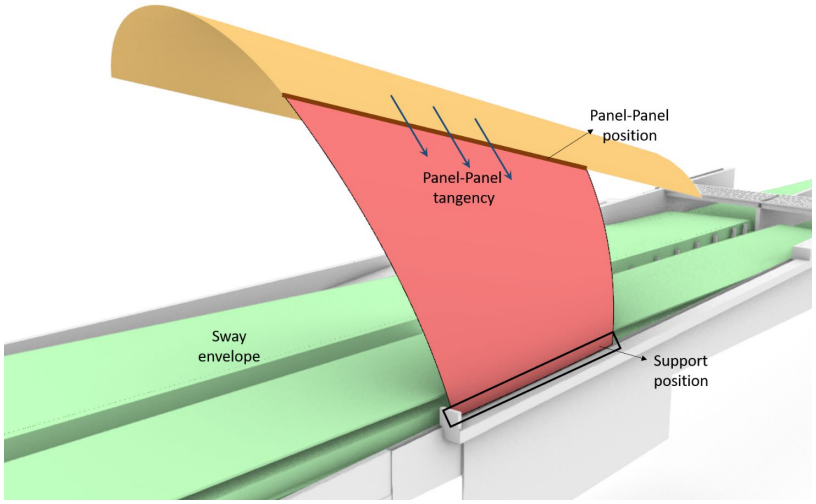

Figure 3. Form finding envelope through rational shapes. Constraints in surface fitting considered for the optimisation process: panel-panel continuity, support location and sway envelope.

We employed a genetic algorithm method (Galapagos [2] plug-in for Grasshopper/Rhino) to determine the multiple parameters that defined optimal conical surfaces (example shown in red in Figure 3) for the remaining envelope sections. Local search methods would have been valid approaches given the nature of the optimisation problem. The following architectural constraints needed to be met:

1. Panel-support interface: the surface edge at the base must coincide with the concrete capping beam of the tunnel dive structure retaining walls.
2. Panel-panel interface: adjacent surface panels must share edge positions and tangent vectors to ensure surface continuity and smooth transitions between surface patches;
3. Vehicle kinematic envelope: the fitted surface must provide adequate clearance for the outline of the space occupied by passing vehicles in motion, considering effects such as tilt, sway, etc.

2.1.3. Initial topology generation

The starting layout of the two-way diagonal topology was established by intersecting two sets of geodesic curves, each spanning a different direction and approximately mirrored about the central axis of the surface. Geodesics, defined as the shortest paths on curved surfaces, form helices when generated on cylinders. By arranging helices in a two-way grid, we can ensure consistent member profiles and node connection alpha and gamma angles throughout the entire topology. However, these properties are not present on conical patches.

To identify parallel geodesic curve sets across non-cylindrical patches, the following process was employed:

1) The top cylindrical section was divided into panels using equally spaced geodesic curves;
2) For each conical surface, initial geodesic curves in both directions were determined to maximise tangency with top cylinder members;
3) A final set of curves, aiming to be as parallel as possible to the initial geodesics from step 2, was calculated.

The generation of curves in steps 2 and 3 was achieved using the Constrained Optimisation by Linear Approximation (COBYLA) method. We used COBYLA to find the parameter t of the support level line that resulted in tangent or parallel geodesics. This process is illustrated in Figure 4.

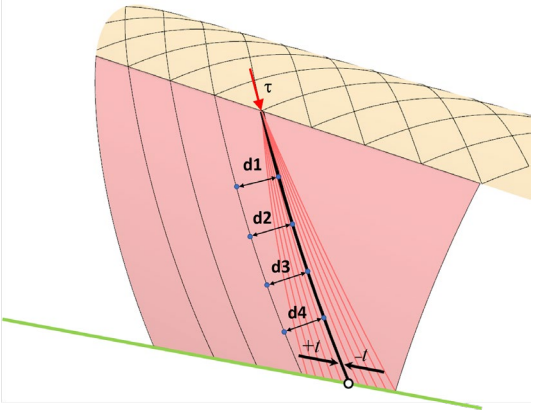

Figure 4. Finding geodesics curves that maximise tangency between curves of different surface panels and parallelism between curves on the same surface patch.

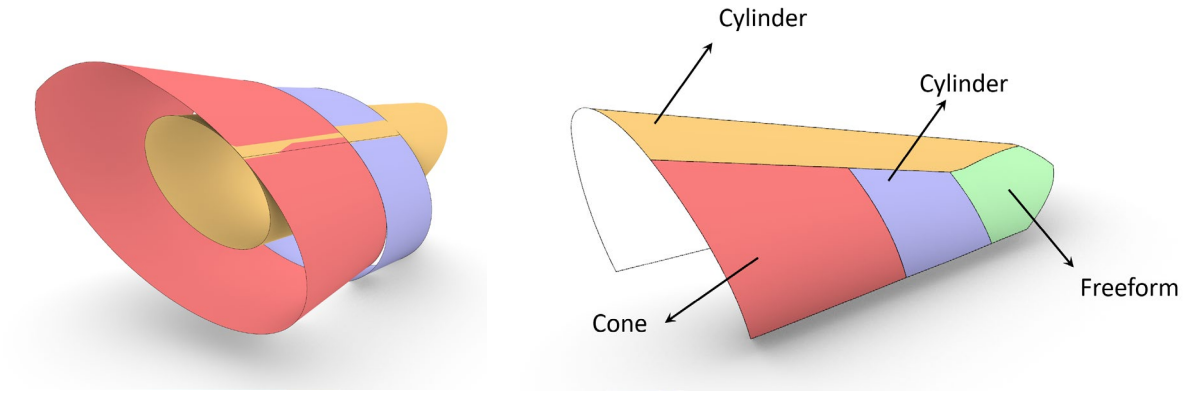
The geodesics found exhibit torsion along their length approximating to the direction of the surface normal sampled at various points along the curve. Because the structure in this area was not intended to be clad, it was not necessary to align the curve to be normal to the surface. Between points of intersection, the twisting geodesics were discretised as circular arcs, each having two parameters: total length and radius. The radius is the most relevant parameter in terms of buildability. To reduce variation in member radii, we clustered member radii into groups of similar values. Subsequently, the radii within these clusters were replaced with their corresponding mean values.

2.1.4. Structural node rationalisation

The use of rational surface patches and our topology generation approach resulted in connection nodes with small variability. However, the resulting configuration still presented a dispersion of alpha angles that required additional steps to maximise the repetition of node families. Gamma angles did not require further improvement since these were set by the relative rotation of consecutive arcs.

Alpha angles were improved through dynamic relaxation to the structural grid using the Kangaroo live physics plugin for Rhino/Grasshopper [3]. We combined base overall shape Kangaroo 'goals' to impose geometric boundary conditions (front arch node position anchors, node proximity to envelope, and top gridshell ridge nodes along generating curve) and a custom 'goal' to guide alpha angles to desired values.



Upon convergence, we took the 'relaxed' structural gridshell and used Accord's [4] mean shift clustering algorithm, with a bandwidth of 0.115, to identify connection node families. Mean shift data points were defined as a sorted and normalised list of angles, in degrees. We clustered both connection node parameters (alpha and gamma) separately and obtained two distinct sets of alpha and gamma connection families. The resulting tolerances were 0.7 degrees for the alpha angle and 0.4 degrees for the gamma angle distributions.

Final node types were defined by the combination of individual alpha and gamma families.

2.2. Results

2.2.1. Envelope rationalisation

The surface envelope was rationalized into seven distinct patches, of which three were cylindrical and two were conical. Freeform surface patches were used in the back region, adjacent to the vent shaft cladding. Figure 5 displays the resulting surfaces and patches obtained from this initial step.

(a) (b)

Figure 5. Example of surface reconstruction for the North portal, composed of two cylinders, one cone, and a freeform region. Expanded surfaces shown in (a) and final trimmed arrangement shown in (b).

2.2.2. Gridshell topology and structural node rationalisation

The rationalised surface envelopes in conjunction with clustering optimisation allowed to reduce the time required for preparing different formworks. As a result, labour costs were also reduced.

Figure 6 and Figure 7 show the distribution of alpha angles for our initial grid topology (generated from the methods described in Section 2.1.3) and for the relaxed gridshell (Section 2.1.4). In the regions that exclude of the front arch, top ridge, and base supports (all of which required a unique connection types), the alpha angles were concentrated around either 79.1 or 101.6 degrees, initially within a range of about 10 degrees. The dynamic relaxation of the gridshell successfully reduced the range of most alpha angles down to 0.9 degrees. Figure 8 shows the final alpha and gamma angles.

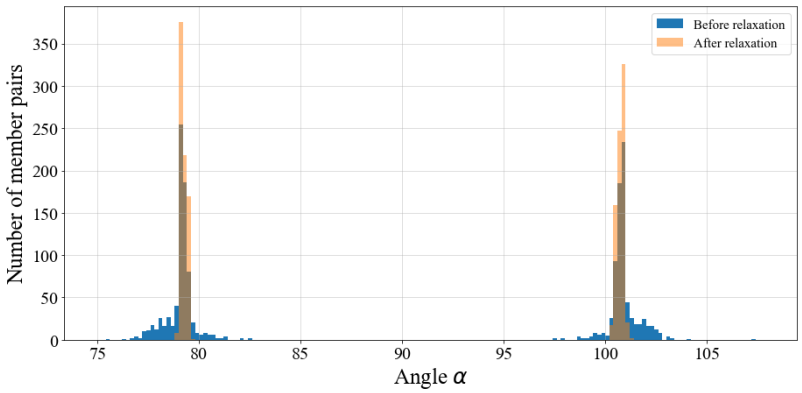


Figure 6. Histogram showing alpha angles before and after mesh relaxation (excl. front arch and top ridge nodes).

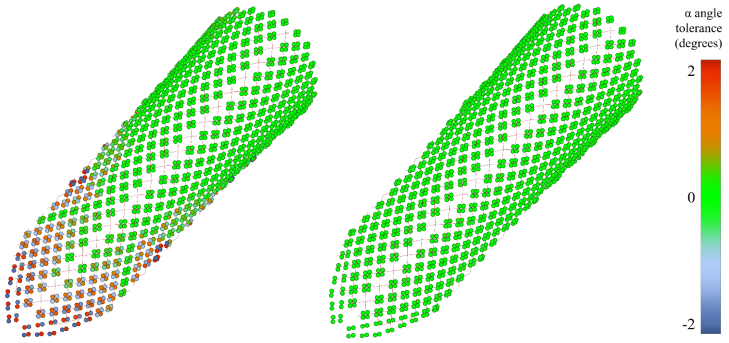

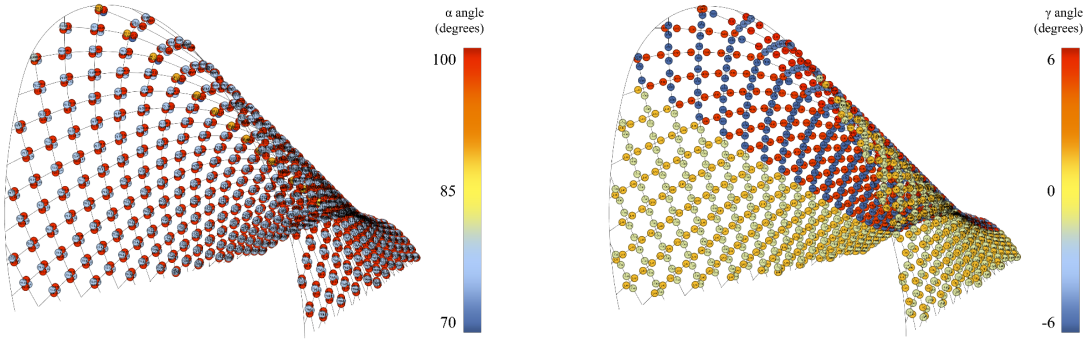

Figure 7. Alpha angle deviation from target angles before (left) and after (right) mesh.

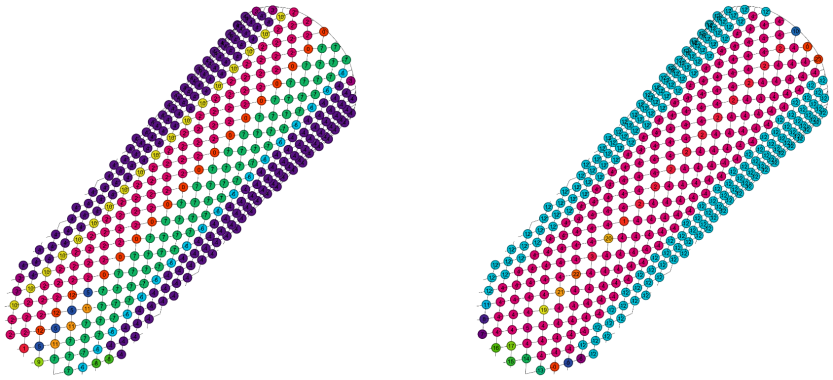
(a) (b)

Figure 8. (a) Alpha angles obtained after relaxation. (b) Gamma angles.

Connection node angles were clustered in the alpha and gamma space into 25 and 12 families, respectively, within the tolerances defined in Section 2.1.4. The cluster families obtained for each case are shown in Figure 9 below. When combining alpha and gamma clustering, 32 total families of nodes are required in the obtained topology, 21 of which lie on the freeform surface shown in Figure 5. When compared to the original concept, developed prior to TTW's engagement, the geodesics approach required roughly 10x fewer families of nodes and as such 10x fewer sets of tooling to fabricate. Figure 10 below shows the 311 cluster families for the initial concept against the geodesics approach.



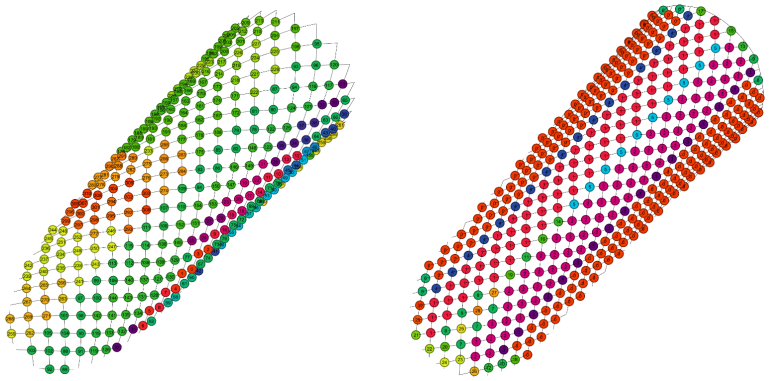


Figure 9. Clustering families when alpha (left) and gamma (right) are computed in isolation. 25 different alpha families were obtained within a tolerance of 0.7 degrees. For gamma, 12 families were required within a tolerance of 0.4 degrees.

3. Geometry: triangular gridshell with parallel hoops

To facilitate erection, an alternative scheme featuring two 'hierarchies' of architecture was proposed: primary parallel 'hoops' and secondary diagonalised infill members, as shown in Figure 11. The scope of TTW's geometric work for this scheme involved discretising the surface envelope in such a way that both the timber members and the cladding panels exhibited consistent patterns and smoothly transitioned between different areas. This work was conducted during the latter part of 2019.

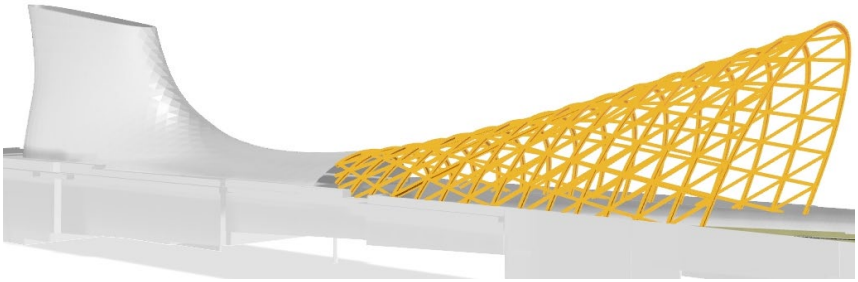

Figure 11. North Portal - Parallel hoop scheme

3.1. Methods

3.1.1. Parallel Hoop Formation

With the original geometry being based on the non-rational surface, the curvature along the length of the beam varied in accordance with the original shape and was asymmetric. After discussions with timber manufacturers, it became clear that planar curved glulam beams could be constructed with varying curvature along their length at no additional cost. For this reason, consistent curvature was not part of the rationalisation of the hoops. Instead, the hoops were converted into Bezier curves and made symmetric. From a visual perspective, the human eye can discern curvature down to the 3rd derivative of a curve (with the first, second, and third derivatives being slope, curvature, and rate of change of curvature, respectively). As such, at the connection between members, not only should the curvature of the members match but also the rate of change of curvature, so that this is not perceived as a discontinuity of the hoop. Therefore, knowing that these members would be subdivided for shipping purposes, the Bezier curves created were of the third degree, with knot vectors based on the chord length of the sampling points. The curves and curvature graphs for the original and proposed hoops can be found in Figure 12.

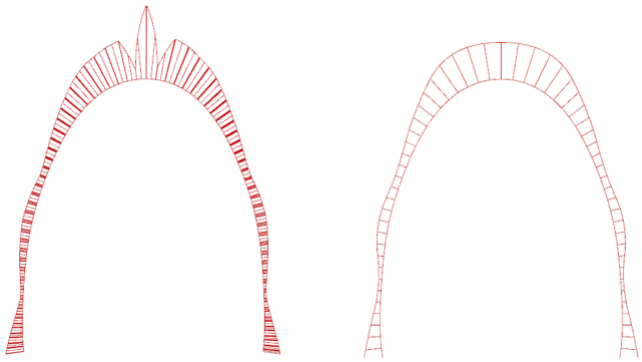

Figure 12. Comparison of non-rational hoop curvature with smoothed symmetric curvature.

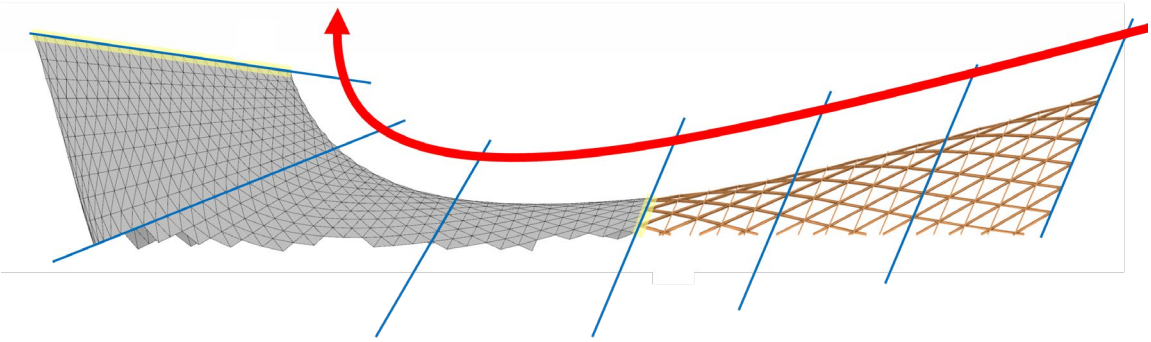
3.1.2. Discretising the envelope

The parallel hoops from the timber structure set the rhythm for the panel arrangement in the cladding section. We opted for generating both timber topology and cladding panels simultaneously to achieve a smooth transition between the 'Eel Net' structures and Vent Shaft panels. Figure 13 illustrates the process. A sequence of planes, starting parallel to the planes of hoops of the timber structure, were gradually varied along the Vent Shaft cladding region. The curves resulting from the intersections between the surface envelope and planes were utilised to create the cladding's edges of the Vent Shaft. These curves were then divided into equal length portions to generate the vertices of the panels. Coop et al. 2023 [1] describes the work by TTW for the concept design of the vent aluminium façade and supporting structural steel.



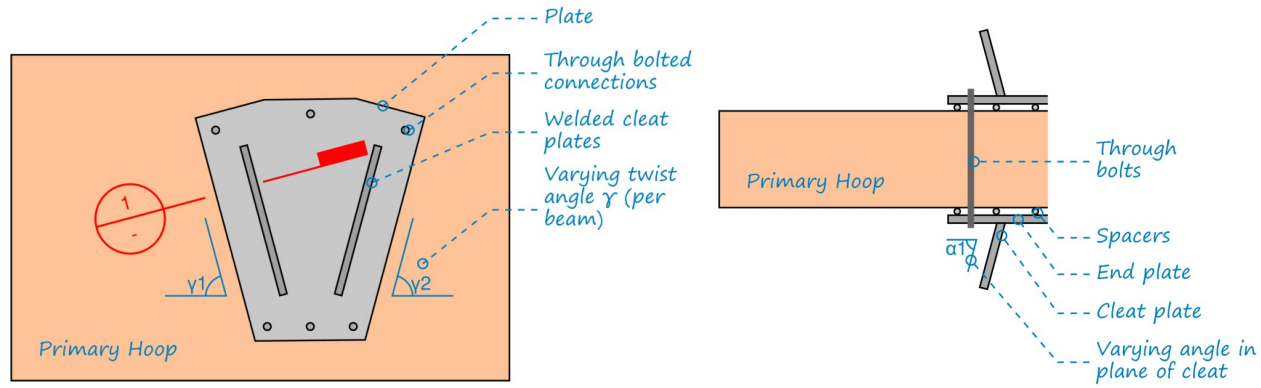


Figure 13. Full envelope discretisation approach. The parallel hoop planes were used to define some of the cladding panel edges.

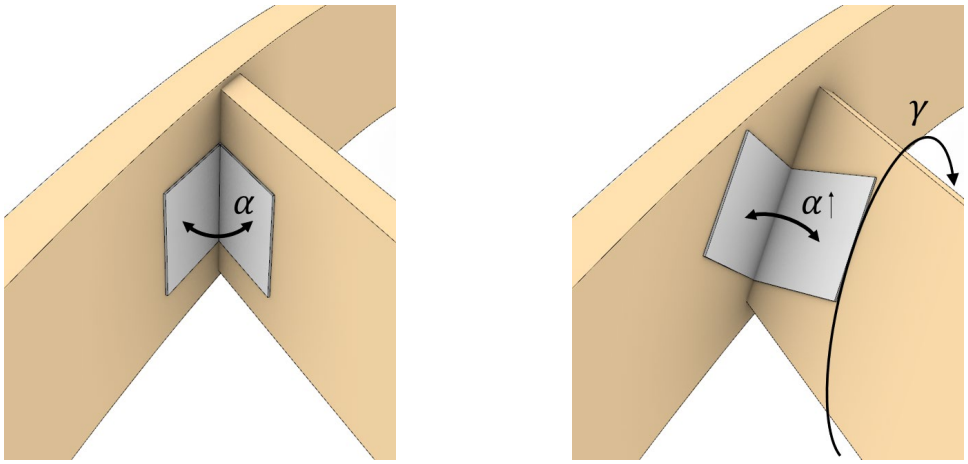
Akin to the scheme described in Section 2, as the member axis trace around the proposed shape, an inherent twist occurs. The same rationalisation of the timber members into arcs was used for the gridshell method, with the same alpha (α), beta (β), and gamma (γ) angles existing at the primary and diagonal connection interface. The connection concept is illustrated in Figure 14.

This detail removes the complexity of fabrication associated with the gamma angle in the connection node presented in Section 2, and therefore, alpha was the only parameter we rationalised. The alpha angle would be materialised in the connection as the bracket angle between primary and secondary members, and its rationalisation would reduce the number of jigs required for connection fabrication.

Elevation on Connection *Section1 - 1*

Figure 14. Connection Details Showing α and γ.

Rationalising alpha angles for this scheme was significantly simpler when compared to previous approaches. Alpha and gamma angles are intrinsically associated. By rotating the secondary timber member (modifying gamma), the alpha angle would change according the Rodrigues' rotation formula [5]. We used COBYLA to find the smallest rotation of the timber members such that the respective connection alpha angles would snap to a prescribed list of values, as illustrated in Figure 15.



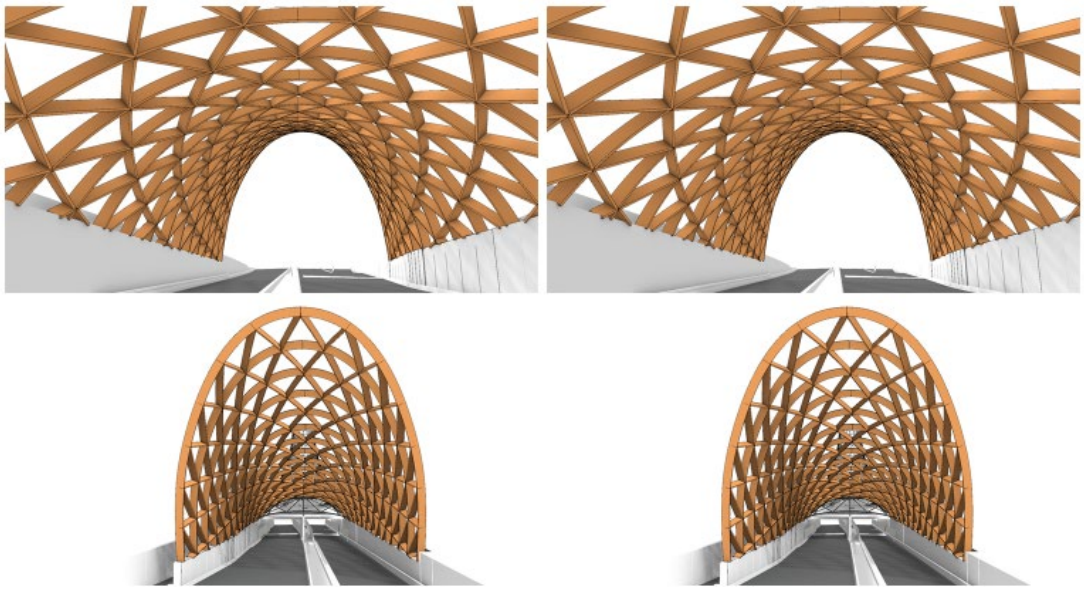


Figure 15. Through very slight timber member rotations, we were able to prescribe defined alpha angles for the node connections. Figure shows an exaggerated case.

3.2. Results

Our approach to discretising the envelope allowed us to address certain constraints and challenges, such as reducing the range of panel sizes, improving repeatability of panel angles and providing a visually striking design that followed the parametrisation of the envelope surface. Figure 16 shows the resulting timber topology.

A study was undertaken to assess the effects of using straight glulam secondary members on the visual appearance of the overall structure, as demonstrated in Figure 16. The visual impact was subtle; however, the merits of utilising straight members were substantial from a cost perspective. This was due to both a saving in manufacturing of the glulam and a reduction in transportation costs, owing to the ability to stack straight members more efficiently in a shipping container.

4. Timber structural design

4.1. Challenges

During the structural design process, we faced several significant challenges. Firstly, calculating wind loads on the Eel Nets proved challenging due to variations in size, rotation, elevation, shading, and other factors among members. Secondly, the diagonal, diamond-shaped scheme structures exhibited high deformations from self-weight. Lastly, the timber structures demonstrated a high sensitivity to connection stiffness.

Our initial attempt to calculate wind loads involved a brute force approach. We created a script that calculated all the factors for every wind direction on each member, in accordance with the code requirements. However, the resultant wind loads were found to be higher than anticipated. After consulting with Windtech Consultants, it was decided to calculate the wind loads on the shell and then distribute the loads onto individual members based on their tributary areas. By assuming that penetrations could be disregarded to ensure conservative design, we significantly simplified the loading process.

For the diagonal grid, the self-weight of the timber was found to be the primary cause of deformation, particularly in the North portal of the diamond-shaped scheme. To account for this, we developed a construction sequence and performed a nonlinear staging analysis to capture locked-in stresses and deformations that occur during the construction phase.

In our beam model, we accounted for the flexibility of the steel node connections. We modelled the nodes using plate elements in Strand7 and extracted the corresponding moment-rotation curves, which were then incorporated into the beam FEM model. Initially, we intended to use a stiff core, with vertical plates welded to end-plates on each connecting member. However, this approach proved to have too much rotational flexibility. After several design iterations, we stiffened up the node by adding top and bottom flanges (Figure 2).

4.2 Workflow

For both schemes, in-house libraries were used for timber member checks in accordance with AS 1720.1:2010. Our timber design components were integrated into the structural optimisation processes.

The design process for the timber methods was fully automated by a Grasshopper script utilising Strand7 for finite element analysis and in-house timber design modules. Strand7 interoperability was achieved by TTW's in-house Grasshopper plugin called Kookaburra. The script took the geometry prescribed in the schemes above and grouped members based on user inputs. Each group had a range of allowable sections assigned to them. An iterative process assigned each group to a given section and proceeded to analyse the structure, complete member checks for all members, and, based on the worst-case utilisation of each group, determine if an increase or decrease in member size was suitable.

An increase in section size occurred if any member in a group exceeded a utilisation of 90%, whilst a decrease would trigger if all members were under a utilisation of 70%. The iterative nature of this process also required modifying the boundary constraints of the FEA model. A change in section depth, for example, resulted in a change in connection stiffness. As such, the script designed would change these properties dynamically in the Strand7 model as each section was changed during the iterations.

A degree of engineering judgement was required during this optimisation process. A certain percentage of members were allowed to exceed their utilisation limit in some design cases, and unique solutions such as steel reinforcement details were considered for such members. This was the case for the diagonal grid scheme on the Northern portal, where the sharp front arch angle resulted in high triangulation forces at the base to prevent overturning, as shown in Figure 17. Whilst not governing in the design manual, engineering checks were also completed for serviceability criteria such as maximum deflection after the optimisation process was completed to ensure that these did not become the governing case.

4.3. Results

4.3.1. Diagonal gridshell

Under self-weight, the majority of the timber members experienced compressive forces. The primary exception to this is within the first four lengths of timber, either side of the dive, that connect the front arch to the supporting wall without arching over the dive. These members carry significant tensile forces to restrain the front arch. Figure 17 (left) shows highlighted the structural timber members of largest utilisation ratio and a deflection plot of the timber gridshell.

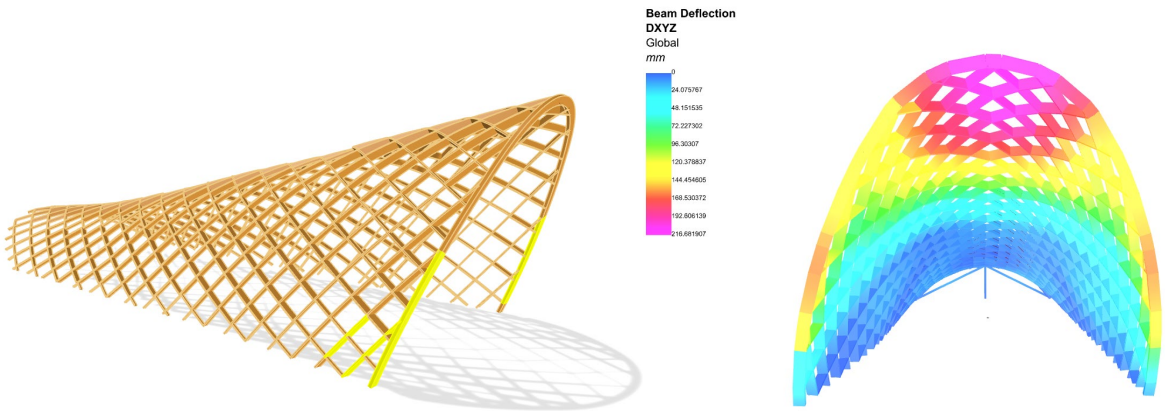

Figure 17. North Portal (1) Allowed over utilised members in yellow, caused due to the front arch wanting to rotate forward (2) Beam deflection contour plot

4.3.2. Triangular gridshell

While the described process allowed TTW to evaluate every member in the structure individually, the results of allowing each diagonal member to be optimised on its own resulted in a wide range of timber sizes being used across the structure (Figure 18).

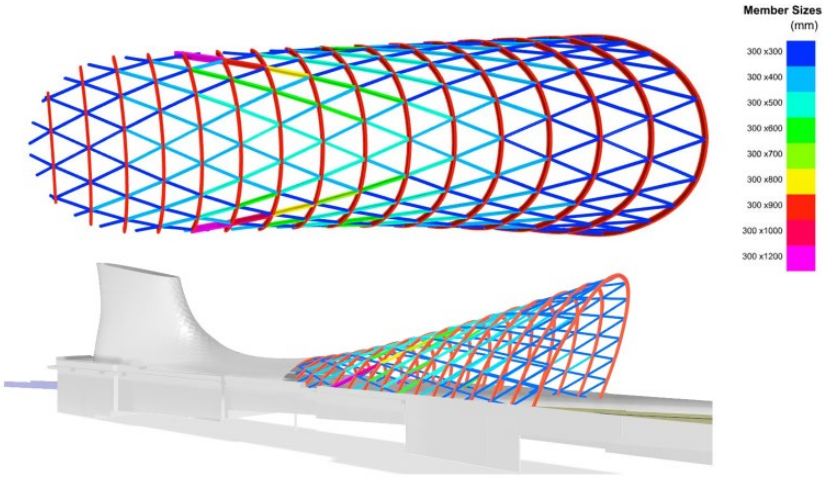

Figure 18. North Portal optimisation result for single size primary and variable diagonal sections

This did not align with the architect's vision for the structure, which eventually called for a single member size for the diagonals and another for the hoops, as per Figure 19. This limited the use case for optimisation and, as such, the main benefit of the automated design process became the ability to rapidly adapt to changing input geometries as we tested variants of each scheme.

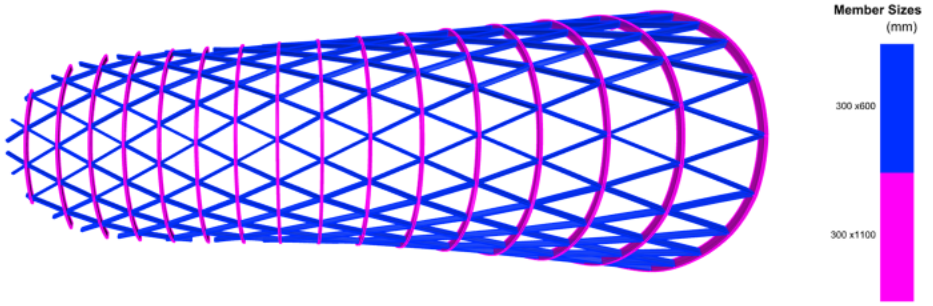

Figure 19. North Portal Final Geometry

5. Conclusions

This paper showcases the advantages of harnessing computational methods in the design of large-scale, geometrically intricate timber structures. By integrating parametric design, structural optimization techniques, and timber design libraries, we successfully established an automated, end-to-end process that enabled efficient analysis and validation of numerous design iterations. Our approach not only

facilitated the discovery of optimal solutions but also contributed to cost reduction and enhanced fabrication processes while preserving the integrity of the original architectural vision.

Acknowledgements

The authors would like to express our sincere gratitude to the whole West Gate Tunnel team for their invaluable collaboration and support throughout this project. Special thanks go to Dean Anderson, Hii King and John Haralabakos from CPBJHJV for their expertise, insights, and commitment to the project's success. We also extend our appreciation to Armin Voelske, Moshe Chong, and Roger Wood from Wood Marsh for their innovative vision, guidance, and unwavering dedication to the design process. Their collective contributions were instrumental in realising the goals and objectives of this complex timber structure.

Abstract

Mycelium-based composites are a suitable alternative to replace oil-based materials since they can rapidly build up complex structures with extreme precision to 'take shape' into larger structures. This paper discusses the relationship between a given geometry and its corresponding constructive system specially tailored to mycelium-based materials. Within this context, we present the Myco Pavilion, as case study for a deep understanding of the material properties of mycelium-based materials and critically analyze how they influence the transformation of a given geometry. The goal was to integrate a bottom-up design process where we developed a construction system based on material-specific construction details. The use of standardized materials such as wood or metal could represent a challenge for double curved structural typologies, transforming the curved into polygonal forms for constructive reasons. On the contrary, fungal mycelium can occupy almost any negative given formwork. The hemisphere typology offers optimized possibilities for the use of fungal mycelium as a balanced structure. This typology can only absorb pressure and must therefore be relieved of tension, condition that correspond to the mechanical properties of mycelium-based composites. For material manufacturing reasons, the hemisphere was divided into modules connected by a material-specific joinery system [Fig. 1]. This system allowed us to explore a variety of joinery-patterns to increase the modules' connection surface, leading to better binding and a stronger cohesion between the parts.

1. Introduction

The construction industry is responsible for approximately 30% of global CO2 emissions and resource consumption as well as 30% of European energy consumption [1]. Therefore, there is an urgent need to develop strategies and concepts to confront climate emergencies. These should include not only thoughtful design and sustainable construction, but also low tech, cradle-to-cradle (C2C), or energy plus concepts. In this context, mycelium-based composites are a suitable alternative to oil-based materials. They can rapidly build up complex structures with extreme precision to take shape of larger structures. This paper discusses the relationship between a given geometry and an emerging design system specially.

Figure 2. The Myco Pavilion in the festival context.

Within this research, we present the case study 'Myco Pavilion' [Fig. 2] as the basis for a deep understanding of the material properties of mycelium-based materials to critically analyze how such

properties can dictate morphological transformation of a given geometry. The goal is to integrate a bottom-up design process where a complete construction system is developed on the basis of material-specific construction details. The use of standardized materials such as wood or metal for double-curved structural typologies could represent a challenge, transforming curved forms into polygonal ones for constructive reasons. On the contrary, fungal mycelium composites can occupy almost any negative given formwork. We use a mycelium and chip wood composite developed by Trako and Dr.-Ing A. Werner for MycoMatrix, research project funded by the German Federal Ministry of Education and Research (BMBF). It consists of a precise combination of the basidiomycete *Ganoderma lucidum* and beechwood chips manufactured under specific environmental conditions. The resulting matrix is a conglomerate with different properties that allow technical applications.

The selected mycelium-based building material is applied to design a sustainable pavilion near RWTH University's main building in Aachen's city center. The project proposes a unique roofing structure for the main stage in the context of a music, theater, and culture festival. Therefore, to fulfill programmatic requirements, we selected a hemisphere-like typology to be fabricated with the mycelium-composite elements. As a statically balanced structure, the hemisphere-like typology offers optimized use of fungal mycelium. Since the selected mycelium-based composite can difficultly resist bending and torsion moments, the selected typology can absorb pressure and must therefore be relieved of tension.

Although the selected mycelium-based material can be negatively formed, it represents a challenge due to manufacturing constraints. That is why the hemisphere has to be discretized into modules. The discretization allows a deep understanding of the binding capacity of fungal mycelium by developing a material-specific joinery system to connect the modules. The system allows us to explore a variety of patterns to increase the connection surface [Fig. 3], leading to better binding and a stronger cohesion between the parts.

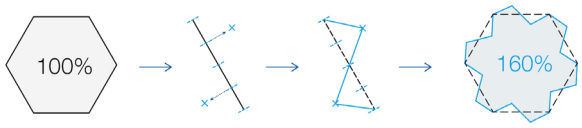

Figure 3. Parametric form-finding principle for increasing the joint area.

The in-depth study of the structural system is essential for addressing material-specific constraints. Consequently, a joinery system based on puzzle balls and the Goldberg polyhedron is analyzed and subsequently applied, considering the aforementioned constraints. Following the joining principles of puzzle balls, the modules are designed to be conically smaller towards the center and curved on the inner and outer surfaces. A detailed study of the geometry is also based on the Goldberg polyhedron. Since the Goldberg polyhedron is a polygonal shape that describes only faces, a connection of the puzzle joinery system was essential to enlarge its edges and, consequently, the binding surface to achieve material-specific requirements. Hence, the planar surfaces become curved modules that can be manufactured with the mycelium-based material. The complex intersection between topology, structural, and material constraints result in applying parametric modeling tools to optimize the Myco Pavilion's design and joinery system.

Prototyping some of the modules within this research requires not only a deep understanding not only of the material properties but also of the modules own construction system and geometry. Manufacturing the modules needs a complex formwork design process; for that reason, we decided to apply additive manufacturing (AM). AM allows us to design unique yet reusable formworks that enable growing the mycelium material under particular environmental conditions [2]. The prototyping helps test the designed joints and proves the feasibility of the design criteria on a scale of 1:2, resulting in the determining strategy within the Myco Pavilion design process.

2. Materials and methods

2.1. Structural typology and joinery system

In the beginning, a given structural typology is chosen to analyze and understand basic static properties of the future construct. In this case, the preferred structural typology is a hemisphere. Spheres are geometrically unique constructions known for having all points with the same distance from the center and same curvature both in two and three dimensions. Spheres are bodies of revolution. In such rotational bodies, there is a distinction between the meridians in the vertical direction and the latitudinal circles in the horizontal plane of the curvature. In the case of deformations or disturbances of the balanced system, increased tensile forces may occur.

As a statically balanced structure, the hemisphere typology offers great potential for using the mushroom mycelium. The fungal mycelium material can occupy all kinds of given forms. The mycelium-based modules are supported by their cross-section and designed as a non-planar system. In this typology, the overall modular system can only absorb pressure and must thus be relieved of tension. The structure is thinned at the top through an adapted cross-section to reduce the load on the components below.

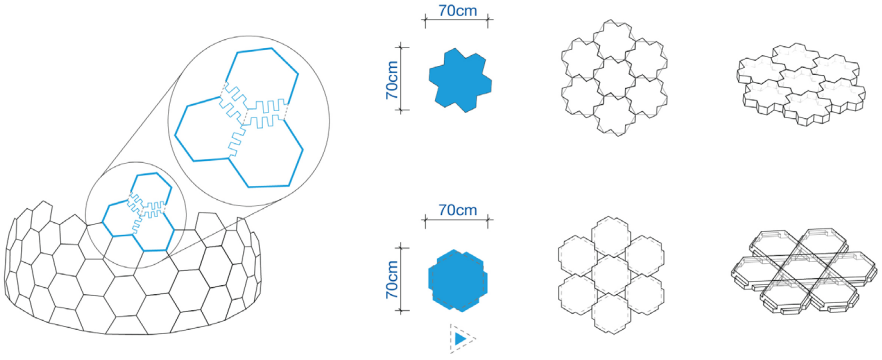

Figure 4. Hemisphere based on the Goldberg Polyhedron. (Left) First approach to geometry discretization and joinery system; (Right) two interlocking or clipping strategies for the modules.

For manufacturing reasons, the hemispherical typology has to be discretized into modules on the basis of the Goldberg polyhedron, which belongs to the icosahedra family and always shows 12 pentagons. The areas in between are filled with hexagons in circles and rows. The number of hexagons and their variants in shape and size depend on the size of the sphere.

As a polygonal shape, the Goldberg polyhedron presents a construction challenge requiring a joinery strategy [Fig. 4 left]. In our case, the material selection and its material-specific binding capacity play a key role. The joinery principle was based on the idea of the puzzle ball where modules are clipped [Fig. 4 right]. and are conically smaller towards the center and curved on the inside. The conical characteristic of the modules presented another geometrical constraint to be considered since the surface of the modules is curved, and the edges are straight.

The Goldberg polyhedron and the puzzle ball system serve as the basis for developing a novel joinery system where the mycelium grows among the interstitial space between the modules acting as a glue. Also, increasing the joint area between the modules with a jagged interface improves the material's binding capacity. Parallelly, an interlocking pattern of the joint was developed to increase the whole system's stability. In this context, the precise coordination of the angles and sizes of the various components is essential to achieve the exact fit of the interlocking connections.

2.2. Material-based joinery system

The selection of the mycelium-based composite consisting of *Ganoderma lucidum* and beechwood chips is based on the ongoing research project MycoMatrix conducted by Trako and Dr.-Ing. A. Werner. One of the research goals is to optimize the fabrication process of the bio-based material. Therefore, six manufacturing steps were determined: 1) Lignocellulosic material selection; 2) Homogenization; 3) Sterilization; 4) Inoculation; 5) Growth; and 6) Denaturation [2], [3]. Further development of the growth step serves as one of the construction strategies adopted for the pavilion's design. By unfolding step 5 in a two-step growth, the binding capacity of the matrix material plays a key role. After inoculation (step 4), the obtained mixture is placed in formworks to shape the modules of the composite material. They are incubated under specific environmental conditions for a week to obtain a cross-linked mycelium growth around the wood substrate. After this first incubation stage, the modules have to be extracted from the formworks and placed together through their binding interface. This second incubation stage takes place under the same environmental conditions for a period of two to three more weeks.

Due to geometry constraints, the mycelium composite modules require the development of a joinery system, which in this case, is based on the binding capacity of the material and its corresponding two-step growth. In similar geometries, the static complexity of the components is usually undertaken either by the edges of their surfaces [Fig. 1]. If the inner and outer surfaces of the modules are planar, the curvature of the whole construction must be completely absorbed in the connection between the parts. This condition leads to complex teeth-like edges shaping. Although it allows three-dimensional interlocking that could be favorable for static reasons, it is unfavorable for constructive reasons since it doesn't allow repetition of the modules. Assuming that the inner and outer surfaces of the modules are curved, the edges between them should be conical and straight—from a simple to a more precise edge shaping, reducing formwork manufacturing complexity. Therefore, we continue with the latter variant which involves an intermediate degree of individuality of the parts: thirteen different modules, excluding the opening edge and bottom's special modules. However, it requires complex negative formwork modeling and manufacturing.

2.3. Parametric modeling

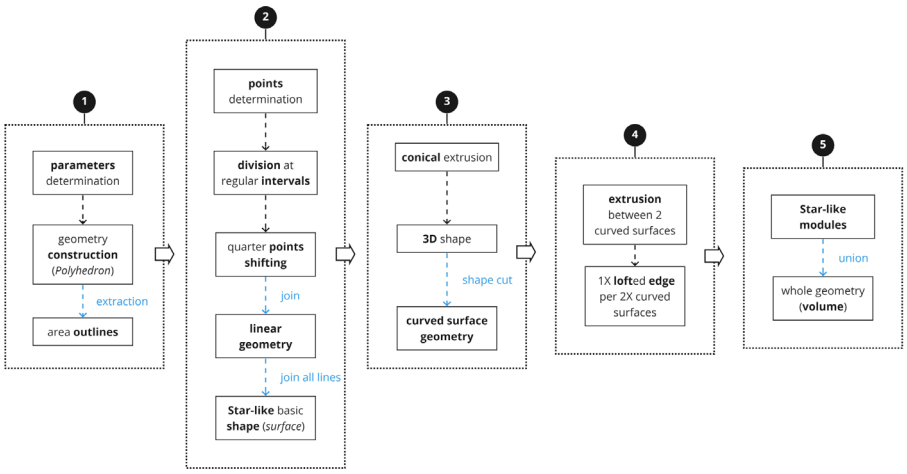

Figure 5. Parametric modeling workflow: general overview from step 1 to 5.

A parametric digital model is developed with the help of the visual programming tool Grasshopper for Rhinoceros [4] and RhinoPolyhedra [5]. The workflow can be divided into five main steps described in

Fig. 5. The parametric modeling enables us to work with a series of possible solutions which could be quickly transformed by improving or adapting the modules to the primary geometry constraints.

Footnotes should not be used. In the rare case where notes are necessary, please use Endnotes.

Step 1. RhinoPolyhedra creates polyhedra in different kinds and sizes, including the Goldberg polyhedron. The diameter and position can be varied on-demand based on the designed geometry. Subsequently, the outer lines of the polygon surfaces and the surfaces themselves are extracted due to design optimization requirements.

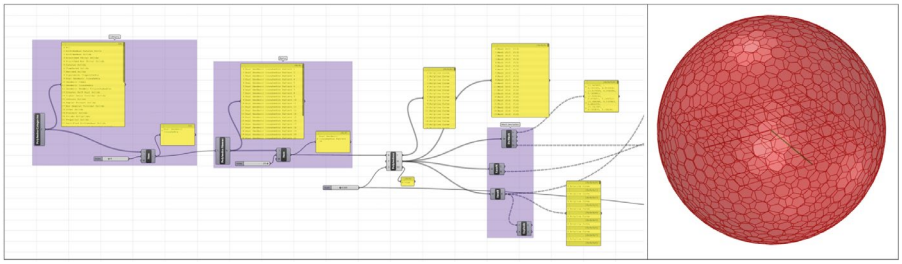

Figure 6. Step 1: Modeling of the geometry with RhinoPolyhedra.

Step 2. The outer edges of the polygons are divided into single lines. Start and endpoints are defined on these lines, and three points are in between at regular intervals. A specific parameter shifts the quarter points in the plane of the line in the opposite directions: one in one order and the other in the other direction - each orthogonally. This principle is shown in Fig. 2. The new points are reconnected to form a line and be joinined to the adjacent lines of the original polygon to create a star-like shape.

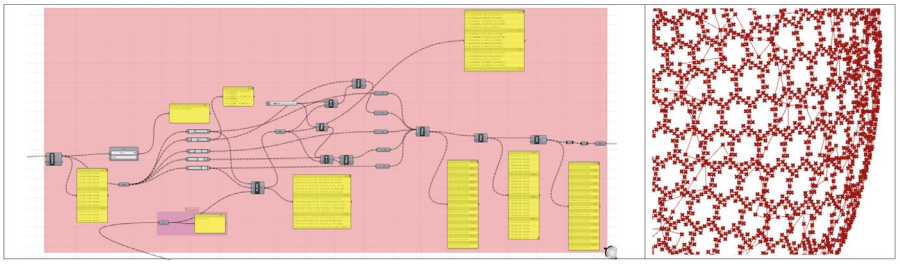

Figure 7. Step 2: from polygon to star-like shapes.

Step 3. The star-like shapes are extruded to the center, giving them their final conical shape. The extrusions are cut with two spheres to obtain the curved surfaces of the modules. The inner sphere is slightly shifted upwards, resulting in a smaller cross-section in the upper part in relation to the lateral pieces that transfer the compressive stress to the ground.

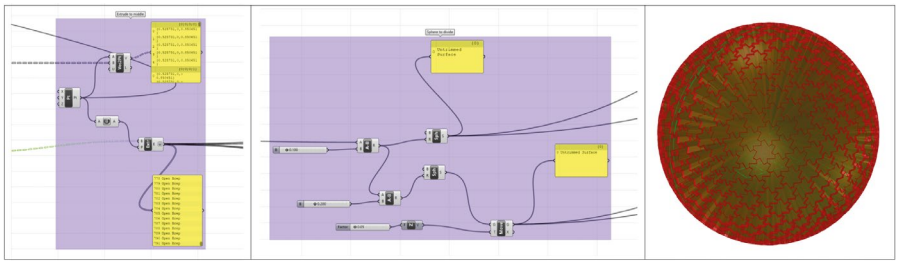

Figure 8. Step 3: curved surfaces.

Step 4. The previous steps result in two curved surfaced polyhedra. Consequently, the edges are lofted, and the modules' surfaces and corresponding lofts can be sorted in the parameter list.

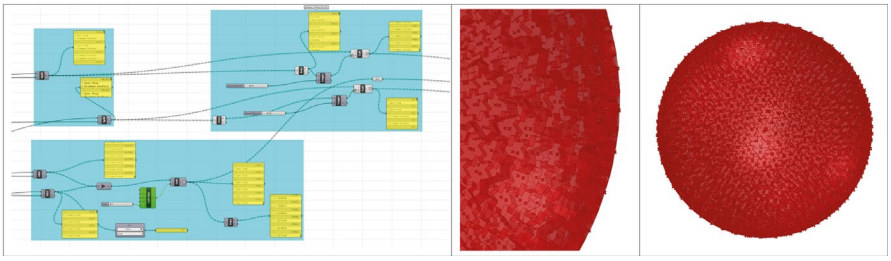

Figure 9. Step 4: conical edges of the modules.

Step 5. Finally, the resulting surfaces and lofted edges are joined to form the final multiple possible geometry variants of the Myco Pavilion. The division into a hemisphere and cutting of the opening are done in Rhino afterwards.

2.4. Function-specific design decisions

Due to function-specific requirements, the hemisphere requires a corresponding opening. The opening design represented a challenge for structural loads as well as constructive reasons. Thus, a series of studies on properly opening the hemisphere is conducted. As shown in Fig. 10, a straight cut is possible in different variants. The version highlighted in blue illustrated in Fig.10 fulfills the programmatic requirements of the Myco Pavilion. It has a shape whose mass can distribute the compression loads in a balanced way, and, at the same time, the load transfer disruption provoked by the opening is minimized.

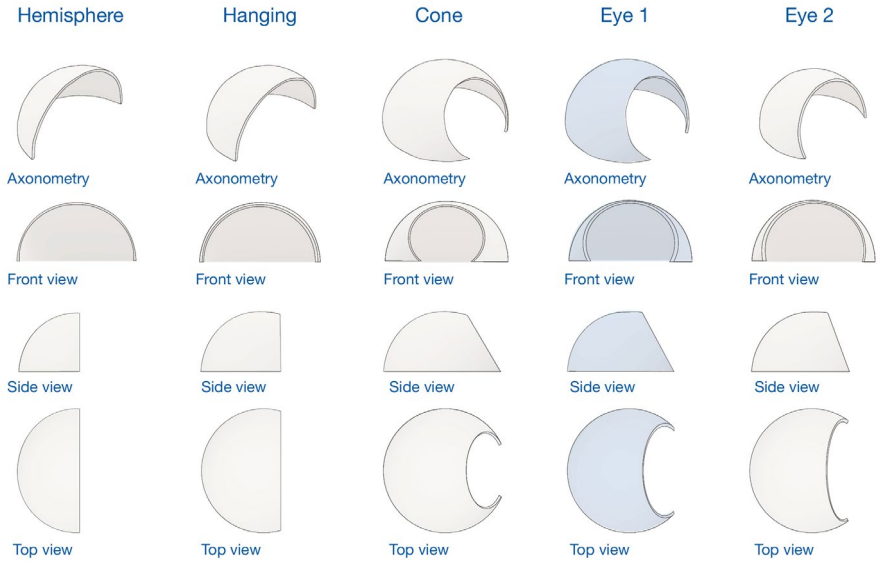

Figure 10. Opening studies. The selected opening is highlighted in blue.

Since the opening interrupt the static equilibrium, and the mycelium-based composite cannot withstand the additional stresses that may occur, the design of an extra support element is necessary. The first consideration is the reinforcement through a mycelium-based cantilever, as it can usually be found in shell structures. However, this first approach is discarded since we saw it questionable whether this principle can be applied with this material based on its deadweight effect. In conclusion, an arch-supported variant is developed—the L-profiled wood arch allows to hold the structure at the top and absorb the additional forces. At the bottom part of the pavilion, a U-profiled wood element serves to contain the stresses arising from the hemisphere.

3. Results

3.1. Final design

Since the Myco Pavilion [Fig. 11] requires extra support at both the opening and the base to allow proper load transfer and stability, the details between the different materials, wood, and mycelium-based composite are specially considered. Consequently, a friction-fit connection is selected for the proper joint of both materials.

A U-profile is selected for the surrounding base to secure the pavilion against slipping, breaking out, or deformation of the hemisphere. The Myco Pavilion is considered to be lightweight with a density of approx. 41.9 kg/m3, with a total weight of approximately 1,215.1 kg. Therefore, protection against wind forces has to be provided. Possibilities for this are anchoring the mycelium-based modules to the U-profile. For example, wooden boards or textile sheets can be used to anchor the structure. Since the design involves curved shapes, the solution with ingrown wooden panels is unsuitable. At the same time, the integration of ingrown textiles may not be friction-fit enough. Thus, the final design considers the ingrown of wooden rods inside the modules during the incubation process to strengthen the connection by anchoring.

The curved parts are to be manufactured with laminated veneer panels of easily bendable woods such as beech, oak, ash, or elm. The curvature is more workable with these materials than with solid wood panels. Due to prior investigations [3], mycelium-based modules should not come into contact with the glue found in laminated veneer since it increases the risk of contamination.

While curved components are designed with veneers, horizontally lying panels, such as the staircase or the floor, are designed with multi-layer wood panels. The floor structure must also compensate for the topographical position so that the system can stand level and no altered force flows occur due to inclination. Therefore, the floor understructure consists of reusable level-able metal feet that absorb possible unevenness of the ground. They have a special head on which the multi-layer boards can be placed. Truncated cone-shaped components secure the panels, and the central cylinder allows subsequent fine adjustments.

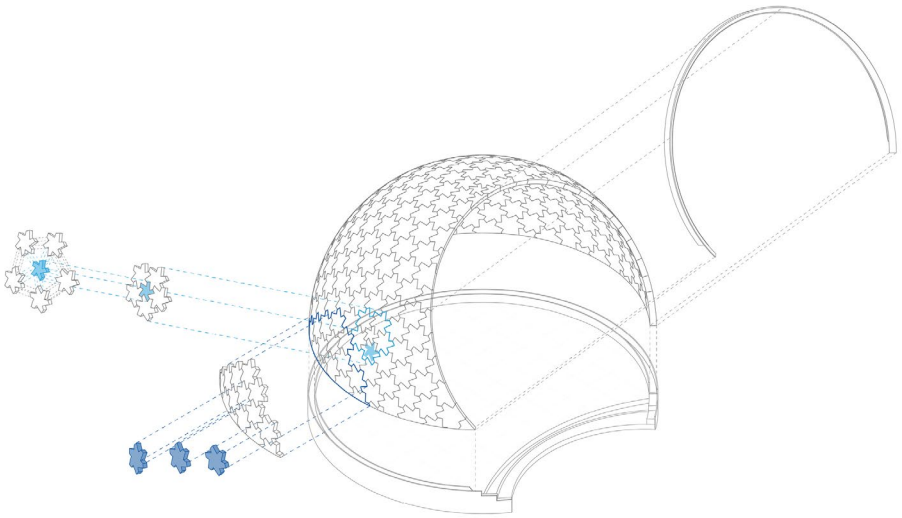

Figure 11. Myco Pavilion's exploded view: puzzle-like composition of mycelium-based modules and floor structure of wooden elements.

The modules on the bottom of the Myco Pavilion (U-profile joint) and those in direct contact with the opening (L-profile joint) are considered special modules. The special modules can also re-use the already developed negative formworks (thirteen different). Extra 3D printed special parts should be produced to fill in the gaps under the required specifications of the cut segments of the opening and the bottom part of the pavilion. Consequently, no new formworks have to be manufactured, only the individual fill-ins. Although it could represent a disadvantage in manufacturing terms, it is essential to highlight that due to the temporary condition of the pavilion, after the festival, all modules can be disassembled and composted.

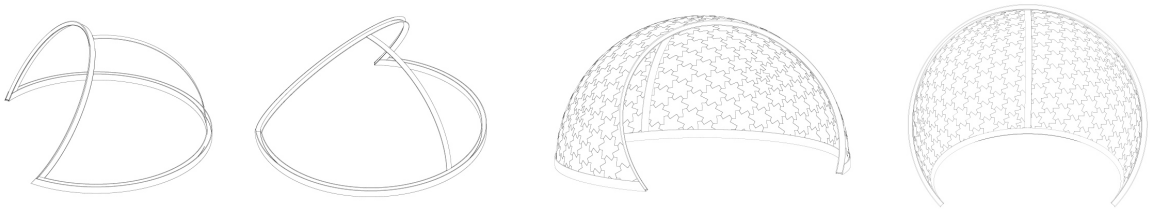

Figure 12. Opening arch and optional extra arch in perpendicular direction.

As described in chapter 2.4, the opening is supported by an L-profile made of bent multi-laminar wood. These are also additionally connected to the mycelium-based modules by ingrown wooden rods. If needed further support, another arch can be used perpendicular to the opening support. The addition of another arch could help hold the pavilion up in the center axis and simultaneously support the tilted design to hold the opening [Fig. 12].

3.2. Mycelium-based modules prototyping

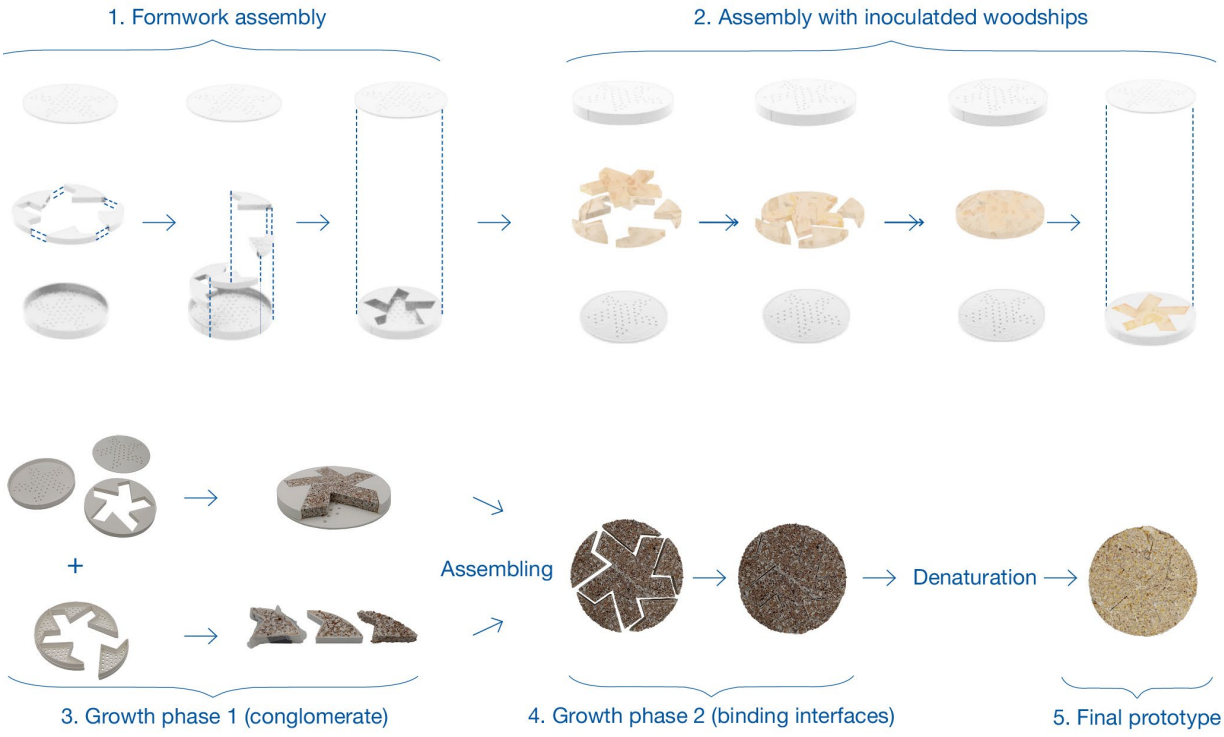

Figure 13. Design and manufacturing of the modules' prototypes and their corresponding AM-formworks.

Due to the mycelium-based composite's experimental characteristics, module prototyping plays a crucial role in the design process. It allowed an implicit perception of the material qualities that drives a certain level of understanding which could hardly be achieved without it [6].

The formwork that shapes the prototype [Fig. 13] presents a kind of complexity that makes additive manufacturing (AM) an accurate solution. The selected part of the Myco Pavilion that was prototyped is part of the designed joinery system and proves that it could be successfully implemented. In addition, the prototype provides further insights into the building material and the planned constructions.

The formwork was perforated for sufficient ventilation, and these ventilation holes were covered with Parafilm [7] during the two-step growth process to inhibit contamination. Once the formwork was properly designed and manufactured with the help of AM, the fungal mycelium and wood chips mixture was inserted and compacted with the top part of it.

After the first growth phase (described in chapter 2.2), the mold was rotated upside-down, and the mycelium-based modules were removed from this first formwork. The formwork was divided so that individual parts could be easily taken out. All modular parts were then put together on a second formwork without division which enabled the second-step growth and consequently the expected binding effect.

3.3. Assembly

Due to the conical shape of the modules, the assembly for second-step growth represents a considerable challenge. This paper proposes an assembly strategy for the pavilion's erection. After the first-growth phase of the individual modules, they should be assembled from the outside with the help of an inflatable structure, starting from the bottom up [Fig. 14]. This concept is based on the formwork studies for lightweight concrete shells using pneumatic structures by W. Sobek [8]. Also, environmental conditions for the mycelium-based composite cultivation, such as the required temperature for mycelia denaturation, could be integrated into this system, e.g., by adding warm air to the interior of the inflatable.

After assembly, second-step growth, and proper denaturation of the mycelium-based modules, the inflatable formwork could be deflated and removed.

Finally, this concept could also grant possible fitting tolerances for mycelium building blocks by using a slightly bigger inflatable.

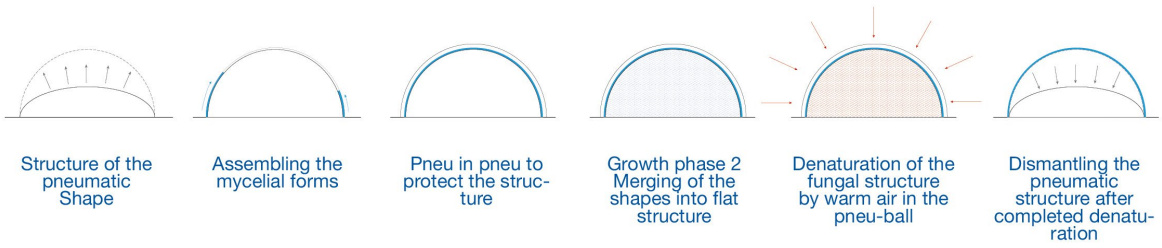

Figure 14. Assembly of the mycelium-based modules into the Myco Pavilion.

4. Discussion

The Myco Pavilion presents itself as a design with great potential for applying the described mycelium-based composite. The temporary nature of the program also supports the selection of the material due to its compostability and the upcycling possibility of old wood in the form of substrate integrating the whole design concept into the circular economy. Also, considering programmatic requirements as the outdoor setup, it is essential to highlight that the selected fungi, *Ganoderma lucidum*, present

hydrophobic characteristics. The fungal matrix tends to form a strong layer of hyphae on the superficies of the construction elements, which could grant waterproofing to the construction. Anyhow, after a series of experiments on the material's workability conducted by the MycoMatrix research team, the addition of an extra coating layer is recommended. This coating should be oil-based to avoid the fungi's hydrophobic nature.

The successful prototyping evidence the feasible application of the proposed material-specific joinery system with two-step growth manufacturing. Mono-materiality reduces the system's material entropy, which discards the use of additional mortar or glue to join the pavilion's constructive modules. The proposed interlocking system could also be further improved on the Y axis, but in that case, the overall section of the modules should be increased. The joinery system also enables the development of complex design details, which were adequately developed with the help of visual programming tools. Understanding the physical and mechanical characteristics of the mycelium-based material opens the game for novel ways of applying this material to structural typologies that require elaborated technical development. To achieve full validation of the design strategies presented in this paper, the complete realization and construction of the project should be necessary on a full scale.

Abstract

Konrad Wachsmann proposed the Grapevine Structure (GS) in 1953 (Figure 1). GS has a shape with regularity, which is obtained by connecting a unit in a pattern. A unit can be determined subject to a geometrical algorithm. The algorithm for GS is described in his book [1]. Note that GS has yet to be realized in practical design. However, a 3D model has been reproduced, and a full-scale physical model was exhibited at Biennale Venice 2018 [2]. GS is a unique pre-fabrication technique with the freedom to select cross-sections of members, while its detail and structural properties have yet to be discussed well. The authors think it is significant to focus on GS and explore the possibility of new architectural geometry realizing more construction efficiencies. This study focuses on the GS to apply as an actual structure. Based on the previous literature, GS is reproduced using 3D CAD. Through observing the obtained geometry and comparison with the original model and previous example, we proposed an improved generating algorithm. Then, the reproduced geometry is discretized using finite elements, and linear static FE analysis is conducted to discuss the mechanical properties. The potential applications of the Grapevine structure for architectural geometry will be discussed through numerical examples.

Keywords: conceptual design, morphology, architectural geometry, reverse engineering, FE analysis

1. Introduction

Many studies have explored the design intention or design philosophy of famous structural engineers by investigating the mechanical behavior of existing buildings designed by them. Paris *et al.* studied the herringbone patterned masonry domes without shore or formwork in the 16th century [4]. They showed the effectiveness of the pattern using Discrete Element Modelling and limit state analysis. Tomas and Montrull focused on F.Candela's concrete shell [5]. The optimization result of the shape of the L´Oceanogràfic at Valencia indicated that slight changes in the shape are enough to achieve the improvements. Barazzeta *et al.* investigated the work designed by Pier Luigi Nervi [6]. They investigated the structural behavior of the airplane hangers, which have already destroyed, using numerical analysis. Andrzejewski and Shaffer investigated the Location Orientation Manipulator, which is proposed by Wacksman and his students in the 1960s [7].

Konrad Wachsmann designed various buildings considering the modularization of joint designs and components. The U.S. air force aircraft hangar (1951) can be mentioned as a representative work. He proposed the Grapevine Structure (GS) in 1953, as shown in Fig. 1. Connecting a unit in a pattern, the shape of the GS can be obtained. Furthermore, a unit can be determined according to a geometrical algorithm. In recent years, a 3D model has been reproduced by Burkhalter *et al.*, and a full-scale

monument was exhibited at Biennale Venice 2018 [2, 3]. GS is a unique pre-fabrication technique with the freedom to select cross-sections of members. However, its detail and structural properties have not been discussed well. The authors think it is significant to focus on GS and explore the possibility of new architectural geometry realizing more construction efficiencies.

In this study, we focus on the GS proposed by Wachsmann to generate its structure and observe its mechanical characteristics as an architectural structure. GS is reproduced using 3D CAD by referring to the previous literature. Through observing the obtained geometry and comparison with the original model and previous example, we proposed an improved generating algorithm. Then, the reproduced geometry is discretized using finite elements, and linear static FE analysis is conducted to discuss the mechanical properties. The potential applications of the GS for architectural geometry will be discussed through numerical examples.

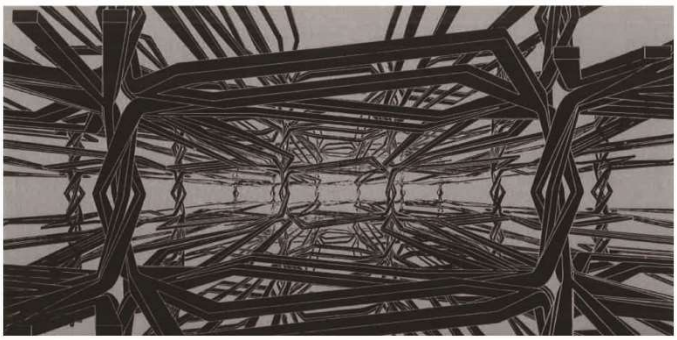

Figure 1. Conceptual image of Grapevine structure proposed by Konrad Wachsmann [1].

2. Grapevine structure

We reproduce Wachsmann's GS (GS-W), which is shown in reference [1], using 3D CAD (Rhinoceros) and Grasshopper, which is a graphical programming editor. The algorithm for generating GS-W can be summarized as follows,

Step 1 Create a cube *A* with a side length of *x* m.
Step 2 Project a square *B* with a side length of *y* m onto the center of gravity of each face of *A*. Its six sides are parallel to each face of *A*.
Step 3 Extrude two rectangles *C* with *B* as faces.
Step 4 Create a cube *D* by intersecting *C*.
Step 5 Create a new cube *E* tangent to the side of *D*.
Step 6 Rotate *E* by *p* degrees and create a new cube *F*.
Step 7 Divide the top and sides of *F* into *s* pieces. On each face, select one of the divided faces.
Step 8 Using the two surfaces and arcs created in Step 7, create the joint element of the basic module.
Step 9 Project *E* onto *A*. Then, create a strip shape on the side of *A* with the same height as *E*.
Step 10 Divide the shape created in Step 9 into t rectangular faces. Then, select two faces.
Step 11 Create the horizontal component of the basic module using the element faces created in Step 8 and the two faces selected in Step 10.
Step 12 Project the top surface of *F* onto the top surface of *A*.
Step 13 Divide the surface created in Step 12 into *u* rectangular faces. Then, select one face.
Step 14 Create the vertical component of the basic module using the faces of the joint element and the faces created in Step 13. Join the components to create basic module *X*.
Step 15 Rotate and duplicate *X* by *q* degrees around the center of gravity of *A*.
Step 16 With the center of gravity of *A* as the center, the group of units obtained in Step 15 is

duplicated vertically and symmetrically. Finally, the basic unit by GS-W is obtained.

Figure 2 represents the whole generation sequence. Figures 3 and 4 represent the basic module and basic unit by GS-W (hereafter named pattern A and pattern B from left to right), respectively.

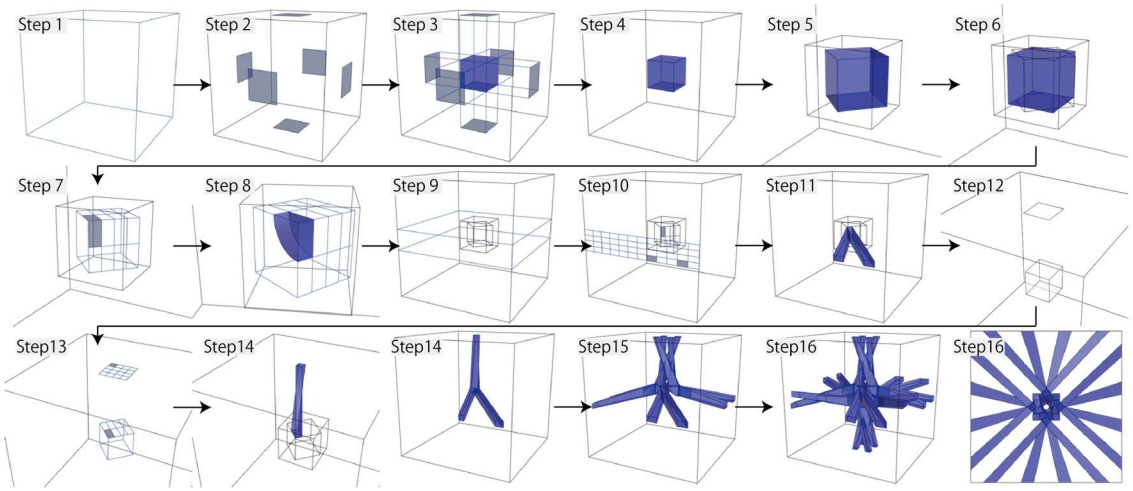

Figure 2. Generating sequence of GS geometry.

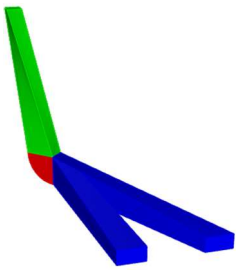

Figure 3. Basic module by GS-W (green: vertical component, blue: horizontal component, and red: joint element).

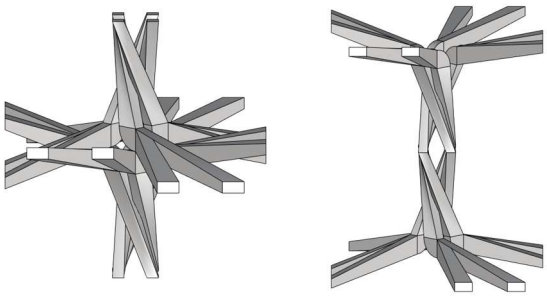

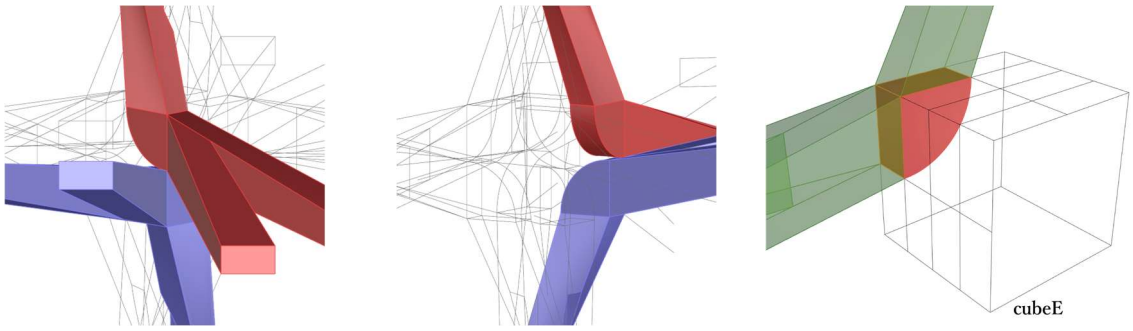

Figure 4. Basic unit by GS-W (left: pattern A, and right: pattern B).

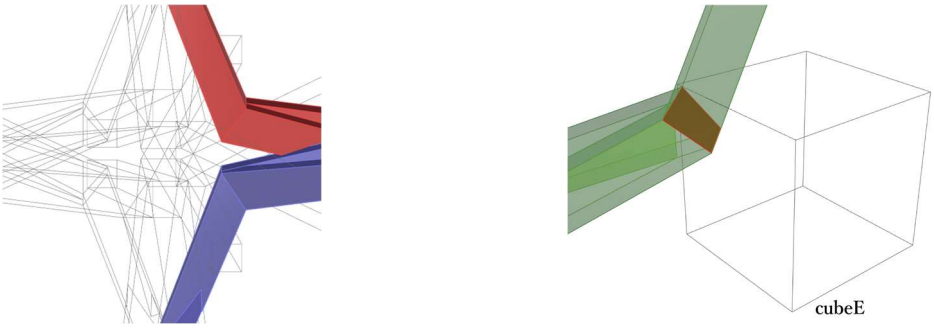

Figure 5(a) represents the joint of Pattern A with the enlarged view. The procedure for generating the joint element of Step 8 is extracted from the whole sequence and shown in Figure 5(b). It can be found that, in the case of pattern A by the GS-W procedure, the upper and lower units are contacted with a tiny area due to a fan-like shape generated in Step 8. From the view of the practical design, a sufficient joint area needs to connect units. Figure 6 shows the shape, which is generated according to the algorithm of

the previous case [2] (hereafter, GS-B). In the case of GS-B, it is hard to find a suitable connection between the upper and lower units because there is a gap between both units.

(a) (b)

Figure 5. Enlarged view of basic unit according to GS-W: (a) Joint of Pattern A, and (b) Procedure for generating joint component (Step8).

(a) (b)

Figure 6. Enlarged view of basic unit to GS-B: (a) Joint of Pattern A, and (b) Procedure for generating joint component.

In this study, we improve an algorithm of Step 8 (named GS-RW). The revised procedure (Step 8') can be expressed as follows,

> Step 8' Divide F into two parts at the top and bottom, and create a new face B' inside. Further, divide B' into $v \times w$ pieces, then select one face. Form a joint component from the divided face and the two faces created in Step 7.

Figure 7 represents the procedure of Step 8' and an obtained shape of a joint component in GS-RW. Note that v and w are assigned as v=w=4 in this study.

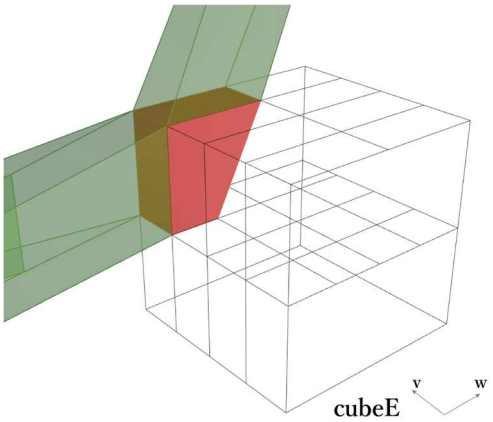

Figure 7. Procedure of Step 8' and shape of obtained joint component by GS-RW.

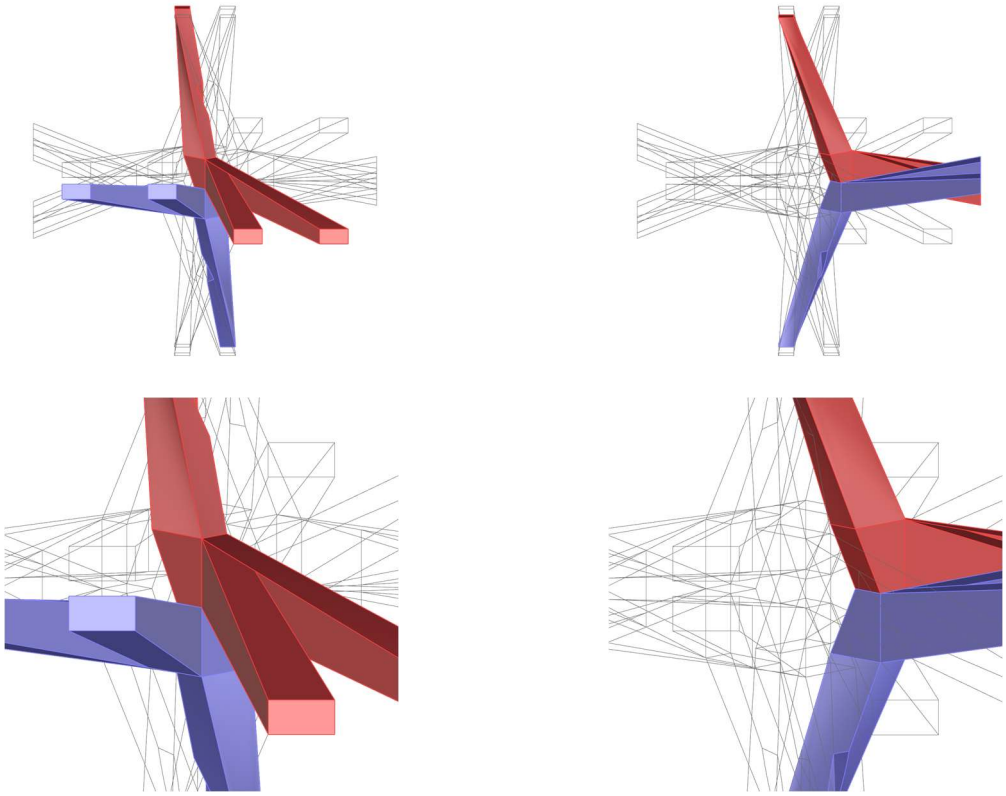
Figure 8 shows the shapes obtained by GS-RW and the enlarged view of the basic unit of pattern A. The shape with the red and blue colors represents the upper and lower units, respectively. Figure 8 shows that the significant connection between the upper and lower units is obtained compared with the shapes of GS-W and GS-B. Considering the stress state, the joint area can also be optimized if v and w are controlled during the generation process.



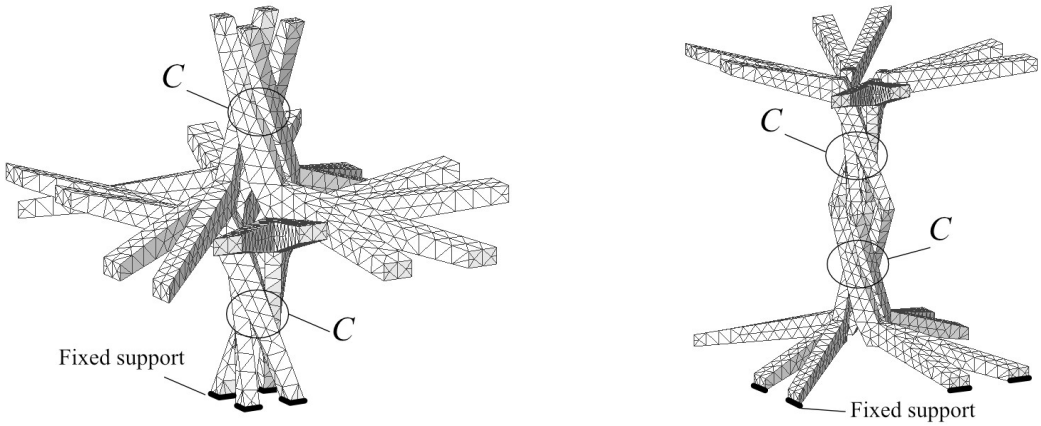


Figure 8. Enlarged view of basic unit by GS-RW.

3. Investigation of mechanical properties

We conducted linear static FE analysis for GS geometry. MIDAS iGen, which is a general FE analysis software is used for solving linear-elastic static analysis. A shape obtained in section 2 is discretized into five-node pyramid elements. The bottom surfaces of GS geometry, as shown in Fig. 9, are fixed supports. The material is concrete with Young's modulus of 21 GPa. Note that basic units are adhesively connected with each other at the domain of *C*, as shown in Fig. 9. For investigating the mechanical properties of GS geometry, four load conditions are assigned in the numerical example. A unit load of 1 kN is assigned on the tip of the horizontal component. The sum of the absolute values of the loads is set to be the same (16 kN) in all cases. Fig. 10 represents the loading pattern.

Table 1 shows the result of FE analysis. The maximum displacement in each direction is listed. Notably, we express d_{xy} and d_{xyz} as $d_{xy} = \sqrt{d_x^{\,2} + d_y^{\,2}}$ and $d_{xyz} = \sqrt{d_x^{\,2} + d_y^{\,2} + d_z^{\,2}}$, respectively. Stress distribution in the case of pattern A subjected to load of CLV can be seen in Fig. 11. Fig. 12 represents the distribution of displacement against CLT. As seen in Table 2, it can be observed that GS geometry has good stiffness against the vertical load. As seen in Fig. 11, it can be found that the vertical and horizontal components behave as the conventional beams and columns, respectively. Contrarywise, a large displacement can be confirmed when the structure is subjected to lateral and torsional loads, as seen in Table 1 and Fig. 12, due to the geometry, which is formed by a rotating array of basic units. From a view of practical design, GS geometry as a building structure is needed proper reinforcement for specific loading conditions. On the other hand, this structural behavior suggests a possibility of a unique microscopically arranged material.

4. Conclusion

In this study, we reproduce the GS proposed by Wachsmann observe its mechanical characteristics as an actual structure. Referring to the previous literature, GS is reproduced by using 3D CAD software. Through observing the obtained geometry and comparison with the original model and previous example, we propose an improved generating algorithm. Additionally, linear static FE analysis is conducted to investigate the mechanical properties. The potential applications of the GS for architectural geometry are discussed through numerical examples. The main conclusion can be summarized as follows,

(1) We reproduced the GS geometry based on Wachsman's algorithm written in previous literature. Through reproduction using 3D CAD, we identify an issue regarding the arrangement of the joints. Furthermore, a properly jointed geometry can be obtained by the updated algorithm.

(2) FE analysis is performed using the updated GS geometry under various loads. It can be confirmed that the GS geometry has good rigidity subjected to vertical load. On the other hand, it can be found to deform significantly subjected to lateral and torsional loads.

Designing GS geometry as a building structure, it should be properly reinforced for specific loading conditions. On the other hand, it suggests that this structure have very different stiffnesses in different directions. The authors think there is a possibility of a unique microscopically arranged material and further investigation of the physical behavior is needed.

Abstract

In the process of designing latticed shells, it is important that the lattice members have the same cross-section (height) and no torsion to avoid eccentricity at the joints and reduce the manufacturing cost, which is known as the property of edge offset mesh (EO mesh). In this study, we propose a two-level optimization approach to generating hexagonal meshes which satisfy the properties of EO mesh for all edges. Using the proposed method, a lattice shell can be designed so that all beams are torsion-free and all beam sizes are equal. In our method, each face of the EO mesh is sequentially added in a manner that the new face is always parallel with the Koebe mesh determined by Möbius transformation from a planar circular net. It is possible in our method to control the shape of each face more directly and individually than the existing methods by varying the edge length parameters of each face. The proposed method generates an EO mesh whose shape is close to a predefined target surface. An example shows that the proposed method can be applied to design of hexagonal lattice shell structures in which all beams and joints have no torsion, all beams have the same height, and therefore, requires less cost and time for construction.

Keywords: edge offset mesh, mesh offset, hexagonal lattice shell, Möbius transformation, torsion-free node, optimization

1. Introduction

Latticed shells are composed of straight lattice beams and are widely applied to the design of architectural roofs. A latticed shell can be regarded as a pair of a polygonal mesh M and its offset mesh M' as shown in Fig. 1 to incorporate the heights of beams. Mesh M consists of nodes $\boldsymbol{x}_i \in \mathbb{R}^3$ and edges e_{ij}, and the offset mesh M' consists of the same number of offset nodes $\boldsymbol{x}_i{}'$ and edges $e_{ij}{}'$. A line passing through $\boldsymbol{x}_i$ and $\boldsymbol{x}_i'$ is called *node axis* A_i. A quadrilateral bounded by two edges e_{ij} and $e_{ij}{}'$, and two node axes A_i and A_j is called *central plane* [1] and describes the symmetry plane of a lattice beam.

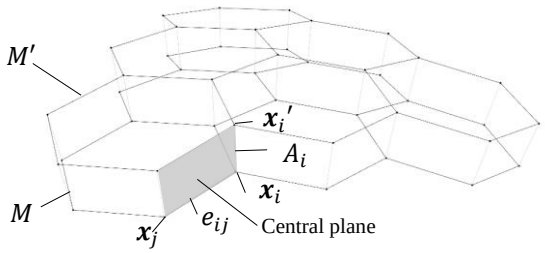

Figure 1. Mesh M and its offset mesh M' determine quadrilateral central planes describing the symmetry planes of the beams

Copyright © 2023 by Ryo WATADA and Makoto OHSAKI. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

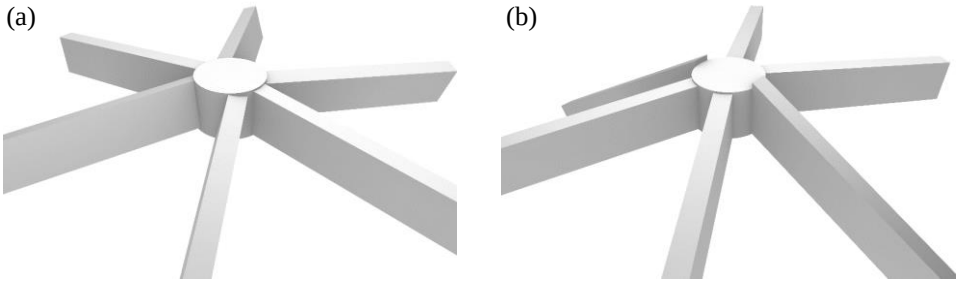

Figure 2. (a) A node with geometric torsion, (b) Kinks due to variation of vertical angles

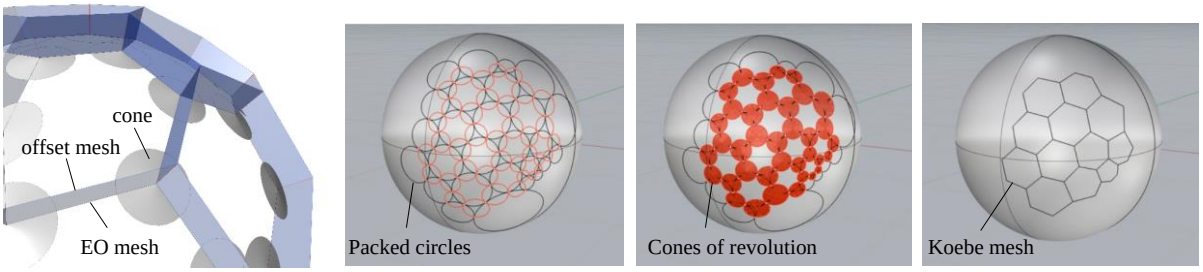

Lattice shell structures constructed by a mesh and its offset mesh generally have several geometric difficulties for construction as shown in Fig. 2. Geometric torsion as shown in Fig. 2(a) occurs when there is no common node axis which is contained in the all central planes of incoming beams. Figure 2(b) shows kinks due to variation of vertical angles between node axis and central axes of beams. Constructing a mesh with planar faces without torsion and kink is highly important for reducing cost and time for construction.

An *edge offset mesh (EO mesh)* is a offset mesh in which the distance of corresponding parallel edges e_{ij} and $e_{ij}{}'$ equals d for every edge [1]. It is known that a latticed shell composed of EO mesh has planar faces with no geometric torsion and kink. A condition for EO meshes is that all edges attached to a node are on a same cone of revolution whose axis is consistent with the node axis, as shown in Fig. 3(a).

Assume two meshes M_1 and M_0 which have the same numbers of nodes and edges with the same connectivity. The mesh M_1 is regarded as *parallel* with the mesh M_0 if the corresponding edges of M_1 and M_0 are all parallel. It is known that a mesh M is EO mesh if and only if M is parallel with a *Koebe mesh* as shown in Fig. 3(d). Koebe meshes are generated from circles packed on a sphere as shown in Fig. 3(b) in black. The edges of the Koebe mesh are determined as common tangent lines of adjacent circles, and nodes of the Koebe mesh are defined as intersections of the tangent lines, as shown in Figs. 3(c) and 3(d). In Fig. 3(c), red cones of revolution are tangent to adjacent edges and have axes passing the center of the sphere.

For obtaining EO meshes from Koebe meshes, Pottmann et al. [1] proposed optimization-based approach. In their method, the variables of the optimization problem are nodal coordinates of the EO mesh and the corresponding Koebe mesh, where the distance to a reference surface and a function representing the fairness of the mesh are considered as the objective functions. Conditions that the obtained meshes only have the planar faces and are parallel with a Koebe mesh are incorporated in penalty functions which are added to the objective functions. The obtained meshes have the property that the distances of all of the edges are approximately constant (*approximate offset*).

Koebe mesh is obtained from the patterns of adjacent circles as shown in Figs. 3(b)-(d). For considering the transformation keeping the angle between adjacent circles unchanged, Möbius geometry [2] has

(a) (b) (c) (d)

Figure 3. EO mesh and related cones of revolution: (a) EO mesh, (b)-(d) Generating a Koebe mesh from circles packed on a sphere

been used in previous researches, e.g., by Liu et al. [3]. Pottmann et al. [1] regarded the offset transformation for generating an EO mesh as one of the Laguerre transformations.

In this study, we propose a method using *two-level optimization approach* to obtain a hexagonal latticed shell satisfying the properties of EO mesh, and its shape is close to the predetermined surface. Two-level optimization consists of *mesh-level* and *face-level*. In our method, variables in a mesh-level optimization are parameters related to Möbius transformation which control the shape of Koebe mesh. For each solution of the mesh-level optimization, the face-level optimization procedures are sequentially executed for each face when it is newly added to an EO mesh, where the variables of the face-level optimization are the edge lengths of each new face so that the new face keeps parallelity to the tentatively decided Koebe mesh. The obtained mesh is an EO mesh where all edge offsets are strictly constant and the planarity of each face and beam is maintained. The effectiveness of this method is demonstrated by a numerical example.

2. Methodology

2.1. Generating Koebe mesh by Möbius transformation

Consider $z \in \mathbb{C}$ as a complex variable. A Möbius transformation on the complex plane is expressed as

$$f(z) = \frac{az + b}{cz + d}, \qquad (a, b, c, d \in \mathbb{C}, ad - bc \neq 0) \tag{1}$$

Figure 4(a) shows a base 2D circle pattern P_0 and its Möbius transformed pattern on the complex plane, which we simply called XY plane in this study. Equation (1) can alternatively be written as follows:

$$f(z) = \rho e^{i\theta}\left(\frac{1}{z + \alpha} + \beta\right) \tag{2}$$

where α and β are complex numbers, ρ is a positive real number, θ is a real number satisfying $-\pi \leq \theta < \pi$ and i is the imaginary unit. Assuming $\alpha = \alpha_{\mathrm{R}} + i\alpha_{\mathrm{I}}$ and $\beta = \beta_{\mathrm{R}} + i\beta_{\mathrm{I}}$, the Möbius

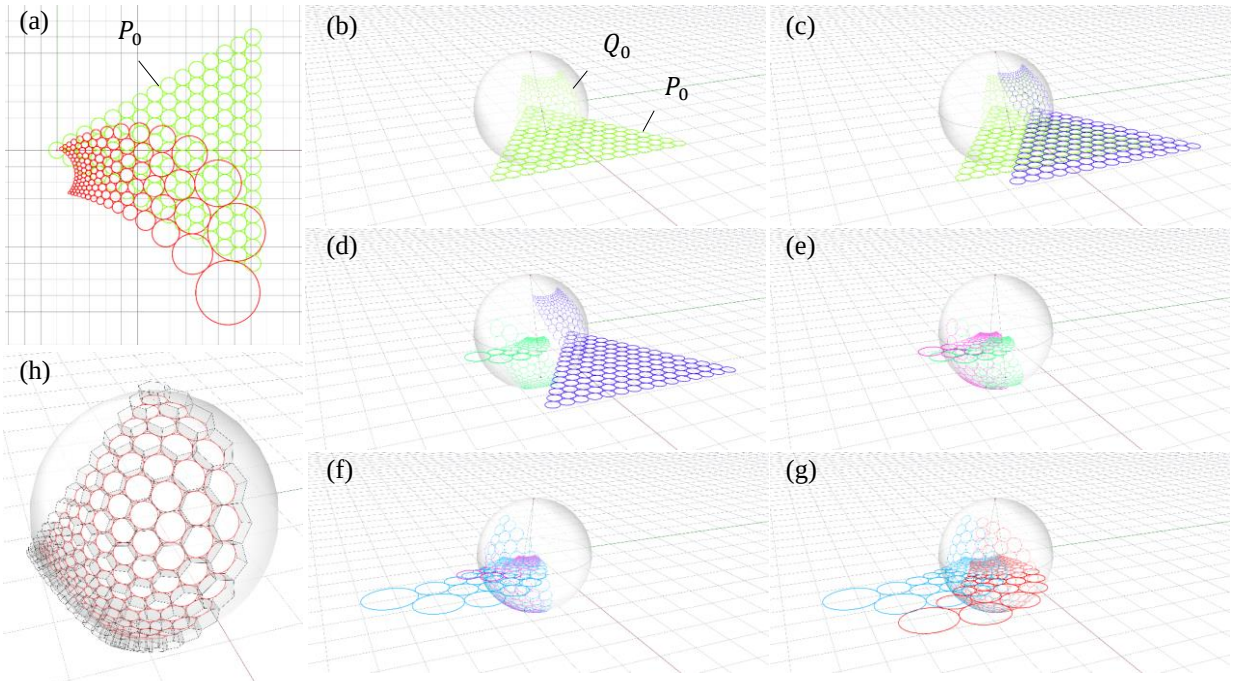

Figure 4. Möbius transformation on the complex plane; (a) Base 2D circle pattern P_0 and its transformed pattern, (b) Inverse stereographic projection from XY-plane to the north pole of a unit sphere, (c)-(g) Decomposition of Möbius transformation, (h) Obtained circle pattern Q on the unit sphere and corresponding Koebe mesh M

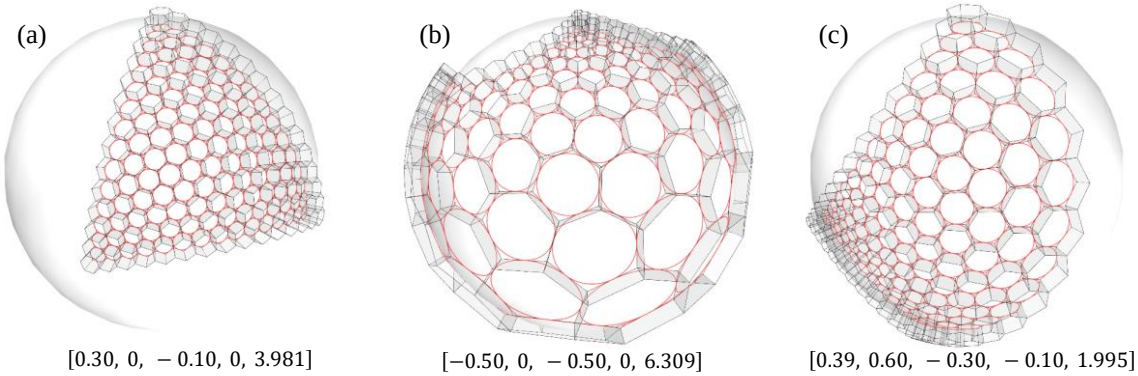

Figure 5. Generation of Koebe meshes by various Möbius transformation parameters from P_0 with the corresponding Möbius transformation parameters $[\alpha_R, \alpha_I, \beta_R, \beta_I, \rho]$

transformation can be determined by six real parameters $\alpha_R, \alpha_I, \beta_R, \beta_I, \rho$ and θ, which we call *Möbius transformation parameters* in this study. The circle pattern P_0 can be expressed as a circle pattern Q_0 on a unit sphere by inverse stereographic projection as shown in Fig. 4(b). Then, the transformation expressed by Eq. (2) acting on P_0 on the XY-plane and Q_0 on the unit sphere can be described as a combination of following steps; translation $z \to z + \alpha$ as shown in Fig. 4(c), inversion and reflection with respect to the real axis $z \to 1/z$ as shown in Fig. 4(d), translation $z \to z + \beta$ as shown in Fig. 4(e), dilation $z \to \rho z$ as shown in Fig. 4(f), and counterclockwise rotation $z \to e^{i\theta} z$ as shown in Fig. 4(g). After the Möbius transformation, rigid body rotation of the obtained circle pattern on the unit sphere to a specified position derives a circle pattern Q on the unit sphere, which generates a corresponding Koebe mesh M as shown in Fig. 4(h) with the corresponding five parameters $\alpha_R, \alpha_I, \beta_R, \beta_I$ and ρ, where the sixth parameter θ is omitted because it only causes rigid body rotation. Figure 5 shows various Koebe meshes and the corresponding Möbius transformation parameters.

2.2. Sequential face generation of EO mesh

EO meshes can be generated as a parallel mesh of a Koebe mesh as shown in Fig. 6. In this study, we propose a sequential face generation method of EO mesh keeping the parallelity to the Koebe mesh as shown in Fig. 7. The number of parameters for the face generation method depends on the number of

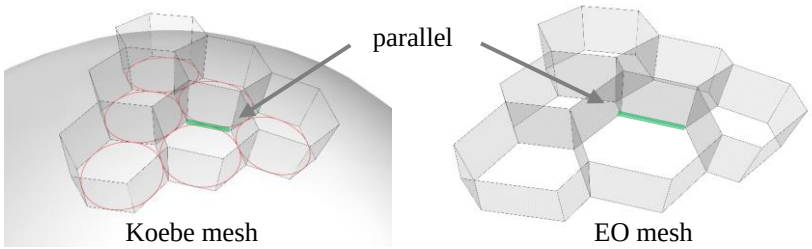

Figure 6. EO mesh as a parallel mesh of a Koebe mesh.

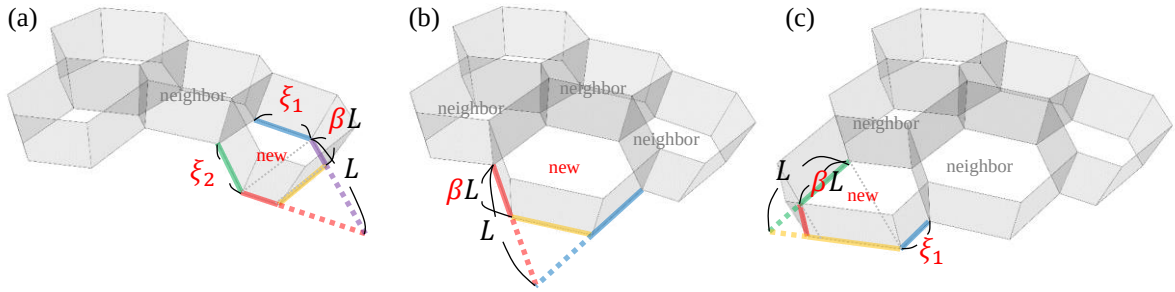

Figure 7. Sequential face generation of EO mesh; (a) One neighboring face, (b) Three neighboring faces, (c) Two neighboring faces

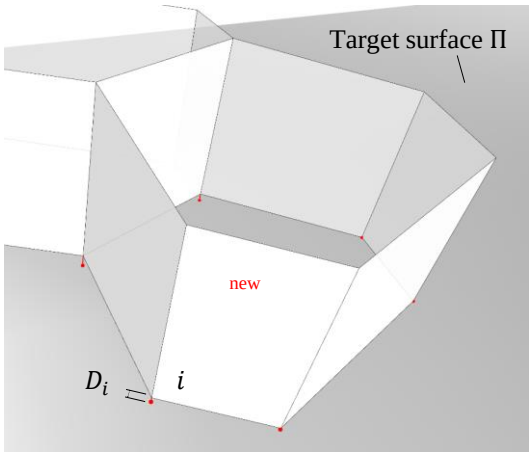

Figure 8. Distance D_i between node i and predetermined target surface Π

already set neighboring faces:

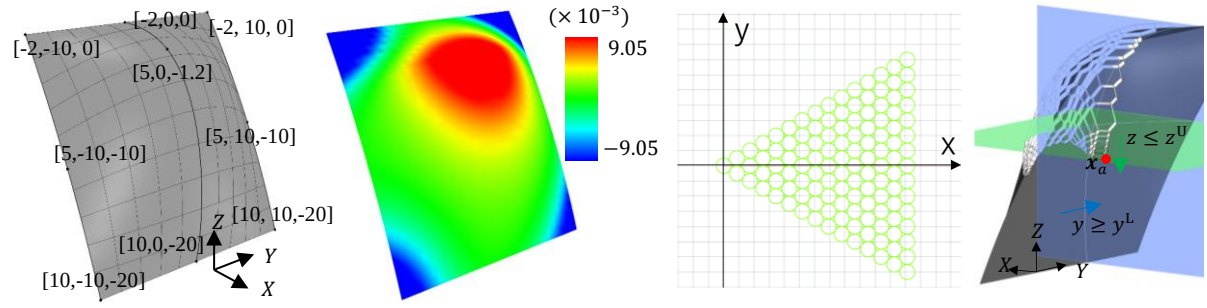
1. If the number of already set neighboring faces is one, the new face can be defined by two edge length parameters ξ_1 and ξ_2 and one edge length ratio parameter β as shown in Fig. 7(a).
2. If the number of already set neighboring faces is three, the new face can be defined by one parameter β as shown in Fig. 7(b).
3. If the number of already set neighboring faces is two, the new face can be defined by two parameters ξ_1 and β as shown in Fig. 7(c).

Parameters ξ_1, ξ_2 and β are defined so that the new face is close to a predefined target surface Π as shown in Fig. 8. Let D_i denote the distance between Π and node i in the new face f. For each face, parameters ξ_1, ξ_2 and β are defined by the following *face-level optimization problem FP*.

$$\begin{aligned} &\text{minimize} && \widehat{D}_f = \max_{i \in I_f} D_i \\ &\text{subject to} && \xi_i^{\mathrm{L}} \le \xi_i \le \xi_i^{\mathrm{U}} \qquad (FP) \\ & && \beta^{\mathrm{L}} \le \beta \le \beta^{\mathrm{U}} \end{aligned}$$

This optimization problem has at most three variables; i.e., each problem is very small.

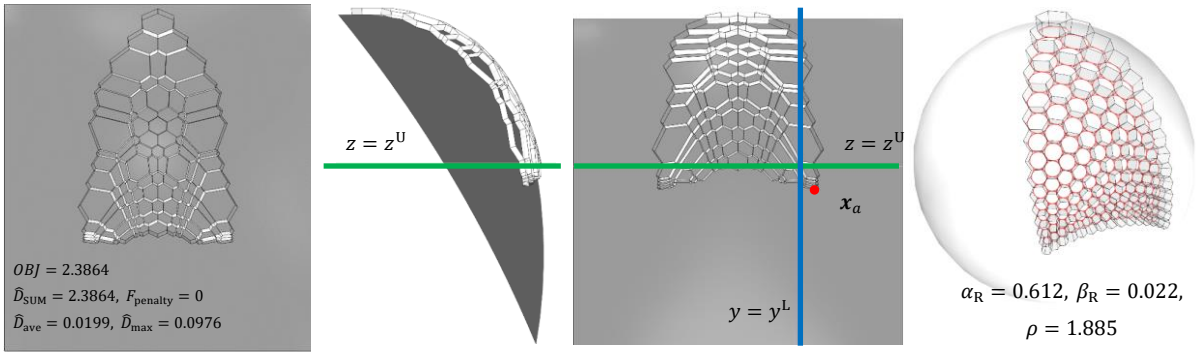
Repeating the calcuration of $\widehat{D}_f$ and the generation of a new face, all faces are generated and the sum of $\widehat{D}_f$ denoted by $\widehat{D}_{\mathrm{SUM}} = \sum_f \widehat{D}_f$ is obtained. Under the condition that the base 2D circle pattern P_0 is unchanged, the sum $\widehat{D}_{\mathrm{SUM}}$ is uniquely determined with respect to the Möbius transformation parameters $\alpha_{\mathrm{R}}, \alpha_{\mathrm{I}}, \beta_{\mathrm{R}}, \beta_{\mathrm{I}}$ and ρ which control the shape of the referenced Koebe mesh.



The EO mesh which mostly follows the target surface Π is determined by minimizing the following objective function OBJ with respect to $\alpha_{\mathrm{R}}, \alpha_{\mathrm{I}}, \beta_{\mathrm{R}}, \beta_{\mathrm{I}}$ and ρ, which we call *mesh-level optimization*:

$$OBJ = \widehat{D}_{\mathrm{SUM}} + F_{\mathrm{penalty}} \tag{3}$$

where $F_{\mathrm{penalty}}(\ge 0)$ is a penalty function for considering some additional geometric constraints which is equal to 0 when the constraints are satisfied.



3. Numerical example

As a numerical example, we find an EO mesh which approximates a target surface Π as shown in Fig. 9(a). The surface Π is an interpolated NURBS surface including nine control points as illustrated in Fig. 9(a), and is symmetric with respect to the central XZ-plane. The Gaussian curvature of Π is distributed

(a) (b) (c) (d)

Figure 9. A numerical example; (a) Target surface Π, (b) Gaussian curvature distribution of Π, (c) Base 2D circle pattern P_0, (d) Geometric constraints of node $\boldsymbol{x}_a$

(a) (b) (c) (d)

Figure 10. Obtained EO mesh; (a) Bird's-eye view, (b) XZ view, (c)YZ view, (d) Associated Koebe mesh and corresponding Möbius transformation parameters

as shown in Fig. 9(b). The base circle pattern P_0 is as shown in Fig. 9(c), in which radii of all circles are 0.1. For consideration of the symmetry, only three Möbius transformation parameters α_{R}, β_{R} and ρ are considered and only half of the faces have independent variables ξ_i and β. The boundaries β^{L} and β^{U} of FP are 0.1 and 0.6, respectively, and ξ_i^{L} and ξ_i^{U} are $0.2L_{\mathrm{B}}$ and $1.3L_{\mathrm{B}}$, respectively, where L_{B} is the average of edge lengths in the neighboring faces. As additional geometric constraints, F_{penalty} is set to have a large positive value if a corner node $\boldsymbol{x}_a$ is not included in the region $y \geq y^{\mathrm{L}}$ or $z \leq z^{\mathrm{U}}$ as shown in Fig. 9(d), where y^{L} and z^{U} are assigned as 3.6 and –9.0, respectively. The distance D_i is calculated using RhinoCommon API. The face-level optimization FP is solved sequentially by SciPy SLSQP, and the mesh-level optimization minimizing OBJ in Eq. (3) is solved by modeFRONTIER 2022R3 Simulated Annealing Solver.

Figures 10(a)-(c) show the obtained EO mesh. It is seen from the figure that the shape of the obtained mesh well approximates the target surface and the node $\boldsymbol{x}_a$ satisfies the geometrical constraints. The average of $\hat{D}_f$ denoted by $\hat{D}_{\mathrm{ave}}$ and the max of $\hat{D}_f$ denoted by $\hat{D}_{\mathrm{max}}$ are 0.0199 and 0.0976, respectively, as shown in Fig. 10(a). Associated Koebe mesh and the corresponding Möbius transformation parameters are illustrated in Fig. 10(d).

4. Conclusion

In this study, a two-level optimization approach has been proposed to obtain a hexagonal latticed shell with EO mesh whose shape is close to a predefined target surface. The numerical example shows that the proposed method generates the EO mesh whose shape is similar to the predefined freeform target surface, strictly satisfying requirements of constant edge offset distance and face planarity.

Abstract

The Dong'an Lake Sports Park Stadium will serve as the main venue for the opening ceremony of the 31st World University Games. Its roof is a perfect circle with a projected diameter of 295m and a cantilever length of 45m. In order to show the history and culture of Chengdu, the Sun Bird pattern was presented on the roof. Through fine structural design, the architectural vision was realized on the light roof with extra-long, large-span and large- overhang. Different from the conventional design, a 25m wide viewing platform of 300m long around the perimeter of the roof was set on the large-span steel roof, enabling visitors to overlook Dong'an Lake Park from different angles and enjoy the beautiful scenery of the landscapes. A single-layer arc cross grid was preferred as the platform support. Four cylinders providing vertical traffic for the 29m platform were arranged on the south side of the building. Considering the complex spatial relationship between the steel roof, large platform and vertical traffic cylinders, a refined design was carried out. In this paper, the technical innovations of the structural design to meet the requirements of architectural functions and cultural creativity were explained in terms of the selection of structural system, optimization of structural arrangement, resolution of complex space and realization of rapid construction.

Keywords: stadium roof, sun bird pattern, high altitude viewing platform, large-span, complex spatial relationship

1. Project overview

The 31st World University Games will be held in Chengdu, and Dong'an Lake Stadium will be the main venue for the opening ceremony, which will not only meet the requirements of the event and its later operation, but also carry the mission to showcase Chengdu as a city with a long history and culture to the world. The architectural scheme uses a "flying saucer" shape to express the image of Chengdu University Games with a sense of technology and sports, symbolizing hope, brightness, and unity. The roof and the infield present the Sun Bird pattern, expressing the combination of the cultural heritage of Sichuan and the spirit of the World University Games across time and space. An extra-long high altitude viewing platform is set up on the roof to provide a beautiful view of Longquan Mountain and Dong'an Lake (Figure 1-3).

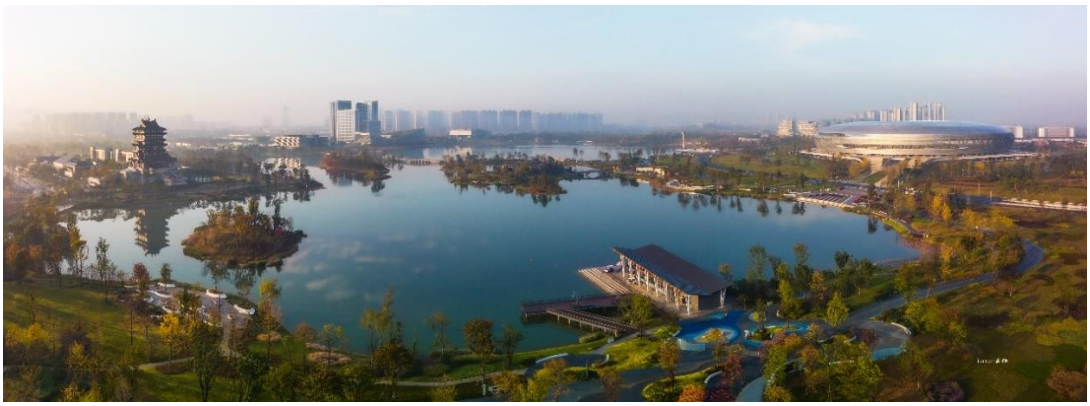
Figure 1. Aerial view of the northwest corner of the stadium

Figure 2. A distant view of the southeast side of the stadium



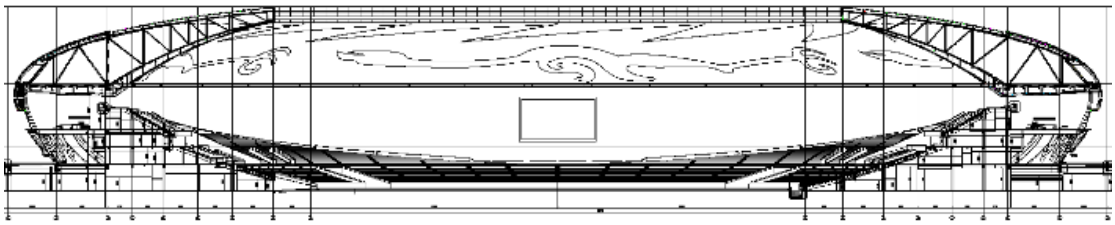


Figure 3. The stadium with a view of the mountains and the lake

The construction area of Dong'an Lake Stadium is about 120000 m^2, which is a Grade A stadium with 40000 seats. There are 5 floors above the ground, with a building height of 49.8m, and the highest point of the concrete grandstand is 22.4m [1]. The diameter of the roof is 295m, and the overhanging length of the canopy is 45m (Figure 4-5). The roof structure consists of 88 cantilever trusses, of which 44 main trusses are supported by concrete columns and 44 secondary trusses are supported by inner three-dimensional transfer trusses. The facade consists of 88 groups of crossed circular tubes forming a single-layer grid, supported by finished hinge bearings on the 7.000m platform.

2. Structural features of the stadium

2.1. Perfect realization of the sun bird pattern

The Sun Bird pattern is presented on both the upper and lower surfaces of the stadium roof, and the long and splendid history and culture can be felt both outside and inside the stadium. The Sun Bird pattern needs to be printed on the roof covering material, and the design compared various roof materials and finally adopted glass roof. The colored glass can better represent the pattern, and the material has good

durability and self-cleaning property. The total area of roof glass is approximately 27000 square meters, which is assembled by 12540 pieces of colored glazed glass. The Sun Bird pattern on the lower surface is completed by polyester fiber grid membrane, which is hung on the lower chord of the steel roof as the ceiling of the field (Figure 6-7).

Figure 6. The sun bird pattern is presented on the glass roof

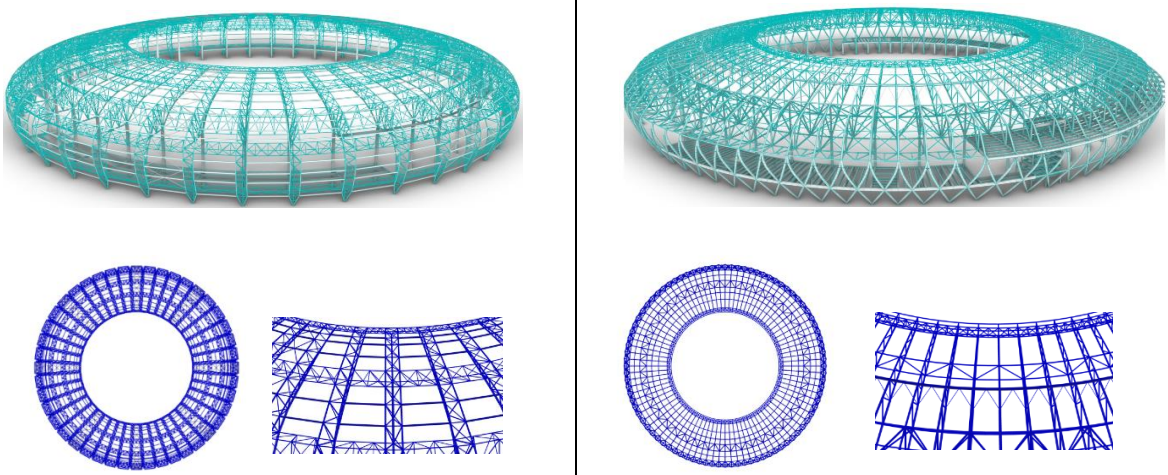

Figure 7. The sun bird pattern is presented on the lower chord membrane

Two structural forms, plane truss and triangular space truss, were compared in the overhang part of the structure. The triangular space truss structure has good overall stability, but due to the large number of members, it will be printed on the inner ceiling membrane in daylight, affecting the Sun Bird pattern. The plane truss projection surface has fewer members, so the plane cantilever truss was ultimately selected (Figure 8).

For the plane truss with a 45-meter overhang, in order to solve the problem of out-of-plane stability of the plane truss, in addition to the edge sealing truss, two annular trusses are installed in the overhang area. One of the annular trusses is located at the boundary between the sun and the bird, and the other truss evacuates the bottom chord to provide out-of-plane support with web members (Figure 9-10). At the same time, efforts are made to achieve the alignment relationship between the glass unit and the rod

to reduce the impact of excess roof lines. By adjusting the curvature of the top chord of the truss and the size of the glass parting plate, and at the same time adjusting the arrangement of the webs of the truss, the structural reasonableness was finally judged by the angle formed by the webs (Figure 11). The shape of the overhanging joist was also determined by combining the curvature of the lower chord membrane.

2.2. Complex spatial relationship between the steel roof, viewing platform and the vertical traffic cylinders

Different from the conventional design, a 25m wide high altitude viewing platform of 300m long around the perimeter of the roof was set on the large-span steel roof, while two viewing platforms of approximately 165m long and 20m wide were set on the elevation of 16.6m, enabling visitors to overlook Dong'an Lake Park from different angles and enjoy the beautiful scenery of the landscapes. In order to reach the 29m viewing platform directly from the ground and meet the evacuation demand of the observation platform, four vertical traffic cylinders need to be designed for setting stairs and elevators. Due to the large size of the traffic cylinders, it is impossible to avoid the planar truss, which results in the lower chord of the truss passing through the vertical traffic cylinders, and the steel roof cannot be detached from the traffic cylinders. In order to shorten the force transmission path of the secondary truss, the lower chord of the secondary truss is connected to the vertical traffic cylinders, which better solves the deformation coordination and connection among the tube, floor, and truss (Figure 12-13). The effect of roof construction is shown in Figure 14-15.

The four vertical traffic cylinders on the south side connect the 7m platform and the 29m observation platform, while the 16.6m observation platforms on the east and west sides connect the curved single-layer cross grid of the facade with the grandstand structure. At the same time, the 16.6m observation platform is connected to the south core cylinder, and the curved single-layer cross grid of the facade is supported on the 7m large platform. Based on the complex spatial relationship between the steel roof, large platform and the vertical traffic cylinders, shrinkage and creep of the concrete were taken into account during the construction stage analysis. The single model and assembly model were considered for envelope, and the design parameters were considered in different regions to achieve a refined design.

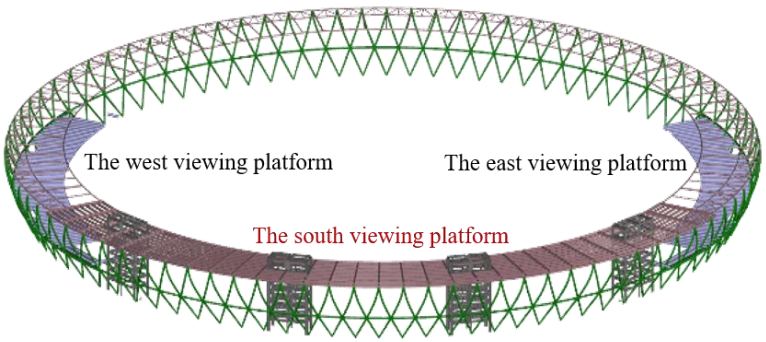

Figure 12. Diagram of the viewing platforms

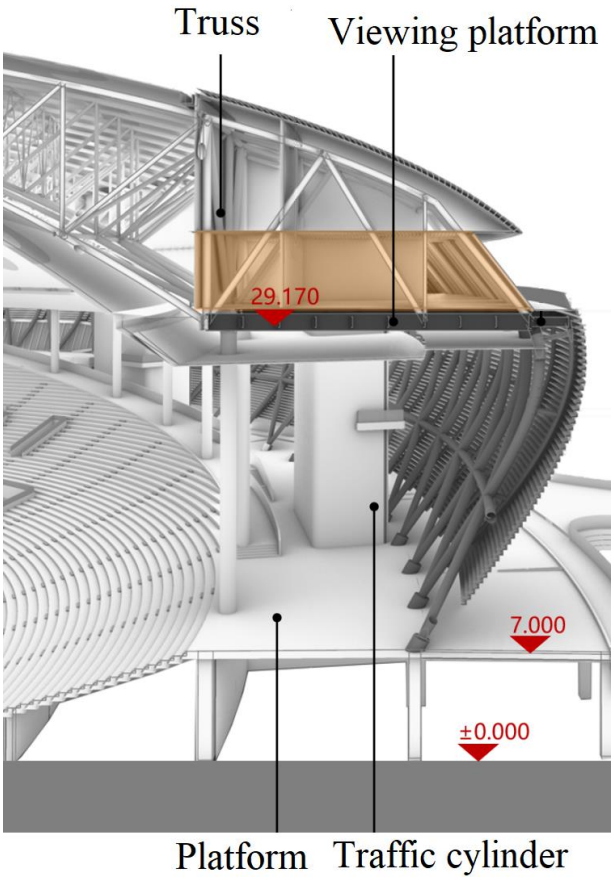

Figure 13. Section drawing of high altitude viewing platform

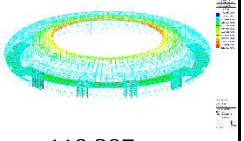
Figure 14. Actual view of the high altitude platform

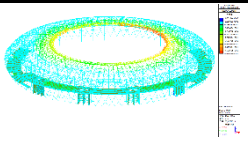
Figure 15. The photo of the completed roof structure

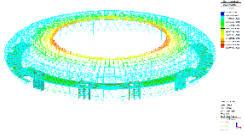
2.3. Rapid construction

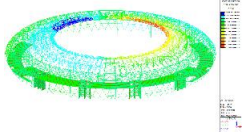
The construction period of the project is extremely tight, with only 23 months from construction to operation, while the average construction period of similar projects in China is 3-4 years, which poses a great challenge to both design and construction. To meet the needs of rapid construction, the stadium roof was shaped in a circle and then the circle was divided into 88 standard units to achieve

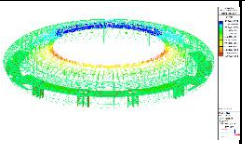
standardization and modularization of the structural system and curtain wall system. The advantages of efficient prefabrication and assembly of steel structures were exploited to improve construction efficiency and save time significantly. Figure 16 shows the roof structure under construction.

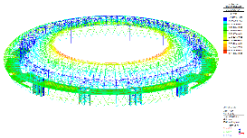


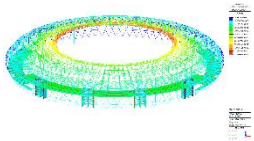












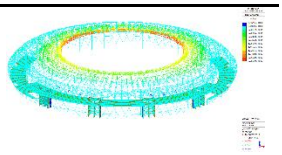


Figure 16. The roof structure under construction

3. Analysis of the roof structure

3.1. Static performance analysis of the roof structure

Considering that there are many types of rods in this project, in order to finely distinguish the importance level of rods, the rods are divided into three levels: general members, important members and key members. The static calculation of the roof structure shows that the stress ratios of the members meet the performance target requirements. The deflection-span ratio under the envelope load condition is 1/199, which meets the code [2] requirements, as shown in Table 1.

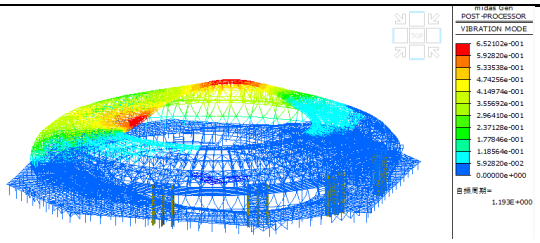
Table 1. Vertical displacement of the structure

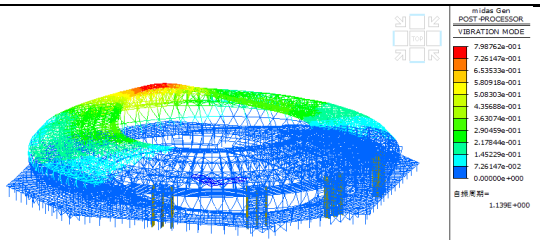
Load case	1.0 D +1.0 L	1.0 D+1.0 L（East）	1.0 D+1.0 L（South）	1.0 D +1.0W（East）
Displacement	 -118.387mm	 -105.589mm	 -88.633mm	 -171.557mm
Load case	1.0 D +1.0 W（South）	1.0 D+1.0 T- rise	1.0 D+1.0 T-down	Envelope condition（1.0 D+1.0 W +0.7 L +0.6 T-down）
Displacement	 -130.926mm	 -54.436mm	 -137.461mm	 -226.399mm

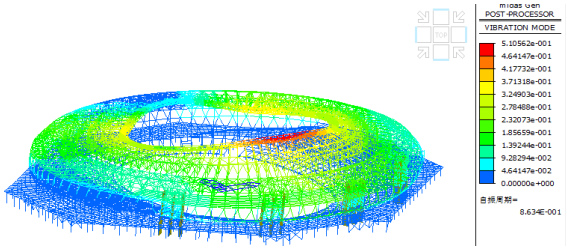
3.2. Seismic performance analysis of the roof structure

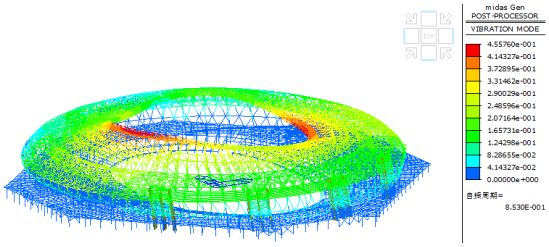
In order to truly reflect the influence of the lower concrete structure on the upper steel structure during the earthquake, a synergistic analysis of the general assembly model was carried out. The first 4 modes of the structure are shown in Table 2, and the low-order vibration mainly focuses on the horizontal vibration of the roof, not the torsional vibration. The stress ratio of each group of rods in the response spectrum analysis meets the design requirements. Under the time history analysis of the rare earthquake (Table 3), the maximum stress ratio of key members was 0.853. The stress ratios of the remaining members were all less than 1.0, which satisfied the performance target requirements.

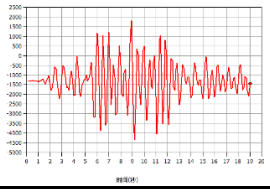
Table 2. The first 4 modes of the structure

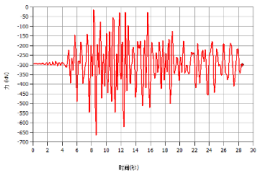
	


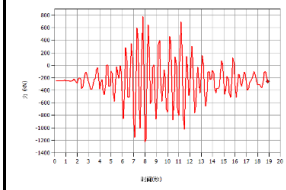


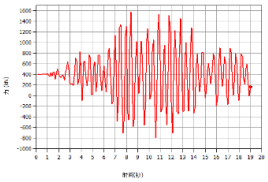












T1=1.193 X-direction vibration on the northeast side of the roof	T2=1.139 Y-direction vibration on the northeast side of the roof
	
T3=0.863 Y-direction vibration on the south side of the roof	T4=0.853 X-direction vibration on the east-west of the roof

Table 3. The time history analysis results of the rare earthquakes

Chord near the support	Remaining cantilever truss chords	Convert truss	Facade single-layer cross grid
			
Stress ratio 0.818	Stress ratio 0.820	Stress ratio 0.853	Stress ratio 0.701

3.3. Stability analysis of the roof structure

The stability analysis of the roof structure was carried out by using the general finite element software ANSYS, considering the double nonlinearity, and using the arc length method to track the equilibrium path of the structure to obtain the load-displacement whole process curve [3]. The stability analysis program was prepared considering the structural characteristics. The maximum initial geometric defect was taken as L/300, and the bilinear follow-through strengthening model was adopted to consider the material nonlinearity. The stability of the structure was analyzed under three load conditions of 1.0 dead load + 1.0 live load, 1.0 dead load + 1.0 east half-span live load and 1.0 dead load + 1.0 south half-span live load. Through the whole process analysis, the ultimate bearing capacity coefficients under the above conditions are 3.79, 4.52 and 4.80 respectively, which are greater than 2 and meet the code requirements. The load-displacement curves of 1.0 dead load + 1.0 live load is shown in Figure 17.

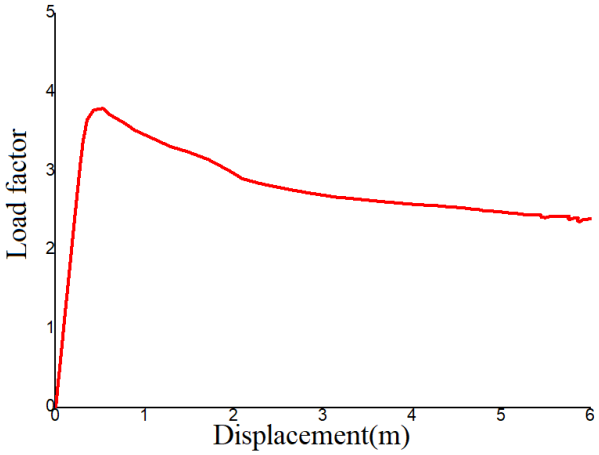


Figure 17. The load-displacement curves of 1.0 dead load + 1.0 live load

3.4. Analysis of structural consecutive collapse resistance

The transient dynamic analysis of the structure was carried out by MIDAS Gen. The damage of the roof was analyzed by removing the roof support columns and truss members separately. The stresses and displacements after removing the main truss chords of the roof are shown in Figure 18. The vertical displacement of the node after the vibration stops is 13.7mm, and the maximum stress of the adjacent upper chord is 89MPa, which is less than the yield strength of steel. When one supporting column is removed, the stress of the two horizontal transfer truss webs near the removed supporting column is 196MPa, and the stress of the remaining roof members is less than 160MPa. The bearing capacity ratio of the adjacent frame columns is 0.35, all of them are in elastic state, and the structure has strong resistance to continuous collapse.

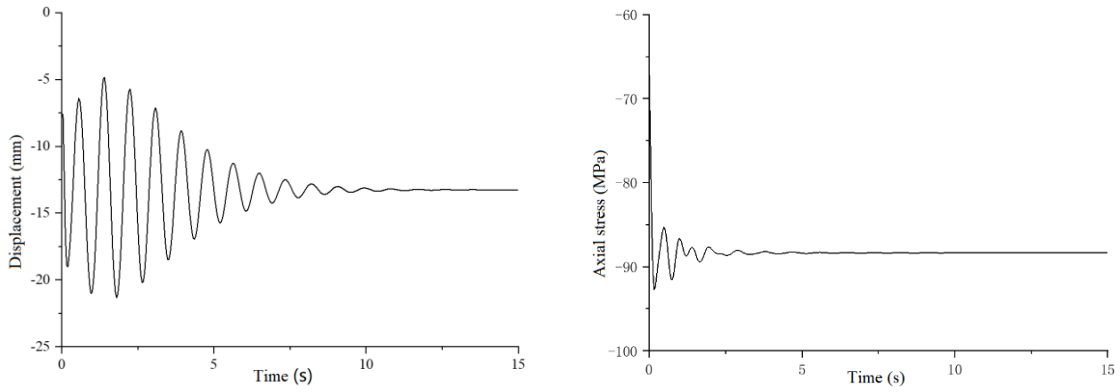

Figure 18. Stress and displacement of the structure after removing the roof main truss chord

3.5. Finite element analysis of the joints

ABAQUS was used to perform finite element analysis of the typical joints. The distribution location of each key joint is shown in Figure 19. Joint 1 has more members and the angle between the members is small, so it is difficult to weld, and finally cast steel joints were used. The calculation results of typical joints are shown in Figure 20. Excluding the local stress concentration, the stress in other parts of joint 9 is less than 290Mpa, and the yield bearing capacity is about 2.1 times the design load.

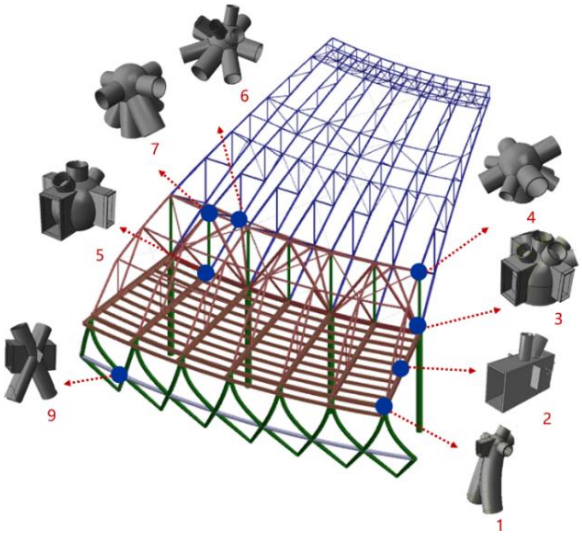

Figure 19. Diagram of key joints arrangement

(a) (b)

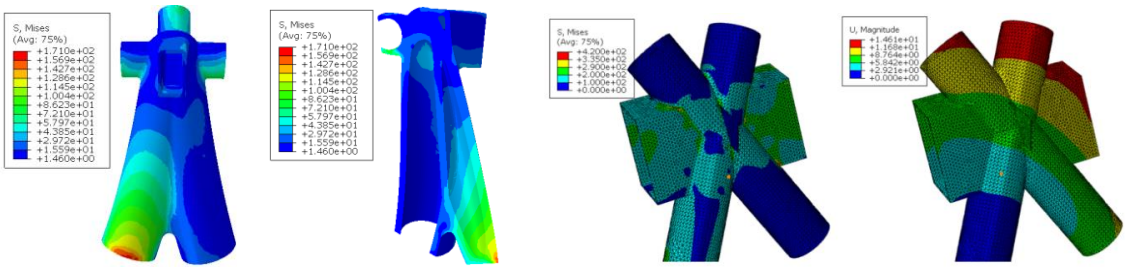

Figure 20. Typical joints calculation results: (a) analysis results of joint 1, (b) analysis results of joint 9

4. Conclusion

The perfect presentation of the Sun Bird pattern on the roof of Dong'an Lake Stadium expresses the combination of the cultural heritage of Sichuan and the spirit of the World University Games across time and space. The combination of ultra-long viewing platforms and steel structure roof creates a new architectural model for the stadium structure. The use of standardized design and prefabricated assembly has broken the time record for rapid construction of stadiums.

The clarity of structural logic display, the coordination of components and architectural space, and the refinement of joint details are key elements of structural design. While achieving the beauty of architecture, the structure itself can also be a part of the beauty of architecture. Projects with reasonable structural system, integration of architectural shape and structural force, and concise and beautiful joints can often leave a deep impression and achieve a perfect integration of structure and architecture.

Abstract

Bamboo is increasingly considered a suitable alternative to established construction materials due to its superior sustainability and relatively low environmental impact. This material has been adopted in construction both in natural and engineered forms in temporary works and structural elements, respectively. Like other biomaterials, bamboo is sensitive to moisture producing permanent deformations that can affect its mechanical properties. To evaluate the influence of moisture on the compression, shear and splitting response of moso bamboo, a detailed experimental investigation is carried out. Culm tubes with aspect ratio (H/D) of 1.0 and 3.0 were tested under the above loading conditions to failure either in oven-dry, ambient-dry or fully saturated conditions. Apart from conventional measurements, the use of digital image correlation techniques enables a detailed assessment of the stress localisation characteristics, including crack initiation and propagation within the bamboo wall tube. Comparative assessments in terms of compression, shear and splitting resistance as a function of moisture and aspect ratio are performed and discussed. The results show that an increase in moisture from oven-dry to ambient-dry to wet conditions shows a proportional decrease in strength by up to 43%, but a slight increase in ductility, as a function of the loading type. Short samples achieved between 5.1-163.6% higher maximum average stress compared to the long samples, indicating increasing the sample aspect ratio decreases the tube strength.

1. Introduction

Natural bamboo has been attracting wider usage in construction as it is a fast-growing renewable raw material and with good mechanical properties when compared with other conventional materials [1,2]. The bamboo plant is better at capturing and storing carbon from the atmosphere compared with timber if it is sustainably grown [3]. Once reaching maturity it creates 15 times more wood per hectare than tree forests [4]. In comparison to conventional construction materials, both full-culm natural and engineered bamboo have a lower environmental impact [5]. Thus, the potential of natural bamboo as a material for sustainable construction and circular economic development is unprecedented. The material was at the centre of the COP27 agenda in response to the wider decarbonisation goals [6].

Bamboo forests serve as a carbon sink and offer significant environmental benefits due to their rapid growth and regrowth after harvesting [7]. Locally sourced bamboo can provide a more environmentally friendly alternative to conventional mineral-based materials, primarily due to transportation distances and other factors. For single-story housing over the lifecycle of the building, locally sourced full culm bamboo is the most efficient material [8]. Bamboo, which originally comes from Southeast Asia [7], is now widespread in Asia, Africa, and Latin America, with roughly 1300 species covering about 0.8% of the world forested area. Moso bamboo, which is the most abundant species in China, is thus significant for testing and potentially developing strength/capacity grading for structural purposes. Despite the extensive historical use of bamboo in construction, rigorous testing and documentation of its mechanical properties are limited [9,10].

Bamboo can be regarded as a naturally occurring composite material that has a complex microstructure and unique properties, in which its properties vary along the thickness of the culm [11]. Such materials are referred to as functionally graded. The strength of natural bamboo comes from densely populated fibres at the culm exterior. Although bamboo has a high strength to weight ratio, it is weak perpendicular to fibres, making it prone to splitting, which regularly governs its structural design. Culms experience failure due to maximum tangential tensile stress, specifically in splitting, rather than in compression, bending, or shear [12,13]. Due to these properties the material has a great potential for structural applications, particularly in axial load carrying applications such as columns and trusses [14], provided that the tangential stresses are maintained below the splitting strength, otherwise splitting occurs.

The parallel-to-grain compression and shear properties of bamboo culms are typically evaluated through axial compression tests on tubular elements having the same diameter and length. For the compression tests the load is uniformly applied to the culm element, whilst for shear test a bowtie-shaped device is used to create four shear planes. The perpendicular-to-grain compression strength is obtained through edge bearing tests, in which a culm element is subjected to compression [15]. The tensile strength of bamboo in a direction perpendicular to the culm can be determined using the split pin test, in which a bamboo tube is pulled apart by a pin passed through a circular hole [15]. The presence and size of this hole influence both the tensile and compressive strength of the bamboo culm [16]. It was previously shown that the resistance of bamboo materials highly depends on the test method [17].

Like other biomaterials, bamboo is sensitive to moisture producing permanent deformations that can affect its mechanical properties. These degrade as the moisture content increases up to the fibre saturation point (around 30%), with less significant degradation beyond this point [18]. The same study showed that immersion in water for a day can achieve the fibre saturation point, causing a 25% reduction in compressive strength compared to air-dry conditions. With regard to the response to various humidity levels, it was shown that bamboo achieves the highest strength values at 60-80% humidity with a subsequent decline in strength beyond that range [18]. All studies indicated that humidity typically increases the ductility of the samples, otherwise having a relatively brittle response.

Existing studies evaluated the mechanical properties of bamboo culms through samples with a height-to-diameter ratio of 1.0. It is well known that stub tubes under compression are prone to failure due to end effects [19]. Conversely, slender tubular members are prone to local buckling. Similarly, in splitting, the crack kinematics and rate of propagation depend on the available length. Shorter tube elements under the split pin test would fail quicker than longer tubes. Due to the inherent stress distribution and end effects in compression, stub elements are likely to give unconservative estimates, whilst in splitting these would provide overly-conservative estimates. A more realistic sample ratio would consider the inter-nodal length, as the diaphragm act as internal restraint to local tube buckling.

To evaluate the influence of moisture on the mechanical properties of moso bamboo, an experimental investigation is carried out. Culm tubes with aspect ratio (H/D) of 1.0 and 3.0 were tested to failure either in oven-dry, ambient-dry or fully saturated conditions, to evaluate the stress localisation characteristics, including crack initiation and propagation within the bamboo wall tube. Comparative assessments with regard to strengths and aspect ratio are performed and discussed. This study is part of

a wider research project aiming at assessing the performance of natural and engineered bamboo under mechanical and environmental loading, developing constitutive relationships and evaluating the life-cycle sustainability of these materials.

2. Experimental methodology

2.1. Specimen details and conditioning

In this paper P. Pubescens (moso) culms with a diameter of around 70 mm and a tube thickness of 7 mm were used. Samples with two aspect ratios of height-to-length of approximately 1.0 and 3.0 were extracted randomly from 5 × 4.0 m culms by cutting with a circular saw. These aspect ratios correspond with specimens of around 70 and 210 mm length. The samples were taken from inter-nodal regions which were in good visual condition and did not show any shrinkage cracks. The inter-nodal regions were marked at each cut end with the sample number, described below, for future correlation of cross-sectional fibre distribution with mechanical strengths.

A total of 90 samples were prepared, equally divided into compression, shear and splitting tests. For the splitting tests, a central hole was drilled using a 13 mm drill bit to allow for a 12 mm pin to pass through. For each test type, three conditioning types were considered. This includes ambient-dry, oven-dry and wet conditions. Prior to conditioning the sample geometry was carefully measured with a digital calliper at a minimum of three locations. These include three measurements of top and bottom diameter, top and bottom tube thickness and tube height. The weight of the samples was measured using a digital scale with an accuracy of 0.1 g.

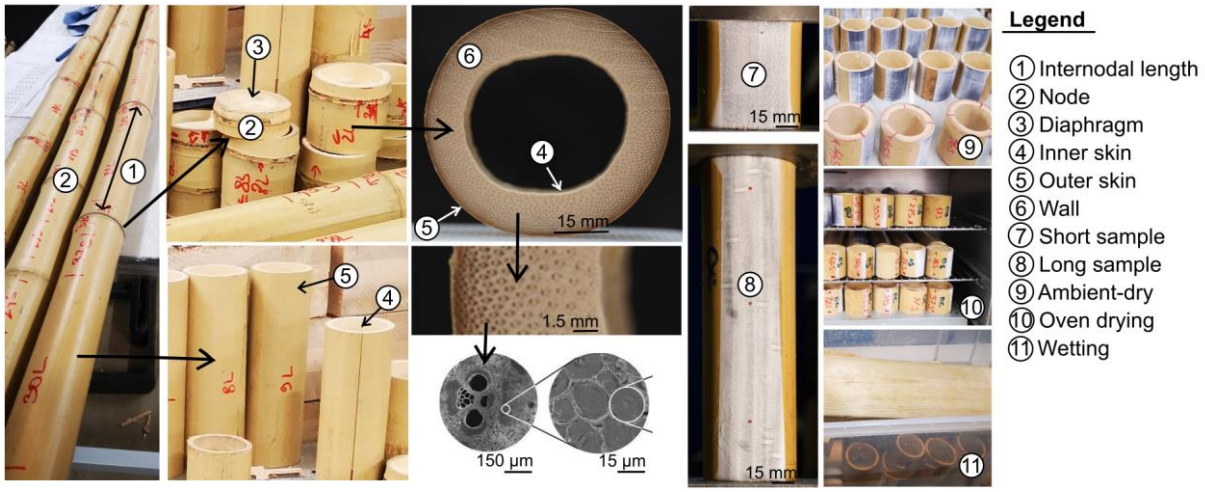

Figure 1. Details of the bamboo culms, terminology, specimen geometry and conditioning (the diagram with the bamboo microstructure is adapted from Ref. [20]).

Ambient dry samples were kept in standard laboratory conditions at 20±2°C and relative humidity of 40±5%. Oven-dry samples were dried for a period of 48h at 30°C. A low temperature for drying was considered to minimise the influence of forced drying to moisture kinematics. A preliminary study on drying showed that temperatures above 30°C are not suitable for drying this type of bamboo, particularly for the case of relatively thin tubes which split during the process. Wet samples were submersed in tap water for 48 hours in a plastic container, which is sufficient to achieve the fibre saturation point as indicated in the literature.

After oven-drying or water immersion, the sample weight was measured again with the same device, to evaluate the mass loss or gain, respectively. The average mass loss due to oven drying for all samples was 4.2±0.7%, whilst the average mass gain due to water submersion was 36.6±8.8%. Sample ID follows the B*xxACT*, in which xx is the sample number, A=S,L refers to the aspect ratio (S for short

H/D=1.0, and L for long H/D=3.0), C=A,O,W is for the conditioning (A is for ambient-dry, O is for oven-dry, and W is for wet), and T=C,B,S is for the testing type (C for compression, B for bowtie shear, S for pin splitting). For example, Sample B20LAB refers to a long bamboo tube with H/D=3.0, tested in ambient-dry conditions under bowtie shear.

2.2. Testing arrangements and instrumentation

The compression and shear samples were tested in an Instron Satec 600 kN machine provided with a data acquisition system (Figure 2). The machine bottom grip was replaced by a steel support with a flat plate, and a supplementary support plate to position the specimens. At the top grip, the machine had a hinge to ensure smooth load transfer without any influence for potential very small inclinations of the top surface of the samples. The compression samples were supported by a thick steel plate and the load was applied through the hinge. For the shear tests, top and bottom bowtie devices were used to create four shear planes for the sample subjected to compression. These tests are widely used to evaluate the shear resistance of bamboo culms. For the splitting tests an Instron 250 kN machine was used. This had a 12 mm pin device passing through the 13 mm hole drilled through the bamboo tube. At the top of the tube a rubber strip and a tee were positioned to apply a compressive load which produces splitting in the tube. All tests were carried out in displacement control at a rate of 0.5 mm/min.

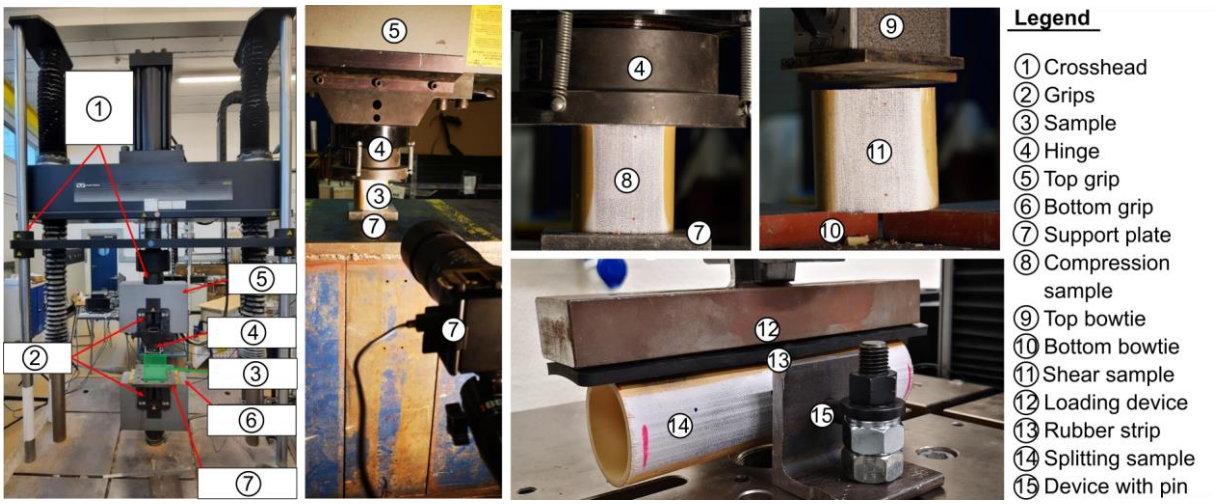

Figure 2. Testing arrangements and instrumentation

To evaluate strain development and crack kinematics, an in-house digital image correlation (DIC) was used. This DIC adopted a non-contact system that uses one high-sensitivity APS-C type (23.5 × 15.6 mm), Exmor CMOS sensor camera with USB 3.0 interface to provide accurate and practical measurements for material and specimen tests. The camera had a resolution of 24.2 Megapixel. To prepare the specimens, they were painted white and speckled with 1.00 mm black dots using black ink and stamping system. Prior to testing, a calibration procedure was done by adjusting the aperture, lighting, and focus while taking photos of a calibration plate. A frequency of 0.1 Hz was used to record the images. After testing, the DIC data was processed to obtain deformation vector fields, and surface strains which are used to identify stress concentrations. For processing the images, Ncorr, an open-access MATLAB-based 2D digital image correlation program was used [21].

3. Test results

3.1. Compression tests

As mentioned in Section 2, bamboo tube samples with a diameter of around 70 mm and wall thickness of 7.0 mm were tested under axial compression. Samples with two aspect ratios were tested in ambient-dry, oven-dry and wet conditions. Figure 3 shows the axial load – deformation response and the main

failure modes observed during the tests. The stress is the machine force divided by the measured cross-sectional area of the sample, whilst the deformation is the sample shortening divided by its length. Grey curves show test data, and black curves are the average response. The average geometrical properties per specimen group are shown in Table 1. The compressive strength of ambient dry long samples (LAC) was 74.0 MPa. Oven-drying increased the strength by 7.97% (LOC), whilst wetting reduced the strength by 43.9% (LWC). Short ambient dry samples (SAC) achieved on average a maximum stress of 66.5 MPa, which is 10.1% lower than the corresponding long elements (LAC). For the short specimens, oven-drying increased the strength by 33.8% (SOC) and wetting reduced it by 25.4% (SWC) compared to the SAC counterparts.

The stiffness properties followed a similar trend with the strength, as a function of the conditioning. With regard to the inelastic response, beyond the linear-elastic proportionality limit, ambient-dry samples (LAC and SAC) had a constant plateau with some ductility. The LOC and SOC samples, showed slight hardening, whilst LWC and SWC showed post-peak softening. This behaviour was associated with a brittle response for oven-dry elements and ductile crushing for the wet samples. The former failed by complete separation and explosive spalling of tube splits, whilst the latter more gradually. The failure modes, shown in Figure 3, were either through outward or inward buckling, both for long and short tubes. It is shown that moisture reduces compression strength, stiffness and ductility, whilst drying increases these properties at the expense of a more brittle response. The short stub specimens exhibited a strength that was 5.1% greater than that of the long samples for all conditions.

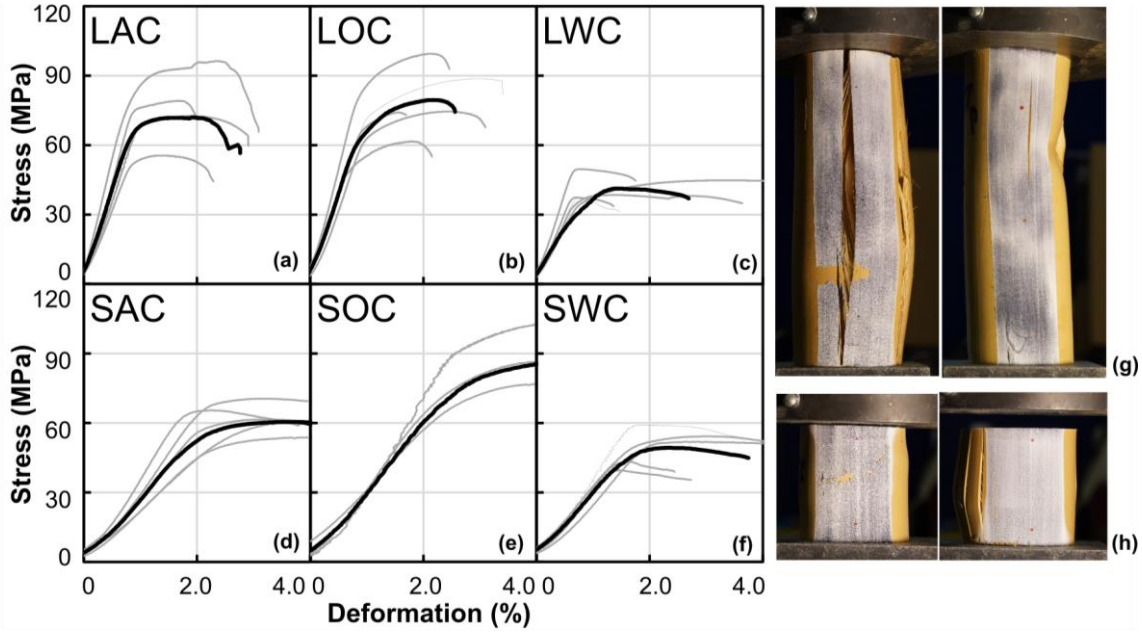

Figure 3. Compression test results for sample group: a) LAC, b) LOC, c) LWC, d) SAC, e) SOC, f) SWC; specimen failure: g) outward buckling (left) and inward buckling (right), h) inward buckling (left) and outward buckling (right) (note: grey curves represent the response of each specimen, and the black curve is the average).

3.2. Shear tests

Figure 4 shows the stress deformation response of the samples tested in bowtie shear by applying a compressive load from the machine. The stress is the machine force divided by the measured cross-sectional area of the four shear planes, whilst the deformation is the sample shortening divided by its length. Grey curves show the test data for each sample, whilst the black curve is the average of all tests from a group. The sample diameters and tube thicknesses were around 70 mm and 7 mm, respectively, as for the compression tests (Table 1). In addition to the deformational response, Figure 4 also shows selected specimens after testing. The shear strength of ambient dry long samples (LAB) was 5.7 MPa.

Oven-drying increased the strength by 36.8% (LOB), whilst wetting reduced the strength by 28.1% (LWB). Short ambient dry samples (SAB) achieved on average a maximum stress of 13.5 MPa, which is 136.8% higher than the corresponding long elements (LAB). For the short specimens, oven-drying increased the strength by 3.7% (SOB) and wetting reduced it by 34.8% (SWC) versus SAB counterparts.

The stiffness properties followed a similar trend with the strength, i.e. lower stiffness corresponds to lower strength and vice-versa. With regard to the kinematics, the sample response can be represented largely by a linear elastic curve for the oven-dry samples (LOB and SOB), and with some gradual softening around 85% of the peak stress for the remaining ambient-dry (LAB and SAB) and wet (LWB and SWB) samples. As for the compression tests, this behaviour was associated with a brittle response for oven-dry elements and ductile shear splitting for the wet samples. The former failed by complete separation and explosive spalling of tube splits, whilst the latter failed more gradually. The failure modes, shown in Figure 2, were generally through one or two shear planes. It is shown that moisture reduces sample stiffness and shear strength, whilst drying increases these properties. On average, the short samples exhibited a strength that was 105.1% higher than the long samples across all conditioning situations.

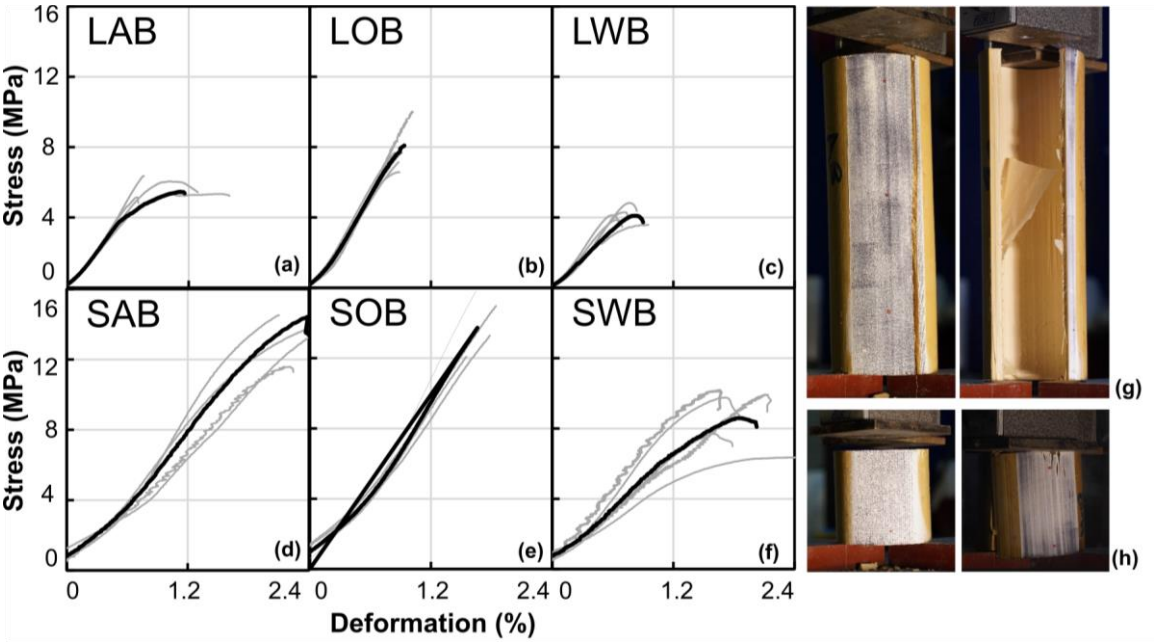

Figure 4. Shear test results for sample group: a) LAB, b) LOB, c) LWB, d) SAB, e) SOB, f) SWB; specimen failure: g) splitting through one plane (left) and full spalling of part of the tube (right), h) typical shear crack (left), rotation by the shear plane (right) outward buckling (note: grey curves represent the response of each specimen, and the black curve is the average).

3.3. Splitting tests

The stress-displacement curves and failure patterns of the bamboo tubes tested under pin splitting are shown in Figure 5. The stresses were evaluated by dividing the machine load to the cross-section of the splitting plane, whilst the displacement corresponds to the value recorded by the machine. As in the other figures, grey curves show the test data for each sample, whilst the black curve is the average of all tests from a group. The sample diameters and tube thicknesses were around 70 mm and 7 mm, respectively, as for the compression and shear tests (Table 1). The splitting strength of ambient dry long samples (LAS) was 1.3 MPa. Oven-drying reduced the strength by 30.8% (LOS), whilst moisture reduced the strength by 15.4% (LWS). Short ambient dry samples (SAS) achieved on average a maximum stress of 3.4 MPa, which is 161.6% higher than the corresponding long elements (LAS). For

the short specimens, oven-drying decreased the strength by 11.8% (SOB) and wetting reduced it 35.3% (SWS) in relation to the SAS counterparts.

With regard to the stiffness, it is shown that these are similar for all long or short specimens, regardless of the conditioning. As indicated by the curves, ambient-dry (LAS and SAS) and oven-dry (LOS and SOS) had a linear elastic response with a sudden drop after the peak. This indicates instantaneous splitting, which is similar to the brittleness levels identified in the other test types. Wet samples, on the other hand, showed some softening before the peak and a softer post-peak response. This indicates some form of tension stiffening due to moisture. It is worth noting that the splitting tests had higher variation than the compressive and shear, and in most cases the differences in maximum stress for different conditioning is within the standard deviation (Table 2). Considering the average strengths and associated standard deviation it is shown that ambient- and oven-dry samples have similar stiffness and strength for the same sample length. Moisture reduces sample splitting strength. The short samples exhibited a strength that was 163.6% higher than the long samples across all conditioning situations.

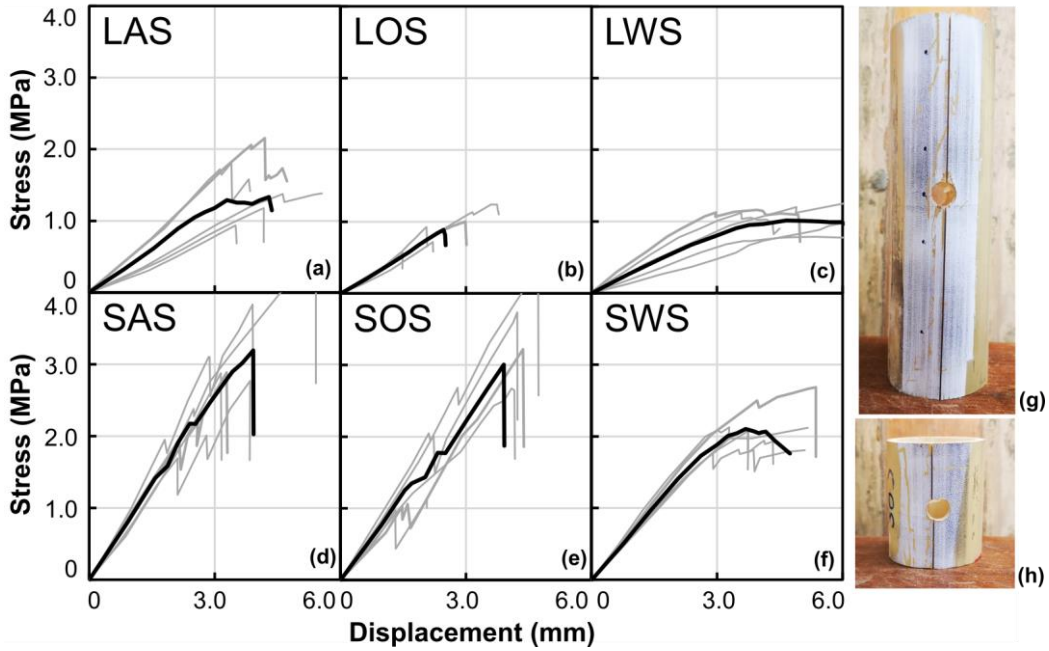

Figure 5. Splitting test results for sample group: a) LAS, b) LOS, c) LWS, d) SAS, e) SOS, f) SWS; splitting failure for g) long specimens, h) short specimens (note: grey curves represent the response of each specimen, and the black curve is the average).

3.4. Kinematics and average strengths

Figure 6 shows strain distributions at the surface of short and long tube specimens. Blue colour are associated with negative stress values indicating compression, whilst red colour is for tension. Figure 6a,b shows the shear behaviour of short elements and Figure 6c,d of the long shear samples. The surface strain maps obtained from the processing of the digital image correlation data show a concentration of compression at the top bowtie edge prior to shear splitting occurring. These maps correlate well with the failure patterns shown in Figure 4. Near the compression stress localisation, the sample had a tension governed response, due to a slight rotation of the hinge around the shear crack initiation point. As shown in Figure 6d, the maximum strain is around 2%, which is above the average deformation at failure for the long samples. The strain maps suggest that for tube specimens under bowtie shear, the failure crack initiates at the top of the sample, at compression strains above the average sample stress.

As shown in Figure 6e,d,g,f failure of the tube samples under compression is either governed by high compressions strains at the middle of the specimen (short sample in Figure 6e), or by a concentration of

compression within the length of the sample. These kinematics correspond with the failure patterns recorded after testing the specimens shown in Figure 3g,h. The short sample in Figure 6a failed in outward buckling, whilst the tube from Figure 6h in inward buckling. The other two compression samples from Figure 6f,h tested in wet conditions had both inward buckling failures evidenced by the compression strain localisation. The maximum strains in all compression samples were between 2-6%, which is about twice the ultimate average strain shown in Figure 3. The strain maps of the compression samples confirm the failure modes observed after testing and indicate ranges at which instability occurs.

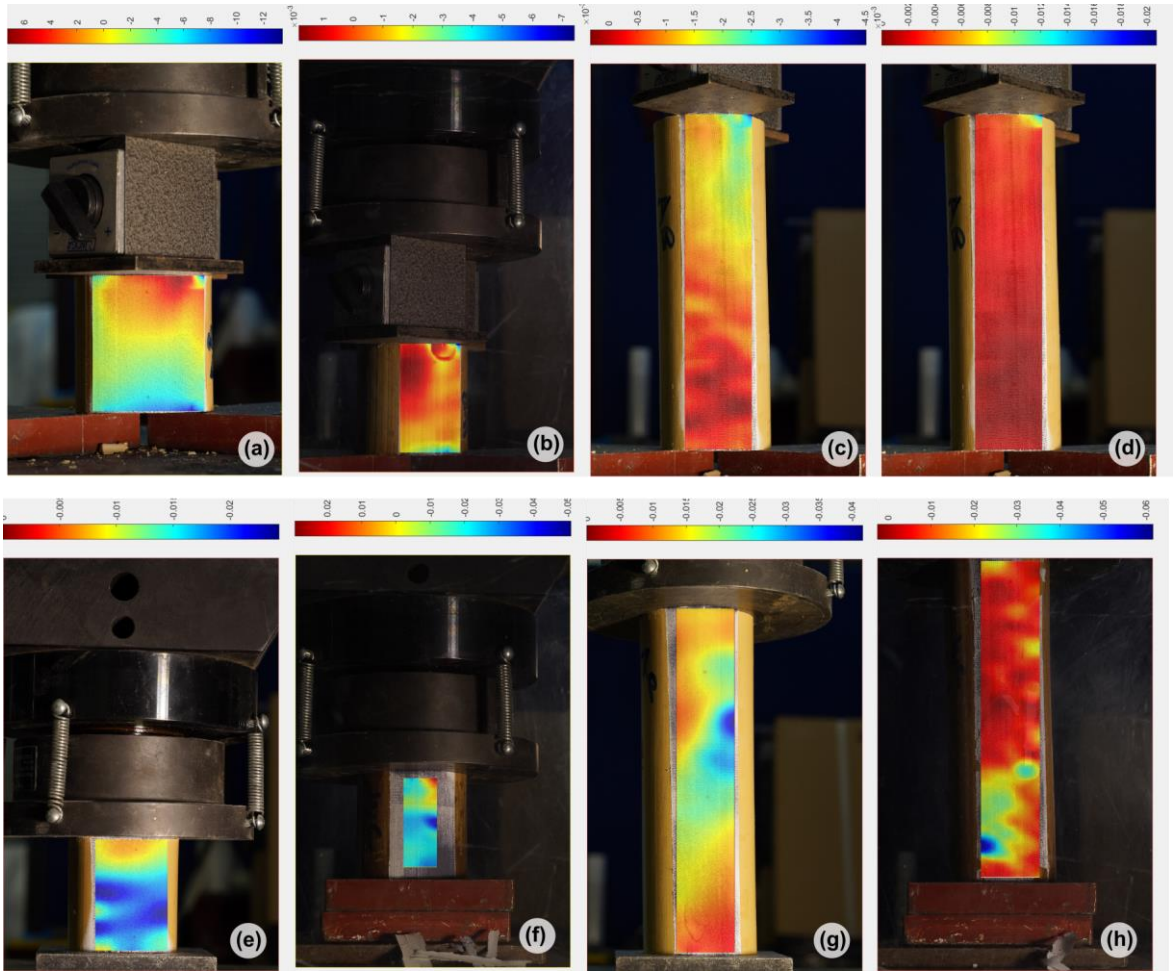

Figure 6. Stress distribution at the face of samples for selected cases: localisation at the bowtie edge in a) a short ambient dry sample, b) a short wet sample, c) a long ambient-dry sample, d) an oven-dried sample; localisation under compression: e) centre of a short tube due to outward buckling in ambient dry conditions; inward buckling initiation f) at mid-height of a wet element, g) centre-top of an ambient dry sample, h) bottom of a wet sample.

Figure 7 shows the comparative average strength for all the tests carried out in this paper. As noted above for the compression samples, the increase in moisture from oven-dry to ambient-dry to wet conditions shows a proportional decrease in strength, but a slight increase in ductility. Overall short stub compression elements had an average strength for all conditioning situations that was 5.1% higher than that of the long samples. A similar trend is observed for the bowtie shear samples, which show a decrease in strength with decrease in moisture, as well as a slightly more pseudo-ductile response, evidenced by a slight post-peak softening. On average, the short bowtie shear samples exhibited a strength that was 105.1% higher than the long samples across all conditioning situations. Finally, the splitting response was governed by higher variance within the same dataset, showing that ambient- and oven- dry samples had similar strengths, and as above, moisture had a detrimental influence on the splitting strength. The

short pin splitting samples exhibited a strength that was 163.6% higher than the long samples for all conditioning situations.

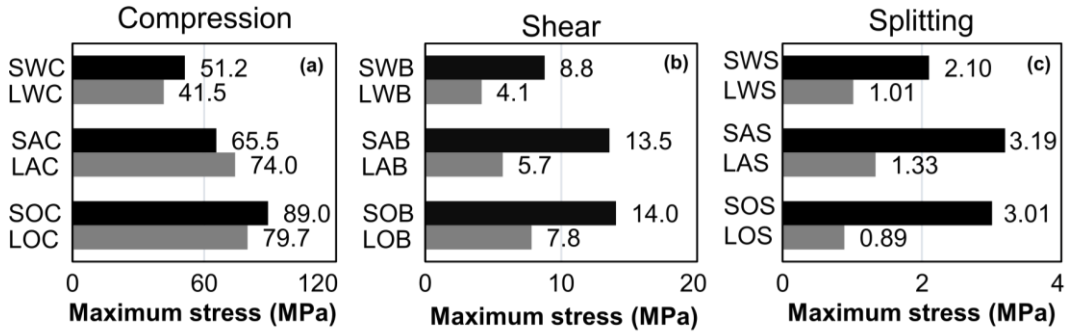

Figure 7 Maximum stress for: a) compression tests, b) shear tests, c) splitting tests.

The bar charts in Figure 7 and above discussion points indicate that short samples with aspect ratio of 1.0 fail at larger average stress levels compared to the long samples with an aspect ratio of 3.0. These tests suggest that tube slenderness influences the overall response, as shown in other twin-walled sections [22]. As shown in the literature, to reliably assess axially loaded tubular members, further experimental assessment on specimens with higher aspect ratios ($H/D \geq 3.0$) would be necessary. Stub tubes with an aspect ratio of $H/D \approx 3.0$ typically provide an accurate representation of the member behaviour, avoid consideration of end effects, they would not experience global buckling and accurately reflect stress and strain distributions. Samples with aspect ratios below $H/D < 3.0$ may be prone to local failures to end effects. These points correlate well with the experimental observations, crack kinematics and average maximum stresses recorded by specimens. When it comes to splitting, longer specimens are expected to have lower average stress compared to shorter specimens since the crack needs to propagate through a relatively longer distance.

Table 1. Sample details and maximum average stress.

Sample group (-)	Test type (-)	Diameter (mm)	Tube thickness (mm)	Height (mm)	Maximum stress (MPa)
LAC	Compression	69.5±2.9	6.2±0.6	207.6±1.0	74.0±15.2
SAC		67.8±4.8	7.2±1.8	68.2±1.6	66.5±6.0
LOC		67.4±4.0	5.7±0.6	208.2±1.0	79.7±14.6
SOC		69.9±1.5	7.7±3.2	68.4±1.7	89.0±13.4
LWC		69.1±3.5	6.9±1.5	208.1±0.8	41.5±5.5
SWC		69.6±3.2	6.2±0.9	67.7±1.0	49.6±8.0
LAB	Shear	69.7±3.0	6.6±1.1	207.8±0.7	5.7±0.5
SAB		67.1±3.3	6.7±1.7	67.8±0.9	13.5±1.3
LOB		68.0±2.1	5.9±0.7	208.2±1.8	7.8±1.3
SOB		68.2±2.3	7.1±1.3	67.8±1.1	14.0±1.7
LWB		70.2±2.3	6.7±1.1	208.7±1.5	4.1±0.5

SAS		68.1±2.5	8.3±1.5	71.1±1.8	3.4±0.8
LOS		72.1±0.8	7.0±0.7	210.3±0.3	0.9±0.3
SOS		63.3±1.4	9.4±0.7	72.7±1.1	3.0±1.2

LWS		64.7±5.5	6.0±0.8	209.8±0.4	1.1±0.2
SWS		66.9±6.3	6.2±1.1	71.3±0.9	2.2±0.3

In full culms, these effects may be influenced by the presence of the diaphragm and inter-nodal length, which may be used for evaluating reliably the strength characteristics of bamboo culms. Using elements with a H/D ratio of 1.0 for evaluating mechanical properties may result in overestimating the material properties, potentially leading to unreliable estimates for designing such members. To further investigate these points, the tests described in this paper can serve as a validation dataset for nonlinear numerical procedures adopted in finite element models. These can be used to obtain a detailed insight into the maximum normal and shear stress and evaluate the limit condition of bamboo tubes. The detailed test measurements, coupled with numerical models and results from literature, will allow for the definition of expressions for evaluating the key mechanical properties used in the design of structural bamboo culms.

4. Conclusions

This paper presented an experimental investigation into the influence of moisture on the compression, shear, and splitting behaviour of moso bamboo. The study involved testing culm tubes with aspect ratios (H/D) of 1.0 and 3.0 under different conditioning, including oven-dry, ambient-dry, and fully saturated conditions, until failure. In addition to conventional measurements, digital image correlation techniques were employed to assess the stress localisation characteristics, including crack initiation and propagation within the bamboo wall tube. Comparative evaluations were performed and discussed, examining the compression, shear, and splitting resistance as a function of moisture and aspect ratio. The main results are presented below.

For the compressive strength, oven-drying increased the strength on average by 22.9%, whilst wetting reduced the strength on average by 34.6% for both short and long samples with respect to ambient-dry samples. Similar trends were obtained for bowtie shear with the oven-dry samples having on average 20.3% higher strength than the corresponding ambient dry samples, and the fully saturated samples by 31.5% compared to the same reference case. The splitting tests showed a higher variation within the same sample group and both oven-dry and wet specimens had lower average strength by 21.3% and 25.3% compared to the elements tested in ambient conditions.

The results indicated that short samples with an aspect ratio of 1.0 fail at larger average stress levels compared to the long samples with an aspect ratio of 3.0. These tests suggest that tube slenderness influences the overall response, as shown in other twin-walled sections. Short stub compression elements had an average strength for all conditioning situations that was 5.1% higher than that of the long samples. Short bowtie shear samples exhibited a strength that was 105.1% higher than the long samples, whilst the short pin splitting elements were stronger by 163.6% than their slender correspondents.

The tests showed a brittle response for oven-dry elements characterized by complete separation and explosive spalling of tube splits, and gradual ductile crushing for the wet samples, with the ambient-dry samples in the middle. The compression failure modes were either through outward or inward buckling, both for long and short tubes. The shear kinematics were similar to those of the compression mode. The shear failures were generally through one or two shear planes. Splitting test curves exhibited a linear elastic response followed by a sudden drop after the peak, indicating instantaneous splitting and brittleness levels similar to other tests. Wet samples showed softening before the peak and a softer post-peak response, indicating moisture-induced tension softening.

Abstract

In recent years, there has been increasing interest in using bamboo as a building material. However, there are still many challenges to promoting the structural use of bamboo, including understanding its mechanical properties, quantitatively evaluating its durability, and developing construction methods. The mechanical properties of bamboo vary significantly depending on the part and shape of the culm, and its anisotropic nature means that its physical properties exhibit significant anisotropy along the fiber parallel and perpendicular directions. Systematic development of these properties requires further experimentation, as research is still ongoing. Therefore, in this study, we conducted a preliminary investigation into the morphology and mechanical properties of Japanese bamboo: *Phyllostachys edulis* and *Phyllostachys bambusoides*. The geometric properties of the culm morphology were clearly expressed by standardizing culm length and other dimensions based on culm diameter at the base. Of the various mechanical properties examined, the strength and elastic modulus in the fiber parallel direction varied greatly depending on culm morphology and position. In contrast, sensitivity to culm morphology and position was low for strength in the fiber perpendicular direction, and little influence was observed.

Keywords: bamboo, Phyllostachys edulis, Phyllostachys bambusoides, structural morphology, plant-structure-optimization

1. Introduction

In recent years, there has been a significant increase in research on using bamboo as a building material [1]. This trend is driven by the need for a decarbonized society, the adoption of United Nations SDGs goals, and a growing interest in materials with low environmental impact. Additionally, with the global population predicted to peak between 2050 and 2090, mainly in developing countries, bamboo is seen as a promising material to meet the explosive demand for housing construction in these regions. Furthermore, the mechanical characteristics of bamboo culms (lightweight, cylindrical shape, high rigidity, and strength) make them highly suitable as a framework for spatial structures, with numerous pioneering examples already in existence [2, 3]. In the future, bamboo is expected to become increasingly important as a material for constructing spatial structures as well as housing structures.

While bamboo is well-known for its excellent mechanical properties in the fiber direction, which is the strong axis, its properties perpendicular to the fiber are much weaker and smaller than those in the strong axis [4, 5]. Weakness in the direction perpendicular to the fiber can cause bending failure of bamboo culms and failure of types of joint with fasteners. Therefore, evaluating the mechanical properties perpendicular to the fiber is crucial for the structural use of bamboo [6].

In this study, we investigate the structural morphology of Japanese bamboo: *Phyllostachys edulis* ("Moso" in Japanese) and *Phyllostachys bambusoides* ("Madake" in Japanese) for the development of bamboo structures in the future. We measure the geometries: positions of nodes, culm diameter, and

Copyright © 2023 by Takuo NAGAI. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

culm-wall thickness to specify the culm structure. We observe the physical and mechanical properties of bamboo culms by investigating the distribution of specific gravity, compressive strength parallel to the fiber, bending strength perpendicular to the fiber, and shear strength over the entire height of the culms. Based on these measurements, we discuss the relationship between the geometries and the mechanical properties of full-culm bamboo. Furthermore, we explore how bamboo reinforces the "weak point" due to the geometric effects, such as nodes, tapered shape of the culm, etc., as a strategy for plant-structure optimization.

2. Bamboo materials for the study

The bamboo species selected for this study were *P. edulis* and *P. bambusoides*, both of which were collected from a bamboo forest (35°15'N, 136°09'E) located in Omihachiman-city, Shiga Prefecture, Japan. The forest contains adjacent both bamboo species groves. The samples used in this study were at least three years old, and their age was determined by visual inspection. Culm diameter at breast height was divided into three categories: 60-80 mm, 80-100 mm, and over 100 mm, and samples were collected to ensure that each category had roughly the same number of samples.

The harvesting procedure involves cutting the culm at the base just above the visible surface of the adventitious roots, and then cutting the upper end of the culm at a position above the first branch, where the culm diameter is 30 mm or less when viewed from the base side. The samples were stored for six months to one year in a well-ventilated, semi-outdoor area that was protected from direct rain exposure. Afterward, various processing and measurement operations were carried out.

An example of the results of a mass change of the samples is shown in Fig. 1. The horizontal axis represents the number of days after harvesting (T), and the vertical axis represents the ratio of the mass of each sample (M_T) to the mass immediately after harvesting (M_0), i.e., M_T/M_0. M_0 was measured within half a day after harvesting. The mass change of all samples did not stabilize, and it was found that natural drying under the storage conditions described above did not reach the equilibrium moisture content within about one year. The moisture content of each sample was measured immediately after the mechanical testing.

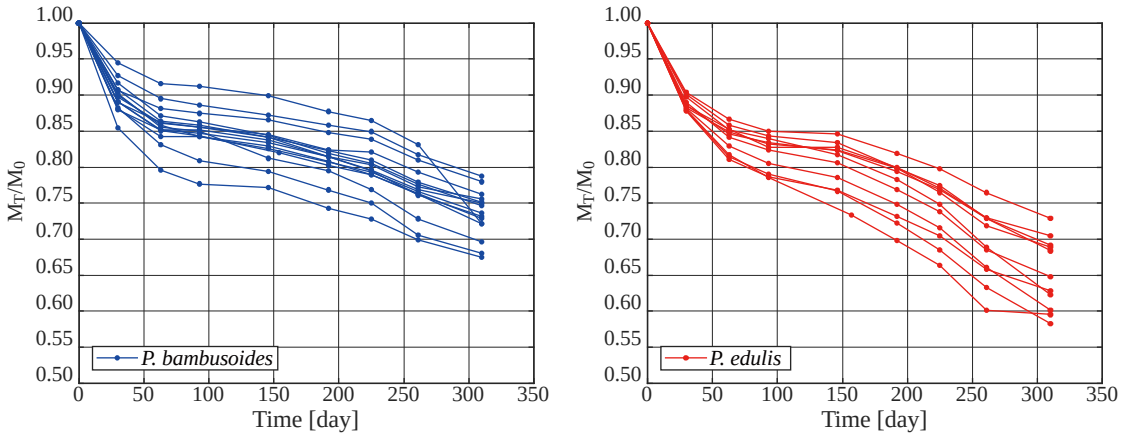

Figure 1. Example of transition of mass ratio M_T/M_0 of bamboo culms for this study.

3. Culm geometries

3.1. Measurement method

Fig. 2 shows the measurement method for culm morphology. The node directly above the underground rhizome, which is visible on the surface, is defined as "Node-1" (N-1). The nodes and internodes are

labeled sequentially from N-1 to the top of the culm as N-2, N-3, ..., N-j, ... and In-1, In-2, In-3, ..., In-j, ..., respectively. The center of In-1 is defined as "Cin-1" (Center of internode-1), and the centers of the other internodes are defined similarly as Cin-2, Cin-3, ..., Cin-j, ...

The coordinate X along the culm is defined with N-1 as the origin, positive in the upward direction toward the top of the culm, and the node of the first branch from the bottom is defined as "Node of branch-1" (Nb-1). The measured dimensions are the coordinate X_N and culm diameter D_N at each node, the culm diameter D_{In} and culm wall thickness t at the center of each internode. The coordinate X_{In} at the center of each internode is defined as the average of the coordinates of the adjacent nodes. These measurements are performed at every node and center of internode within the measurement range. Culm diameter is measured by tape measure, and calculated by dividing the circumference by π. Culm wall thickness is measured using calipers at two of the four points that divide the circumference into four equal parts (N, S, E, and W), and calculated as the average of the values at the two points.

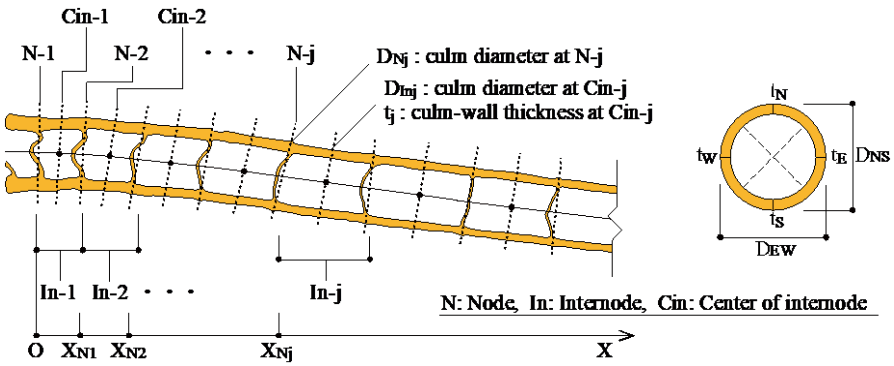

Figure 2. Measurement method of bamboo culm geometries.

3.2. Results of measured culm geometries

The relationship between N, In, and each measured value is shown in the left column of Fig. 3, while the relationship between X and each measured value is shown in the right column. Since the length of bamboo culms varies, the general tendencies of culm morphology are more easily understood by examining N and In rather than X. First, it is clear that there are significant differences in the external shape of culms between *P. edulis* and *P. bambusoides*. For example, the culm diameters, D_{In} of *P. edulis* are very large near the base and decrease rapidly upward, whereas those of *P. bambusoides* are relatively constant for a certain distance from the base and then gradually decrease. The internode length, L_{In}, is smallest near the base and largest in the middle for both species, with a decreasing tendency toward the top, but the L_{In} near the base of *P. edulis* is significantly smaller than that of *P. bambusoides*. These tendencies are similar to the results of previous studies [6], [7], [8].

On the other hand, culm wall thickness t shows a similar tendency for both species, decreasing rapidly near the base, becoming less steep thereafter, and becoming linear. Additionally, the wall thickness t of *P. edulis* is larger than that of *P. bambusoides* for most of the samples.

Fig. 4 shows the results of normalization of each measured value, which demonstrates the geometrical characteristics of the bamboo culm more clearly. The horizontal axis on the right-hand side represents the normalized coordinate X/D_{In1}, where D_{In1} is the culm diameter at the center of internode 1 (Cin-1). As Inoue *et al*. [9] mentioned that the culm diameter at the base are dominant factors in determining the bamboo culm morphology as well as species, this normalized coordinate is considered an important index for generalizing the characteristics of the bamboo culm morphology.

The vertical axis in (a) and (b) of Fig. 4 represents the aspect ratio of the internode length to the culm diameter (L_{In}/D_{In}), which increases monotonically from the base to the top. When comparing bamboo species, they are almost equal at the top, but *P. edulis* is smaller overall and below 1 at the base.

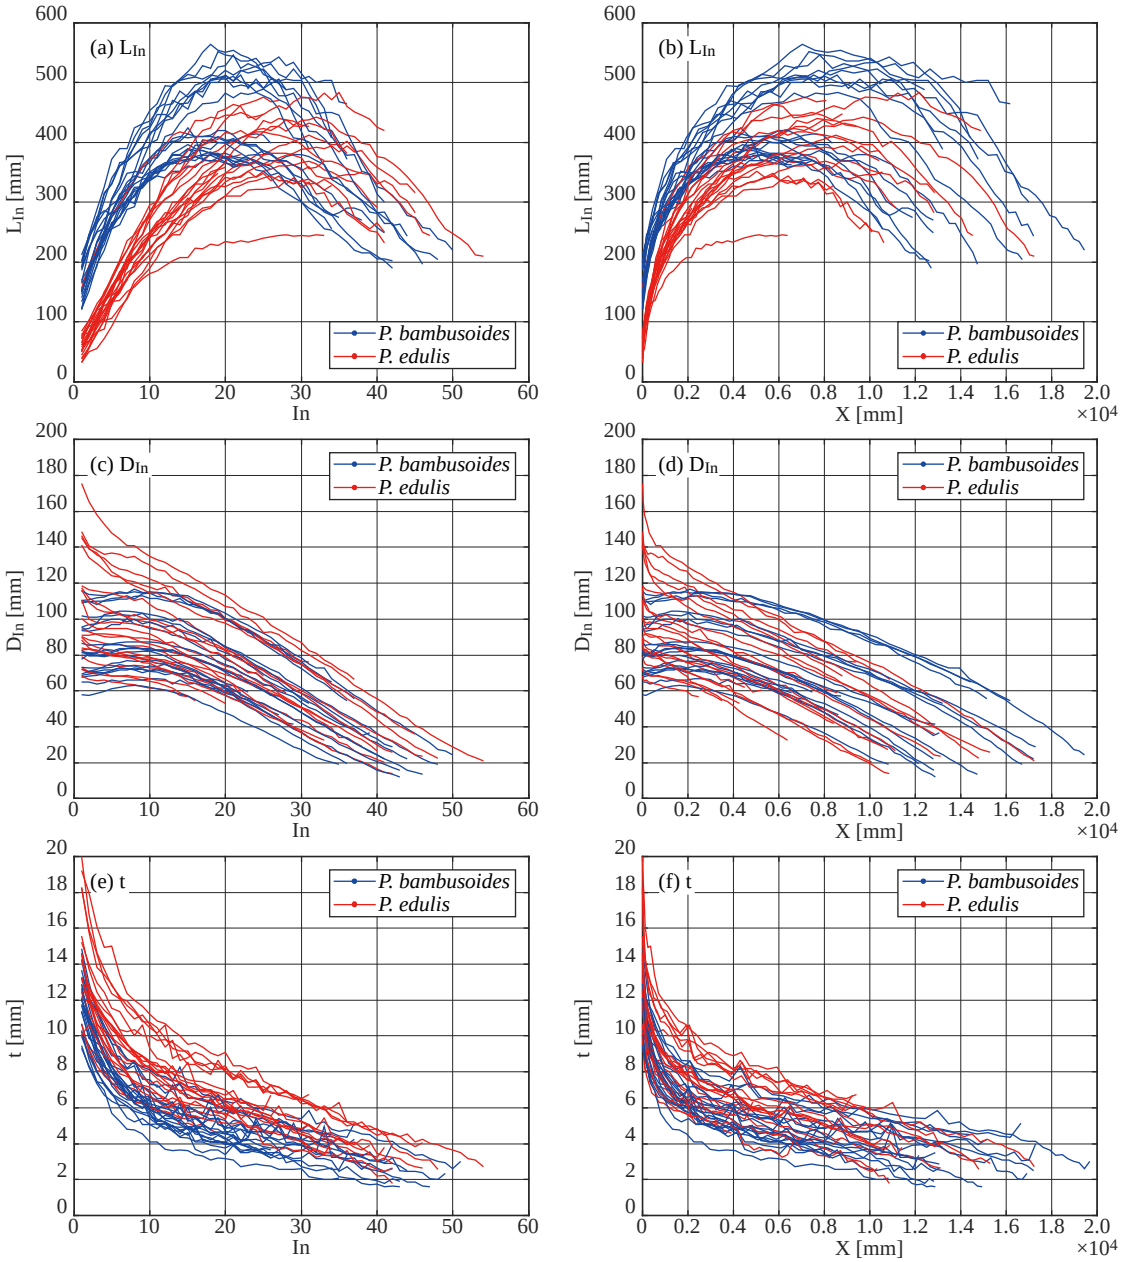

Figure 3. Left row: measured dimensions vs node index N and internode index In, right row: measured dimensions vs culm coordinate X.

The vertical axis in (c) and (d) represents the internode diameter ratio to the culm diameter at Cin-1, D_{In1} (D_{In}/D_{In1}). These figures clearly demonstrate the distinct differences in culm morphology between bamboo species. The vertical axis in (e) and (f) represents the wall thickness-to-diameter ratio (t/D_{In}) of the culm, which is obtained by dividing the wall thickness at the center of internode by the culm diameter at that location. The t/D_{In} of *P. edulis* is larger than that of *P. bambusoides*, with an average of about 0.1

and 0.08, respectively. In both species, t/D_{In} is maximum at the base, minimum in the middle, and increases again at the top.

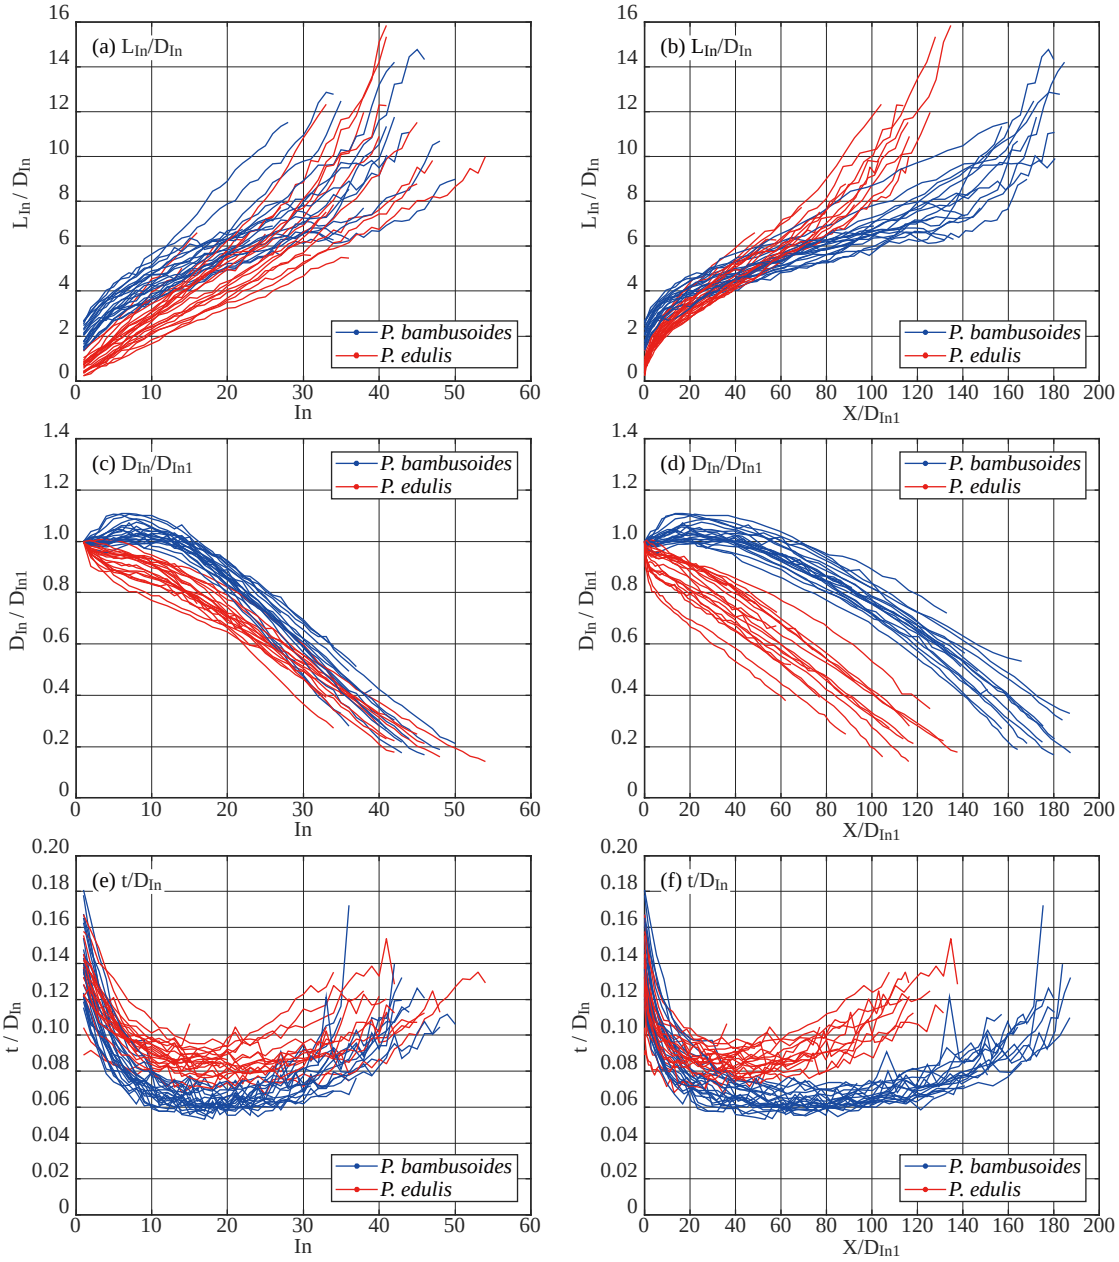

Figure 4. Left row: generalized dimensions vs node index N and internode index In, right row: generalized measured dimensions vs generalized culm coordinate.

Fig. 5(a) represents the relationship between D_{In} and t. There is a very strong proportional relationship between D_{In} and t in both bamboo species. However, near the base, t is relatively much thicker than D_{In}, and the correlation between those is locally disrupted. The vertical axis of Fig. 5(b) is the width-thickness ratio of the culm wall, t/D_{In}. In both species, t/D_{In} is not constant, and it is found that t/D_{In} increases as D_{In} decreases, except for the local increase in culm wall thickness near the base.

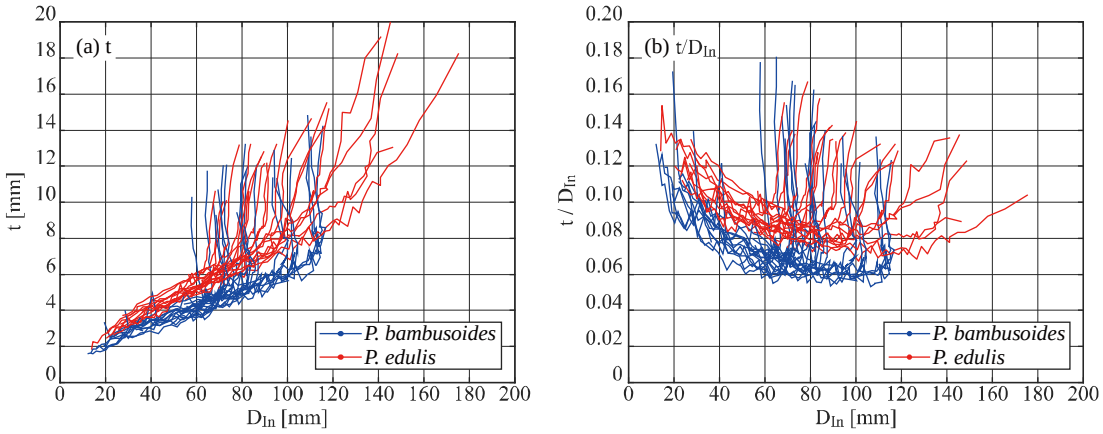

Figure 5. Relationship between culm diameter and culm wall thickness at center of internodes.

4. Mechanical properties

4.1. Testing method of mechanical properties

Fig. 6 shows the method of specimen collection and preparation for mechanical testing. In order to grasp the distribution of mechanical properties over the entire length of the culm, the culm was divided into segments of equal length, and specimens were collected from each segment for mechanical testing. The segment length, L_S, was defined as the length obtained by dividing the lower portion of the culm from the first branch node (Nb-1) into three equal parts and labeled Segment-1 to 3 from the basal end. The upper portion of the culm above Nb-1 was also divided into segments of length L_S, labeled Segment-4, 5, etc. from the basal end side. Specimens were collected from near the center of each segment, and the mechanical properties obtained from the mechanical testing were taken as representative values for that segment.

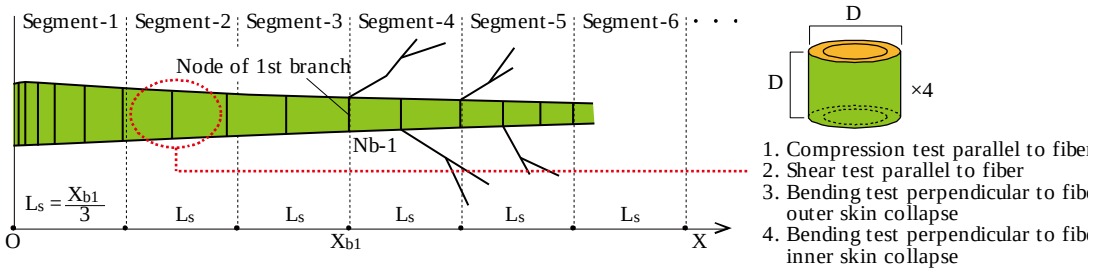

Figure 6. Sampling method of test specimen from bamboo culms.

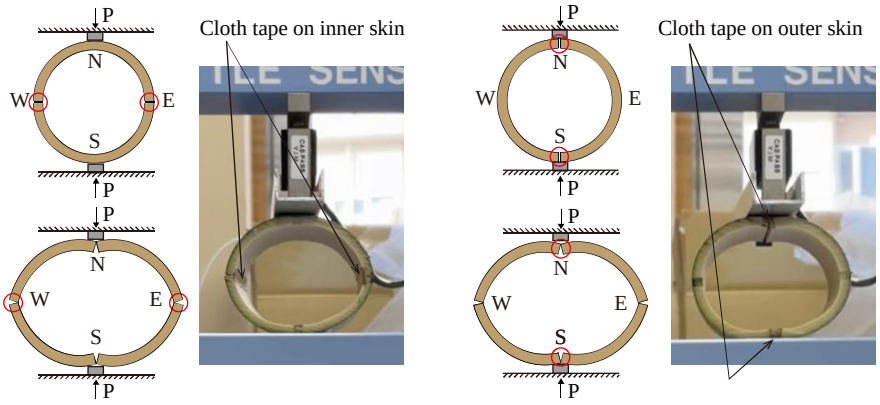
Three types of mechanical properties are measured: F_c, which is the fiber parallel direction compressive strength, F_s, which is the shear strength, and ${}_TF_{bo}$, which is the outer bending strength in the fiber orthogonal direction. The specimens for F_c testing are of two types: with and without nodes. The reasons for selecting these properties are as follows. Firstly, since the test specimens for all the tests are small and have the same dimensions (test specimen length $\geqq$ culm diameter D), many test specimens can be obtained from a single culm. Secondly, F_c is highly correlated with tensile strength and bending strength [1], [4], and it is considered possible to estimate the changes in fiber parallel direction properties on the culm without conducting tensile and bending tests. The reason for investigating F_s and ${}_TF_{bo}$ is that the failure of the culm wall occurs mostly in response to orthogonal stresses, and the shear strength and fiber orthogonal direction bending strength are important properties for identifying the culm collapse mode. We can obtain that the bending failure of full-culm bamboo culms is caused by the Brazier effect



(flattening of the cross-section) that occurs during culm bending [10], with the bending failure in the fiber orthogonal direction of the culm wall outer surface being the cause. Therefore, ${}_{T}F_{bo}$ is considered an especially important property value for using round culms as bending members.

The test methods and specimen sizes used were based on ISO 22157 [11], but ${}_{T}F_{bo}$ was measured using a hinge-attached lateral compression test method shown in Fig. 7. We used the test method in which the bending failure occurred at either point E or W. The equations for calculating ${}_{T}F_{bo}$ and the bending Young's modulus (${}_{T}E_{bo}$) are provided as follows.

$$ {}_{T}F_{bo} = \frac{3P_{\max}R}{th^2} \tag{1}$$

$$ {}_{T}E_{bo} = \frac{\pi R^3}{4} \cdot \frac{P_{60} - P_{20}}{\delta_{60} - \delta_{20}} \tag{2}$$

Here, R is the radius from the centroid of the section to the core of the wall thickness, h is the depth length of the test specimen, P_{max} is the maximum load, P_{20}, P_{60}, δ_{20}, and δ_{60} are the load and displacement at 20% and 60% of the maximum load, respectively.

(a) EW-hinge bending test, Outer skin collapes at NS

(b) NS-hinge bending test, Outer skin collapes at EW

Figure 7. Modified test method of bending test perpendicular to fiber.

Note that in this method, the stress on the left and right sides of the hinge is not exactly the same, so it is assumed that the load is evenly distributed between the left and right sides when calculating each value. On the other hand, Molari *et al.* [12] proposed a method to statically determinate the test specimens by processing the cylindrical bamboo into C-shape, but it was difficult to keep the test specimens stabilized posture during loading, so this method was not adopted in this study. In addition, after various mechanical tests, the moisture content (MC) and oven-dry density (ρ_{dry}) of the test specimens are measured. These measurements are also carried out according to the ISO 22157 method.

4.2. Results of mechanical test

Fig. 8 shows the relationship between MC and various strengths, and Fig. 9 shows the relationship between ρ_{dry} and various strengths. Table 1 summarizes the mean values and coefficients of variation (CV) for each property. The specimens used in this study were allowed to dry naturally for a certain period after harvesting, so the MC of most of the specimens was between 10% and 20%. While there were not many samples with an MC above 25%, a clear trend was observed where the strength of F_c decreased as the MC increased. Regarding ρ_{dry} and various strengths, a particularly strong correlation

was observed for F_c. The correlation for F_s and ${}_TF_{bo}$ was smaller compared to F_c, but a relatively large positive correlation was observed between ρ_{dry} and F_s for *P. edulis*.

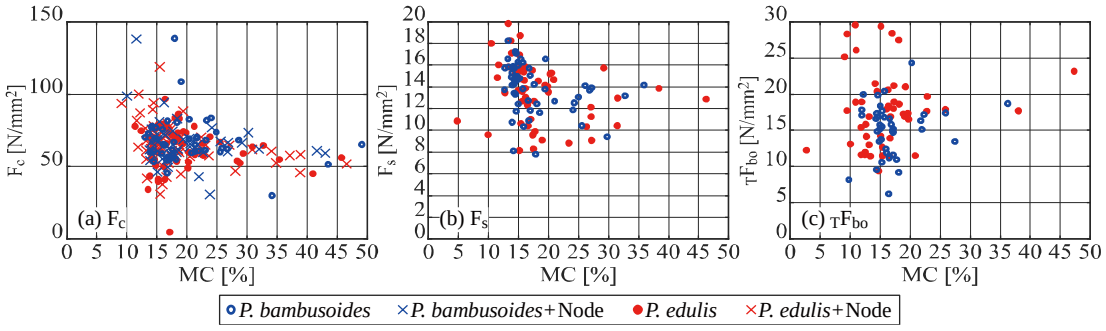


Figure 8. Relationship between moisture content ratio and various strengths.

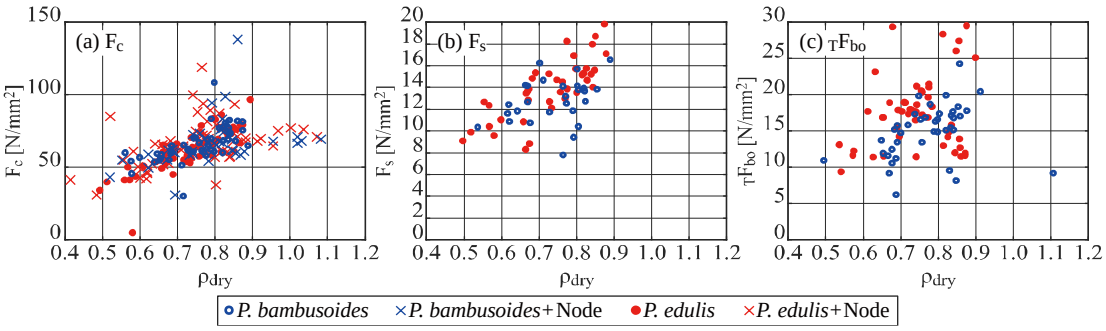

Figure 9. Relationship between oven-dry specific gravity and various strengths.

Table 1. Mean value and CV of various strengths and physical properties.

	F_c	F_c*	F_s	F_{bo}	ρ_{dry}	MC	F_c	F_c*	F_s	${}_TF_{bo}$	ρ_{dry}	MC
	N/mm^2	N/mm^2	N/mm^2	N/mm^2	-	%	N/mm^2	N/mm^2	N/mm^2	N/mm^2	-	%
Mean value	67.5	66.5	13.6	15.0	0.74	20.4	62.3	66.6	13.1	18.6	0.69	19.3
CV [%]	23.7	23.9	29.6	31.5	27.6	46.1	23.6	23.2	31.8	37.3	29.7	46.6

NOTE: F_c* = compression strength of specimen with node.

5. Discussing the relationship between culm geometries and mechanical properties

Fig. 10 shows the relationship between segment of culm and normalized coordinate X/D_{In1} and ρ_{dry}. In both species, ρ_{dry} tends to increase from the base to the top. In the left figure, Avg means the mean value of each segment. Fig. 11 shows the relationship between In, X/D_{In1}, and various strengths. Fig. 12 shows the relationship between D_{In} and various strengths. It was evident that F_c increased towards the top of the culm from the base, and a strong correlation with D_{In} is observed. As shown in the previous chapter, F_c has a stronger correlation with ρ_{dry} than other strengths and clearly varies depending on the position on the culm. The comparison of F_c between at nodes and at internodes shows no significant difference in both bamboo species. For F_s and ${}_TF_{bo}$, the correlation with In and X/D_{In1} is considerably smaller than that with F_c, and particularly for F_s, there is almost no correlation. While the scatter is larger than F_c, ${}_TF_{bo}$ also shows a slight correlation with F_s and a clear tendency to increase from the base to the top, similar to F_c.

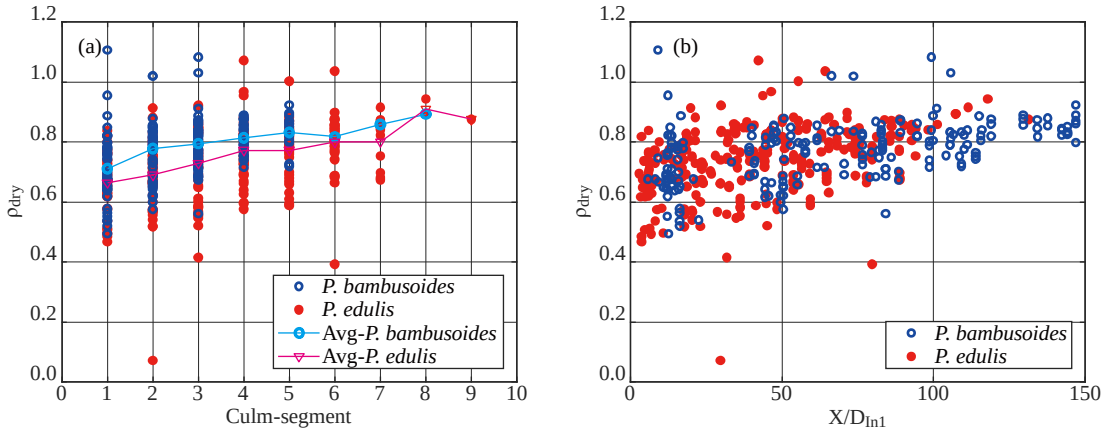

Figure 10. Relationship between relative location on the bamboo culm and oven-dry specific gravity.

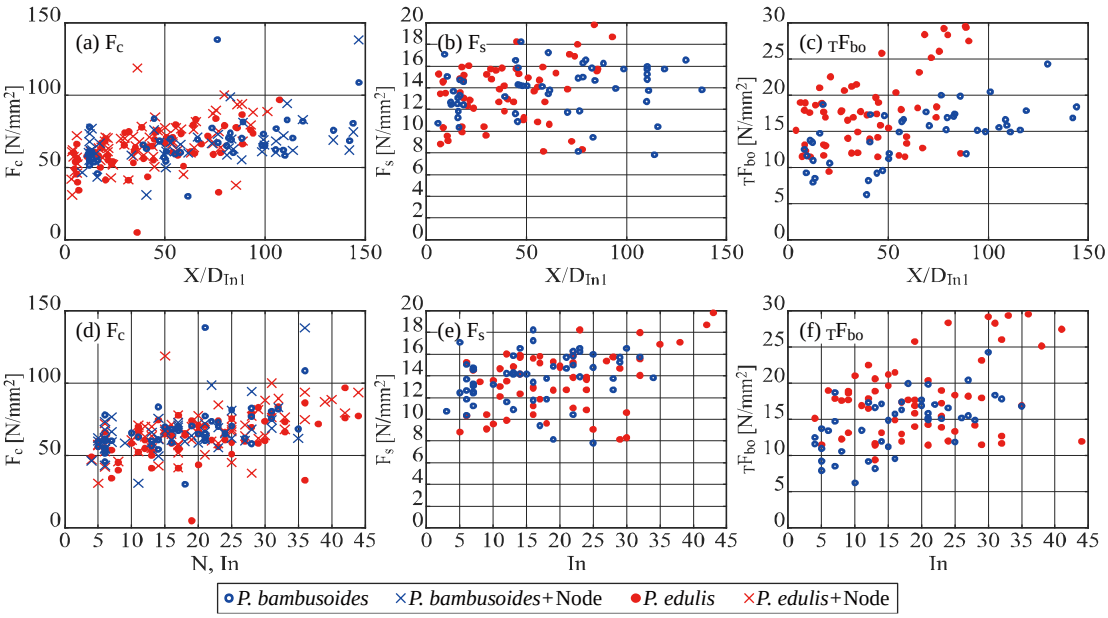

Figure 11. Relationship between relative location on the bamboo culm and various strengths.

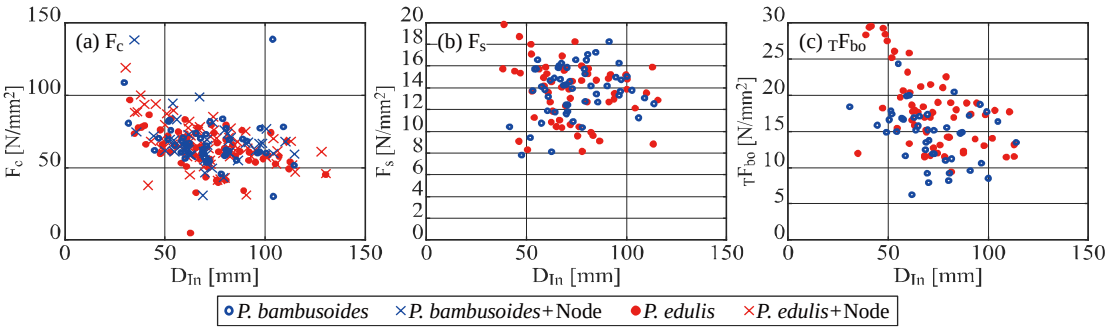

Figure 12. Relationship between culm-diameter and various strengths.

The tendency of increasing strength and stiffness from the base to the tip end of a bamboo culm is a characteristic observed in many bamboo species e.g., *Guadua*. This is mainly due to the increasing

density of vascular bundles towards the tip end (e.g., [1], [4]). Therefore, properties that depend on vascular bundle density (e.g., tensile/compressive strength and Young's modulus in the fiber parallel direction) generally exhibit higher performance at the tip end compared to the base end.

Finally, we show our preliminary results of the bending Young's modulus E_b of bamboo culms. The test specimens were bamboo culms harvested within 1-2 months after harvesting (MC ranged from 12-96%). The test method was a three-point bending test with a span of 1.6-2 m, and E_b was calculated from the load-deflection curve until a deflection of about 1/200 of the span was reached. Fig. 13(a) shows the relationship between the cross-sectional area A_{av} and E_b of the bamboo culms, and Fig. 13(b) shows the relationship between the culm diameter D_{av} and E_b. A_{av} and D_{av} are the average values of the both ends cross-sectional areas of the test specimen. In both species, a clear correlation was observed between the cross-sectional size and E_b. In addition, in both species, E_b ranged from 15-20 GPa at D = 50 mm and from 7-12 GPa at D = 100 mm, indicating a significant difference in E_b depending on the cross-sectional size.

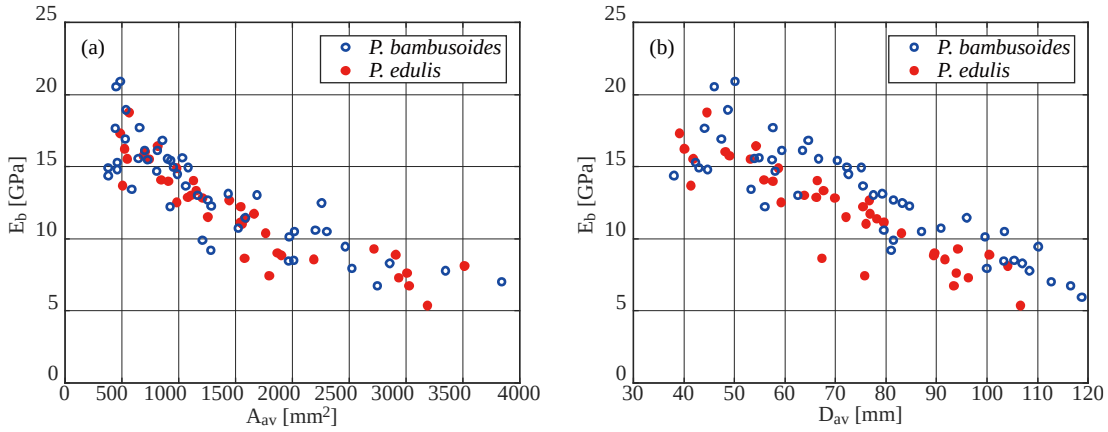

Figure 13. Relationship between cross-sectional area of bamboo culms and bending Young's modulus.

6. Concluding remarks

In this study, we conducted a fundamental investigation on the relationship between the culm morphology and mechanical properties of Japanese bamboo (*P. edulis* and *P. bambusoides*). Both bamboo species showed distinct differences in culm morphology, with a linear decrease in culm diameter from the middle to the top, but with a sudden increase in culm diameter near the base for *P. edulis* and relatively stable diameter for *P. bambusoides* up to around 5 meters from the base. On the other hand, culm wall thickness was generally greater in *P. edulis*, but the change along the culm axis was similar for both species.

Among the investigated mechanical properties, the axial compressive strength showed the strongest correlation with culm geometry. The bending Young's modulus was suggested to vary greatly depending on the cross-sectional size. From these results, it is suggested that the axial strength and stiffness, which strongly depend on the properties of the vascular bundles, are greatly influenced by culm geometry and density, while the strength in the transverse direction (shear strength, transverse bending strength, etc.) may be less affected by the position on the culm or cross-sectional dimensions.

In the future, we aim to expand the sample size and perform statistical formulation of the relationship between mechanical properties and culm geometry, with the goal of further promoting the use of bamboo structures.

Abstract

This study aims to establish a method for estimating the compression strength of full-culm bamboo columns. To achieve this, the comparison between results of buckling tests using small specimens of Japanese representative bamboo species and numerical analyses is discussed. The results showed that the buckling load of the full-culm bamboo column can be estimated with high accuracy by FEM linear buckling analysis, taking into account the variation of the bamboo culm cross-sectional area and bending Young's modulus. However, since various physical properties such as moisture content and dry density can affect bending Young's modulus, it is necessary to clarify their relationship with each property. This research contributes to a better understanding of how to evaluate compression strength in full-culm bamboo columns and could inform future studies on sustainable building materials.

1. Introduction

The construction industry, including architecture and civil engineering, accounts for approximately 40% of the world's greenhouse gas emissions, consumption of fossil fuels, and industrial waste emissions. In addition, there is an expected exponential demand for housing construction, particularly in developing countries with rapid population growth in the future, which underscores the need for the construction industry to transform into a sustainable industrial structure. Against this background, bamboo is attracting great expectations as a sustainable building material with low environmental impact since its fast growth, regenerative properties, and abundant resources.

Various challenges still need to be addressed in order to utilize bamboo in building structures, including the systematic organization of physical and mechanical properties of bamboo materials and construction methods, and the establishment of protective treatment methods for durability improvement. Evaluating the compression strength of bamboo is an essential challenge to overcome when using full-culm bamboo poles as columns or trusses. While pioneering research on bamboo scaffoldings by Yu *et al*. [1], [2] and numerous studies and proposals have been conducted, such as the establishment of design formulas in ISO 22156 [3] and design codes [4], [5], many of these assume that the bamboo culms are uniform and homogeneous beam-column elements with a constant cross-section. This can lead to extremely conservative compression strength estimates. On the other hand, in recent years, attempts have been made to evaluate the effects of the taper characteristics of bamboo culms with respect to buckling strength and the influence of initial irregularities in bamboo culms, in order to calculate more practical design strengths [6], [7].

In this study, we investigate the calculation method of compression strength for bamboo culms by comparing the results of buckling tests using small specimens of Japanese representative bamboo species and numerical analyses.

2. Research methods

2.1. Bamboo materials for the study

The bamboo species investigated in this study were Moso (*Phyllostachys edulis*), Madake (*Phyllostachys bambusoides*), both of which were collected from bamboo forests in Omihachiman-city, Shiga Prefecture, in Japan (35.15'N, 136.09'E). The bamboo forest consists of adjacent Moso and Madake stands. The bamboo samples used in this study were aged three years or older, and their age was visually determined.

After harvesting, the bamboo culms were stored in a semi-outdoor area with good ventilation that was not directly exposed to rain. All processing and testing were conducted within three months from harvesting. No special protective treatment was applied due to the short storage period.

2.2 Research process

Since bamboo culms are variable cross-section members with changing dimensions along the culm axis, they cannot be modeled as simple, homogeneous members with a constant cross-section. Therefore, to estimate the buckling strength of bamboo culms, a finite element model that takes into account the cross-sectional variation was used, and linear buckling analysis was performed. To obtain the required values of the cross-sectional dimensions and bending Young's modulus of each part of the bamboo culm, the following experimental and measurement procedures were performed.

First, a bending test was conducted on the bamboo culm to determine its bending stiffness from the load-deflection relationship. The bending test was a small-deflection test in which the stress and strain in the specimen remained within the elastic range to avoid inducing plastic deformation. Subsequently, to prevent changes in moisture content, the buckling test was conducted promptly. In this study, experiments were conducted on small specimens with a column length of 1600 mm due to equipment limitations. After the buckling test, the bamboo culm was cut at the center of each node, and the cross-sectional dimensions were measured, and the moisture content was determined. To ensure a uniform distribution of aspect ratios ranging from 40 to 150 for the buckling test specimens, the cross-sectional sizes were selected accordingly. A total of 38 Moso specimens and 48 Madake specimens were tested.

3. Measurement and modelling of culm shape of full-culm bamboo poles

Fig. 1(a) shows the method for measuring the shape of the bamboo culm specimens. The measurement items were the length of each internode (L_{IN}), the culm diameter (D) at the center of each internode, and the culm wall thickness (t) at the four points (N, E, S, and W) where the cross sections intersect. After the buckling test, the bamboo culm was cut at the corresponding position and measurements were taken. D was calculated by measuring the circumference of the culm at the center of each internode with a tape measure and dividing by π. Although the actual cross section of the bamboo culm is not a perfect circle, this study assumes a perfect circle with diameter D for the analysis. The culm wall thickness t was defined as the average value of the wall thickness at the four points where the cross sections intersect at right angles.

Fig. 1(b) shows the FEM modeling method used to calculate the bending Young's modulus. The nodes of the model were located at the corresponding coordinates of nodes of the bamboo culm, and the internode between them was connected with planar (2D) beam elements with a uniform cylindrical cross section. The characteristic values of the beam element cross-section were determined using the cross-sectional dimensions measured at the center of each internode. Therefore, the FEM model approximated

the cross-sectional variation of the bamboo culm in the axial direction as a stepped model. Nodes were also placed at the load point at the center of the span and at the support points at both ends. The boundary conditions at the support points were set as one end pinned and the other end roller supported.

Fig. 1(c) shows the FEM modeling method used for buckling analysis. Based on the bending analysis model, nodes were added at the midpoints (centers of the internodes) between the nodes to obtain a smoother buckling mode shape. The boundary conditions at both ends were set as one end pinned and the other end roller supported.

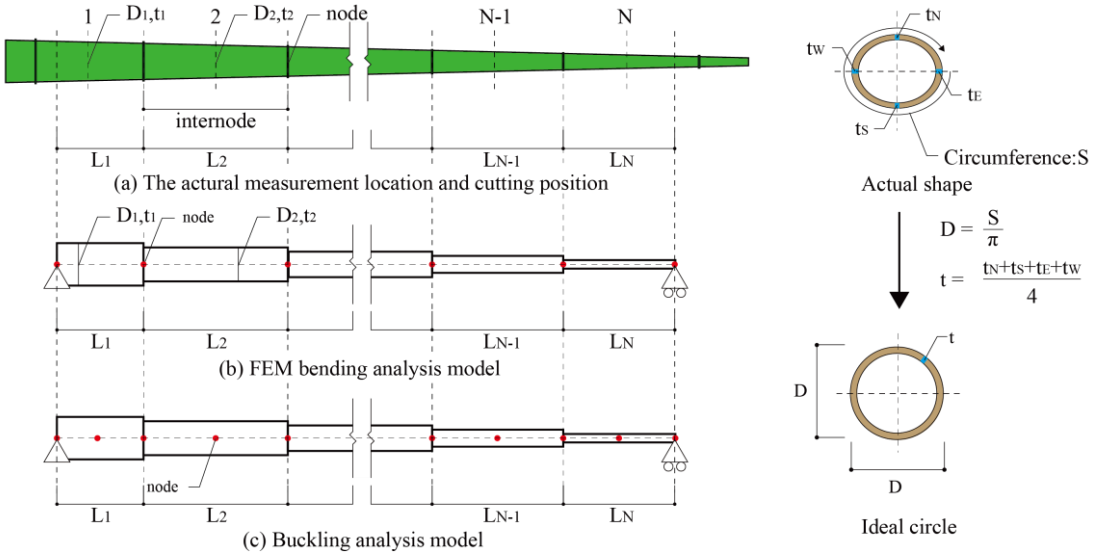

Figure 1. Measurement method and FEM modeling of dimensions for round bamboo columns.

4. Micro-deformation bending test of full-culm bamboo poles

4.1. Test methods and calculation methods of bending Young's modulus

Fig. 2 shows the bending test method. The bending test was a three-point bending test in which the specimen was loaded at the center of the span, and the load point was located near the center of each internode to avoid the nodes. The span of the specimen was determined to satisfy the conditions that the bending stress at the load point was less than 30 N/mm^2 when the deflection at the load point was about 1/200 of the span and the shear span ratio was 10 or greater, following the method specified in ISO 22157 [7]. The upper limit of the bending stress was estimated to be about one-third of the bending strength (approximately 100 N/mm^2) of Moso and Madake. As a result, the span between the supports varied depending on the specimen, ranging from 1700 to 2000 mm.

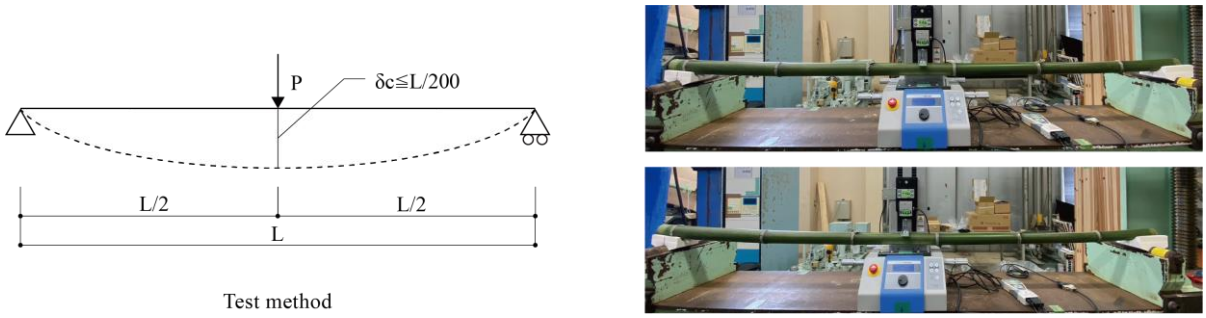

Figure 2. Method of Micro-deformation test.

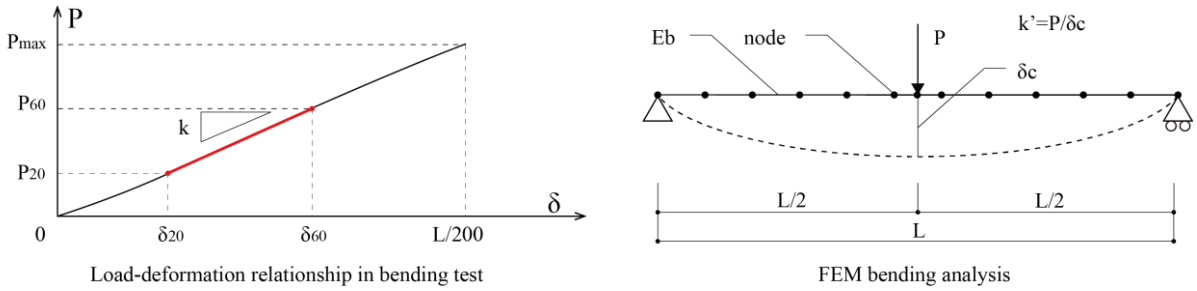
Fig. 3 shows the method used to calculate the bending Young's modulus (E_b). First, the gradient k was obtained by connecting two points on the load-deflection curve obtained from the bending test. Next, linear elastic analysis using the bending analysis model shown in Fig. 1(b) was performed, and E_b was determined such that the ratio k' of the load P to the deflection δ_c in Eq. (1) was equal to k.



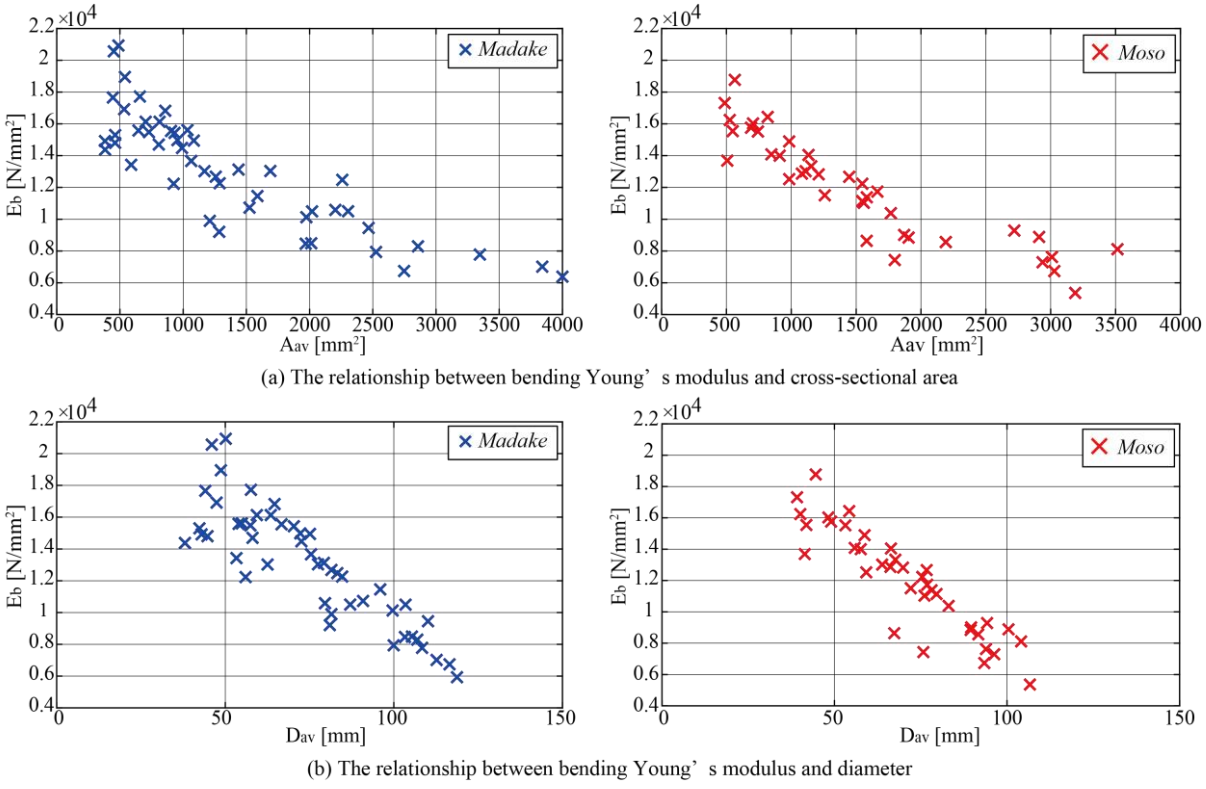


Figure 3. Method for calculating bending Young's modulus.

$$k = \frac{P_{60} - P_{20}}{\delta_{60} - \delta_{20}} = k'(E_b) \quad (1)$$

Here, P_{20}, δ_{20}, P_{60}, and δ_{60} represent the load and displacement at 20% and 60% of the maximum load, respectively.

4.2. Experimental results

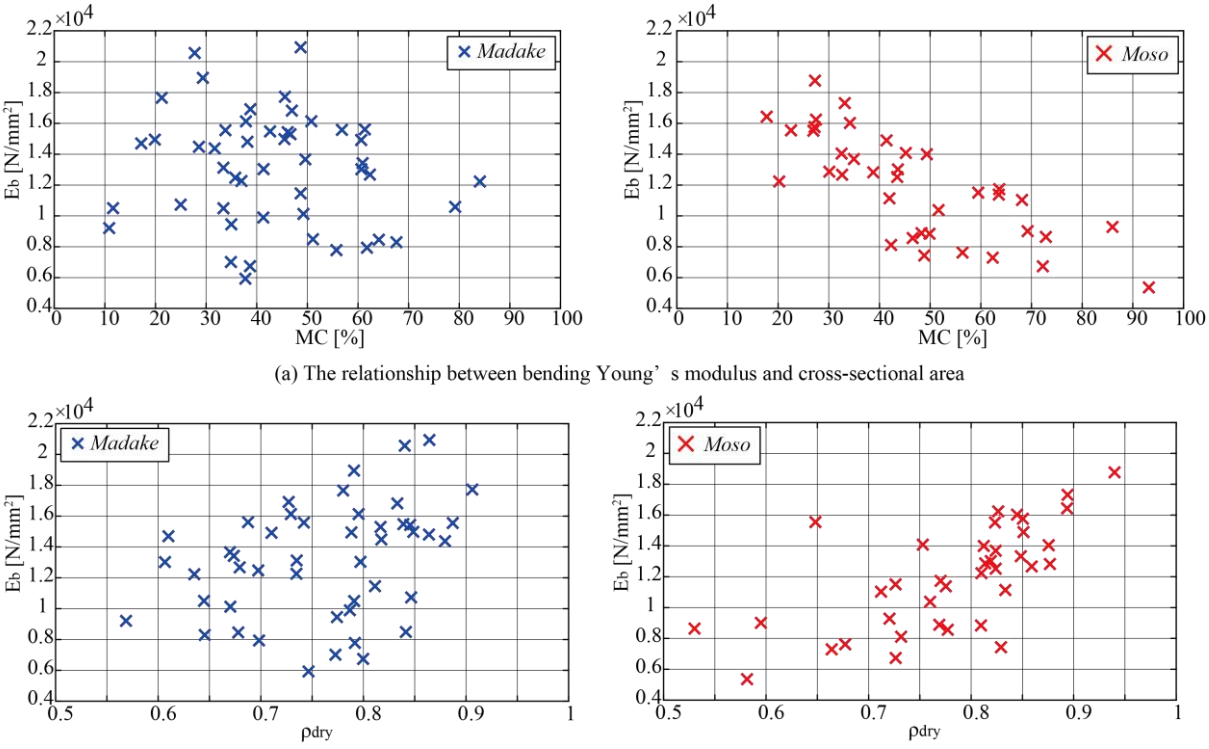

Fig. 4 shows the relationship between the average cross-sectional area (A_{av}) and the bending Young's modulus (E_b) of the test specimens. A_{av} is defined as the average of the cross-sectional area at both ends of the test specimen. For both Moso and Madake, a clear correlation between the cross-sectional size and E_b was observed. The E_b values for D = 50 mm were 15,000-20,000 N/mm^2, and those for D = 100 mm were 7,000-12,000 N/mm^2 for both species, indicating a significant dependence of E_b on the cross-sectional size. It is well known that many bamboo species have a negative correlation between the cross-sectional size and the axial properties, such as tensile, compressive, and bending strength in the longitudinal direction. This is because the volume density of vascular bundles in the cross-section increases relatively towards the top of the bamboo culm [8], [9].

(a) The relationship between bending Young' s modulus and cross-sectional area

(b) The relationship between bending Young' s modulus and diameter

Figure 4. Relationship between cross-sectional size and bending Young's modulus.

(a) The relationship between bending Young' s modulus and cross-sectional area

(b) The relationship between bending Young' s modulus and diameter

Figure 5. Relationship between the oven-dry specific gravity, moisture content and the bending Young's modulus.

In Fig. 5, the relationship between moisture content (MC), oven-dry density (ρ_{dry}), and E_b is shown for both Moso and Madake. A negative correlation between MC and E_b, and a positive correlation between ρ_{dry} and E_b were observed for Moso. This suggests that it is difficult to determine the bending Young's modulus from the cross-sectional area alone, as MC can also affect material properties. However, for Madake, a clear correlation was not observed, and the large variation in the scatter plot raises questions about the relationship between material properties. Further investigations are necessary to clarify the correlations between different material properties for Madake.

5. Buckling test of full-culm bamboo poles

5.1. Test methods

Fig. 6 shows the method for conducting the buckling test on the bamboo columns. The test specimens were prepared by cutting them to a length of 1600 mm after conducting the bending tests. Aluminum alloy ball joints were attached to the top and bottom load points to serve as pin supports.

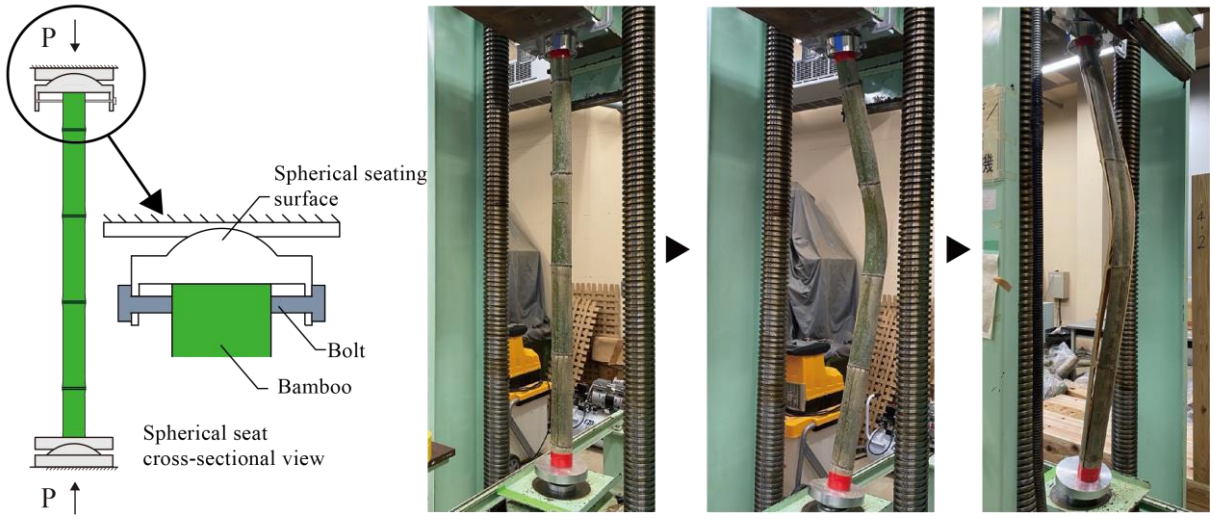

Figure 6. Method of buckling test for full-culm bamboo columns.

5.2. Comparison between test results and linear buckling analysis

Fig. 7 shows an example of the results of the buckling test. In both Moso and Madake, the relationship between the load and deformation up to the maximum load is linear and the axial rigidity hardly changes regardless of the load magnitude. In addition, it was confirmed that the greater the equivalent slenderness ratio λ_{eq}, which will be described later, the faster the load decreases after the maximum load, and the smaller the maximum load, the gentler the subsequent load decrease becomes. In this study, the experimentally obtained maximum load P_{max} was defined as the buckling load.

The analytical value P_{cr} of the buckling load was defined as the first-mode buckling load obtained by linear buckling analysis using the model in Fig. 1(c). The bending Young's modulus E_b obtained in the previous chapter was used for each test specimen. Fig. 8 shows a comparison of the experimental and analytical values. The two values are distributed evenly above and below the 1:1 slope. Table 1 shows the mean and coefficient of variation of the ratio P_{cr}/P_{max} between the analytical and experimental values. The mean values for both Moso and Madake are very close to 1.0, and the coefficients of variation are both less than 10%. Therefore, it can be concluded that the buckling load of the full-culm bamboo

column can be accurately determined by linear buckling analysis if the sectional changes of the bamboo culm and the bending Young's modulus in the small deformation range are properly evaluated.

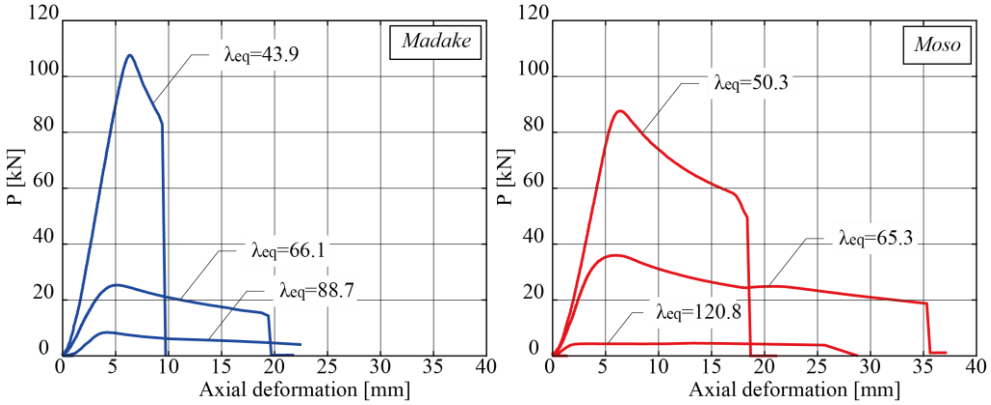

Figure 7. The example of load-axial displacement relationship in the buckling test

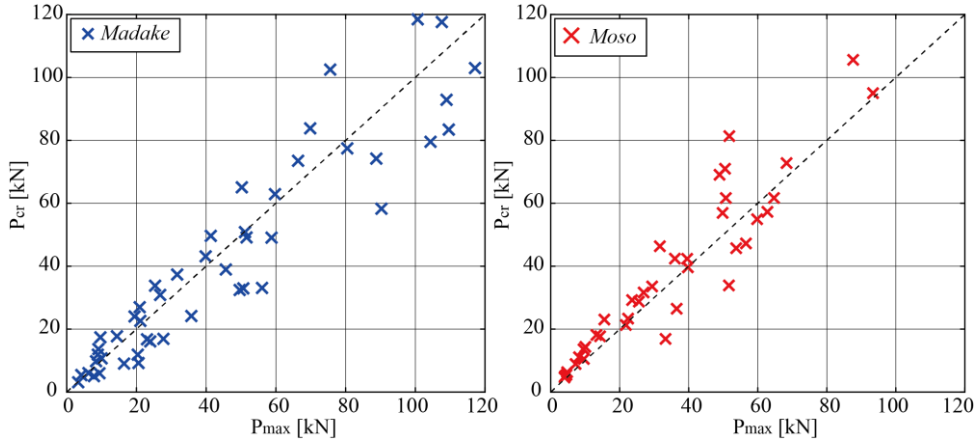

Figure 8. Comparison of buckling loads between experiments and linear buckling analysis.

Table 1. The mean value and coefficient of variation (CV) of the ratio of the analytical buckling load to the experimental buckling load.

Bamboo speceis	Mean value of P_{cr}/P_{max}	CV [%] of P_{cr}/P_{max}
Madake	0.99	9.1
Moso	1.04	3.1

5.3. Equivalent uniform cross-section model for bamboo column

The buckling load of a column member subjected to axial force is generally expressed as a function of the slenderness ratio. However, the radius of the cross-section of a bamboo culm is not uniform, and the slenderness ratio cannot be defined. Therefore, an equivalent uniform section model with the same buckling load as the one obtained by FEM is derived, and the equivalent slenderness ratio λ_{eq} is determined as following equation.

$$I_{eq} = \frac{P_{cr}L^2}{\pi^2 E_b} \tag{2}$$

Here, L represents the length of the specimen (1600 mm). Additionally, λ_{eq} is calculated using the following equation.

$$\lambda_{eq} = \frac{L}{\sqrt{I_{eq}/A_{av}}} \tag{3}$$

Here, A_{av} denotes the average cross-sectional area of the specimen at both ends. The compression strength of both the experimental and analytical values is determined using A_{av}, and is calculated using the following formula.

$$\sigma_{cr} = \frac{P_{cr}}{A_{av}}, \quad \sigma_{\max} = \frac{P_{\max}}{A_{av}} \tag{4}$$

In addition, the Euler buckling curve using λ_{eq} is expressed as follows.

$$\sigma_{cr} = \frac{\pi^2 E_b}{\lambda_{eq}^2} \tag{5}$$

Fig. 9 shows the relationship between λ_{eq} and the experimental maximum stress σ_{max}. The two curves in the figure represent the Euler buckling curves using the maximum and minimum bending Young's moduli for each bamboo species obtained from the bending tests. Most of the experimental results fall between the two Euler buckling curves, and there is a general trend of decreasing buckling strength with increasing slenderness ratio, although the scatter is large. Therefore, it is important to evaluate the bending Young's modulus of the member appropriately for calculating the buckling strength, as mentioned earlier.

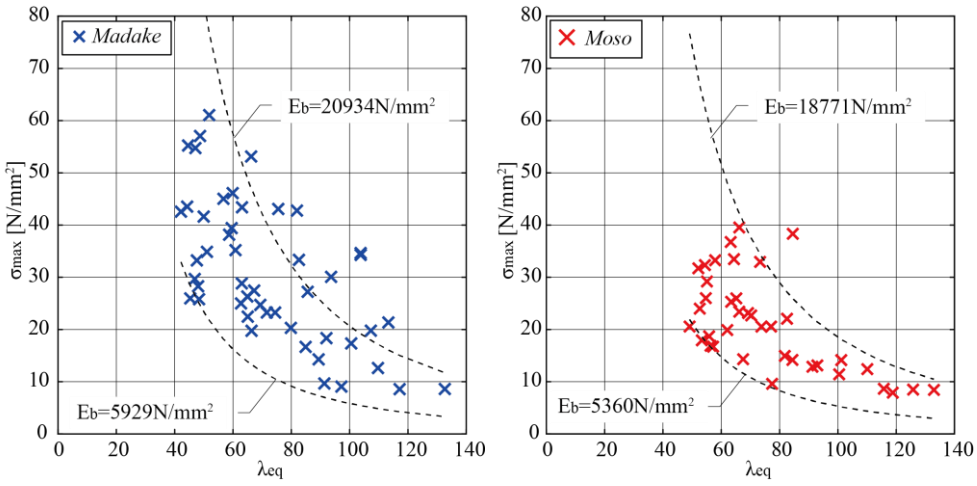

Figure 9. Relationship between slenderness ratio and compression stress of experimental results.

6. Conclusion

In this study, we investigated the method for determining compression strength of bamboo. The following findings were obtained.

The purpose of this study was to establish a method for estimating the compression strength of full-culm bamboo columns, and a comparison was made between buckling tests with small-scale specimens and numerical analysis. The buckling load of the full-culm bamboo column can be estimated with very high accuracy by FEM linear buckling analysis, taking into account the variation of the bamboo culm cross-sectional area and bending Young's modulus. However, since the bending Young's modulus is thought

to be affected not only by the cross-sectional size but also by various physical properties such as moisture content and dry density, it is necessary to clarify the relationship with each property. Additionally, the full-culm bamboo columns used in this study were small in size, so the variation in the bending Young's modulus within a single specimen was considered to be small, which may have facilitated the estimation of the buckling load by assuming homogeneity in the buckling analysis. Therefore, future studies will examine test specimens with column heights (2-3m) that are typically found in general buildings.

Acknowledgements

We gratefully acknowledge the support received for this study from The Maeda Engineering Foundation through research grants for the fiscal years 2021 and 2022, the Grant-in-Aid for Scientific Research (21K14292), as well as the Grant-in-Aid for Scientific Research (21H00373) in the New Academic Area Research category, specifically for the "Plant-Structure-Optimization". Additionally, many of the experiments in this research were conducted as a graduation thesis research project by Ayumi SAGUCHI (The univ. of Shiga pref.). We express our sincere appreciation for their invaluable assistance.

Abstract

By utilizing low-density aggregates in concrete, it is possible to achieve reductions in weight, density, and the carbon footprint of concrete. The study found that improved thermal performances are also possible with all three of the technologies: Infra-Lightweight concrete, Ultra-lightweight concrete, and functionally graded concrete. This paper serves as an analysis of the contemporary homogeneous and inhomogeneous low-density concrete technologies that succeed in exhibiting the aforementioned characteristics. The highlighted advantages of these technologies showcase innovative advancements in the field of concrete technology and the potential for concrete to be used in a wider range of site and environmental conditions worldwide.

Keywords: low-density concrete, infra-lightweight concrete, ultra-lightweight concrete, functionally graded concrete

1. Introduction

This article provides an overview of various low-density concrete systems, specifically focusing on their compressive load-bearing and thermal performance. The article also considers the mixture compositions and fabrication processes of these concrete types. The research aims to contribute to the broader objective of reducing weight and material usage in the concrete construction industry. Areas of interest include structural optimization, the incorporation of aggregates, and specific material compositions and fabrication methods.

Weight and material reduction can be achieved through structural optimization of building components. Notable examples of this approach include the works of Pier Luigi Nervi (1891-1979) [1] and Angelo Mangiarotti (1921-2012) [2], who employed optimized structural designs that minimized material usage while shaping the aesthetics of their designs. The DFAB House project by ETH Zurich is another recent example, where 3D printing was used to create customized formwork for structural components, achieving formal structural optimization. These examples demonstrate how a design-oriented approach can lead to reduced material consumption and weight.

Another avenue for weight and material reduction is the addition of aggregates and specific material compositions, resulting in low-density concrete composites. Extensive research has been conducted on the properties of these composites, and this article focuses on the most advanced technologies in this area.

While structural elements made of standard concrete can be optimized to reduce dead loads, they typically require additional material layers when used in external building envelopes. In contrast, low-density concrete systems with lower thermal conductivity pursue a monolithic, monomaterial wall approach, achieving weight and material savings. This approach allows for the combination of structural performance and thermal insulation within a single material, thereby enhancing resource efficiency and recycling rates. The ultimate goal of advancements in this field is to provide materials that meet or exceed structural and thermal requirements while consuming less material, thus reducing the carbon footprint of the concrete industry.

The current state of research in this field is characterized by studies that focus on specific low-density concrete technologies and their performance. This analysis serves as a platform for further research in the field of low-density concrete, offering an overview and comparative study of the technologies under consideration.

2. Literature review

2.1. Lightweight concrete

Although lightweight concrete has been in use in various forms around the world for centuries, Peck describes a renaissance of this technology in the mid-20th century, "Lightweight concrete technology was developed in the 1960s with the goal of reducing concrete structural components' own weight without changing their load-bearing capabilities" [3].

Patrick Gartman's house in Chur, Switzerland, 2003, is an example of monolithic concrete design. The house is built of lightweight concrete containing expanded glass with thermal conductivity of 0.36W/mK. The concrete Gartman developed for this project has since been called 'insulating concrete', although this was not a technical term at the time [3].

2.2. Three concrete case studies

This study addresses low-density concrete as a potential alternative to conventional concrete in terms of establishing industry best practices for (external) wall-based concrete constructions. Given the common attributes of the concrete systems covered in this study, a concise overview is presented that depicts the performance of each example against a set of criteria. These attributes are a monolithic morphology and insulating properties that combine to provide a concrete typology for single-layer construction which has the potential to meet current energy efficiency requirements in parts of the world. The technologies addressed in the study are as follows:

(1) Infra-lightweight Concrete (ILC). This system is comprised of concrete layers with varying properties that in combination work to decrease component density, increase thermal performance, and facilitate load-bearing capacities [4].

(2) Ultra-lightweight Concrete (ULC). This technology is another variant of lightweight concrete with its main point of difference being the use of fly ash and binders that allow for a more densely packed matrix of expanded glass aggregates. Depending on its matrix and mixture, ULC is intended to have load-bearing capacities as well as increased thermal performance in comparison to conventional concrete (Yu et al. 2015) [5].

(3) Functionally graded concrete (FGC). This technology also contains artificially produced aggregates that work to decrease density within a component while providing thermal insulation. Another effect of gradation throughout a component made from FGC is an increase in the efficiency of the use of the material by reducing its overall mass [6].

2.3. Cross-sectional structure descriptors

In the first step, three material properties are defined: monolithic, homogeneous, and inhomogeneous. In the second step, the three material properties – monolithic, homogeneous, and inhomogeneous – are assigned to the three technologies for low-density concrete infra-lightweight concrete (ILC), ultra-lightweight concrete (ULC), and functionally gradient concrete (FGC).

Homogeneous / homogeneity

'A homogeneous material consists of the same or a similar kind or nature and is of uniform structure or composition throughout,' as in the Merriam-Webster dictionary, accessed 28 April 2022.

Inhomogeneous / inhomogeneity

'An inhomogeneous material is the condition or an instance of not being homogeneous and is where a material has a part that is not homogeneous with the larger uniform mass in which it occurs,' as in the Merriam-Webster dictionary, accessed 28 April 2022.

Monolithic

'A monolithic material is cast as a single piece, moulded or composed of material without joints or seams, and consists of or forms a single unit.' as in the Merriam-Webster dictionary, accessed 28 April 2022.

2.4. The aim of this study

Considering the previous discussion, this study has the following objectives:

- identify contemporary advanced low-density monolithic concrete technologies;
- define homogeneous and inhomogeneous concrete;
- identify the solutions provided by advanced low-density monolithic concrete technologies;
- identify thermal performances of advanced low-density monolithic concrete technologies;
- identify future benefits of advanced low-density monolithic concrete technologies; and
- identify opportunities for further development within this field of research.

3. Materials and methods

3.1 Analysis criteria

3.1.1 Technology description

An introductory description is given for each technology. Aspects of this introduction include names and information about the researchers, the institution with which the technology is associated, and the country of origin of each technology.

3.1.2 Technology type and solutions offered

The technology type describes the current status of each technology (project, prototype, or product). The solutions offered by each technology are also described.

3.1.3 Mixture

The mixture of each concrete technology is given and displayed graphically.

3.1.4 Morphology

The structure refers to any concrete technology as if a cross-section were cut through a sample. This is linked to the mix and is used to describe the overall porosity of each type of concrete and whether it is a homogeneous or stratified system.

3.1.5 Fabrication method
An image and a short description of the fabrication process are given for each concrete technology.

3.1.6 Future research
Possible aspects of research are suggested to describe what information is currently lacking in the research and to allow for future adaptation of the present work.

3.1.7 Thermal Performance
The thermal performance of each technology is given based on its thermal resistance using a 50-mm example (R-value) and its thermal transmittance (U-value). The R-value is defined by the New Zealand Standards Council as the 'sum of the surface resistances on each side of the building element' according to the current energy efficiency standard [7]. The U-value is defined as 'a measure of the thermal transmittance of a building element (e.g., a wall or window) or a given thickness of material (e.g., insulation), with lower values indicating better insulating properties,' as in the Merriam-Webster dictionary, accessed 29 April 2022.

3.2 Procedure
The method used in this research is a comparative review. A literature review was conducted, summarised in Section 2, to identify criteria and data relevant to the research objective and to discuss and compare the case studies provided. The research process proceeded in four phases: Planning Phase (purpose and protocol), Selection Phase (case study search and screening), Extraction Phase (quality assessment and data extraction) and Execution Phase (analysis of results and review) [8]. In the planning phase, the aim of the research and the protocol were defined. The protocol included a review procedure of relevant databases using specific keywords to build the framework of lightweight concrete and to identify a set of criteria to perform the investigation on case studies.

The literature search was conducted using four research databases (ScienceDirect, Google Scholar, Scopus, and Web of Science), technical information sheets from industry and proprietary systems manufacturers, and several resources already available to the authors (i.e., books and websites). The selected keywords produced a large variety of scientific journal articles. Secondary keywords added were 'porous concrete' and the names of specific technologies such as 'functionally graded concrete', 'ultra-lightweight concrete', and 'infra-lightweight concrete'. Additional resources on specific topics were added during the writing of this study. Peer-reviewed academic articles were researched through online databases such as Francis & Taylor and Elsevier.

4. Results

Table 1. Overview of technology type, structure, fabrication, institute, and country of origin for all three of the concrete technologies.

Technology	**Technology Type**	**Structure**	**Fabrication**	**Institution**	**Country of origin**
Infra-Lightweight	Prototype	Inhomogeneous	Computer Operated	Berlin Institute of Technology – department of design and construction – solid construction.	Germany
Ultra-Lightweight	Project	Homogenous	Conventional methods	Eindhoven University of Technology	Netherlands
Functionally graded v1	Prototype	Inhomogeneous	Computer Operated	Institute for Lightweight Structures and Conceptual Design, University of Stuttgart	Germany
Functionally graded v2	Prototype	Inhomogeneous	Computer Operated	Institute for Lightweight Structures and Conceptual Design, University of Stuttgart	Germany

4.1 Ultra-lightweight concrete (ULC)

4.1.1 Technology description

Similar to lightweight concrete, ULC is a homogeneous material that has both insulating and load-bearing properties [5]. ULC contains expanded glass and fly ash [5]. Research on this technology at Eindhoven University in the Netherlands was completed in 2015 by Yu, Spiesz and Brouwers [5].

4.1.2 Technology type and solutions offered

ULC is a prototypical material with potential use in monolithic structures, such as wall or façade elements [5]. Similar to FGC, the goal is to obtain a single-layer material that has both insulating and load-bearing properties, thus reducing the need for additional insulation [5]. ULC has a thermal conductivity of 0.12 (W/mK) and a density ranging from 600-750 kg/m³. The single-layer matrix of this technology is also well suited for recycling, as there are no glued-on layers as in a conventional concrete building. ULC can also be used as a highly insulating concrete used as a core layer within other concrete composites, as is the case with ILC, and has a 28-day compressive strength of around 10-12 Mpa [5].

4.1.3 Mixture

Figure 1 shows the mixture of ULC [5]. Both the expanded glass and fly ash are products of reuse and therefore contribute positively to the environmental sustainability of ULC by reducing the amount of cement required. However, fly ash is a by-product of the coal industry – something many countries are turning away from Wesche [9].

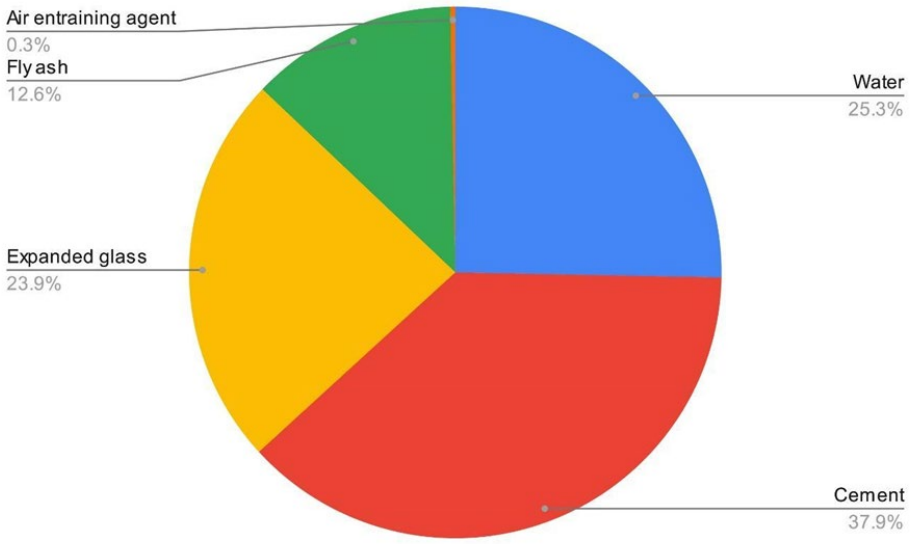

Figure 1. Chart showing the mixture composition of ultra-lightweight concrete

4.1.4 Morphology

The structure of ULC is homogenous through its cross section with visible porous aggregates [5]. Figure 2 shows an isometric drawing of an example wall component of ultra-lightweight concrete.

4.1.5 Thermal performance

R-value at 50 mm thickness: 0.4 m²K/W [5].

U-value at 50 mm thickness: 2.4 W/(m²K) [5].

4.1.6 Fabrication method

The mix for ultra-lightweight concrete is produced using a planetary concrete mixer and is therefore similar to standard concrete production processes, making it suitable for both prefabrication and in-situ use [5]. This process is illustrated in Figure 3.

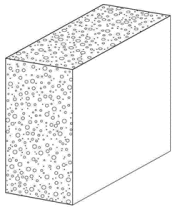

Figure 2. Isometric drawing of an example wall component of ultra-lightweight concrete.

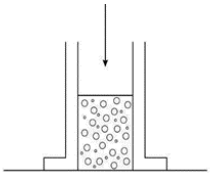

Figure 3. Diagram showing the fabrication process of ultra-lightweight concrete.

4.1.7 Future research

In the future, research could be undertaken in the area of structural design to understand how reinforcement works with this technology. Structural connections and joints could also be designed and tested to determine their performance in the context of a building. Due to the lightness of the material compared to standard concretes, they would also benefit from seismic testing.

4.2 Infra-lightweight concrete (ILC)

4.2.1 Technology description

Unlike conventional concrete or lightweight concrete, ILC is an inhomogeneous material with two distinct properties that alternate in cross-section. The outer layers are stronger and designed to meet load-bearing requirements, while the core is made of a lighter concrete mix that provides thermal insulation. Research in this area is being carried out by the Technical University of Berlin. The team members are Claudia Losch, Arno Richter, and Mike Schlaich [4].

4.2.2 Technology type and solutions offered

Due to its layered morphology, an ILC wall can provide both load-bearing and insulating properties in a single material', which could eliminate the need for additional insulation [4].The core of the structure consists of a lower density concrete with a high proportion of expanded glass and expanded clay, while the outer, stronger layers provide the required load-bearing properties [3]. In addition, photocatalytic layers enable a reduction in air pollutants [4]. Another application of ILC is the 'building simply' project led by Florian Nagler, where the material is used in much thicker external walls of 500 mm depth. This strategy has the potential to increase the thermal performance of exterior walls and allows for in-situ construction instead of prefabrication. The thicker application of this material also means that steel reinforcement is not required in the Central European context due to low seismic activity [10].

4.2.3 Mixture

Figure 4 shows an example mixture of ILC in percentages [4]. These values aggregate both the core and outer shell concrete mixes, which account for 33% and 67% of the total cross-sectional area, respectively. For the mix shown, it is assumed that 25% of the total composition is water to better understand the quantities compared to the other 3 concrete mixes.

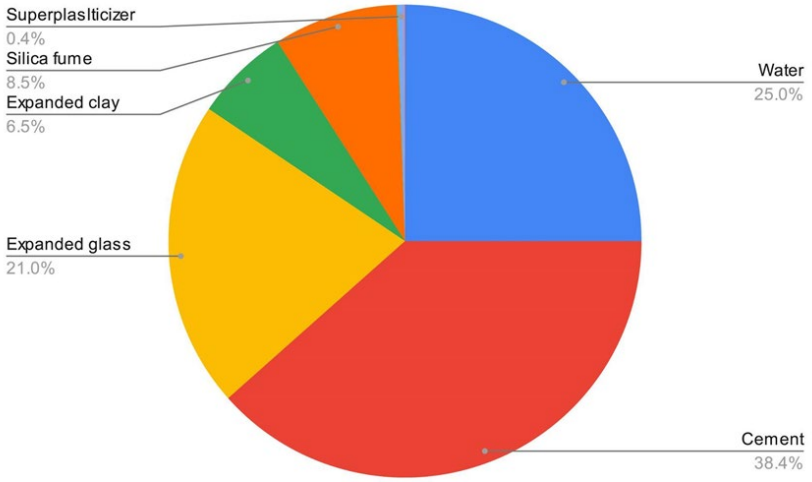

Figure 4. Chart showing the mixture composition of infra-lightweight concrete.

4.2.4 Morphology

ILC has a core that is tailored to provide a lighter product and insulative properties, with a density of 456 kg/m3 and thermal conductivity of 0.088 (W/mK). The outer layers have a higher density of 804 kg/m³, compressive strength of 15.8 MPa for load-bearing properties, and thermal conductivity of 0.169 (W/mK) [4]. The layers are formed like a sandwich panel, but where each layer is joined to another during the casting and curing process to make a monolithic building component [4]. Figure 5 shows an isometric drawing of an example wall component of infra-lightweight concrete.

4.2.5 Thermal performance

R-value of 0.345 m²K/W considering 2x10 mm shell layers and a 30 mm core [4].

U-value of 2.9 W/(m²K) considering 2x10 mm shell layers and a 30 mm core [4].

4.2.6 Fabrication method

ILC is made in stages, with the outer shell poured into a horizontal mould, followed by the core mix and another layer of shell mix [4]. In this way, the outer surfaces act as lost formwork for the inner mix. A certain amount of time must elapse between the individual phases so that the different concretes do not mix [4]. This process is illustrated in Figure 6.

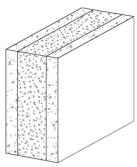

Figure 5. Isometric drawing of an example wall component of infra-lightweight concrete.

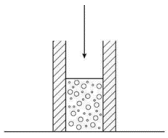

Figure 6. Diagram showing the fabrication process of infra-lightweight concrete.

4.2.7 Future research

The team from the Technical University of Berlin points out that their proposed calculations on the loading properties of ILC and possible design approaches need to be verified by further research [4]. The possible use of glass fibre rods for crack strengthening is also being investigated by the team and

could be compared to steel in terms of performance, both thermally and structurally [3]. Seismic testing is another area the team could investigate and could make the technology internationally applicable.

4.3 Functionally graded concrete (FGC)

4.3.1 Technology description

Gradient concrete is also an inhomogeneous and monolithic material like ILC; however, there is a relevant difference in the mixture of the concrete and the graded nature of the material's matrix. Instead of using a lightweight aggregate to decrease density, the team at the University of Stuttgart, Institute of Lightweight Structures and Conceptual Design (ILEK) has opted for air cavities, created using concrete hollow spheres [6]. FGC is a prototype that is still being researched. The main research headed by Werner Sobek, Walter Haase and Lucio Blandini [11]. The evolution of the team is dynamic. Currently, the research is now in the third generation of PHD (1. Michael Hermann, 2. Daniel Schmeer, 3. David Nigl).

4.3.2 Technology type and solutions offered

By avoiding the use of lightweight aggregates, the team at Stuttgart is working on decreasing the overall concrete used in building. Currently, this can be reduced by up to 62% when combined with carbon fibre reinforcing [11]. Additionally, the overall weight of a structural component can be reduced by 42%, which makes the use of concrete construction on sites with softer ground more viable [11]. Currently, the use of hollow spheres can reduce the mass of FGC by 50% without compromising the load-bearing capacity [12]. In addition to these factors, FGC also has insulating properties that can provide sufficient thermal comfort according to EnEV 2014 specifications, depending on the climate [13]. So far, FGC is a prototype material, but ILEK is currently working on an experimental university laboratory using FGC elements, as explained in an interview with W. Haase (personal communication, 25 February 2021).

4.3.3 Mixture

Figure 7 shows an example mixture of FGC in percentages [14]. The example used for the purpose of this study follows the composition of 'MIITS' concrete mixture, which is one among many test mixtures to date [14].

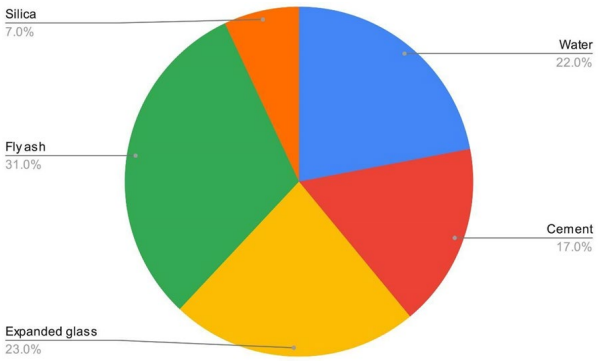

Figure 7. Chart showing the mixture composition of gradient concrete.

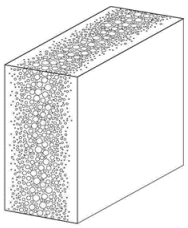

Figure 8. Isometric drawing of an example wall component of gradient concrete.

4.3.4 Morphology
There are currently two variations of FGC. Micrograded concrete features a "continuous variation of porosity" achieved by the use of lightweight admixtures, such as expanded glass and foam-forming aggregates, or through targeted placement of material regarding the requirement [15]. Pore sizes vary from 1 to10 mm diameters in micrograded FGC [15]. Mesograding on the other hand is characterized by larger cavities varying from 10 to 250mm in diameter, which are achieved with "mineral hollow bodies" [15]. The structure of FGC is inhomogeneous in cross-section and has a graded, varying porosity due to the air cavities inside the component. Conceptually, FGC is a multi-layered structure in which the outer layer with integrated reinforcement defines the shape, provides impermeability and facilitates load-bearing capacity, while the inner layer serves as thermal insulation and has the potential to reduce the overall mass [12]. Figure 8 shows an isometric drawing of an example wall component of gradient concrete.

4.3.5 Thermal performance for mixture MIISG (LM)
R-value at 50 mm thickness: 0.55 m²K/W [15].

U-value at 50 mm thickness: 1.8 W/(m²K) [15].

4.3.6 Fabrication method
The initial production of FGC was done with a manually poured, layered system that formed a sandwich slab with denser concrete on the outside and micrograded concrete on the inside, as shown in Figure 9 [15]. This is similar to the integral formwork fabrication that is used to produce ILC. ILEK then developed a two-part gradient spray technology that sprays the concrete in thin layers, while simultaneously compacting and achieving the desired degree of porosity within the component [6]. This process is illustrated in Figure 10 and is another example of micrograding [15]. However, Figure 11 shows the latest method of production, which uses automatically placed concrete hollow balls, an example of mesograding (Schmeer and Sobek 2019). The concrete spheres are robotically placed in the desired locations in combination with poured concrete, with wet-on-wet application ensuring that each layer bonds [15]. The diameter of the hollow spheres ranges from 1-10 mm at the micro-level and 10-250 mm at the macro-level [12].

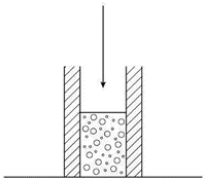

Figure 9. Sandwich diagram.

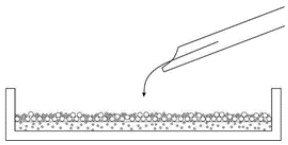

Figure 10. Spray diagram.

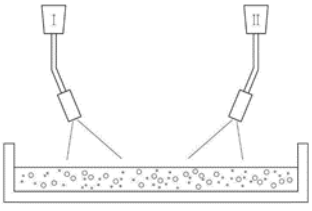

Figure 11. Hollow sphere diagram.

4.3.7 Future research
The market acceptance of FGC continues. However, one area that could be further explored is the performance of FGC in seismic testing. FGC is favourable to the industry as it reduces both weight and material usage. Further development of the mix in terms of its resistance to seismic activity would help make FGC applicable to a wide range of site conditions and environments. In the future, the mix could also be adapted to be more sustainable by replacing the use of fly ash with a substitute material.

5. Discussion

5.1 Solutions provided

The results presented in the study agree with the results of previous studies and are indicative of increasing interest in the field of low-density concretes. The solutions offered by the concrete technologies/systems discussed aim to reduce weight and increase thermal performance to obtain a monolithic building element that does not require additional insulation. The benefits of these factors for the construction industry would be very positive. The use of less material allows for more environmentally sustainable buildings, while the potential of monolithic construction indicates an improvement in recyclability. These are significant improvements over traditional concrete systems. The thermal performance of all three technologies has great potential in monolithic concrete construction, especially FGC, ULC, and ILC. The differences between them are evident. Gradient concrete (MIISG(LM)) reaches the lowest U-value of 1.8 W/(m²K) at a thickness of 55 mm [12].

5.2 Future benefits

In theory, all the technologies in this study can be seen as an improvement over conventional concrete, their main benefits being the reduction in weight, reduction of materials used, insulative potential, and the fact that they are all monolithic, single-leaf systems that are easier to recycle than layered systems. However, this depends on the type of application being considered. In many cases, the stronger and more durable traditional concrete will still be preferred. However, considering wall panels for low-rise buildings, lightweight alternatives may be preferred.

5.3 Gradient concrete

Gradient concrete has the greatest potential but is also the least mature of the technologies covered in this study. With gradient concrete, a 50 % weight reduction is possible, allowing concrete to be used in a wider range of locations, while its insulating properties allow for more comfortable buildings, i.e., performance beyond the bare minimum requirements [12]. Gradient concrete results in a 50-60% lighter concrete that requires fewer resources to produce and reduces emissions by 45-60% [11]. It is a purely mineral, multifunctional element made of a single material with insulating properties that is recyclable. In building construction, the weight of concrete floor slabs accounts for up to 70% of the total structural mass. The design of gradient concrete leads to a significant reduction in the weight of floor slabs and load-bearing walls, thus reducing the overall load-bearing structure [11]. This means, for example, that substantial buildings can be constructed on sites that are currently restricted due to the weight of concrete structures. Gradient concrete has reduced emissions by using less material and energy and the change in porosity over the component cross-section enables efficient control of thermal insulation properties [11]. The University of Stuttgart based Institute of Lightweight Structures and Conceptual Design (ILEK), is currently working on a project to construct an experimental university laboratory using functionally graded concrete elements. The first buildings with graded concrete slabs are currently in the preliminary design phase.

5.4 Limitations of this study

One of the preferred topics for further research directions among the prototype technologies discussed in this article is the area of structural connections, especially when thinking about how these

technologies might behave in an earthquake compared to conventional concrete. This highlights one limitation of this study as the research could have included seismic resistance as a criterion in the search for case study technologies. Another limitation is that the research did not include any contemporary concrete technologies that make use of alternative organic materials in their composition. This is another stream of research that is being developed within the topic of contemporary concrete technologies.

6. Conclusions

The solutions provided by the technologies discussed in this article highlight the need for the construction industry to enhance conventional standards. The use of lower density materials reduces the overall amount of material required, while the monolithic nature of these concrete technologies offers improved potential for effective recycling. Although the technologies examined in this study share a monolithic morphology, their cross-sectional structures vary: ULC is homogeneous, while ILC and FGC are inhomogeneous. It is worth noting that despite these differences, all three technologies possess load-bearing capacity.

The thermal performance offered by these technologies is also of great significance, as it enables professionals to advocate for healthier buildings in a broader range of climates. While the study indicates that all three technologies provide insulation, gradient concrete exhibits the greatest potential in this regard, depending on the specific mix and porosity achieved in a given component. These advantages combine to present a new approach to future concrete construction. The reduction in mass and weight, insulation properties, load-bearing capacity, and recyclability all point to the potential for a more environmentally sustainable monolithic approach to building with concrete, as well as the possibility of using concrete in a wider variety of climates and soil types.

However, further development is needed to address the seismic performance of ULC, ILC, and FGC to enhance their applicability at a geographical level. Since these technologies have cross-sectional structures that significantly differ from conventional concrete, conducting seismic testing would be a beneficial next step for their development, particularly in terms of designing joints and connections used with prefabricated structural elements. Additionally, when considering the precast approach to construction using these technologies, it is important to address thermal bridging between panel edges and connections between various components. Although these aspects are not covered in this paper, they should be taken into account for future research. Furthermore, comparing low-density concretes to conventional concrete in terms of environmental sustainability and conducting more research on mixes and component composition would be valuable, especially as there is an increasing interest in utilizing naturally obtained substitutes for concrete ingredients and reinforcement.

Overall, the findings of this study highlight the potential benefits of these concrete technologies and suggest avenues for further investigation and development in the field.

Abstract

Natural thin-shell structures have been in focus owing to their interesting forms and features. A seashell form is considered in terms of its potential for application to architecture structural systems. Besides, biomimetics has flourished in the architectural filed recently so that the features of seashells' form deserve more attention. Herein, we study the mechanical and geometric features of bivalve shells. In addition to these studies, a dynamic analysis should be conducted to apply seashell features to structural systems, and we modified to shell element from solid element of the model with a low computational load for the dynamic analysis on finite element (FE) analysis reflected bivalve shell form. This study presents a natural vibration analysis of the bivalve-shell form using modified FE models to reveal its vibration features. The analysis was performed multiplied equally by the size of real buildings. By comparing this with the results of the FE model reflected a hemisphere form same as building size, the response properties of the FE models reflected bivalve shell form to vibration are revealed. Up to the 100th order mode, the shell model had a broader range frequency than the dome model by natural vibration analysis. Consideration of the cumulative mass participation showed that the shell model has fewer natural period to consider when structural designed than the dome model in the case of vertical vibration.

Keywords: biomimetics, seashell, vibration analysis, image-based finite element analysis

1. Introduction

Biomimetics has become a key instrument in a wide range of engineering technologies. It is utilized in the form of train head, folding systems of space structure in the fields of mechanics, material science, and robot engineering [1-4]. Thus, biomimetics is crucial in engineering technology, and structural engineering in architecture recently as well. For example, foundational research has flourished to learn from various living things, such as research focusing on the growth patterns of trees and leaves and the ability of plants to grow themselves [5-7]. While a few examples of partial applications exist, these are not widely used in structural systems [8-12]. This is because the mechanical properties of natural organisms have not been revealed in detail, as evidenced by the fact that fundamentals are still the primary focus on the previous studies. However, other fields of architecture have been used in decorative design, such as the botanical form as a pattern [13, 14] and the ventilation system from the termite nest system [8], and a strong affinity exists between architecture and biomimetics. Therefore, we have focused on seashells, particularly bi-valve shell, which have a form similar to architectural spatial structures.

Previously, natural thin-shell structures have been the focus of study owing to their interesting forms and features such as seashells, eggshells, and soap films [15]. Among these structures, the forms of the

seashell evolve and can be optimized to adapt to their habitat. The seashell form has been considered for potential applications in architectural structure systems [15, 16]. Research on seashells is ongoing in various fields. Biology and paleontology factor the ecology and relationships of each species, geology, and natural history discuss their role in the long history of Earth, and morphology discusses the geometric features of their shells [17-19]. These factors are evidently interrelated. This knowledge should be beneficial in new fields such as biomimetic application studies. Many studies have been conducted on the relationship between the ecology of shells and their forms, and various experiments have been conducted on their strength [20-22]. In one of them, the mathematical model of the seashell was used to elucidate mechanical properties [20]. This is a good example of how findings from an independent issue in one field can be used for another issue in another field within seashell topic. In particular, the mathematical model of seashell is considered useful in the field of building structure because various formulas have been proposed depending on the type of expression desired [17, 18, 23, 24], and shape expressions based on these formulas can also be used in CAD and other applications. Previous studies have primarily focused on molluscs' habitat. However, the advantages it offers as a spatial structure in human life are unknown.

To clarify basic knowledge, we studied the mechanical and geometric features of the bivalve shell form [25, 26]. In [26], a static analysis was performed for a bivalve shell form through image-based finite element (FE) analysis. Results were matched with geometric features, and their relationships were verified. However, many dynamic forces act on buildings, and this is a crucial factor to be considered. When architectures are subjected to dynamic loads, such as earthquakes and typhoons, spatial structures comprising a structural system that bivalve shell features can refer to are generally used as shelters. Therefore, the response should be elucidated to these loads.

This study presents a natural vibration analysis of the bivalve shell form to reveal its vibration features using an FE model, which reflects the form of the bivalve shell. The model used in this study has a small computational load while maintaining detailed geometric features for dynamic analysis [27]. By comparing this with the results of the FE model, which reflects the form of a simple dome, the response properties of the bivalve shell form to vibration are demonstrated.

2. Methods

In this study, the specimens used in previous studies [26, 27] were employed. This section describes the specimen and method used to develop the FE models. The FE models reflecting the form of the specimen and a simple spherical dome were developed. Finally, this section describes the conditions for vibration analysis.

2.1. Specimen

The specimen used in this study was a shell fragment from seven-month-old *Fulvia mutica* cultivated in Ishikawa Prefecture, Japan. As shown in Figure 1 [26], the specimen was cleaned; its size was approximately 50 mm (X direction) × 50 mm (Y direction) × 30 mm (Z direction). This species was selected because it is a species of *Veneroida* with large internal space in bivalve shells, and it is edible,

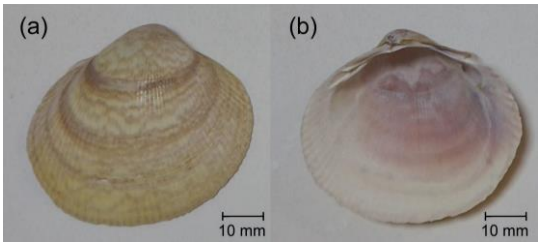

Figure 1. (a) Front and (b) back surface of specimen [26].

easily accessible, and familiar to humans. The specimens were scanned using X-ray computed tomography (CT) apparatus (Skyscann2211, Bruker Corp.). The scanning details are described in [26]. CT images were the same as those in previous studies [26, 27].

2.2. Developing the analysis models

2.2.1. Seashell model

A seashell model was developed using the CT images obtained in Section 2.1. The detailed method is described in previous studies [26, 27]. First, CT images' resolution value was decreased for the computational costs of image processing and FE analysis. The CT images were reduced to 180 μm / voxel and fragments were removed. Furthermore, the CT images were through several filters to prevent false solutions. These were processed by Image-J (Wayne Rasband and contributors National Institutes of Health, ver.1.53e), which is the software for image processing, and MATLAB (MathWorks, ver. R2020a), which is the programming language for science technology. An STL model was developed based on CT images processed through Invesalius (Center for information Technology Renato Archer, ver. 3.1) with a threshold value set at 55. Invesalius is the software for reconfiguration the CT images. The STL model in this state can be used to obtain an FE model composed of solid elements with an FE mesh creation software. However, we expect the computational cost of dynamic analysis using the solid FE model to be significantly higher. Therefore, an FE model modified to reduce computational load was proposed to convert the element type from solid to shell [27]. In this study, a modified model that reduced computational load was applied for dynamic analysis. Three types of FE models, reflecting each surface form, were obtained with this method. In this study, the FE model reflecting the front surface, which showed properties closest to the actual shape (the model configuration with the solid element) in [27], was selected. The properties of the STL and FE models used in this study are listed in Table 1. In this study, the FE model described in this section is called as the shell model.

2.2.2. Dome model

A model reflecting a simple hemispherical dome was created with three-dimensional modeling software. The rise and span were suited to the span of the shell model. After outputting the STL file format, this model was divided into a more detailed mesh using Hypermesh, which is a meshing software with the same number of elements as the shell model. The size of each element was also adjusted with the software. The FE model described in this section is called as the dome model in this study.

2.3. Conditions for the analysis

In this study, natural vibration analysis was performed on both the shell and dome models. As shown in Figure 2, the boundary conditions were considered to be pinned at the periphery and the coordinate space was set. The material properties of the models were considered to be those of ordinary concrete, where the Young modulus was 2.17×10^4 MPa, the Poisson's ratio was 0.2, and specific gravity was 24.0 kN / m^3. The analysis was performed using Abaqus (SIMULIA, ver.2019), a general-purpose FE analysis software, and S3 elements were used in Abaqus for both models. Additionally, shell element enabled the thickness distribution of these FE models to be easily changed. The thickness distribution and mean thickness of the specimens were obtained through the method in [26] into the shell and dome

Table 1. Details of each model.

Model	Nodes	Elements	Min element size [mm]	Max element size [mm]
STL model	158 718	317 430	0.000674	1.054
Shell model	94 683	188 351	0.00209	0.338
Dome model	176 091	351 254	0.00442	0.175

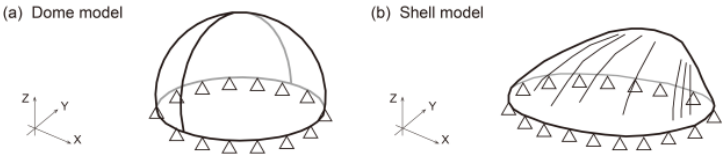

Figure 2. Conditions for the vibration analysis on (a) Dome model and (b) Shell model.

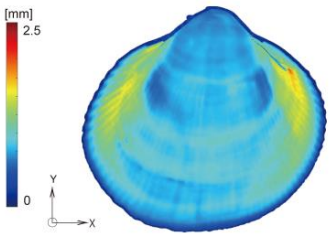

Figure 3. Distribution of thickness [26].

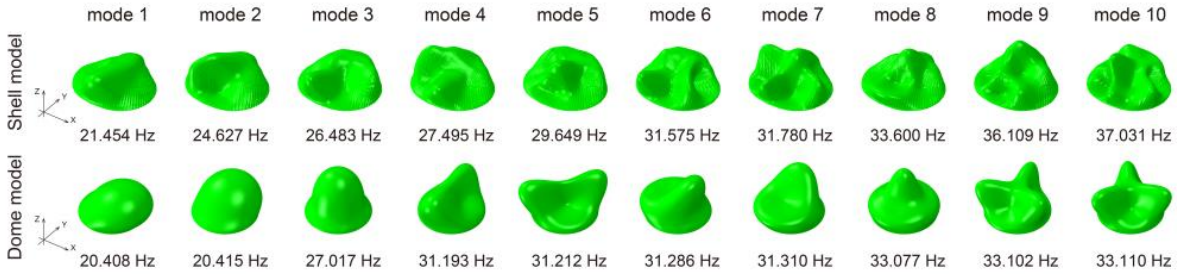

Figure 4. Deformations of the natural frequency first to tenth modes. Deformation diagrams are magnified by 5000.

models. The thickness distribution is shown in Figure 3 [26]. The mean thickness was 0.838 mm. All model sizes and thicknesses were multiplied by 500 times as the actual architectural building size before analysis. This was because the real bivalve shell size was extremely small to consider accurate deformation properties owing to the prediction of excessive entire movement when the next planned history analysis was performed using this result. This was considered on a human scale.

3. Results

Figure 4 shows the deformation diagrams and the natural frequency values of the lower-order modes on both models. The deformations of the lower-order modes were not complex in both models under the 5th mode. After the 5th mode, the deformations of the shell model showed a complex form. Deformations of the dome model maintained a simple symmetry after the 5th mode same as under the 5th mode. The dome model deformed to response for vibration wave as a whole, while the shell model's deformation concentrated on abdomen area on every mode shown in Figure 4. Therefore, when the shell model is attacked by vibration wave, large deformations would occur in the abdomen area. On the other hand, the shell model's deformation on the umbo area was small on the lower-order modes. This feature is same as the case of the elastic analysis under the dead weight [26], and [21] reported that deterioration (e.g., scraping) at the apex area of the shell reduces the mechanical capacity of the entire shell. In the case of time history response analysis as a next step, focusing on the umbo area is likely to get the beneficial knowledge about seashell form.

Figure 5 (a) shows the transitions of the frequency values up to 100th modes of both models. As shown in Figure 4, the first frequency values of both models were similar. At the lower-order modes under the 5th mode, the dome model covered wider range of the frequency. After the 5th mode, the slope of the frequency values became smaller on the dome model. However, the slope of the frequency values was constant on the shell model. The shell model and the dome model also had approximately same the first natural period so that there was no difference in point of the susceptibility to resonance for long-period earthquakes, which is an important point on the seismic analysis. In addition, when the shell model is attacked by vibration wave, there is a high probability of the shell model getting resonance with respect to short-period wave than the dome model. Subsequently, the transitions of cumulative mass

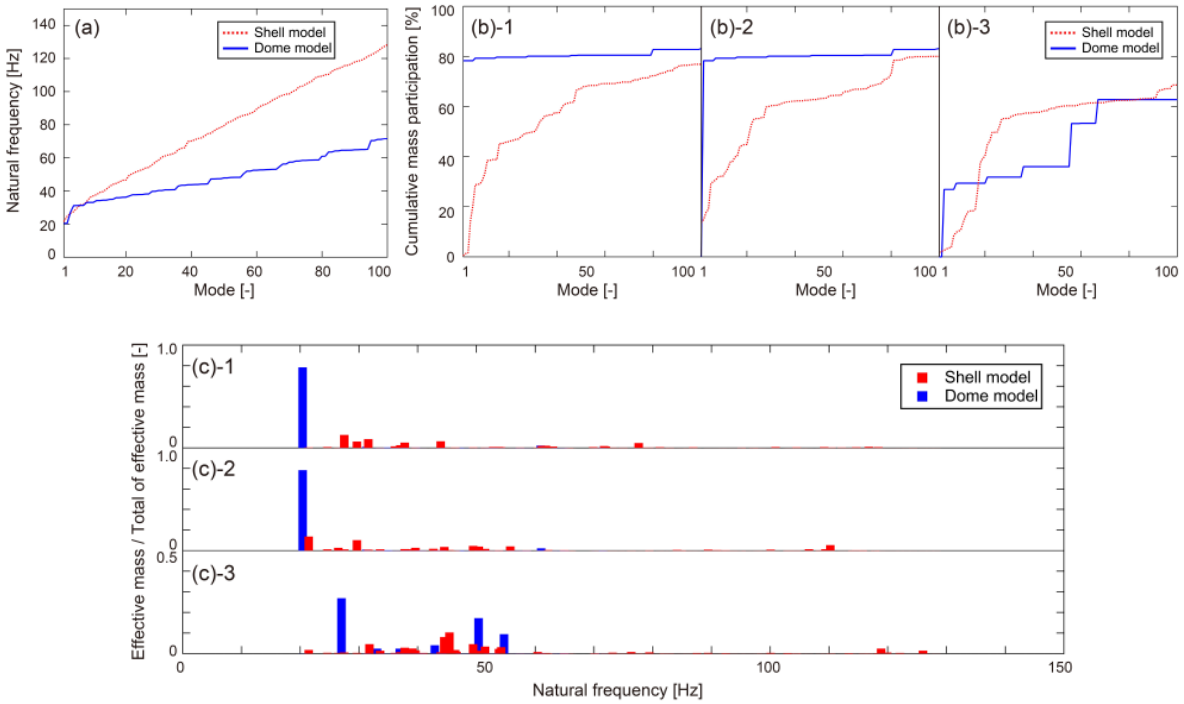

Figure 5. (a) Natural frequency transition of both models. (b) Cumulative mass participation in each direction, (-1) is X direction, (-2) is Y direction, and (-3) is Z direction. (c) Ratio of the effective mass distribution in each direction, (-1) is X direction, (-2) is Y direction, and (-3) is Z direction.

participation were examined to ascertain the contribution of each mode, and the cumulative mass participation up to the 100th mode was used to determine how much of the total was covered for each direction on both models. Figure 5 (b) shows the cumulative mass participation up to the 100th modes. The final cumulative mass up to the 100th mode for all directions almost matched on both models.

Figure 5 (b)-1 and (b)-2 show the transition curves of the horizontal direction. The cumulative mass participation of the dome model almost occupied on the lower-order modes, on the other hand, the cumulative mass participation of the shell model distributed wider range. Even beyond the mode indicated by Figure 4, the transition curves of cumulative mass participation were increasing at a constant slope in the case of the shell model. Figure 5 (b)-3 shows the transition curve of the vertical direction. In the case of the dome model, the cumulative mass participation of lower-order modes were smaller than the horizontal direction. In addition, there were also the large cumulative mass participation on the vertical direction after the 50th mode. In the cases of horizontal direction, the cumulative mass participation of the shell model did not exceed the dome model's one up to the 100th mode, but in the case of vertical direction, the cumulative mass of the shell model exceeded the dome model's one and became almost unaltered around the 20th mode. When consideration the structure attacked by vibration wave, the number of vibration eigenvalues to be considered on vertical wave in the case of the shell model is less than the dome model, whereas the number of vibration eigenvalues to be considered on horizontal wave in the case of the dome model is less than the shell model.

Moreover, in the case of the dome model, the transition curves of cumulative mass participation for X direction (Figure 5 (b)-1) and Y direction (Figure 5 (b)-2) were almost matched because of the horizontal geometry was symmetrical. However, the transition curves of cumulative mass participation were similar in the case of every direction on the shell model as well even though the model's geometry was not symmetrical for every direction. Therefore, the effective mass ratio of each frequency value was considered to confirm distribution of these. Figure 5 (c) shows the effective mass ratio for frequency

values of each mode. In the case of the dome model, the ratio in the vicinity of 20 Hz, which indicated by the first mode, occupied almost the total on the horizontal direction. In the case of vertical direction on the dome model, the mode which had the ratio same as lower-order mode appeared after 50 Hz. On the other hand, the shell model's effective mass ratio distributed between 20 Hz and 80 Hz randomly for every direction. The transition curves of cumulative mass participation for each direction were similar, but the effective values and the distribution of frequency in the case of the shell model seems to be different for each direction. Additionally, the mode which had the ratio same as lower-order mode appeared after 100 Hz in the case of the shell model. The shell model needs considerations for every direction, X, Y, and Z, by each mode on dynamic analysis because the effective mass ratio of the shell model distributed randomly and wider compared the dome model. The wide distribution of the mode which has large mass participation ratio on the shell model is different feature from the dome model. Whether this is a better feature for the structure or not must require the results of the next step, time history response analysis, and this study alone is not sufficient to judge. When these results are matched with acceleration response spectrum of typical earthquake, they have outstanding natural period between 0.2 s and 0.8s. The shell model has natural period distributed wider range under 0.05s. In the case of construction which has mechanical behavior nearly same as the shell model on vibration wave, it's hard to say because substructure and base ground condition also affect it, designing the natural period short by construction its light is an effective countermeasure against resonance.

4. Conclusion

In this study, the FE model reflected bi-valve shell form using shell element was used to perform the natural vibration analysis, and the results were compared with those of the dome model to verify the features of the bi-valve shell form with responded to vibration wave. This study can be summarized as follows:

1. In the range up to the 100th order, the shell model had a broader range frequency than the dome model by natural vibration analysis.

2. Consideration of the cumulative mass participation showed that the dome model has fewer natural period to consider when structural designed than the shell model in the case of horizontal vibration, however in the case of the vertical vibration, the shell model has fewer natural period to consider.

3. The shell model needs considerations for every direction by each mode on vibration condition like earthquake, because the effective mass ratio of the shell model distributed randomly and wider compared the dome model. Whether this is a better feature for the structure or not must require the results of the next step, time history response analysis, and this study alone is not sufficient to judge.

4. When referring to acceleration response spectrum of typical earthquake, the shell model's natural period was shorter than the outstanding natural period by the spectrum of the typical earthquake. In the case of construction which has mechanical behaviour nearly same as the shell model on vibration wave, designing the natural period short by construction it light is an effective countermeasure against resonance.

5. The dome model deformed as a whole, while the shell model's deformation concentrated abdomen area and the deformation of umbo area was small for every mode on the natural vibration analysis. On the other consideration for example, time history response analysis and more, focusing on the umbo area is likely to get the beneficial knowledge about seashell form.

Future works should focus on studying the following points:

1. We should discuss the participation factor and the sensitivity of response to each property that could not be discussed in this paper by the vibration analysis.

2. About the distribution difference of the natural period on both models found from this study, we will examine from time history response analysis whether which feature is better with respect to vibration wave.

3. We are going to continue our research with the aim of proposing a new method of morphogenesis using the features of the bi-valve shell's form obtained in this study and other the features already published on [26] about static loading.

Abstract

To facilitate commuters crossing the railways near the high-speed rail station in Shenzhen, China, a five-span pedestrian bridge with a main span of 152 m is being planned. We propose an innovative pedestrian bridge design based on multi-material topology optimisation, which realises the process from conceptualisation to detailed design considerations. This bridge is expected to satisfy unique architectural and engineering challenges, providing an iconic, cost-effective and low-maintenance solution, and complying with various construction requirements. The superstructure was designed for a variable-depth spinal-shaped girder in the centre of the deck with an elegant curving facade, from which one pathway cantilevers on either side. On the one end of the bridge, due to the considerable difference in elevation between the bridge deck and the ground, we provided a two-level Fibonacci-type spiral-shaped bicycle ramp. It is supported by a series of organic tree-branch-shaped piers obtained from topology optimisation. The elegant profile of this bridge creates an enjoyable and dynamic crossing experience with scenic views in all directions. In this paper, the main aspects of the construction requirements and challenges, conceptual development process, form-finding with the bi-directional evolutionary structural optimisation (BESO) strategy, structural design, and construction method of the bridge are presented.

Keywords: bridge design, form finding, finite element analysis, topology optimisation, spinal-shaped girder, tree-inspired branching pier

1. Introduction

Bridges are man-made structures that overcome barriers and facilitate human traveling. Thanks to developments in design theories, modern bridges with larger spans and superior structural performance are emerging. However, the homogenisation of traditional design methodology and ideology usually causes bridge structures almost the same pattern. To date, topology optimisation has become an effective strategy for architects and engineers to probe elegant and high-performance structures. Without relying on the initial configuration of form and structure, this state-of-the-art technology can inspire designers to achieve innovative bridge structures that will be efficient, lightweight, and versatile [1]. Overview of several topology optimisation methods, evolutionary structural optimisation (ESO) [2, 3] and its enhanced version bi-directional evolutionary structural optimisation (BESO) [4] are two of the most commonly used in architectural and structural design. Recently, the multi-material bi-directional evolutionary structural optimisation (MBESO) method [5, 6], which was proposed by Li and Xie, has been capable of solving multiple material topology optimisations. Hence, lighter and more effective

structural forms can be achieved by using the MBESO method in the conceptual design of bridges [7, 8].

Nevertheless, the bridges obtained by topology optimisation typically feature irregular and complex nonlinear geometric appearances, which are difficult or expensive to realise by conventional construction techniques. Currently, various bridges with unique forms and excellent structural performance have been obtained through topology optimisation methods, but rarely of these been reported to be successfully built. Due to the huge scale that bridges typically exhibit, their design is quite different from the design and manufacture of mechanical or industrial products. Successful implementation according to the design intentions requires a combination of the current technology level and construction logic. Given this, it is essential that topology optimisation techniques are introduced into bridge design with full consideration of constructability in addition to fulfilling safety, economics, and durability.

In this paper, we proposed a novel and unique pedestrian bridge according to the construction requirements and challenges of a real project and then optimised its structure using the MBESO method. Inspired by the obtained forms from topology optimisation, we conceived this bridge based on the multiple objectives and constraints such as construction boundary conditions, functional requirements, aesthetic appeal, and structural mechanical performance. The major aspects related to design considerations and structural analysis are presented.

2. Overview of the project

2.1. Project profile

A pedestrian bridge with a main span of 152 m is planned to be built in Shenzhen, China, to improve accessibility for commuters to cross the rails adjacent to the high-speed train station. The bridge should be designed and built not only to meet the commuting function but also to achieve novelty, aesthetics, and uniqueness.

2.2. Construction requirements and challenges

Shenzhen is an attractive emerging city in southern China. The business centre of the high-speed rail station, where this pedestrian bridge is located, is one of the most animated urban areas. The construction requirements and challenges of this project are as follows:

(1) The boundary around the project is complex and restrictive factors are multifarious. Water source protection zone, ecological control lines, fundamental agricultural land, etc. must be considered comprehensively.

(2) The bridge crosses a road and several high-speed railways are in operation. Due to the stringent requirements of rail operations for a newly built bridge overhead, the construction must be completed at the fastest speed within the time window specified by the railway administration department.

(3) The owner has high requirements for the landscape and implementation of the bridge. The project needs to be a masterpiece for the community. The bridge should enhance the aesthetic taste of the city and become a landmark to shape the influence of the city.

3. Conceptualization of the novel pedestrian bridge

3.1. Concept development

For the consideration of minimising the maintenance of the cross-bridge on the operating rails and the electrical protection of the overhead contact line system, the railway administration department disallows the structure of steel or steel-concrete composite structure bridge across. As the project is located in the central business district, surrounded by numerous high-rise buildings, the bridge should

blend in with the environment and adopt a low-profile form according to the urban design. Therefore, cable-supported bridges with lofty pylons are unsuitable, while concrete girder and arch bridges are economical and reasonable solutions with minor maintenance work. Shenzhen is a seaside city with a thick cover of soft soil foundation. If a deck arch bridge (as shown in Figure 1a) is adopted, the arch seats cannot be located directly on the rock foundation. The enormous long-term horizontal thrust from the arch is prone to cause soil creep, thus endangering the bridge itself and the railways. A prestressed concrete (PC) girder bridge (as shown in Figure 1b) with variable cross-section may be appropriate, however, as the main span is 152 m, the girder depth at the main pier requires 11 m following the conventional design. However, similar to deck arch bridges, variable cross-section PC girder bridges will cause excessive elevation lift of the bridge deck. This would significantly increase the climb length of such a ramp for bridges that need to pass bicycles. Thus, conventional structural solutions have disadvantages.

How to reduce the girder depth, but still meet the bearing capacity requirements of such a long-span bridge? Given this situation, we propose to set part of the load-bearing structure above the bridge deck based on the variable-section girder bridge, forming a distinctive combination consisting of a spine structure and variable-section girder (as shown in Figure 1c). This lowers the deck elevation by two meters compared to a conventional PC girder, significantly reducing the ramp length. However, if we do not improve on this unique structure, it will seem too bulky. Therefore, we optimised this structure by using the MBESO method to achieve a strikingly elegant bridge with high efficiency.

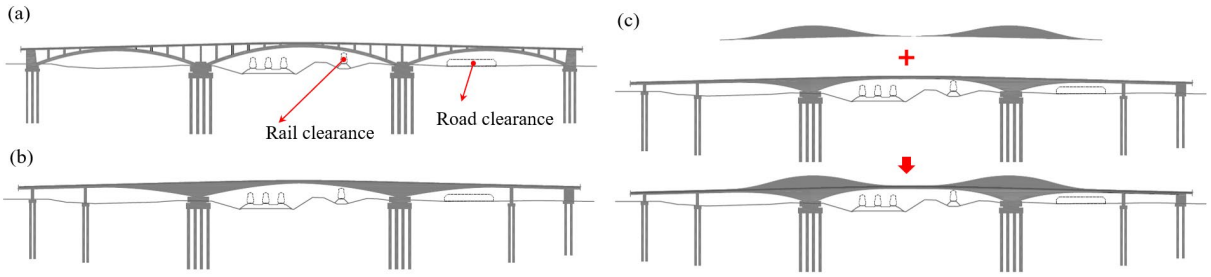

Figure 1. Concept development process: (a) deck arch bridge with flat arch, (b) variable-section PC girder bridge, (c) variable-depth spinal-shaped PC girder bridge.

3.2. Structural optimisation

3.2.1. Topology optimisation settings

Given that the length and height of the bridge structure are significantly greater than the width of the cross-section and that the load is primarily concentrated in the vertical plane, the structural model can be simplified to a plane stress problem, and this project uses a 2D topology optimisation algorithm. Compared with 3D topology optimisation, the 2D topology optimisation method can present more details with more FEA elements, making it more suitable in this case.

This project involves a series of topology optimisation calculations, with material parameters mostly remaining the same across these cases. The parameters for the two materials used for tension and compression are: steel with E_t = 200 MPa and concrete with E_c = 50 MPa. The allowable stresses for the two materials are: $[\sigma_s]$ = 200 MPa and $[\sigma_c]$ = 50 MPa. The magnitude of the line load on the flat bridge deck and the curved pedestrian walkway is set to q_1: q_2 = 2: 1. In different cases, the total number of elements in the design domain varies, but the size of individual elements remains the same, with four-node rectangular elements measuring 0.1 m × 0.1 m in length. If the design domain is a complete rectangle, the total number of finite elements is 292,340, sufficient to show small structural details. Other topology optimisation parameters are set as follows: the evolution rate *er* is set to 2%, and the filter radius is r = 0.5 m.

3.2.2. Evolution of the Initial Design Domain

Adjusting the initial design domain is a simple way that can directly influence the topology optimisation result. For a new structural form, like the one studied in this paper, an ideal optimised structure can be obtained by continuously adjusting the design domain, until a suitable design domain is determined.

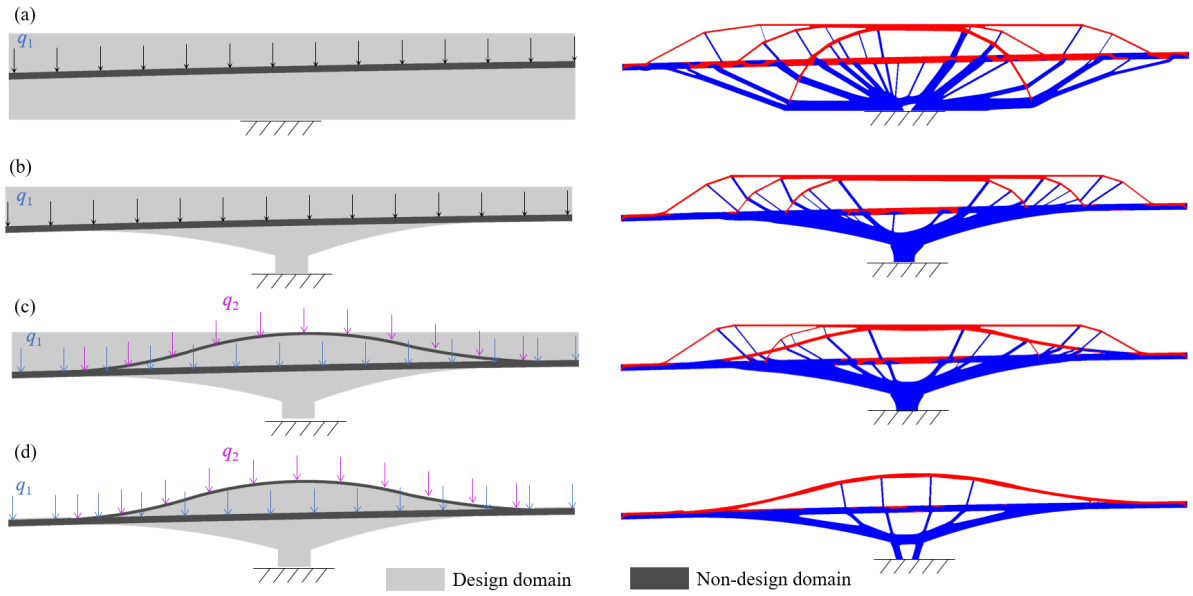

Figure 2. Various design domains, support and loading conditions, and corresponding topology optimisation results: (a) complete rectangular design domain, (b) design domain with the space below the bridge deck removed, (c) design domain with added non-design space for pedestrian walkways, (d) design domain with the space above the pedestrian walkway removed.

Figure 2 shows a series of topology optimisation results achieved by modifying the design domain boundaries. In Figure 2a, the optimised structure is obtained using the rectangular design domain, with the bridge deck as a non-design domain and fixed boundaries at the bridge piers. The blue compressed materials are radially distributed around the pier, providing support to the bridge deck, while the red tensioned materials are mainly concentrated above the bridge deck to resist bending. The force transmission path and the synergistic mode between the two materials are reasonable, but some components do not meet the functional requirements of the bridge, such as the inclined branches that almost touch the ground, obstructing traffic under the bridge deck. Therefore, the design domain boundaries in these local areas need to be adjusted. In Figure 2b, the redundant space under the bridge deck is removed, and the optimised structure presents a simple form, with blue compressed materials forming tree-shaped columns, and tensioned members above the bridge deck forming a bow-shaped inverted beam string structure system. To meet the functional requirements of pedestrians, the design domain after setting the non-design domain above the bridge deck is shown in Figure 2c, and accordingly, the optimised result also includes the pedestrian area. Furthermore, by restricting the space above the bridge deck, the tensioned members above the pedestrian walkway can be removed, and these cable-like tensioned members are merged into a single tension cable, as depicted in Figure 2d.

3.2.3. Driving topology optimisation by setting non-design domain

In Figure 2, setting non-design domains ensures that the topology optimisation results meet the functional requirements of the structure, such as retaining the bridge deck and pedestrian walkway in the results. In addition, by setting non-design domains appropriately, the evolution direction of topology optimisation direction can be driven to an ideal design reference prototype. In Figure 3a, the design domain is further adjusted based on the optimised result in Figure 2d by adding the lower chord arch of the bridge as a non-design domain, increasing the target volume fraction to 0.8, and adjusting the filter

radius to r = 1.0 m. The optimised result shows a stable tree-like structure with four inclined columns radiating from the piers and elegant curved lines of tensioned material. In Figure 3b, to obtain diverse designs, the area where the vertical columns are located is added as a non-design domain. Due to the existence of this non-design domain, the material within a certain range around the central column converges towards the vertical columns in the topology optimisation process, resulting in an optimised structure with three columns. Both of these structural forms have certain design reference values, and it is evident that setting non-design domains in very small areas can lead to completely different topology optimisation structures.

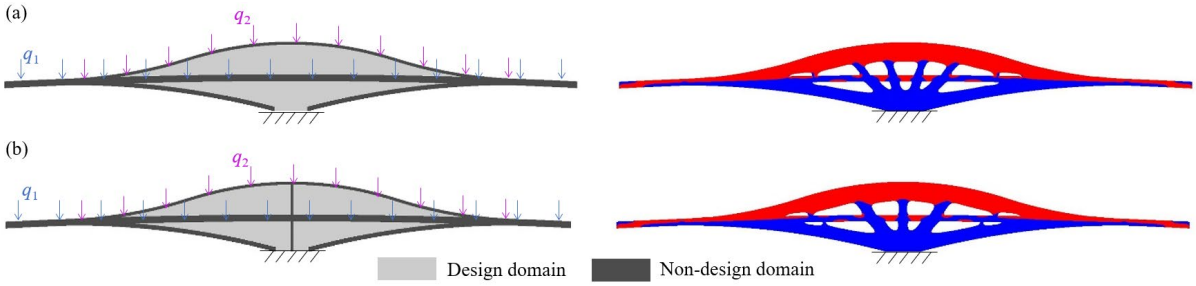

Figure 3. Driving topology optimisation direction by setting non-design domain: (a) optimisation result without setting the middle vertical column as non-design domain, (b) optimisation result with the middle column set as a non-design domain.

3.2.4. Setting different filter radius

In addition to employing non-design domains, adjusting the filter radius in topology optimisation provides an effective means to influence the direction of optimisation and achieve diverse structural designs. Expanding on the settings demonstrated in Figure 3a, increasing the filter radius to r = 3.0 m yields an entirely different topologically optimised structure, as showcased in Figure 4. The structure obtained with a smaller filter radius features slender and more members, including 4 inclined columns. On the other hand, the structure produced with a larger filter radius has fewer, sturdier members, incorporating only 2 inclined columns. When designing structures for practical engineering applications, the selection of an appropriate topology optimisation outcome should be comprehensively considered based on other factors such as construction complexity and aesthetic value.

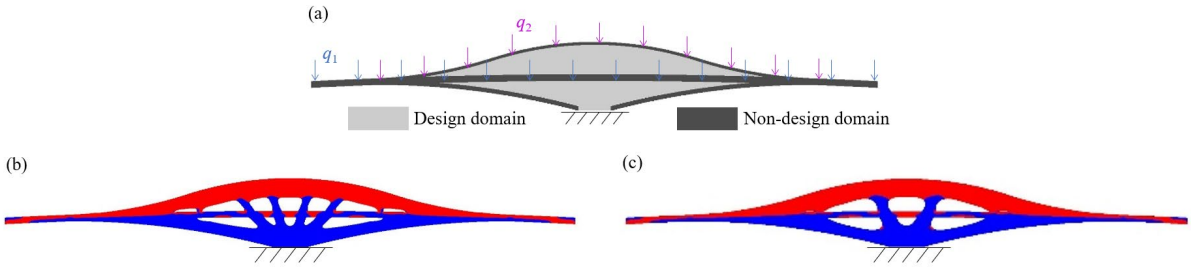

Figure 4. Obtaining diverse topology optimisation results by adjusting the filter radius: (a) design domain, support, and load conditions, (b) topology optimisation result obtained with a filter radius of 1.0 m, (c) topology optimisation result obtained with a filter radius of 3.0 m.

4. Structural design

4.1. Overall design

Based on the boundary conditions and various constraints of the bridge site, this bridge was designed as a five-span with a span arrangement of (41+85+152+85+41) m and a width of 17 m. The design for the superstructure is a variable-depth spinal-shaped PC girder with an elegant curving facade in the centre of the deck, from which one pathway cantilevers on either side. The stairway above the spinal-shaped

girders (SSGs) gradually rises to the top at the main pier, which offers scenic views of the surroundings. The segregated twin pathways allow the faster commuter bicyclists to be safely separated from the slower pedestrians. Figure 5 shows the rendering of the proposed bridge.

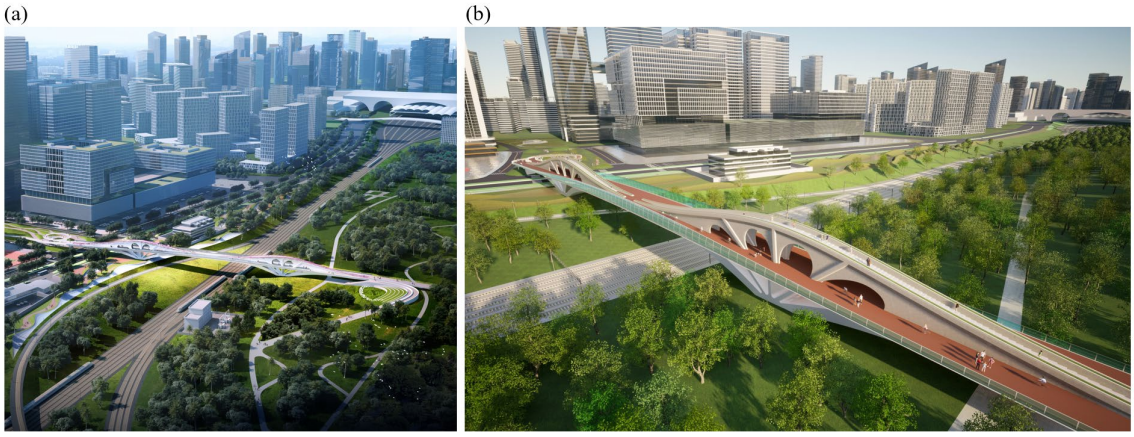

Figure 5. Rendering of the proposed bridge: (a) aerial view, (b) close-range perspective view.

4.2. Construction method

To minimise the safety risk and disruption to the railways during the bridge construction, we propose to use of the horizontal swivelling construction method for the superstructures. For ensuring weight balance during rotation, the superstructure is arranged symmetrically along the main pier. First, each section of the superstructure was cast by the temporary support along the direction of the railways, until the maximum cantilever state was formed before horizontal swivelling. Afterward, the hinges are sealed immediately after the superstructure is in place to avoid large displacements caused by small rotations of the ball hinges. Finally, the spinal-shaped superstructures are closed with the side span cast-in-place sections and the mid-span rigid hinge is installed. Figure 6 shows the construction method of the bridge.

Figure 6. Schematic diagram of the construction method: (a) cast-in-place of the superstructures, (b) horizontal swivelling process, (c) horizontal swivelling in place.

4.3. Structural design

4.3.1. Spinal-shaped superstructure

Based on the form-finding by the MBESO method, we manually simplified and adjusted the shape of the bridge slightly, and then detailed the design of this structure with full consideration of constructability. The superstructure (as shown in Figure 7) was designed as a thin-walled concrete structure with a regular curved surface. Both the main girder and the lower chords are of the single-box three-cell structure with aligned webs, which naturally transition through a converging section. The abreast SSGs are set above the deck and aligned with the middle webs of the main girders. A top slab is set between the two SSGs to strengthen the integrity of the structure, while the pedestrian steps can be set on it. By making arch-shaped holes in the webs of the SSGs (which are inefficient areas), the bridge not only reduces its self-weight but also seems lighter. Besides, people can reach the other side of the

deck through these holes, and the interior of the SSGs creates a space for pedestrians to get shelter from the sun and rain. The top of the SSGs are inverted horseshoes, in which most of the longitudinal prestressed tendons of this bridge are arranged, and only a few parts are configured in the top and bottom slabs of the main girder. In the lateral direction, due to the considerable cantilever length of the girder flange, the lateral prestressed tendons are configured in the top slabs.

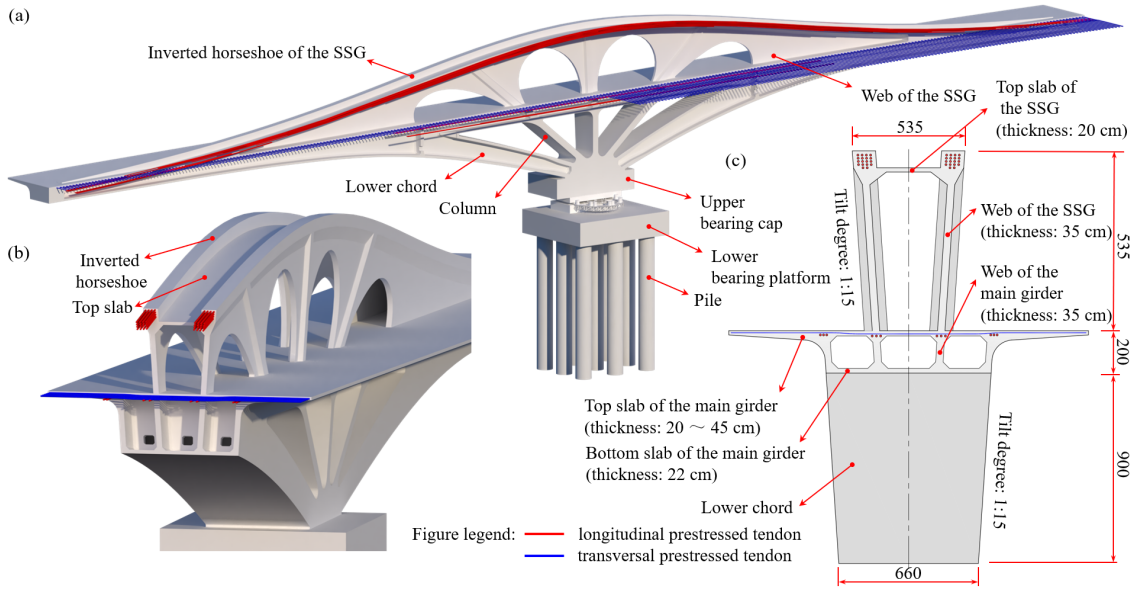

Figure 7. Schematic diagram of superstructure: (a) schematic along the axial direction, (b) schematic along the lateral direction, (c) typical cross-section of the superstructure (unit: cm).

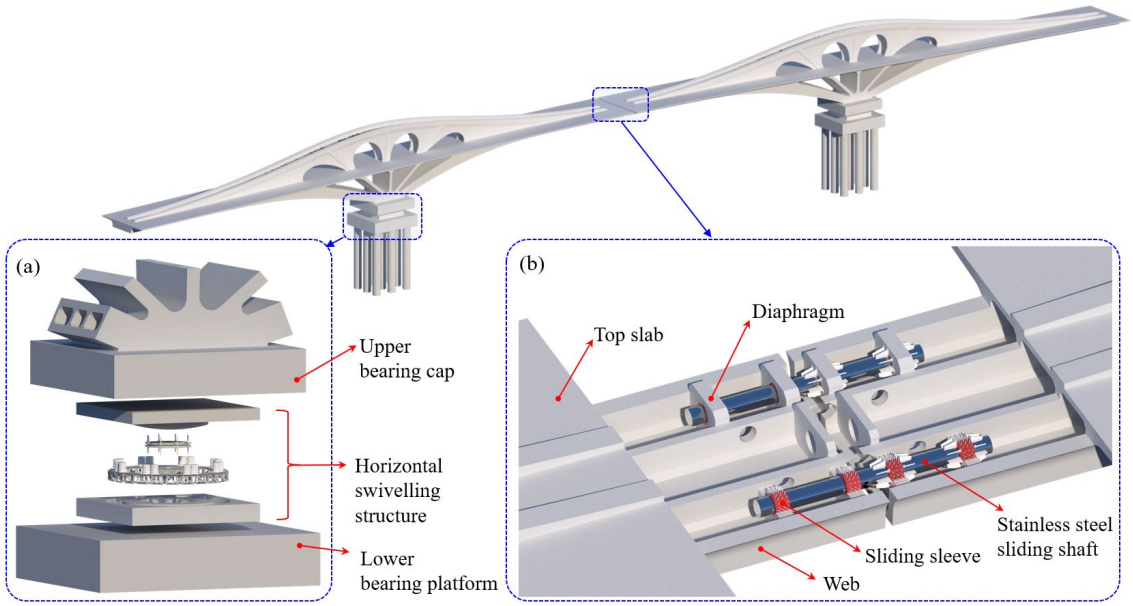

Figure 8. Schematic diagram of horizontal swivelling structure and rigid hinge expansion device: (a) horizontal swivelling structure decomposition diagram, (b) rigid hinge expansion device.

4.3.2. Horizontal swivelling structure

The horizontal swivelling structure consists of rotation, traction, and balancing system (as shown in Figure 8a). The core component is the ball hinge, which is installed below the upper bearing caps and

offers horizontal rotation around a positioning steel shaft in the centre of the main pier under the action of continuous tension jacks, thus driving the overall horizontal swivelling of the superstructure.

4.3.3. Rigid hinge expansion device

Since the bearing caps of the main piers are equipped with horizontal swivelling structures, without space to install movable bearings. To reduce the adverse effect such as temperature influence on the bridge while ensuring the continuity of the deck, we propose to disconnect the main girders at mid-span and install a rigid hinge expansion device (as shown in Figure 8b). This solution releases the longitudinal degrees of freedom of the main girders and limits the remaining degrees of freedom.

4.3.4. Bicycle ramp

On the one end of this bridge, due to the considerable difference in elevation between the bridge deck and the ground as well as the site area constraints, we provide a two-level variant Fibonacci spiral-shaped bicycle ramp with a 3.5% slope (as shown in Figure 9a). The superstructure of the bicycle ramp adopts a continuous steel girder with a depth of 30 cm for a lighter appearance. To reduce the spans of the superstructure and achieve a more uniform force, we adopted the tree-inspired branching (TIB) piers obtained from the Ameba [9]. The curved continuous steel girder is supported by a series of organic TIB piers, which conforms to the principle of minimum transfer path and reflects the convergence process of force flow from top to bottom and from dispersion to concentration. Thanks to the efficient load transfer, the bicycle ramp structure is elegant and rational, creating an enjoyable and dynamic traversing experience with scenic views in any direction (as shown in Figure 9b).

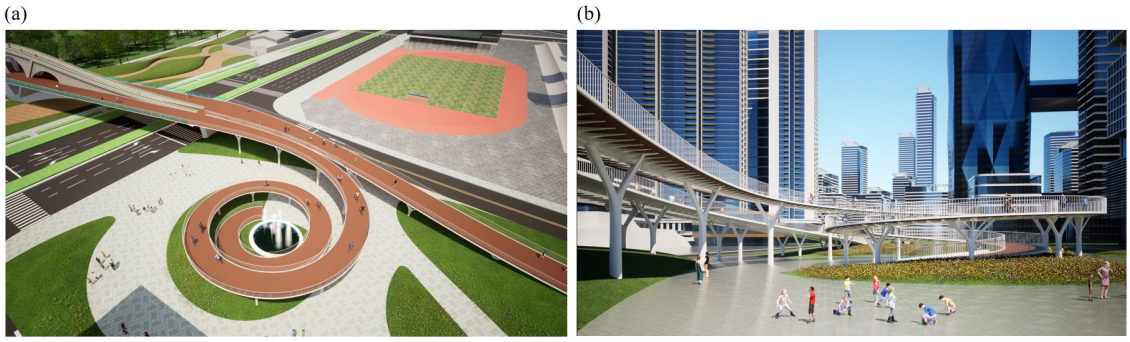

Figure 9. Rendering of the bicycle ramp: (a) aerial view, (b) close-range perspective view on the ground.

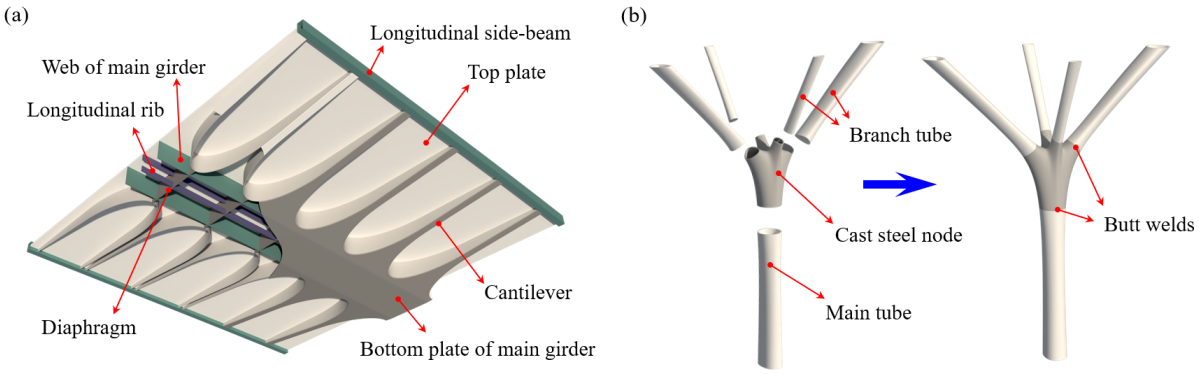

Figure 10. Structural schematic of the continuous steel girder and the TIB pier: (a) details of steel girder segment, (b) TIB pier decomposition diagram.

For achieving the organic shape, the TIB piers require a natural and harmonious transition at the intersection of the main and branch tubes. We absorbed the unique merits of cast steel members. The tree-shaped cast steel nodes are used to replace the nodes where the main and branch tubes intersect,

through integral casting. It is connected by butt welds instead of coherent welds, and the welds are dispersed, avoiding the stress concentration of welds brought by the use of steel tube coherent welding. The structural schematic of the continuous steel girder and the TIB pier is shown in Figure 10.

5. Structural analysis

5.1. Finite element model

To analyze the structural performance of the proposed pedestrian bridge, a detailed finite element model (FEM) was established using Midas/FEA NX. All structures were simulated with solid elements, except for prestressed tendons, which were simulated with tendon elements. The model was discretized into 3,408,842 solid and 22,062 tendon elements, with a mesh size of 0.1 m and 0.5 m, respectively. The constraints of the structure were: fixed constraints at the bottom of the bearing cap and simple constraints at the side supports. Since rigid hinges are provided in the mid-span, symmetric restraint and release of axial restraint were used.

5.2. Design parameters

The relevant parameters of the design loads are as follows:
(1) According to the design specification [10], Table 1 summarizes the parametric values of concrete and prestressed strands. A second-stage dead load of 16.8 kN/m was applied to the superstructure including deck pavement and railings.

Table 1. Parametric values of concrete and prestressed strands.

Material	Material grade	ρ (kg/m^3)	E_c (GPa)	$f_{cu,k}$ (MPa)	f_{cd} (MPa)	f_{td} (MPa)	f_{pk} (MPa)	f_{pd} (MPa)
Concrete	C50	2,600	34.5	50.0	22.40	1.83	/	/
Prestressed strand	1,860	7,850	195	/	/	/	1,860	1,260

Note: ρ = density; E_c = elastic modulus; $f_{cu,k}$ = standard value of cubic compressive strength; f_{cd} = design value of axial compressive strength; f_{td} = design value of axial tensile strength; f_{pk} = standard value of tensile strength; f_{pd} = design value of tensile strength.

(2) Prestressing loads: The prestressed strand's tension control stress value is 0.72 times its standard tensile strength, namely 1,339.2 MPa. The effective prestressing force in the tendons has taken full account of various prestress losses, such as: ① concrete shrinkage and creep, ② tendon relaxation, ③ anchorage deformation, ④ friction between tendons and pipes, etc., all calculated according to the specifications.

(3) Temperature effect: An Overall temperature variation range of ± 25 °C. The gradient temperature for the superstructure was set at 14 °C for the positive difference and 7 °C for the negative difference.

(4) Live load: The pedestrian load was considered at 3.5 kN/m^2, including a full crowd on the whole bridge deck and a full crowd on one side of the deck.

5.3. Static response

The effects of pedestrian load, concrete shrinkage and creep, second-phase dead load, temperature effect, and their combined effects were taken into consideration in the structural analysis. Figure 11 shows the stress distribution at the ultimate limit state in each structural component, which clarifies the load transfer path of the superstructure.

As can be seen from Figure 11, the maximum principal tensile stress is 1.8 MPa and the maximum principal compressive stress is 18.7 MPa. Only a few spots where stresses are concentrated at the corners of the structure, but these regions are minor and the stresses dissipate fast. Except for the localized stress

concentrations, the principal compressive and tensile stresses in the superstructure are all below the design value of material strength with sufficient safety reserves.

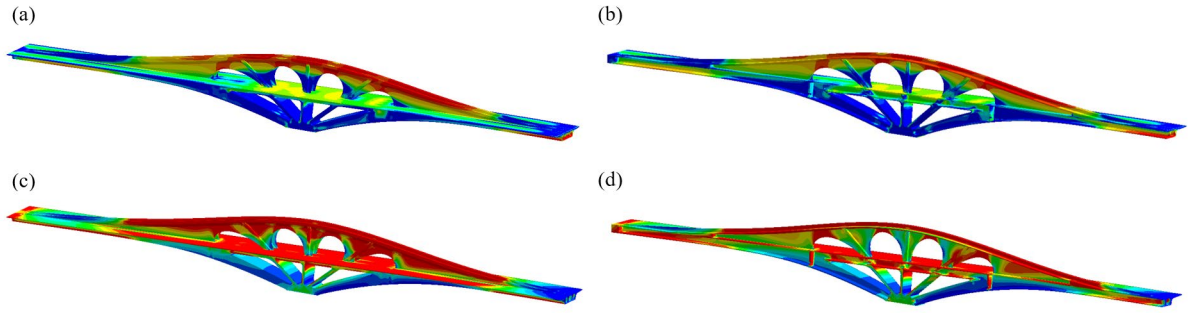

Figure 11. Stress distribution of the superstructure (unit: stress in MPa): (a) maximum principal tensile stress distribution of external surface, (b) maximum principal tensile stress distribution of inner surface (along the axial direction), (c) maximum principal compressive stress distribution of external surface, (d) maximum principal compressive stress distribution of inner surface (along the axial direction),

Since the maximum mid-span vertical deflection under the live load is 125.6 mm (the sum of the absolute values of positive and negative deflection), the deflection-to-span ratio is 1/1,209 (less than 1/600), which is sufficient to meet the requirements.

5.4. Dynamic response

Based on FEM, the analysis of structural dynamic response characteristics was performed. The structural self-weight and the second-phase dead load were converted into mass in the FEM. The natural vibration frequency of the bridge for the first-to-four and first-to-eight orders is shown in Figure 12 and Table 2, respectively.

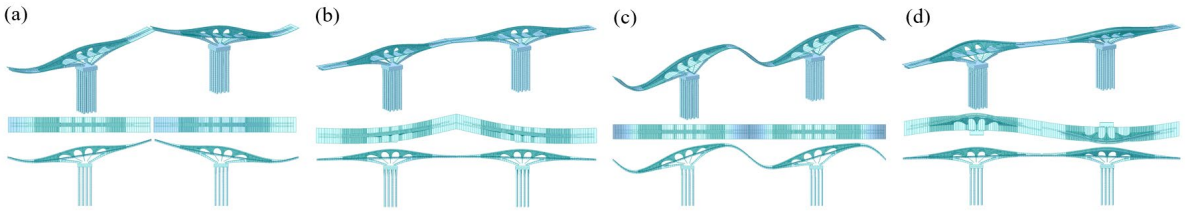

Figure 12. Vibration modes of the proposed bridge: (a) first order, (b) second order, (c) third order, (d) fourth order.

Table 2. First-to-eighth order vibration modes of the bridge.

Mode order	Frequency (Hz)	Vibration characteristics
1	0.714	symmetrical vertical bending
2	0.977	symmetrical horizontal bending
3	1.162	asymmetric vertical bending
4	1.683	asymmetric horizontal bending
5	1.757	symmetrical horizontal bending
6	1.782	symmetrical vertical bending
7	2.877	asymmetric vertical bending
8	2.930	asymmetric horizontal bending

With the ever-increasing span of pedestrian bridges and their fundamental frequency decreases, pedestrian-induced vibration and walking comfort issues become increasingly prominent. Therefore, vibration comfort level can be evaluated for different crowd density conditions by combining the

sensitive frequency range evaluation guidelines [11] and relevant codes [12–14]. The sensitive frequency range is 1.25 to 4.60 Hz for vertical vibrations and 0.50 to 1.20 Hz for transverse vibrations. When the self-oscillation frequency of a pedestrian bridge is outside the above sensitive frequency range, it can be considered as naturally meeting the requirements of pedestrian-induced vibration. Otherwise, it is necessary to check whether the acceleration response of the pedestrian bridge under the crowd walking load satisfies the walking comfort condition. Therefore, the second, sixth, and seventh order modes need to be verified for the pedestrian-induced vibration acceleration response, and the results are shown in Table 3.

Table 3. Pedestrian-induced vibration acceleration response.

Mode order	Vibration direction	Frequency (Hz)	Peak acceleration (m/s^2)	Specification limit value (CL1 level)(m/s^2)	Evaluation conclusion
2	lateral	0.977	0.066	0.1	fulfilling the requirements
6	vertical	1.782	0.499	0.5	
7	vertical	2.877	0.185	0.5	

6. Structural efficiency comparison with a continuous girder bridge

A structural efficiency comparison between the SSGs bridge and a conventional variable-section PC continuous girder bridge was conducted to assess the value of the novel SSGs bridge, as shown in Table 3. In this comparison, the span configuration, deck width, load, and other design criteria were the same.

Table 4. Comparison of the structural efficiency between the proposed bridge and conventional variable-section PC girder bridge.

Structure system		SSGs bridge	Conventional girder bridge
Quantity of materials	C60 concrete (m^3)	5,900.6	6,902.0
	Prestressed strand (t)	261.8	336.9
	Rebar (t)	885.1	1,035.3
Structural self-weight per square meter (kg/m^2)		2,796.6	3,276.8

It can be seen from Table 4 that the SSGs bridge requires less material than the conventional variable-section PC girder bridge. The innovative pedestrian bridge obtained from the MBESO method eliminates inefficient parts of the structure and enables such a long-span bridge technically and economically efficient.

7. Conclusion

In this study, an innovative long-span pedestrian bridge over several high-speed rails was designed using the multi-material bi-directional evolutionary structural optimisation (MBESO) method. In the topology optimisation process, several strategies, including setting various design domains, fixing and prohibiting part of the design space, and specifying different filter radii were adopted to achieve an optimised conceptual design. After manually simplifying and slightly adjusting the form-finding result from the MBESO method, we conducted detailed design of the structure with full consideration of constructability. In addition to the unique and elegant appearance, this bridge also shows excellent structural performance in terms of static and dynamic responses. Furthermore, a comparison between the proposed bridge and a conventional variable-section prestressed concrete continuous girder bridge under the same conditions reveals that the new design has higher structural efficiency.

As topology optimisation techniques are increasingly developed, it will be feasible for engineers to use them as intelligent tools to help design innovative bridges with high structural performance. Currently, although this technology is not yet able to consider all of the complex factors in engineering design (e.g. the construction logic and constructability of large-scale projects), the design does not need to follow a fixed routine. The designers can gain valuable insights from the outcomes of topology optimisation. On

this basis, further rethinking the structural solution by combining human cognition and wisdom, with simplifying complexity, an elegant structure may be found near its rationality.

Integrated bridge structure design process through finite element analysis (FEA) and pixel-based visibility culling method

Ana Gabriela LOAYZA[*], Taeyong KIM[a]

[a,*] Harvard Graduate School of Design
aga.loayza@gmail.com

Abstract

Through industrial evolution, bridges could accommodate various requirements, from transportation to harmony with surroundings. However, ensuring minimum visual impact over their surrounding environment has not been ordinary criteria in the traditional design solutions due to the structural implications. Through an integrative view between minimal design and engineering, this study proposes a novel bridge design method using a building system of multiple slender columns in the design of pedestrian bridges. The method seeks to maximize the structural performance and material efficiency, while minimizing the visual impact of the bridge, relaying in a two-fold structural and visual analysis which assists iterations on the section and culling of columns, following allocation options that create different group densities, transit paths, and boundary conditions along the perimeter of the bridge. The analysis uses a parametric design method that computes the results of Finite Element Analysis (FEA), shape optimization, and visibility analysis based on the provided bridge structure design. Rhino 3D and grasshopper programs are used as a platform where predefined definitions, customized C# components, and the Millipede plugin assemble the procedure, to drive decision-making on bridge design. Outcomes are delivered through numeric values and graphical analysis. Through this pipeline, it is possible to estimate deflection, smallest section for each column, and visibility levels from inside and outside of the bridge from masked rendering images. This method helps unveil the hidden implications of early design decisions during the prototyping phase, while exploring the possibilities of a minimal building system.

Keywords: finite element analysis, visibility analysis, bridge, conceptual design, morphology, optimization, steel structure

1. Introduction

The profession and the executions of bridge structural engineering are as old as the human race [1]. And the development of civilization and industrial evolution increased the need for stronger and wider crossing. Especially, the inventions of the new transports such as automobiles and trains and their surging populations increased the demands of the bridges that can accommodate high traffic flow. The introduction of the steel materials and the availability of them in the market replaced the wooden trusses, leading to the longer spans supporting the heavy loads [4]. In accordance with the structural analysis, there have been efforts to improve the design features of the bridges introducing the harmonious or integrating approach to the landscape: the use of specific colour scheme, the choice of the structure, and adding ornamented features. Current design of the bridges became more diverse with the support of the computational design methods [8]. The form-finding methods and the optimization tools allowed the final design of the bridge as close as the conceptual design [5]. However, there are limited number of studies concentrated on the numerical analysis of the visual impact of the bridge design on the surroundings, fulfilling the structural requirements of the bridge.

Through the integrated study of the history, contemporary computational design process of the bridge, this study introduces a novel perspective on how to balance the visual and aesthetic notions with structural behaviour, using slender steel columns as a building element within defined computational and parametric pipeline with multiple stages: parametric design, finite element analysis, shape optimization, and visibility analysis.

2. Design background

The idea of columns as vertical elements is associated with both the structural safety and the spatial implications of their allocation in space, which is possible to see across architectural and infrastructural examples. On one hand, columns are a traditional element in the framework of structural configurations, subject different dimensioning, and modulation in space according to material and spatial needs. Le Corbusier's Villa Savoye's principles involved the use of columns (pilotis) to obtain a free plan, reducing the presence of such vertical elements to only an honest structural need. [10]

On the other hand, the perception of an enclosure and limits of an architectural space requires elements that build a physical or virtual boundary in between conditions. The sense of boundary depends as much as on the elements used to construct a boundary, as on its arrangement. For the enclosure to be perceived, there is no need for an impenetrable limit or physical surface [11]. As an example of classical architecture, the Parthenon creates a spatial condition with a specific number of columns along a rectangular perimeter, achieving a bounded outdoor and a sense of limit and enclosure.

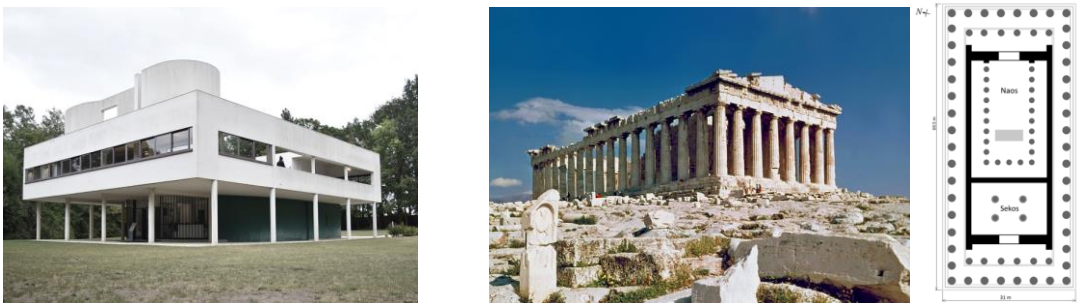

Figure 1. (Left) Le Corbusier's Villa Savoye, Poissy. [Source: Image by author*]. (Right) The Parthenon, Ancient Greece. Photo by *Steve Swayne* CC BY 2.0. (Right) Floor Plan of The Parthenon. [Source: Io Herodotus. CC BY-SA 4.0]

The use of iron during the Industrial revolution and steel in later decades allowed the transition from wood. These bridges attempted longer spans while using thin elements in their configuration [12]. At the same time, the overall configuration provides a sense of enclosure around the circulation path without the need of surfaces.

Figure 2. Bollman truss in Savage, Maryland, US. Built in 1869, moved to Savage in 1887. [Source: Public domain]

Contemporary examples such as Carmody Groarke's Regents Pavilion or Junya Ishigami's Japanese Pavilion display the qualities of vertical elements in ad hoc placement. The density and allocation of vertical elements determine different barrier grades and meanings of lightness and transparency.

Figure 3. (Left) Carmody Groarke. Regents Place Pavilion. Photograph by Luke Hayes. Source: lmoa.info (Right) Interior view of Kanagawa Institute of Technology Workshop. [Source: © junya.ishigami+associates]

From this window, this paper argues for a simultaneous interpretation of vertical thin elements as structural components and barrier elements to shape a bridge, aiming for minimal design operations and economy.

3. Design application

The paper presents a method of analysis for a building system based in multiple thin vertical columns as main elements of assembly for pedestrian bridges. Such system was customized for the design of pedestrian bridges suitable for contexts where a non-invasive formal quality and minimal visual footprint is required. For instance, natural contexts, historic urban spaces, or indoor bridge interventions.

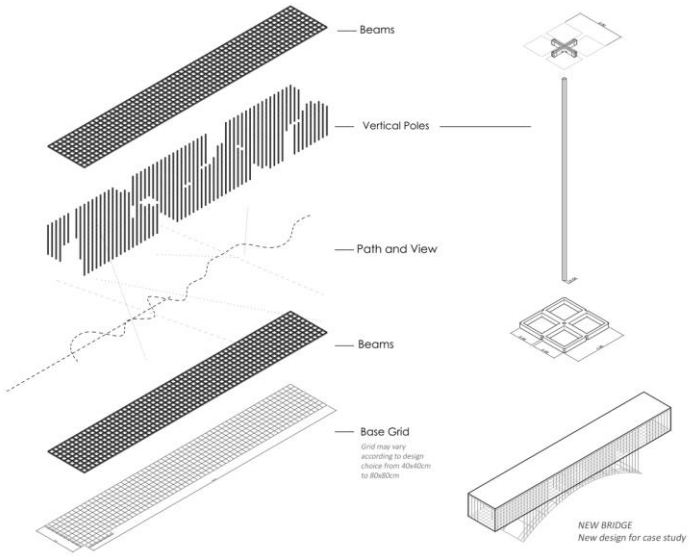

Figure 4. Diagram of columns and components of the bridge, showing the underlaying modulation (grid), columns, beams, and overall shape. [Source: Author of this paper, 2023]

The prefabricated thin steel columns meet steel beams within a rectangular boundary, modulated by a dense orthogonal base grid. Together, columns and beams shape a transitable enclosed path across two

points, where the concentration and allocation of columns along the boundaries of the bridge define the circulation paths and provide different grades of physical and visual permeability.

The study is meant to assist in early design stages for the application of this building system, to introduce structural considerations with anticipation.

4. Method

The study relies in a two-part analysis where structural performance calculations and visual impact tests act in mutual feedback, providing numerical values for both types of analysis as the designer engages in the bridge design process.

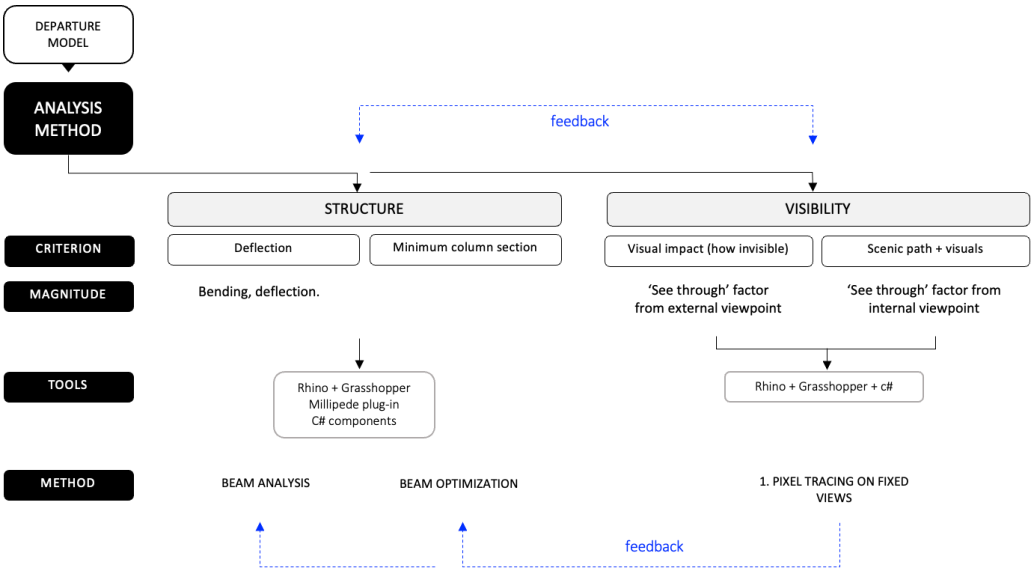

Figure 5. Overall logic of analysis. [Source: Author of this paper, 2023]

The structural assessment addresses the performance of the general assemblage regarding the material and section. From the first pipeline, The Finite Element Analysis and shape optimization of the structures are proceeded with the values of the parameters decided by the designers to understand the deflection and vulnerable areas of the bridges [3], [6], [9]. From the other pipeline, the visibility is computed by the pixel-based visibility culling methods. The images for the visibility analysis can show the inside out view along the paths of the bride, and the 360 degrees of the outside in view. The pixel dimensions of each image are 1588 by 787 pixels. And each image depicts bridge, relevant scape, and irrelevant scape with three distinct colour coded geometries: white, red, and black.

After going through the entire pipeline, the designers can iterate this process until the final decision of the bridge design. This method can provide a solution to minimize the amount of material in each column, and its number. Meanwhile, it also computes the visibility of the bridge that affects the surrounding environment. To present the process, this paper uses an arch pedestrian bridge assembled with the thin steel columns building system as a case study.

Rhino, grasshopper, and millipede plugin are used as tools to create a digital model and run the analysis.

4.1. Parametric design

As the starting point, the parametric design process allows the designer to change the shape and the number of the pedestrian's paths that affects the distribution of the vertical columns. The designer can

decide the design features of the bridge's overall form and set the parameters for both structure analysis and visibility at later stages.

The material of the bridge was set to steel. The beams and columns are made of squared shaped structures. The length of the bridge is 48 m. And the width of it is 7.2 m. The thickness of the slabs is the same as the thickness of the column structures. The columns are generated on the squared shaped grid layout. The designer can decide the density of the columns by changing the column density parameter. The layout of the column is also affected by path curves, and path width parameters, culling the columns within the specific distance to the path. The design of the paths can be modified or added by changing the shape or the number of curves. In this paper, the general load on the bridge was set above 5600 N/m^2, considering the distributed load of pedestrians and livestock on the footbridge [7]. Depending on the requirements, the designers can customize their own sets of parameters [Table 1] [Figure 6].

Table 1. Design Parameters [Source: Author of this paper, 2023].

Name	Value Type	Description
Bridge Length	Positive Number	This parameter changes the length of the bridge.
Bridge Width	Positive Number	This parameter changes the width of the bridge.
General Load	Positive Number	The general load can be set by this parameter. The user can also decide the direction of the load.
Column Density	Natural Number	This parameter decides the density of the columns supporting the roof of the bridge.
Column Height	Positive Number	The height of the columns that support the roof can be set by this parameter
Path Curve	Curve	It is possible to import multiple curves to design the path of the bridge. The columns of the bridge within specific distance are removed, making paths for the bridge users
Path Width	Positive Number	The designer can set the width of the bridge using this parameter.
Slab Thickness	Positive Number	This parameter is the slab thickness of the roof and the road.
Beam Thickness	Positive Number	This parameter defines the thickness of the square beam the supports the roof and the road of the bridge.
Beam Width	Positive Number	This parameter defines the width of the square beam the supports the roof and the road of the bridge.
Column Thickness	Positive Number	This parameter defines the width of the square columns that support the roof of the bridge.
Column Width	Positive Number	This parameter defines the width of the square columns that support the roof of the bridge.
Material	Material	This study uses steel for the structure
Support	Boolean	This parameter can decide the location of the support and type of the support. In this research, we set all the supports to fixed supports.

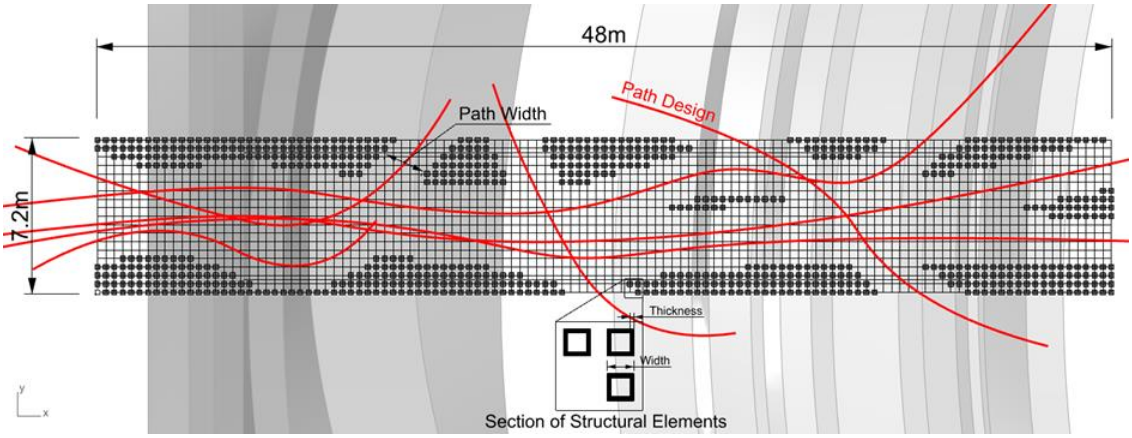

Figure 6. Parametric bridge design diagram [Source: Author of this paper, 2023].

4.2. Finite element analysis

The finite element method is widely used in various problems in civil engineering. And there are number of studies testing the buckling and deformation of the structure with given steel structure. As the millipede plug-in also supports the function of testing deformation behavior of the structure based on the FEM, it is possible to incorporate the pre-defined parameters that decide the shape of the bridge with the deformation analysis. In this study, two different cases of structure were tested by adding webs between the floor slab and arch structure. Comparison of the two cases shows that adding extra webs between the slab and arch significantly reduces both the local and global deformation behaviors of the bridge. But different solutions can be suggested by the designer. And adding more columns can also be an effective solution for this problem.

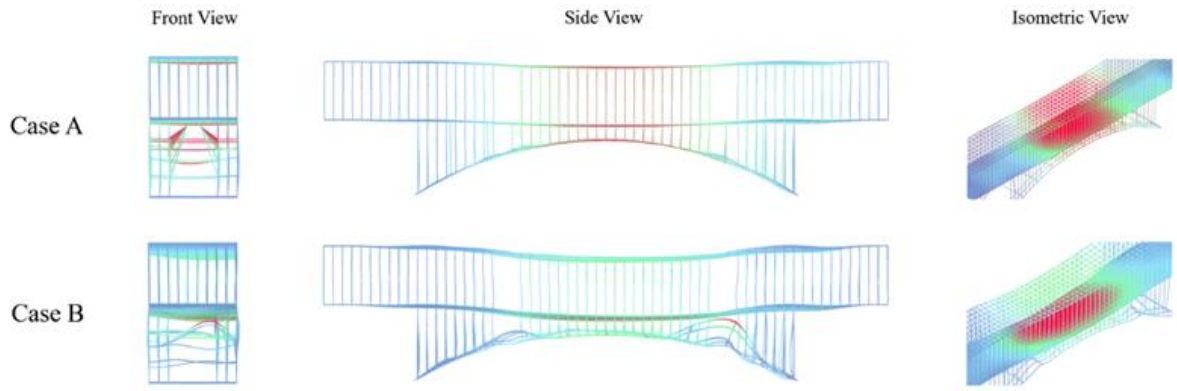

Figure 7. Deflection computed by finite element method. Case A shows the result of adding extra webs between the arch and floor slab. And Case B shows the deformation behavior without the webs. Deflection is exaggerated 500 times more than the computed value. [Source: Author of this paper, 2023].

4.3. Shape optimization

There are three distinct categories of structural optimization: sizing, shape, and topology optimization [6]. In this paper, Shape optimizing method is applied to the structure of the bridge, computing the optimized shape of the structure based on the given shapes and the loads [Figure 8]. The results of the tests show that columns, arch, and floor structure may require extra materials to increase structural

performance. And the optimized shapes of the columns are different depending on the locations of them. So, it is possible to increase the material efficiency by adjusting the thickness and width of specific columns and using relatively less material on the roof.

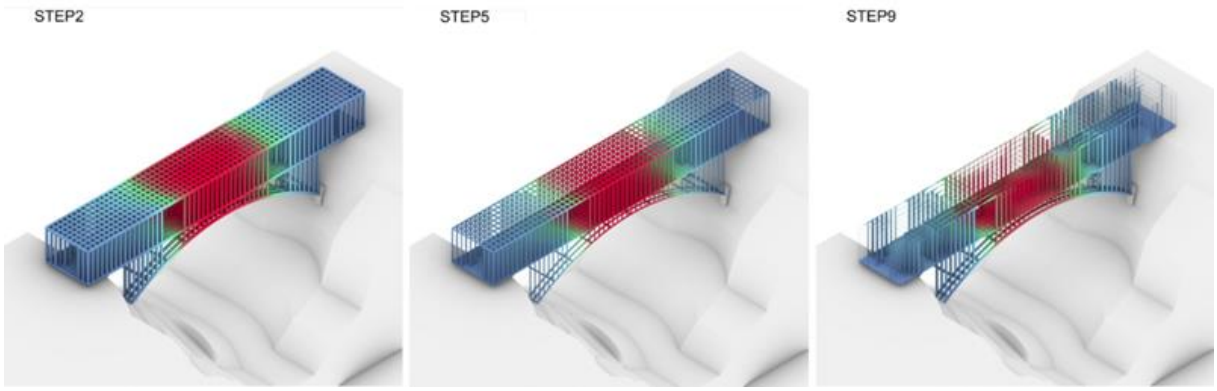

Figure 8. Topology Optimization by different steps [Source: Author of this paper, 2023].

4.4. Visibility analysis

Visibility culling method is often used to decrease the computing time of the rendered scenes [2]. In this stage, pixel-based visibility culling method is used to compute the visibility of the scene around the bridge [Figure 9]. Two collections of the images, interior and exterior image collections, are used to calculate the average number of pixels of relevant scape scenes. The interior image collection is generated from the frame of the camera, moving along the pedestrian path of the bridge. And the exterior images are captured with the camera frame that turns 360 degrees around the bridge. During the iteration of the pipeline, the averages of the visibilities from different sets of design parameters are compared to find out the best set. When *Px* is the total number of pixels of an image and *Pa* is the relevant scape pixels the visibility *V* is calculated as follows:

$$V = Pa/Px \cdot 100 \quad (1)$$

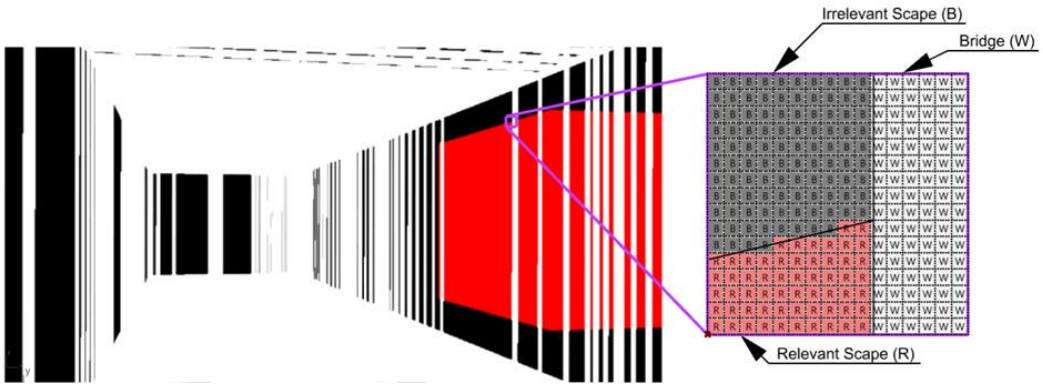

Figure 9. Pixel-based visibility culling [Source: Author of this paper, 2023].

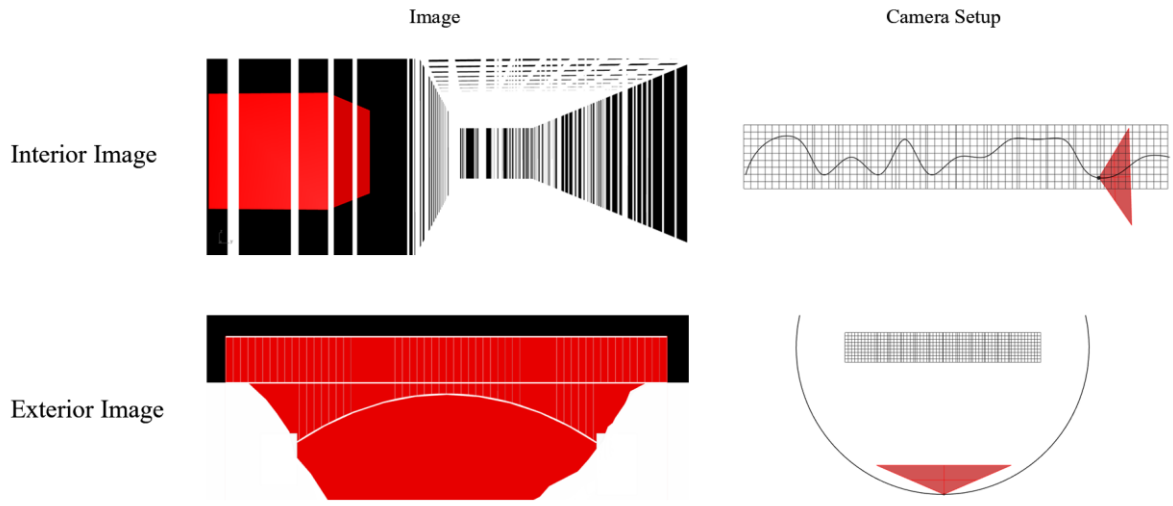

Figure 10. Camera setup example of interior and exterior views. Thick black curves are camera paths. Red triangles are camera scenes. [Source: Author of this paper, 2023].

5. Results and discussion

The result of this research shows that the iteration of the pipeline gives the designer good amount of information for the design decision. As shown in the beam analysis of the case study specific bridge, the deflection responds to the general assemblage of the bridge and grouping of vertical studs. Once the overall configuration of the bridge has been defined, it is possible to optimize columns sections. Making specific structures thinner will not necessarily derive in surging values of deflection, making the column section a flexible parameter to explore through optimization tasks.

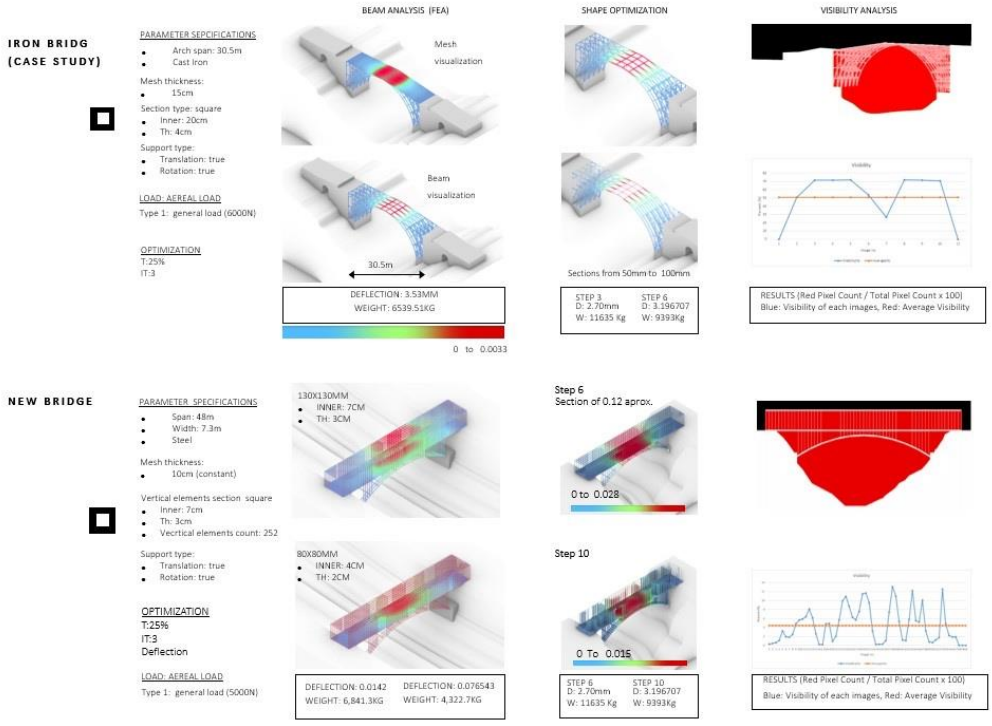

Figure 11. Analysis results of the sample bridges. [Source: Author of this paper, 2023].

The three primary limitations relate to the structure of the parametric design, the colour coding for the visibility test, statistical analysis tool. The parameters of this bridge design came from the historic study of the bridge the contemporary architectural case study, introducing the methods of improving the quality of visibility. For this reason, applying the new theme or concept of design requires enough knowledge about the computational design, and even computer language. The limitation from visibility test come from the colour coding and camera movements. This paper introduced the use of three distinct colours to differentiate the objects in each view. To make the hierarchical colour codes with various levels, the designer should set different rendering colours for each geometry The current camera movements are also set to the pedestrian path and the rotation views. The visibility analysis can also be done from fixed exterior point of views which would help to measure how light or non-invasive the bridges generate visual impact over the context.

Lastly, as the results from each stage are unique, there should be an effort to unitize the results and make statistical analysis tools to guarantee an objective interpretation of the data.

6. Conclusion

The study seeks for the minimal use of material and structural elements to design a bridge with constant information flow from numerical values obtained from finite element analysis, shape optimization, and visibility test. The future work envisions the compatibility to the unique design themes. The user-friendly setup of parameters may expand the freedom of the design decision. The application of the statistical analysis tools for structure and visibility can help the designers to compare the data from each stage and improve the accuracy of the design decisions.

Figure 12. Bridge in different locations [Source: Author of this paper, 2023].

Even though the further structural engineering is required to satisfy the building and design code of the site, the results could assist the better design decision for aesthetic purposes, safety, efficiency of the resources. Depending on the projects, the significance of the result from each stage can vary. In some cases, the visibility of specific scenery can outweigh the shape optimization result. So before and while iterating the pipeline, it is important to set the hierarchy of each result.

Abstract

The desire for material economy and efficient structural performance has been prevalent for many years [1–3]. The research in this paper adds a new perspective and strategic means of achieving efficient performance of architectural structural systems [4,5] through the lens of topological optimization. Through the applications of computational bi-directional evolutionary structural optimization (BESO), the research presented illustrates how architectural design can be supported by a digital environment that automatically proposes reconfigurations by reprioritizing material to areas of maximum efficiency; the idea of form follows force. This is achieved through translation of BESO to a workable technology that can take traditional frame layouts or sketch proposals for a structural scheme, and present the designer with an array of efficiency-conditioned alternatives. The fluid non-orthogonal BESO outcomes consequently display greater structural efficacy when responding to the parameter-based loading conditions and initial geometry. We are not aware of a similar customised application of BESO technology as an architectural design and development tool.

Keywords: topological optimisation, BESO, form, force, material efficiency, design tool

1. Introduction: scope and intentions

The technological developments aimed at material economy and efficient structural performance is a natural aspect of progress towards a more sustainable approach to delivering new buildings or retrofitting and modification of existing buildings. Key figures have made significant contributions to this evolution [1–3], an evolution where contemporary computational means have been shown to have the potential to provide further tools to support the associated design processes [4–6].

In this paper explore the idea of a somewhat loose strategic approach in relation to design support relating to topological optimisation of structure in architecture. The system that we have developed aims to provide a development environment where the form of a structure is primarily, and directly, responsive to the physical forces exerted on the structure. The BESO-enabled environment is intended both to give a means of reconfiguring the structure to behave more efficiently in terms of load carrying, and to propose new efficient configurations that may not have been considered.

2. Process

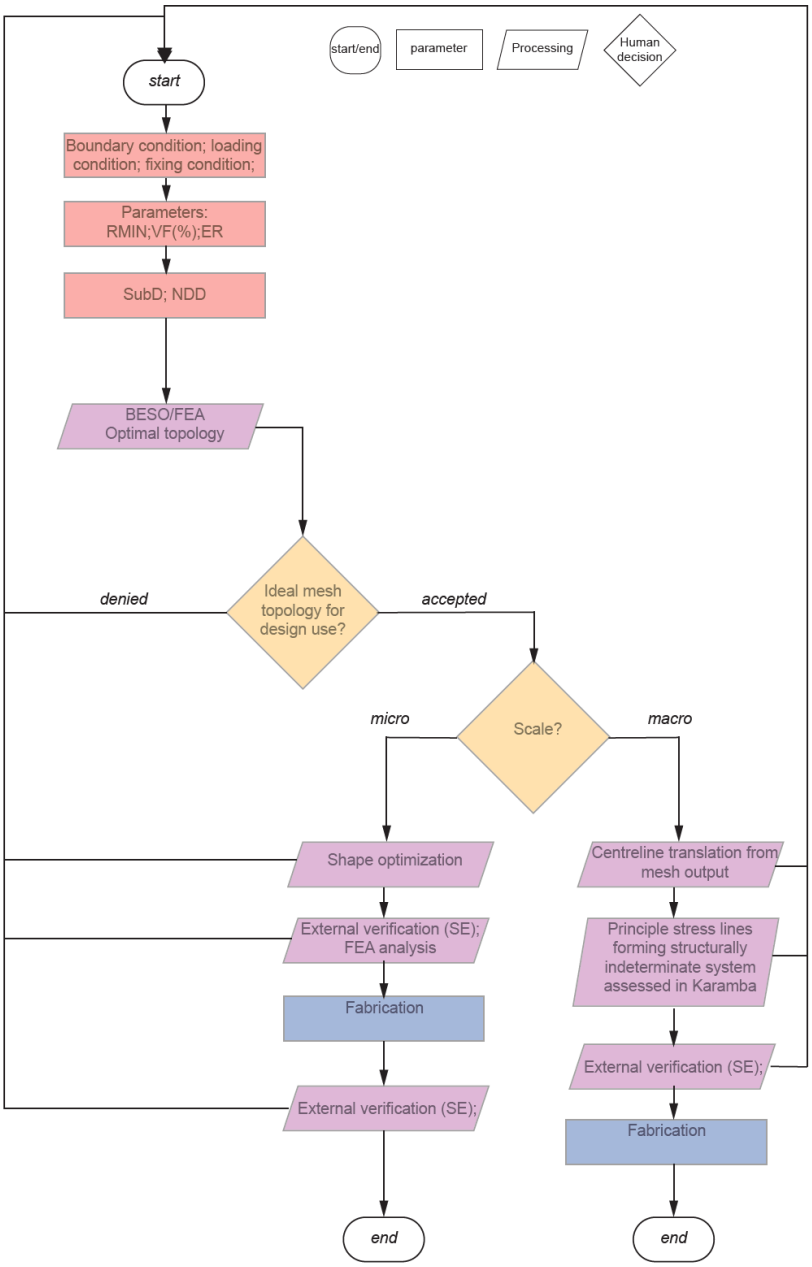

Figure 1. Computational Process Schematic

The process adopted is summarised Figure 1. The BESO facility is enabled through the Ameba plug-in for the scripting addition Grasshopper, an algorithmic node based interface, to the free-form modelling software Rhino. Selmi and Yesim [9] undertook an interesting and comprehensive comparative study of different Grasshopper Plugins for Topology Optimization in Architectural Design. In this they also refer to Millipede, an additional stress line analysis solver, that is also used in the later aspects of our study.

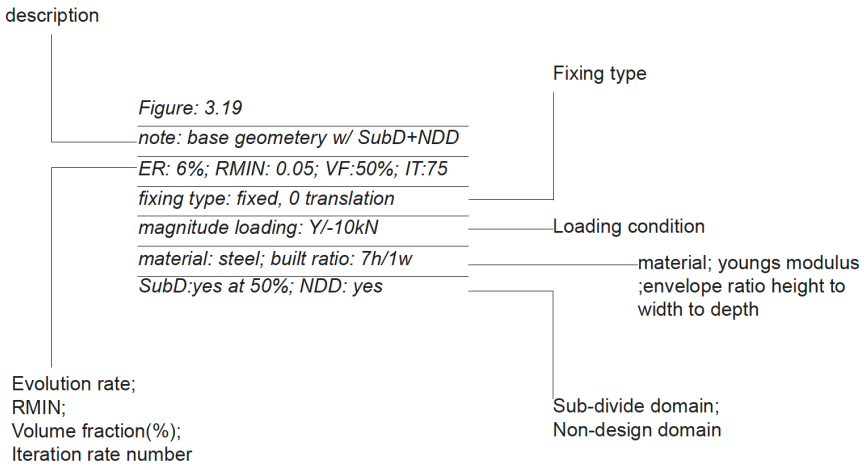

Figure 2. Key to notation used on output structural configurations proposed by the system

The basic procedure that we adopted incorporating the BESO approach is described by the computation schematic in Figure 1. Loadings are simplified for the purposes of illustration. Structural diagrams are produced by the system are annotated as shown in Figure 2. The scope of work was at three scales: S as micro elements, M as residential and pavilion scales, and L as larger multistorey structural systems. There is a branch in the process shown in in Figure 1 that indicates the stage where the process splits into different scales and the different

3. Illustrative cases

3.1. Initial trials

The first tests of the system were undertaken with simple cases of a flat plane with intermediate floors subject to (i) vertical loading and then (ii) a vertical face subject to horizontal loading (Figure 3)

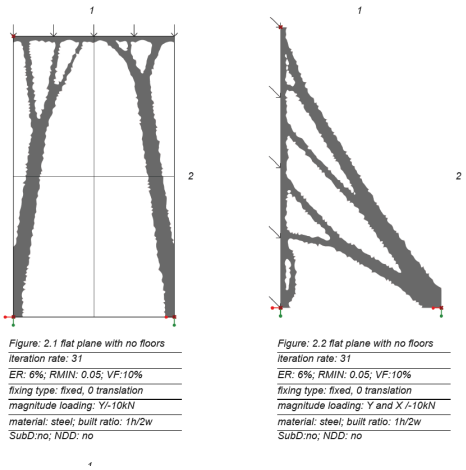

Figure 3. First test cases

3.2. Initial frame analyses

With the basic system established, we then looked at a multi-storey structure and the proposed optimal layouts both for the floor and it supports, and for the end frame on the wall. We could vary the percentage

of the area/volume that the wall structure or any other part of the structure would occupy. In figure 4 below the percentage material is relatively high and so the end wall is consequently relatively solid.

3.2. Extension to 3D frames

The technique was subsequently expanded into the third dimension. The results for test frame are shown in figure 6.

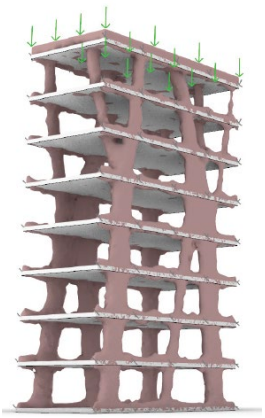

Figure 6. Extension into 3D

The work has further been developed and extended to apply to smaller building elements such as staircases. Additionally, we have looked at modernist buildings that are ruthlessly rectilinear and 'minimal'. It is interesting to apply the analytical tool to such buildings to see how a more biological and structurally efficient system changes the nature and form of such buildings.

4. Conclusion

The work described in this paper saying that developing a tool to support the architectural designer during the process in which there is a desire to produce structural form that optimise this material use.

In the case of the designer using the technology as a prompt to suggest forms that resist loading in a more efficient way, the architectural designer becomes a *curator of tool* that can be refined and reconfigured. That tool shows how the reprioritization of material to areas of efficient load sharing and transmission can drive the symbiosis of engineering performance and architectural outcome. Forms proposed by the system can be easily exported to more traditional engineering analysis software like Karamba 3D. The centre lines are extracted, either internally within Grasshopper or extracted as a line drawing on each façade as a 2d plane. In addition to addressing ideas of structural efficiency, the technology developed also responds to contemporary capabilities presented by digital fabrication such as concrete printing. Such technologies, as we know, mean that non-rectilinear form is more easily facilitated.

Applied within a contemporary computer mediated design environment BESO is shown to be a potentially useful tool in the practitioner's kitset. The computer and its computational script operated as a co-designer, side by side the human as aid. Consequently the BESO tool can be viewed as a *computational sketching tool.* Resultant meshes are often not precise due to practical resolution issues, however the mesh following the direct line of force offers sufficient indication of optimal response to a structural problem, how one can go about rationalizing a structural scheme, and offers conceptual typologies that expand the scope of architect's possibilities of a given project.

Abstract

Topology optimisation has gained popularity as a powerful tool for creating elegant and innovative forms for architectural and structural designs. However, balancing structural performance, aesthetics and functional criteria can be challenging. To address this problem, we have developed a novel approach based on the bidirectional evolutionary structural optimisation (BESO) method to generate diverse designs. In this approach, the optimisation process is perturbed by applying randomly varied angles to the applied loads, and the interim results are presented to the designer for selection based on their aesthetic and functional preferences. By incorporating human guidance, this approach enables a trade-off between exploring diverse solutions and integrating the designer's preferences into the optimisation process, making it suitable for architectural and structural designs. Furthermore, serialised diverse designs can be easily generated by using combinations of perturbations at different iteration steps. Potential applications of this approach in architectural and structural designs are presented, demonstrating the ability of the proposed method to produce optimised solutions that effectively integrate the designer's functional requirements and aesthetic preferences.

Keywords: topology optimisation, BESO, diverse designs, form finding, Hangai Prize applicant

1. Introduction

Topology optimisation is a widely recognised computational design tool in engineering and architecture that enables designers to create optimised structures tailored to specific conditions, such as design domain, load and support conditions. Numerous topology optimisation techniques have been developed [1–5]. Among them, the bidirectional evolutionary structural optimisation (BESO) method [6–9] has received considerable attention in architectural and structural designs. Aesthetically pleasing and high-performance designs have been created using BESO-type methods [10–12].

While traditional topology optimisation techniques focus on generating a single optimised solution, the ability to generate diverse and competitive designs has become increasingly crucial for designers. By comparing and selecting the best solution based on their aesthetic intuition or other functional requirements, designers can make better-informed decisions and develop more effective solutions. This growing need for diverse and competitive designs in topology optimisation has led to increased research and development efforts.

Several studies have contributed to this topic by proposing various strategies for generating diverse designs in topology optimisation. Wang et al. [13] achieved diverse designs by introducing graphic diversity constraints in 2D optimisation problems. Yang et al. [14] propose five simple strategies to obtain diverse and competitive designs, which can be easily integrated into commonly used topology optimisation techniques. He et al. [15] presented three stochastic approaches: penalising elemental sensitivities, changing initial designs and integrating the genetic algorithm into the BESO method. These methods obtain diverse solutions by adding noise to the optimisation process.

Copyright © 2023 by Yulin XIONG, Hongjia LU and Yi Min XIE. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

Other researchers have explored diverse designs by controlling structural features. For instance, Zhao et al. [16] proposed an approach to control the number and size of the interior holes of structures, and He et al. [17] developed an approach to control the number of structure members. Although the perturbation noise approach enables designers to explore various design possibilities in these two methods, it may not necessarily capture their preferences in the optimisation process. In contrast, the feature control approach allows for more-accurate design customisation but limits the exploration of the design space to predefined features.

In this work, we presented a novel approach to generating diverse and competitive structural designs. An extensive collection of diverse designs can be achieved by applying angular perturbations to loads at different iteration steps. Furthermore, designers' selections can be incorporated into the optimisation process so that designers can efficiently identify the desired solutions according to their specific requirements. Overall, this approach provides a powerful tool for exploring the design space and achieving innovative and optimised designs.

This paper comprises the following sections. The load perturbation approach is described in Section 2. We use an example of apple growth to demonstrate our algorithm's ability to generate multiple solutions in Section 3. Section 4 shows the applications of the human-guided process and the serialised diverse designs. Finally, conclusions are drawn in Section 5.

2. Methodology

2.1. Review of the traditional BESO method with self-weight loads

This study aims to develop a diverse design approach based on the BESO method. First, we introduce the topology optimisation formulation. The optimisation objective is to minimise the average structural compliance of all the multiple load cases. The mathematical representation of the optimisation problem is:

$$\begin{aligned} \text{Minimise} \quad & C = \frac{1}{2}\sum \boldsymbol{f}^{(l)}\boldsymbol{u}^{(l)} \\ \text{Subject to} \quad & \boldsymbol{K}\boldsymbol{u}^{(l)} = \boldsymbol{f}^{(l)} \\ & v_f = \sum_{j=1}^{n} V_j x_j \Big/ \sum_{j=1}^{n} V_j \le V^* \\ & 0 < x_{\min} \leqslant x_i \leqslant 1, \end{aligned} \tag{1}$$

where C is the structural compliance, $\boldsymbol{K}$ is the global stiffness matrix, $\boldsymbol{f}^{(l)}$ is the global force vector, $\boldsymbol{u}^{(l)}$ is the displacement vector for the *l*-th load case and x_i refers to the *i*-th design variable, which can take a value of either 1 for the solid elements or a prescribed $x_{\min}$ for the void elements. Note that $x_{\min}$ is greater than zero to prevent possible singularity issues in the finite element analysis. In this study, $x_{\min}$ is set to 0.001. v_f represents the structural volume fraction constraint, while n, V_j and V^* are the total number of elements, the volume of the element j and the target volume fraction, respectively.

In addition, when considering design-dependent self-weight loads, the relationship between the material property and the design variable is established according to the following material interpolation scheme [18]:

$$E_i = E_0 \frac{x_i}{1 + q(1 - x_i)}, \tag{2}$$

where E_i is the Young's modulus of the material for the element i, E_0 is the Young's modulus of the solid material (i.e., $x_{solid} = 1$) and q is the penalty factor, which is larger than zero for topology

optimisation problems considering design-dependent self-weight loads [19]. The gradient of compliance for the design variable can be derived using the adjoint method [20]:

$$\alpha_i = \frac{1}{q+1}\frac{\partial C}{\partial x_i} = \begin{cases} -\dfrac{v_i \rho_0 g}{q+1}\boldsymbol{G}\boldsymbol{u}_i^{(l)} + \dfrac{1}{2}\boldsymbol{u}_i^{(l)}\boldsymbol{K}_0\boldsymbol{u}_i^{(l)}, & \text{if } x_i = 1 \\ -\dfrac{v_i \rho_0 g}{q+1}\boldsymbol{G}\boldsymbol{u}_i^{(l)} + \dfrac{1}{2[1+q(1-x_i)]^2}\boldsymbol{u}_i^{(l)}\boldsymbol{K}_0\boldsymbol{u}_i^{(l)}, & \text{otherwise} \end{cases}, \tag{3}$$

where α_i, $\boldsymbol{K}_0$ and $\boldsymbol{u}_i^{(l)}$ denote the sensitivity of element i, the solid elemental stiffness matrix and the displacement of element i for the l-th load case, respectively. The symbols g and $\boldsymbol{G}$ represent the gravitational acceleration and the gravity load vector, respectively.

Note that the sensitivity values need to be processed further with an elemental filter [21] and then averaged with historical values [12]. Further details about these steps can be found in [22].

2.2. The load perturbation method

A perturbation angle is added to the force $\boldsymbol{f}^{(l)}$ to achieve diverse designs:

$$\begin{aligned} \boldsymbol{f} &= \boldsymbol{f}_i^{(t)} + \boldsymbol{f}_j^{(t)} \\ \boldsymbol{f}_i^{(t)} &= f_i \cos\left(\theta \pm \epsilon^{(t)}\right) \\ \boldsymbol{f}_j^{(t)} &= f_j \sin\left(\theta \pm \epsilon^{(t)}\right), \end{aligned} \tag{4}$$

where $\boldsymbol{f}_i^{(t)}$ and $\boldsymbol{f}_j^{(t)}$ are the components of $\boldsymbol{f}^{(t)}$ in different directions for the t-th iteration, θ is the original load angle and $\epsilon^{(t)}$ is the perturbation angle for the t-th iteration.

As depicted in Figure 1, $\epsilon^{(t)}$ is randomly selected within a specified range [-ε, ε] at each iteration. Since the BESO method employs an iterative process that progressively applies minor structural modifications until the algorithm converges, we introduce perturbations by starting with a large ε value in the initial iterations and then gradually decreasing ε to zero. This approach enables the algorithm to explore various design alternatives and concentrate on minimising compliance for the given loads at the convergence point. In addition, an extensive collection of diverse structures can be generated by modifying the ε values used in the different stages of the optimisation process.

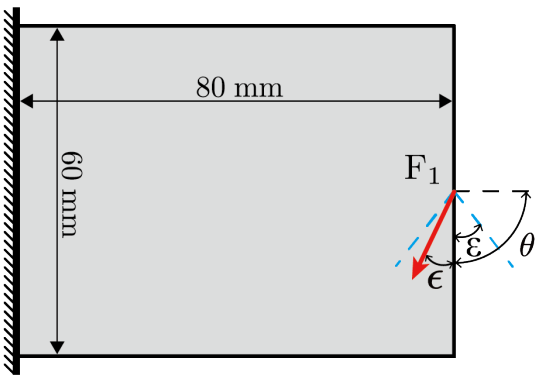

Figure 1. Illustration of a force with a perturbation angle.

3. Example 1: diverse apple shapes

This section presents an intriguing example demonstrating the load perturbation approach's ability to generate diverse solutions. The growth of an apple is a complex process influenced by various physiological and environmental factors, such as load, light and temperature. Xie and Steven [23] used

the evolutionary structural optimisation method to optimise the shape of an 'apple' under its own weight. Based on this, we use the load perturbation method to investigate the assortment of apple shapes that can be achieved by introducing random horizontal perturbation forces during growth.

The initial model is shown in Figure 2. By taking advantage of the symmetry condition, half of the domain is considered. Approximately 280,000 triangle plane stress elements are used to mesh the half domain. A non-designable stalk measuring 12 mm long and 2 mm wide is incorporated to create a 'hanging' apple. The top of the stalk is fixed, and the primary load applied on the domain is gravity, donated as G.

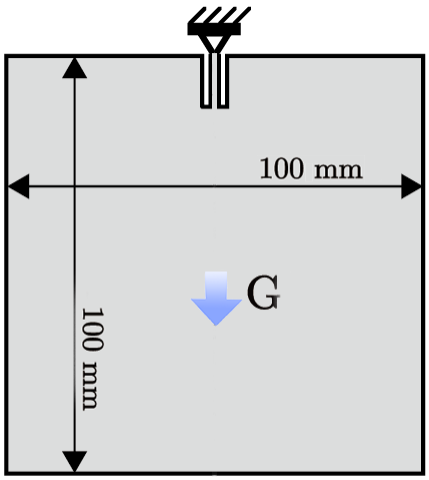

Figure 2. Design domain and boundary conditions of an apple under gravity loading.

We employ a small ball hanging from the stalk as the initial design to simulate an apple's growth, as illustrated in Figure 3(a). In the iterative process, we use the elements in direct contact with the apple structure in the current iteration as material candidates so that the material (i.e., apple pulp) is added layer by layer. Following the approach in [23], the BESO technique is applied to select the added material with a volume fraction v_f of 20%, a filter radius of 2 mm and an evolutionary ratio of 2%. Note that by adding elements from the apple structure boundaries based on the stress level, we obtain shapes with uniform stress on the surface. Figures 3(b) and 3(c) display the interim results, while the final solution is shown in Figure 3(d), which closely resembles the result reported in [23].

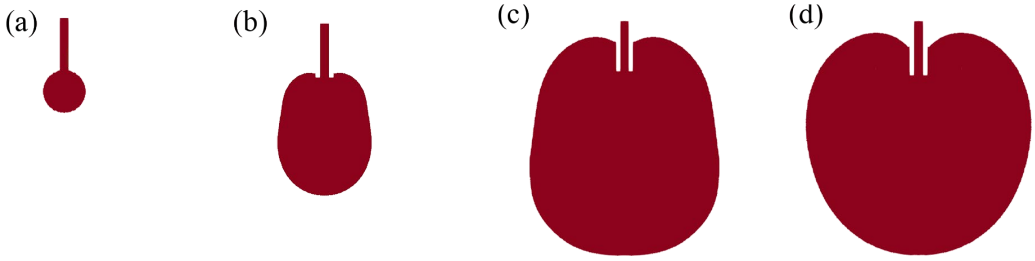

Figure 3. Optimisation process of an apple: (a) initial design, (b) interim solution of the third iteration, (c) interim solution of the tenth iteration and (d) final solution.

Using the same BESO parameters, the load perturbation approach is applied to generate diverse apple shapes. The range of the load perturbation angles is set to $[-60°, 60°]$. Variations of perturbation angles lead to three apples with distinct shapes. The original result is shown in Figure 4(a), which is an oval-shaped apple with a long length and a relatively narrow width, making it more susceptible to wind loads.

The second result (see Figure 4(b)) is a round apple with a similar width at the top and bottom. The third apple (see Figure 4(c)) also has a round shape but has a flattened region at the bottom that is wider than the region near the stalk; this apple is also shorter than the second round apple. The last apple (see Figure 4(d)) is short and wide, with an inwardly recessed area at the bottom. Most of the material accumulates horizontally, resulting in a curved shape.

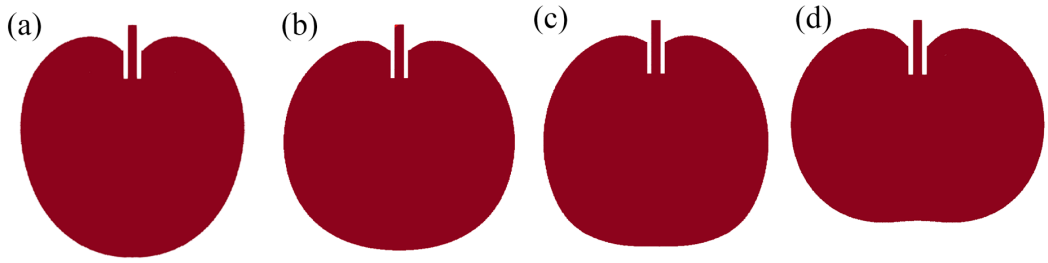

Figure 4. Apples with diverse shapes: (a) oval-shaped apple (the original result), (b) round apple, (c) round apple with a flat bottom and (d) short and wide apple.

From these results, it is clear that introducing horizontal perturbation forces significantly influences the shape of the apple. The width of the apple increases when the applied horizontal perturbation loads are relatively large. In contrast, the material tends to accumulate more in the vertical direction when gravity loading dominates. Note that in this example, all apple shapes are forced to be symmetrical. If symmetrical boundary conditions were not imposed, the positive and negative horizontal perturbation forces would result in more material remaining on the apple's left or right side.

4. Example 2: human-guided dome design

In this section, a dome with a radius of 32 m is designed using the load perturbation approach. The inner circle of the dome has a radius of 4 m, and its height is 5 m. The loading and boundary conditions are shown in Figure 5(a). A design-dependent self-weight load is applied to the dome, and pinned supports are applied on the edges. The optimisation takes advantage of the symmetry—it considers a quarter of the design domain and discretises it into approximately 1.32 million tetrahedral elements. The target volume fraction is $V^* = 60\%$, the filter radius is set to 0.5 m, and the Young's modulus and Poisson's ratio are 30 GPa and 0.3, respectively. The optimised result using the traditional BESO method is shown in Figure 5(b).

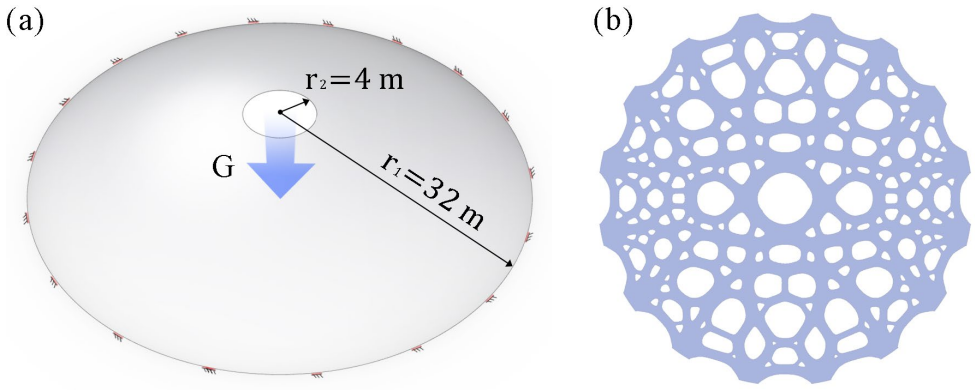

Figure 5. A dome design: (a) loading and boundary conditions of a dome, where G represents gravity, and (b) topology-optimised result obtained using the traditional BESO method.

In this example, load perturbations are added throughout the optimisation process, with the range of perturbation angles decreasing as optimisation progresses through iterations. When the volume fraction

$v_f > 90\%$, the range of the perturbation angle is $[-10°, 10°]$ (i.e., $\varepsilon = 10°$). When $v_f \in [80\%, 90\%]$, $\varepsilon = 8°$. When $v_f \in [70\%, 80\%]$, $\varepsilon = 5°$. The perturbation angle remains at zero until the optimisation converges.

Using various perturbation angles during the iterative process can generate diverse solutions, but this abundance of options can complicate decision-making. To tackle this problem, we incorporate human selection into the iterative process, taking advantage of BESO's history-dependent feature (i.e., the solution for the next iteration is modified based on the solution of the current iteration). BESO's high computational efficiency enables the simultaneous execution of multiple cases with different perturbation angle values [21]. The interim results from these parallel cases can be presented to the designer, who can then intervene in the optimisation process by selecting one preferred interim result to continue. Once an interim result is selected, multiple new cases are initiated using the chosen result as the starting point, with different perturbation values applied in the subsequent steps for each case. One or multiple selections can be made based on the designer's requirements. Since force perturbation gradually reduces during the iterative process, selections made in later stages lead to diverse designs with higher similarity. Consequently, this approach effectively balances the exploration of different design possibilities by incorporating the designer's preferences.

To illustrate the effectiveness of our human-guided process, we present an example in Figure 6. In this example, when v_f is reduced from 100% to 90%, the interim result β is selected. Without further interference in the later process, the load perturbation approach can lead to diverse solutions with vastly different geometries. Figure 7 displays six of these diverse solutions, with relative compliance values of 0.999, 1.004, 0.992, 0.999, 0.986 and 1.001 compared to the original design. These minor performance differences demonstrate that our proposed approach can effectively explore different design possibilities without substantially compromising performance.

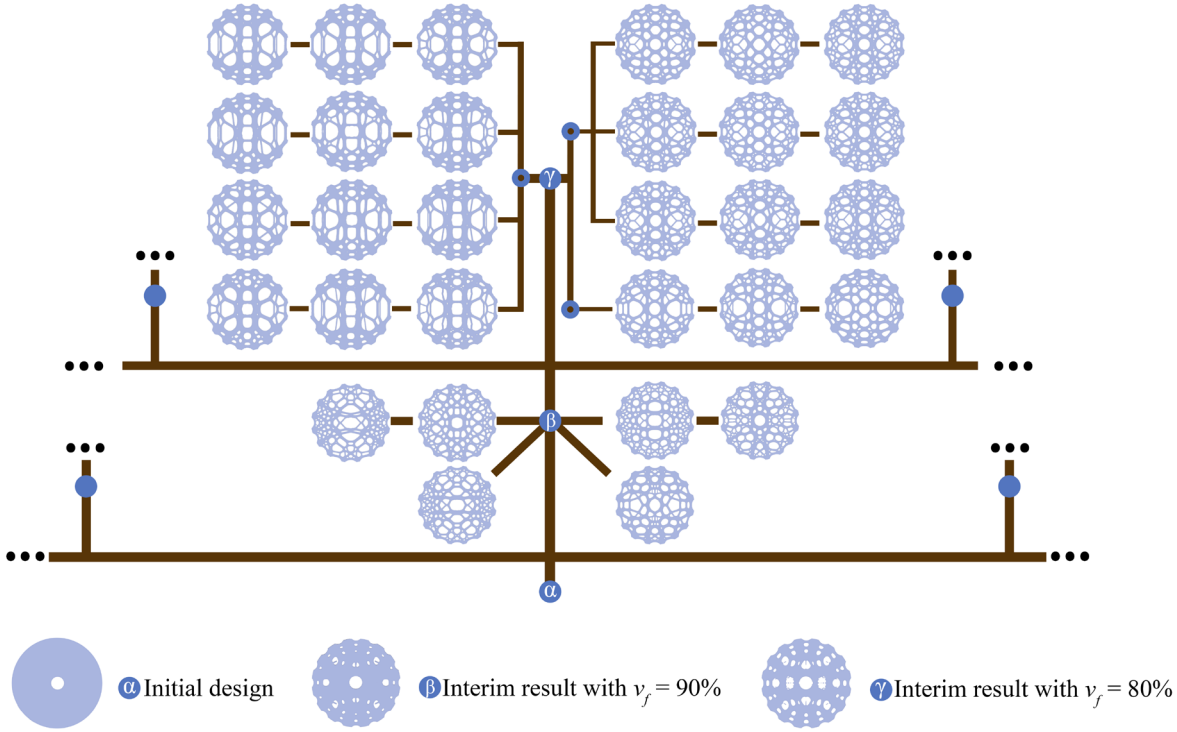

Figure 6. A tree of the diverse domes, where blue nodes represent interim optimisation results. The tree can grow horizontally to explore different design possibilities or vertically to introduce the designer's specific preferences.

Based on the selection of β, further selections can be made to better incorporate the designer's preferences into the optimisation process. In this example, we select the interim result γ at $v_f = 80\%$ (as shown in Figure 6). When solutions from only one selection in Figure 7 are compared with those from two selections, we observe that solutions become more similar as the number of selections increases. For clarity, we present 24 diverse solutions divided into three categories based on their structural topology in Figures 8, 10 and 12.

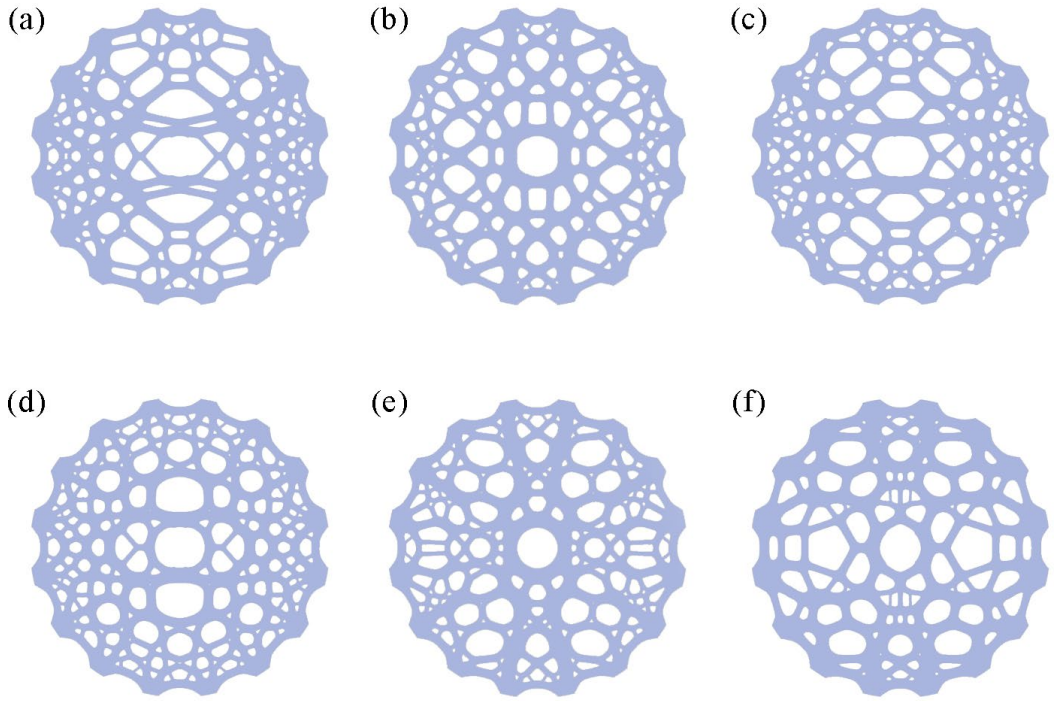

Figure 7. Diverse dome designs selected by humans from interim result β (see Figure 6).

The three designs in Category 1 primarily differ in the yellow regions of the designs. For the domes in Figure 8, the structures in the yellow regions of Figure 8(a) contain three vertical members, while Figures 8(b) and 8(c) feature X-shaped components. Compared to Figure 8(c), Figure 8(b) includes four small holes near the X-shaped component. The relative compliance values for these designs are 0.994, 0.987 and 1.014, respectively. A 3D rendering of the dome in Figure 8(c) is shown in Figure 9.

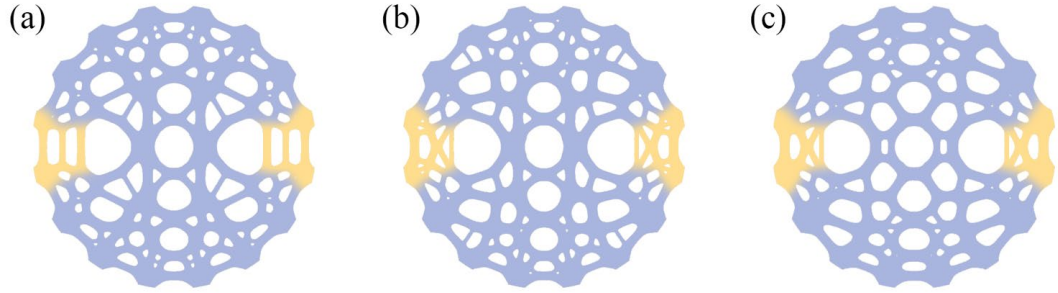

Figure 8. Category 1 of diverse dome designs with human selections from interim results β and γ (see Figure 6). The primary differences between the domes are predominantly noticeable in the yellow regions.

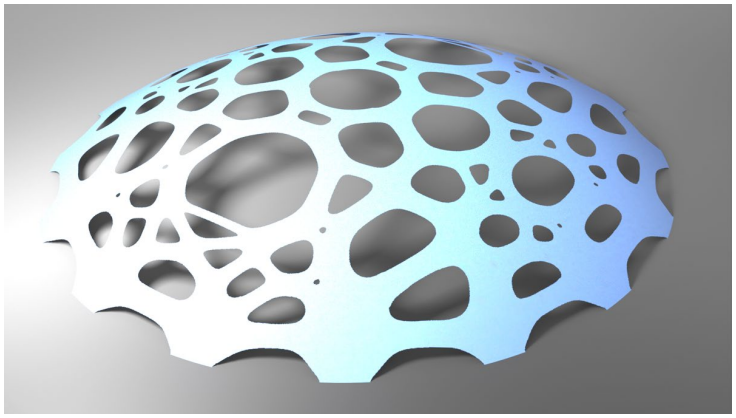

Figure 9. Rendered dome of the design in Figure 8(c).

Category 2 is similar to Category 1 but has two additional X-shaped components on either side of the central hole. As shown in Figure 10, the middle portions of the yellow regions in these designs are distinct. The intermediate structures can be classified into X-shaped and asterisk-shaped structures. All designs exhibit a similar pattern in the upper and lower parts of the yellow region, but the number and size of the holes in this region differ. The difference in structural compliance between these designs and the original design ranges from −3.347% to 1.846%. A 3D rendering of the dome in Figure 10(f) is shown in Figure 11.

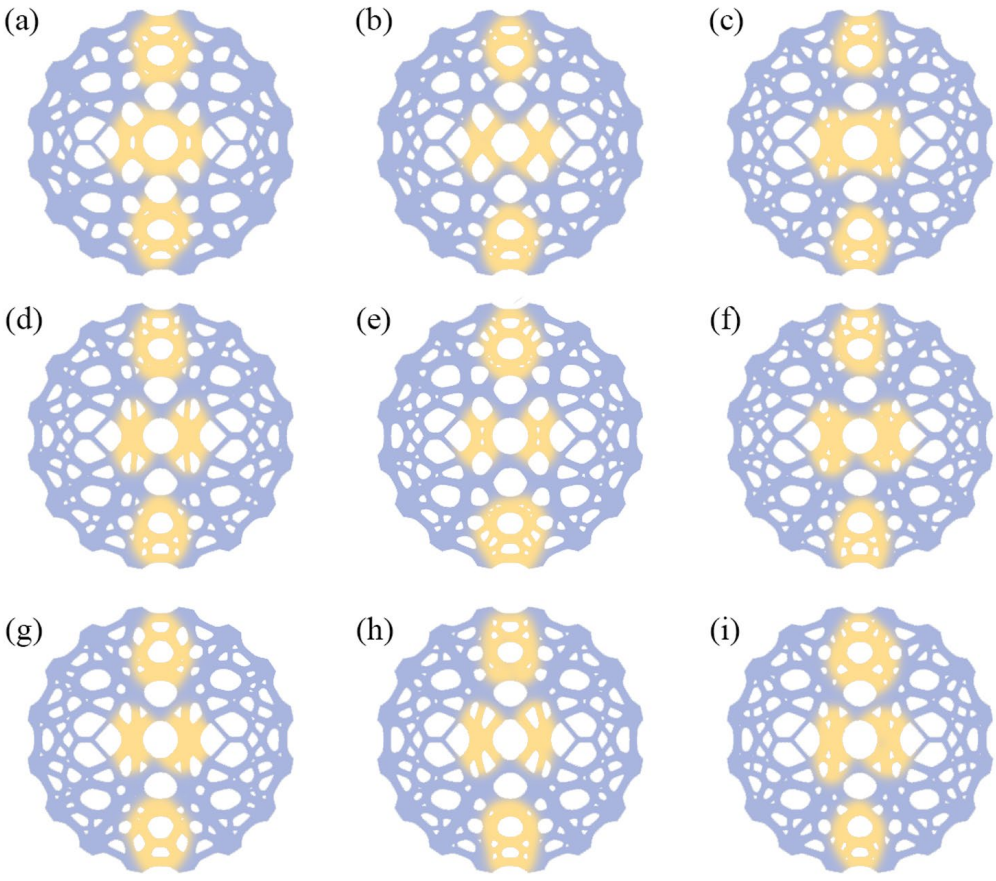

Figure 10. Category 2 of diverse dome designs with human selections from interim results β and γ (see Figure 6). The primary differences between the domes are predominantly noticeable in the yellow regions.

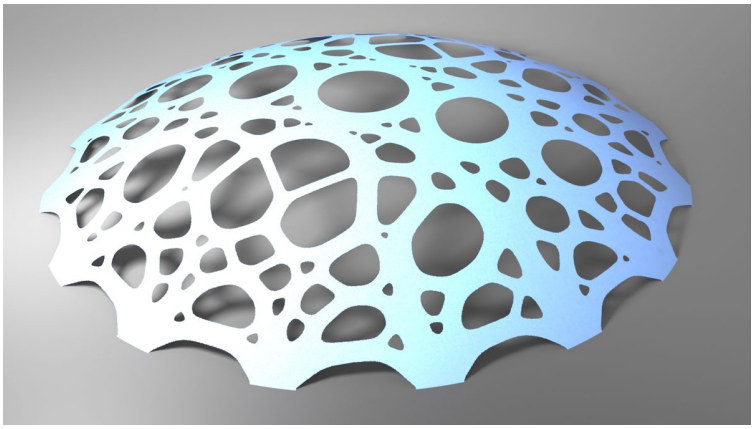

Figure 11. Rendered dome of the design in Figure 10(f).

Category 3 is notably distinct from Categories 1 and 2, with the most prominent feature being the two thick chords that span the entire structure. As shown in Figure 12, all designs have a triangular part in the yellow region, but the number, position and thickness of the members connecting this triangular part differ. The difference in structural compliance between the designs in Figure 12 and the original design ranges from −3.011% to 2.074%. A 3D rendering of the dome in Figure 12(g) is shown in Figure 13.

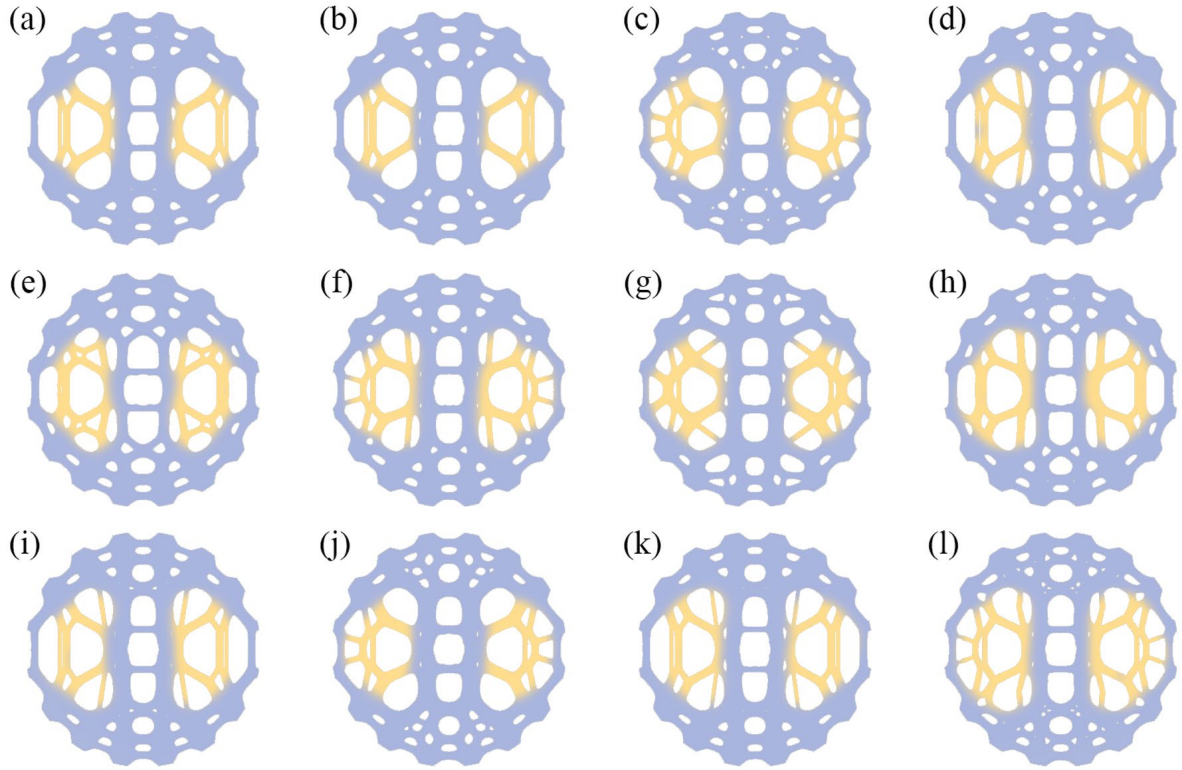

Figure 12. Category 3 of diverse dome designs with human selections from interim results β and γ (see Figure 6). The primary differences between the domes are predominantly noticeable in the yellow regions.

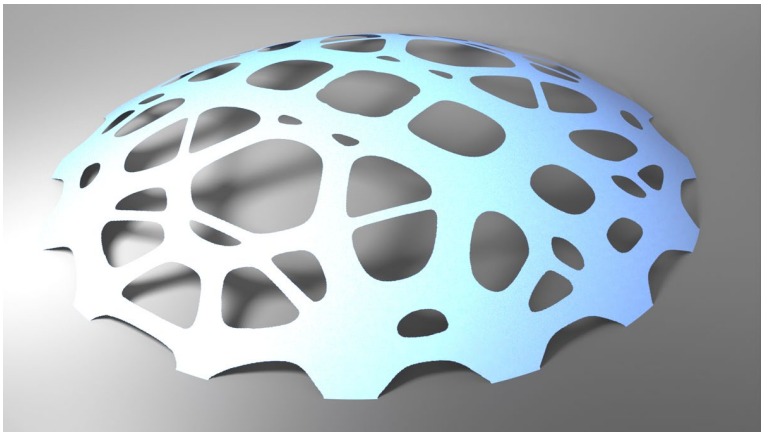

Figure 13. Rendered dome of the design in Figure 12(g).

The tree in Figure 6 can be further expanded according to the designer's requirements. For example, additional designer selections can be introduced after selecting structure γ to incorporate more designer's preferences (i.e., expanding the tree vertically). Alternatively, the designer can change the previous selection on structure β or γ to start a new branch to explore more design possibilities (i.e., expanding the tree horizontally).

In addition, it is worth noting that the proposed approach can generate serialised diverse designs with controlled similarities by introducing different numbers of selections. When designers need to generate a series of similar designs, they can explore the tree generated by this approach to compare and select multiple designs that align with their aesthetic intuition or other functional requirements. A conceptual series of diverse designs for domes is shown in Figure 14.

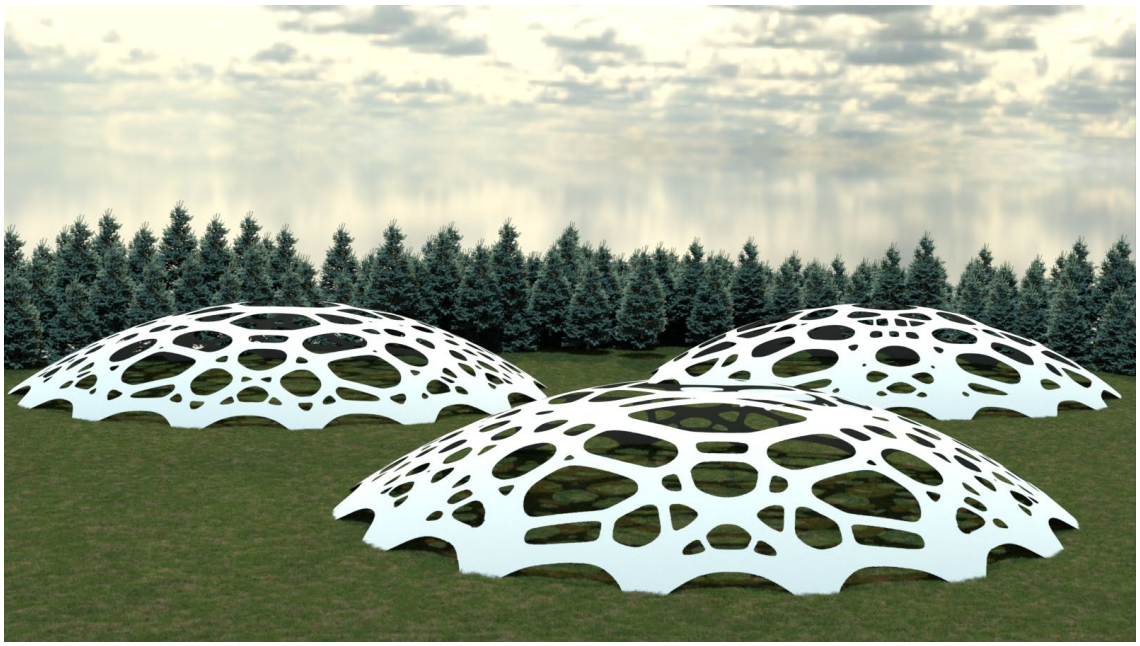

Figure 14. Serialised diverse designs for domes.

5. Conclusions

This paper proposes a novel approach to generate diverse and competitive structural designs by incorporating angular perturbations to loads during the topology optimisation process. In addition, a human-guided design process allows for the identification of desired solutions that align with the

designer's aesthetic preferences or other functional requirements. The similarity between diverse solutions increases as more human selections are introduced, effectively balancing the exploration of design possibilities with the consideration of designers' preferences.

Furthermore, the proposed approach is straightforward and can be integrated into various topology optimisation problems. We demonstrate the effectiveness of our approach through examples of apple growth and dome design. This work provides a fresh perspective on helping designers create elegant and efficient designs using topology optimisation.

Abstract

Gridshells can span long distances efficiently if they have an adequate form. Numerical form-finding methods coupled with optimization algorithms generate such efficient shapes for gridshells based on different stiffness assumptions. These stiffness assumptions may condition the optimality of the generated shape. This paper presents a comparative study between the constrained force density method (FDM) and the finite element analysis (FEA)-based shape optimization (FSO) in the generation of shapes of gridshells that make the optimal use of material as quantified by their strain energy. Three different gridshells with fixed horizontal projection are optimized for minimal strain energy with each form-finding method: a barrel vault, a dome and a gridshell with complex plan view. The optimized gridshell are evaluated after optimization in terms of their strain energy, their maximum height and the incurred optimization runtime. High-performance numerical computing is utilized to execute experiments efficiently and automatic differentiation is leveraged to conveniently obtain the value of the derivatives needed to solve the shape optimization problems herein. The findings of this work provide insights on the strengths and weaknesses of these two form-finding methods, and open new research directions for the practical design of lightweight structures that can mitigate the carbon footprint of the built environment.

1. Introduction

One of the goals of structural shape optimization is to arrive at a shape for a structure that bears load using the minimal amount of material as measured by its strain energy [1]–[3] and we limit the scope to the shape optimization of gridshells for this goal herein. Numerical form-finding methods like the force density method (FDM) [4] coupled with gradient-based optimization and the finite element analysis (FEA)-based shape optimization (FSO) [2] generate such efficient shapes for gridshells based on different stiffness assumptions.

The FDM takes as input the geometric stiffness of a gridshell modeled as a network whose elements only resist axial forces. The geometric stiffness of structure is calculated based on the *force densities*: the expected ratio between the internal force and the length of the elements of the network. The FDM calculates the 3D coordinates of the nodes of the network based such that the network is in a state of static equilibrium with a design load. To minimize the material usage of a gridshell with FDM, one then solves an optimization problem that calibrates the force densities in the network such that the total load path of the gridshell is minimal [5]–[7]. The minimization of the load path is equivalent to the minimization of the strain energy in the geometric-stiffness domain for a fully stressed design of a pin,

jointed bar network [7]. The structural response of the FDM-optimized shape needs to be assessed with a FEA in a second and separate stage after assigning material properties and cross-sections to obtain the strain energy of the structure.

In contrast, FSO directly receives the material and cross-section properties of the members of a gridshell as inputs to characterize its elastic stiffness matrix. Moreover, FSO assumes that the elements of the structure can take axial forces, shear forces and bending moments, thus capturing a more nuanced structural response of the structure. The shape that makes an optimal use of material is generated with FSO after minimizing the total strain energy of the gridshell via optimization with the nodal coordinates as the design variables. Despite the structural elements have a bending stiffness at the outset, the minimization of strain energy also diminishes the bending behavior of a structure [1]–[3], making FSO consistent with the assumptions in FDM. Thanks to the FEA coupling, FSO achieves coherence between the shape generation and structural analysis but at the cost of iteratively performing a potentially expensive FEA throughout the optimization process.

While extensive work on successfully applying these two approaches to the shape optimization of gridshells exists separately, a unified comparison between FDM and FSO is missing. In this paper, a numerical study is conducted that compares FDM and FSO in the task of generating optimal shapes for gridshells that minimize material consumption. This study quantifies the effect of the different stiffness assumptions each of these two form-finding methods make on the optimality of the form-found shapes they generate as measured by their total strain energy, geometrical attributes, and the resulting computational cost for optimization. To evaluate their strain energy, the gridshell elements are dimensioned according to two different sizing strategies.

After introducing the theoretical underpinning of both methods (Section 2. Form finding methods), FDM and FSO are applied to three different gridshells with fixed horizontal projection: a barrel vault, a dome and a gridshell with free-form plan (Section 3 Numerical study). Both form-finding methods, as well as the experiments carried out in the study, are implemented in JAX [8], a Python library for high-performance numerical computing and automatic differentiation (AD) [9]. A discussion of the findings of the study and future research directions are provided in Section 4. Discussions.

2. Form finding methods

2.1. The force density method (FDM)

The FDM models a structure as a pin-jointed bar network. For a network with m edges and n nodes, a connectivity matrix $\boldsymbol{D} \in R^{m \times n}$ establishes the relationship between the edges and the nodes of the structure. The entry $\boldsymbol{D}_{ij} = +1$ if node j is the start node of edge i, and $D_{ij} = -1$ if the j-th node is the end node of i. Otherwise, $D_{ij} = 0$. The matrix D is decomposed into two submatrices: $\boldsymbol{D} = [\boldsymbol{D}_{IN}\ \boldsymbol{D}_F]$ where $\boldsymbol{D}_{IN}$ includes all the columns of the matrix corresponding to the free nodes and $\boldsymbol{D}_F$ consists of the columns representing the fixed nodes. The force density q_i is defined as $q_i = F_i/L_i$, where F_i is the expected force and L_i is the expected length of the i-th edge. Given a force density vector $\boldsymbol{q} \in R^m$ and the matrix $\boldsymbol{D}$, the 3D coordinates of the free nodes of a structure in static equilibrium are obtained after solving a linear system of equations:

$$\boldsymbol{x}_{IN} = (\boldsymbol{D}_{IN}^T \boldsymbol{Q} \boldsymbol{D}_{IN})^{-1} (\boldsymbol{p}_{X,IN} - \boldsymbol{D}_{IN}^T \boldsymbol{Q} \boldsymbol{D}_F \boldsymbol{x}_F) \tag{1}$$

$$\boldsymbol{y}_{IN} = (\boldsymbol{D}_{IN}^T \boldsymbol{Q} \boldsymbol{D}_{IN})^{-1} (\boldsymbol{p}_{Y,IN} - \boldsymbol{D}_{IN}^T \boldsymbol{Q} \boldsymbol{D}_F \boldsymbol{y}_F) \tag{2}$$

$$\boldsymbol{z}_{IN} = (\boldsymbol{D}_{IN}^T \boldsymbol{Q} \boldsymbol{D}_{IN})^{-1} (\boldsymbol{p}_{Z,IN} - \boldsymbol{D}_{IN}^T \boldsymbol{Q} \boldsymbol{D}_F \boldsymbol{z}_F) \tag{3}$$

where $\boldsymbol{Q} = diag(\boldsymbol{q})$ is the diagonal matrix of the force densities; $[\boldsymbol{p}_{X,IN}\ \boldsymbol{p}_{Y,IN}\ \boldsymbol{p}_{Z,IN}]$ are the loads applied to the nodes of the structure; and $[\boldsymbol{x}_F\ \boldsymbol{y}_F\ \boldsymbol{z}_F]$ are the 3D coordinates of the fixed nodes. The internal force F of k-th edge of the structure are calculated as the element-wise product between the force density vector q and its length in the static equilibrium state:

$$F_k(\boldsymbol{q}) = q_k L_k(\boldsymbol{q}), \qquad k = 1, \ldots, m$$

A structure that minimizes material volume has a low strain energy [2]. Directly minimizing strain energy with the FDM is unfeasible as this form finding method does not provide information about the displacement or the elastic stiffness of a structure to calculate its strain energy. However, for a fully stressed, pin-jointed bar structure, minimizing its total *load path* $V(\boldsymbol{q})$ is an equivalent approach to reducing its strain energy:

$$\begin{aligned} &\text{Minimize} && V(\boldsymbol{q}) = \textstyle\sum_{i=1}^{i=m} |F_i(\boldsymbol{q})| L_i(\boldsymbol{q}) \\ &\text{Subject to} && \left|X_i - X_{i,INI}\right| \le \varepsilon_X, \quad i = 1, \ldots, n \\ & && \left|Y_i - Y_{i,INI}\right| \le \varepsilon_Y, \quad i = 1, \ldots, n \end{aligned} \tag{4}$$

Constraints can be added to the optimization problem defined by Eq. (4) to preserve the horizontal projection of the structure on the plan view. In these constraints, X_i, Y_i denote the coordinates of the i-th node in static equilibrium; $X_{i,INI}$ and $Y_{i,INI}$ are the initial coordinates of the i-th free node; and ε_X and ε_Y are tolerance thresholds whose values are typically small. This constrained optimization problem can be solved efficiently with a gradient-based optimizer, like the sequential least-square programming (SLSQP) [10]. The derivatives required by the optimizer, such as $\frac{\partial V}{\partial \boldsymbol{q}}$, are automatically calculated with AD (see Section 2.3 Software implementation).

2.2. Elastic stiffness-based shape optimization

The FEA-based shape optimization (FSO) incorporates the elastic stiffness of a structure directly into the form finding process and the members used are 3D frame elements with bending stiffness. An optimal shape is found by solving an optimization problem wherein the total strain energy of a structure is minimized, as well as the bending behavior. The FSO problem reads:

$$\text{Minimize} \qquad C(\boldsymbol{z}) = \frac{1}{2} \boldsymbol{f}^T \boldsymbol{u}(\boldsymbol{z}) \tag{5}$$

where C is the strain energy (i.e. the compliance) of the structure; $\boldsymbol{z}$ denotes the design parameters, which are the Z-coordinate of all the design nodes in the domain; $\boldsymbol{f}$ is the generalized load vector; $\boldsymbol{u}(\boldsymbol{z})$ is the displacement. To solve the optimization problem listed in Eq. (5) via gradient-based optimization, the *sensitivity* of the objective function, $\frac{\partial C}{\partial \boldsymbol{z}}$, must be obtained. The adjoint sensitivity method [11] is implemented herein for the sensitivity derivation and the sensitivity with respect to the i-th design variable then reads:

$$\frac{\partial C}{\partial z_i} = \frac{\partial \boldsymbol{f}^T}{\partial z_i} \boldsymbol{u} - \frac{1}{2} \boldsymbol{u}^T \frac{\partial \boldsymbol{K}}{\partial z_i} \boldsymbol{u} \tag{6}$$

Where $\boldsymbol{K}(\boldsymbol{z})$ is the elastic stiffness matrix, as characterized by the material properties and cross-sectional properties. Assuming that the applied loads are independent from the Z coordinates of the structure, the sensitivity is simplified to:

$$\frac{\partial C}{\partial z_i} = -\frac{1}{2}\boldsymbol{u}^T \frac{\partial \boldsymbol{K}}{\partial z_i}\boldsymbol{u} \tag{7}$$

The calculation of $\frac{\partial C}{\partial z_i}$ is decomposed into two separate tasks: i) conducting a FEA to obtain $\boldsymbol{u}$ and ii) calculating $\frac{\partial \boldsymbol{K}}{\partial z_i}$. Similar to Section 2.1. The force density method (FDM), the calculation of $\frac{\partial \boldsymbol{K}}{\partial z_i}$ is obtained with AD. This required derivative is then input to a gradient based optimizer to solve the optimization problem.

With the adjoint sensitivity obtained, the FSO problem becomes an unconstrained optimization problem and can be solved by various gradient-based optimizers. To make the numerical comparison in the following section consistent, SLSQP, the same optimizer as the one used for FDM-based optimization, is selected herein to solve FSO.

2.3 Software implementation

The authors have implemented both form-finding methods in JAX, a Python library for high-performance numerical computing and automatic differentiation. These implementations have been released as open-source software packages: JAX FDM [12] and JAX-SSO [13] for FDM and FSO, respectively. Thanks to JAX, some of the important features of these packages to automate and accelerate form-finding compared to standard form-finding implementations include: function *vectorization* to parallelize function evaluations; *just-in-time* (JIT) compilation to transform Python code into a leaner, lower-level level representation that can be executed by a computer more efficiently; and *automatic differentiation* (AD) to automatically get the exact value of the derivatives of the objective function w.r.t. the form-finding design parameters required to generate the optimal shapes in this study (see Section 3 Numerical study). Interested readers are referred to the repositories of the software packages for details.

3 Numerical study

3.1 Scope and comparison framework

The study focuses on three different gridshell of growing complexity whose members have axial, shear and bending resistance. The comparison framework for the outputs of FDM and FSO is shown in Figure 1. In this study, the optimality of a structure in terms of material usage is quantified by measuring its strain energy. Low strain energies are desirable [1]–[3]. The framework starts with the initialization of the structure, which includes the initial geometry and boundary conditions. The applied loads are then specified.

For the geometric stiffness-based FDM, the minimization of the total load path of a structure given by Equation (4) is formulated and solved iteratively with SLSQP, a gradient-based optimizer. The value of the force densities of the structure are the design variables. The solution to this optimization problem converges when the relative change of $V(\boldsymbol{q})$ between two consecutive iterations is smaller than a prespecified value ε_{tol}. Material and cross-section properties are assigned to the load path optimized structure to assess its strain energy via FEA, as illustrated in Figure 1. The required material properties include the allowable axial stress σ_{MAX}, Young's modulus E, and shear modulus G, which can be arbitrarily selected. In this study, the cross-section properties are selected according to two different strategies, based on the internal forces output by FDM: i) constant cross-sections (suitable for fabrication

efficiency); ii) customized cross-sections (preferable for structural efficiency). In both strategies, rectangular sections with a depth to width ratio ($\frac{h}{b}$) of 1.5 are used. For the constant-area case, the maximum absolute value of the axial force F_{MAX} obtained with FDM as per Equation (4) and the allowable stress σ_{MAX} are used to determine the constant cross-section as $A = F_{MAX}/\sigma_{MAX}$. In contrast, we customize the cross-sectional area for each element in the second case: the sectional area of the i-th element is calculated by $A_i = MAX\{\frac{F_i}{\sigma_{MAX}}, A_{MIN}\}$ where A_{MIN} represents a prespecified minimum area value to avoid numerical instabilities, as $\frac{F_i}{\sigma_{MAX}}$ alone may give a sectional area that is close to zero.

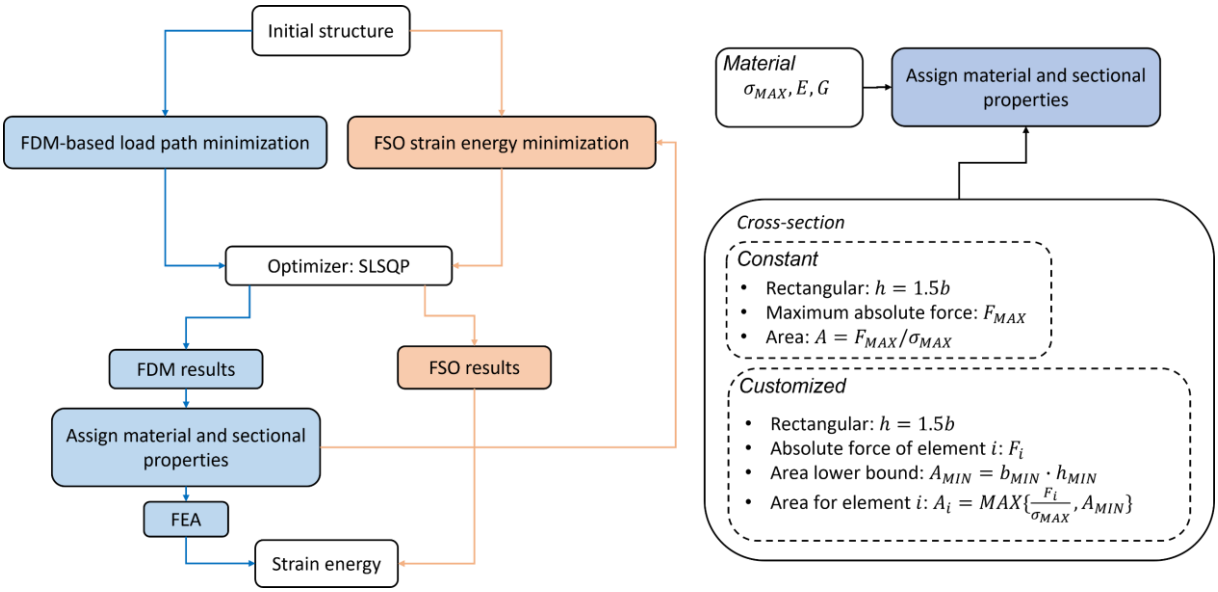

Figure 1 Comparison framework between FDM and FSO (left) and description of constant and customized strategies for the assignment of cross-section properties (right).

For elastic stiffness-based FSO, material and cross-section properties are the inputs to the optimization problem that directly minimizes strain energy. For consistency, the same properties determined after optimizing the load path of a structure with FDM are taken as inputs to the FSO-based form finding. SLSQP iteratively updates the Z coordinates to minimize the total strain energy until convergence. The same convergence criterion used in FDM is used in FSO. The strain energy measured in the last iteration as FSO is used for comparison purposes. The characteristics of the optimized geometry and the value of final strain energy resulting from both form-finding methods are discussed. In addition, the computational time to solve the optimization problems is discussed for reference purposes only. In all the experiments, the prespecified Young's modulus E is 37.9 GPa and the Poisson's ratio is 0.3. The allowable axial stress σ_{MAX} is 10 MPa. For FDM, the coordinate deviation thresholds ε_X and ε_Y are both set to 0.05 m. The stopping criterion of optimization is $\varepsilon_{tol} = 10^{-5}$.

3.1 Barrel vault

3.1.1. Problem setup

A barrel gridshell in 3D is studied (Figure 2.a). The gridshell consists of a 15 by 15 grid where the spans in the X and Y directions are 15 m each. The gridshell has 225 nodes and 420 structural members, and a starting height of 2.45 m. The 30 nodes along two longitudinal edges of the barrel vault are restrained with pin-supports. The other 195 nodes are free to move during form-finding. The load applied to every

node has a magnitude of 500 kN. In FDM, there are 420 design parameters, corresponding to force densities; in addition, there are 390 constraints, corresponding to the X and Y coordinate constraints on the 195 free nodes. In contrast, there are 195 design parameters in the FSO problem, corresponding to the Z coordinate of the free nodes, and no constraints.

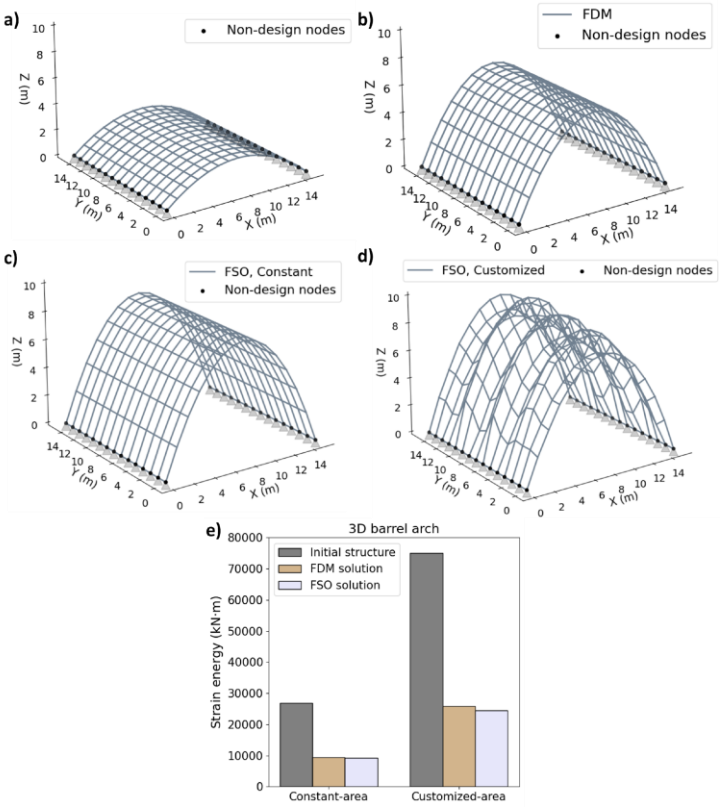

Figure 2 Barrel vault. a) Initial geometry. Optimal shapes: b) FDM; c) FSO, constant cross-section; d) FSO, custom cross-sections. e) Strain energy summary

3.1.2. Case 1: constant cross-sections

For the initial barrel, the load path is 1.38×10^7 kN·m. Solving the FDM-based optimization with the SLSQP optimizer takes 12 iterations, and the total load path decreases by 34.7% to 8.99×10^6 kN·m. The final geometry output by FDM is illustrated in Figure 2.b. It is a parabolic barrel with a height of 6.52 m. As per the constant cross-section strategy, the rectangular cross-section assigned has a width of 504 mm and a depth of 756 mm. The FEA shows that the total strain energy decreases from an initial value of 26966.72 kN·m to 9414.74 kN·m, manifesting a reduction of 65.1% from FDM-based optimization. In FSO, the optimization terminates after 11 iterations. The SLSQP optimizer successfully decreases the strain energy down to 9182.95 kN·m, which is 2.5% lower than the FDM solution. The final geometry from FSO is shown in Figure 2.c, and it has a height of 8.25m.

In this example, both methods successfully find an efficient geometry that minimizes strain energy. Although the SLSQP optimizer takes around 10 iterations in both methods to converge, the computational time is different due to the difference in the problem formulation: the geometric stiffness-based FDM takes 36.0 seconds to converge while the elastic stiffness-based FSO solution is found within 8.5 seconds. One plausible reason why FDM takes longer is that there are more design parameters and constraints when compared to FSO.

3.1.3. Case 2: customized cross-sections

For each rectangular cross-section, the minimum area is set as: $A_{MIN} = 250 \times 375 = 93750$ mm^2. Based on the FEA results, the FDM solution has a total strain energy of 25796.70 kN·m, which indicates a reduction of 65.6% compared to the initial geometry whose total strain energy is 75009.51 kN·m. When it comes to FSO, the optimization terminates after 58 iterations and outputs the minimized total strain energy of 24490.72 kN·m, which is 5.0% less than the FDM solution. However, the final geometry output by FSO is not smooth (Figure 2.d). While the form-found geometry follows the shape of arches along the X direction, the frames show zigzag patterns along the Y direction. The jagged geometry might be the result of a non-uniform gradient vector, which is triggered by the implementation of customized cross-sections. This problem can be resolved in the future by methods like sensitivity filtering or geometry parameterization [14]. For the customized-area case, FDM successfully finds a 3D barrel arch geometry that reduces the total strain energy. The optimization time needed for FDM is 36.0 seconds. On the contrary, although FSO greatly reduces the strain energy of the structural system and converges faster (12 seconds), it fails to provide a smooth geometry which could be important for aesthetic reasons.

3.2 Dome

3.2.1. Problem setup

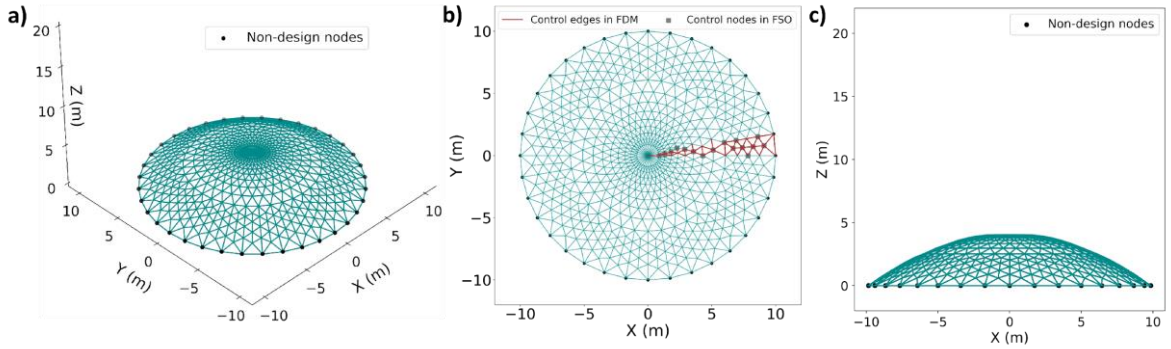

Figure 3 Initial geometry of a circular dome: a) perspective view, b) plan view and c) elevation.

The configuration of this example is adapted from an example in the work by Liew [7]. The initial geometry and its projected views can be seen in Figure 3. The initial geometry of this gridshell is triangulated, consisting of 613 nodes and 1800 structural members. The projection on plan is a circle with its center at the coordinate origin and a radius of 10 m (Figure 3.b). The height of the structure is 4.03 m. The 36 nodes on the perimeter are pin-supported and fixed. The original load applied is a 100 kPa distributed area load and it is later converted to point loads applied on the structural nodes. Despite the considerable number of nodes and edges, the radial symmetry of the initial structure and the loading condition can reduce the number of design parameters in both FDM and FSO. For FDM, the design parameters are the force densities of the 34 edges, as highlighted in Figure 3.b. For the rest of the edges, if the edge shares the same distance to the origin as one of the 34 highlighted edges, an identical force density value as the highlighted edge will be assigned. In FSO, the Z coordinates of the 17 highlighted nodes are set as the design parameters (Figure 3.b). The Z coordinates of other nodes are similarly set via radial symmetry.

3.2.2. Case 1: constant cross-sections

The initial circular dome has a total load path of 570412 kN·m and this value decreases by 40.8% to 337565 kN·m by implementing the FDM-based optimization. The load path optimization takes 37 iterations to converge, and the final geometry is illustrated in Figure 4.a and Figure 4.b. The optimized geometry has a height of 7.99 m that is 98.3% taller than the initial geometry. The constant cross-section is a rectangle with a width of 242 mm and a depth of 363 mm. The FEA shows that the total strain energy of the system is reduced from 30.50 kN·m to 17.70 kN·m, representing a decrease of 42.0% (Figure 4.g). With the same constant section assignment, the FSO takes 44 iterations to converge and outputs a total strain energy of 12.82 kN·m, which is 27.6% lower than FDM (Figure 4.g). The shape product by FSO is illustrated in Figure 4.c and Figure 4.d. The FSO solution has a height of 11.97 m, taller than the FDM solution. In addition, the central zone of the FSO solution is more curved than the FDM solution, manifested by the larger bump near $X = 0$ m and $Y = 0$ m.

The optimization takes 25.85 seconds for FDM and 65.76 seconds for FSO. The reason for the faster optimization in FDM-based optimization is the reduced number of design parameters and constraints thanks to the symmetry. While there are fewer design parameters in FSO which saves the time of calculating $\frac{\partial \boldsymbol{K}}{\partial z_i}$ in the sensitivity evaluation stage, conducting FEA for the displacement $\boldsymbol{u}$ is more computationally consuming than obtaining the static equilibrium from FDM, explaining the difference in the optimization time.

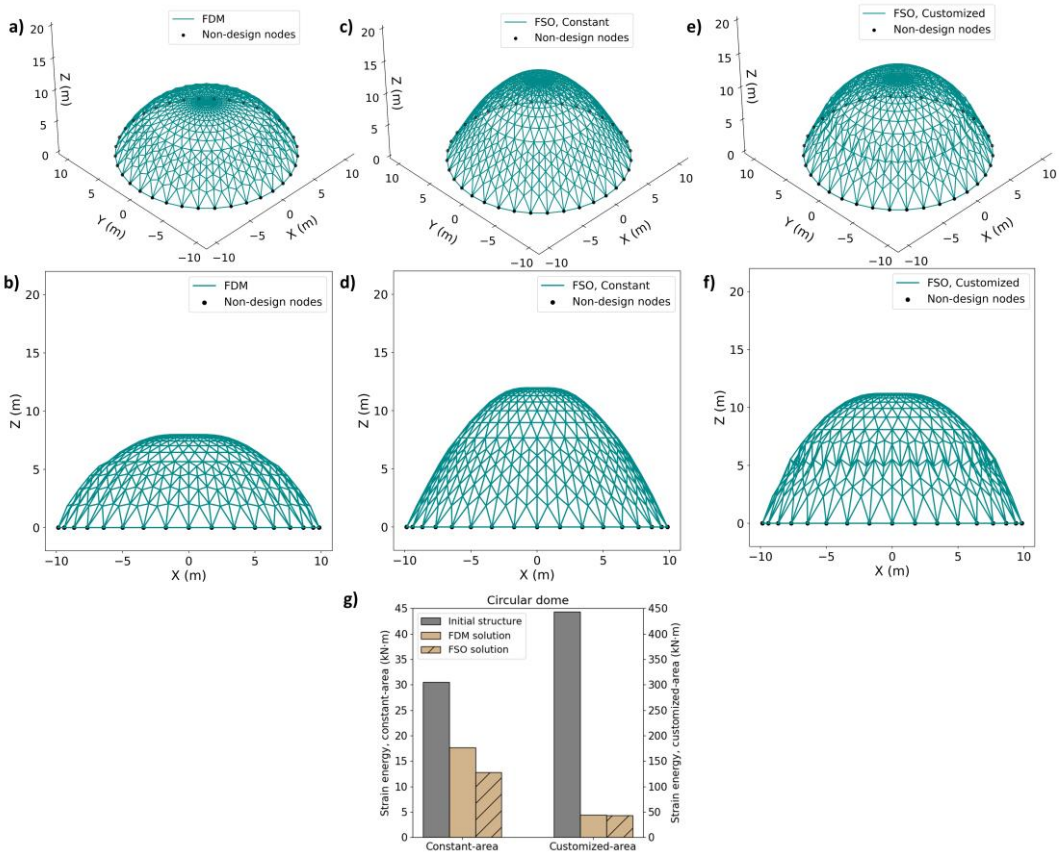

Figure 4 Dome, optimal shapes. FDM: a) perspective and b) elevation. FSO, constant cross-section: c) perspective and d) elevation. FSO, custom cross-sections: e) perspective and f) elevation. g) Strain energy summary

3.2.3. Case 2: customized cross-sections

The minimum sectional area is set as $A_{MIN} = 5 \times 7.5 = 37.5$ mm^2. With the customized sectional area assignment, the initial geometry has a total strain energy of 443.18 kN·m. With the FDM solution, this value is reduced by 90.0% to 44.51 kN·m. With FSO, the strain energy decreases to 43.45kN·m after 39 iterations and this value is 2.2% lower than the FDM solution. The form-found geometry is illustrated in Figure 4.e and Figure 4.f, and it has a maximum height of 11.21 m. Compared to the FSO solution with constant cross-sections, this geometry is less smooth at $Z = 5$m when the mesh pattern changes for the gridshell (Figure 4.f). The smoothness transition of frames can also be noticed in the FDM solution (Figure 4.b) when the gridshell pattern changes but it is less abrupt. Similar to the constant-section case, the FSO takes more time than FDM: it takes 63.84 seconds to converge compared to 25.85 seconds of FDM.

3.3 Gridshell with free-form plan

3.3.1. Problem setup

Both form-finding methods are applied to optimize the geometry of a complex gridshell roof over an exhibition center, inspired by the Mannheim Multihalle. The initial structure is shown in Figure 5.a. It spans 60 m along the X direction and 80m along the Y direction. When $Y = 0$ m and $Y = 80$ m, there are two openings that serve as gates to the main exhibition area. The width of the gates is about 10 m. The gridshell consists of 440 nodes and 1215 structural members. The 92 nodes on the boundary are fixed with pin supports. The initial structural height is 10.96 m and a downward load of 1000 kN is applied to each node. In FDM, there are 1215 design parameters and 696 constraints. In FSO, the number of design parameters is 348.

3.3.2. Case 1: constant cross-sections

In FDM, the starting geometry has a total load path of 1.41×10^7 kN·m and this value is reduced by 46.8% to 0.75×10^7 kN·m after 69 iterations in SLSQP. The optimized geometry is illustrated in Figure 5.b. Through the entrance to the main exhibition area, an arch shape can be observed. Above the main exhibition area, a doubly curved dome geometry is found. Around $X = 25$ m, the form-found geometry has a saddle-like geometry manifested by its negative Gaussian curvature, while it has positive Gaussian curvature elsewhere in the main exhibition area. The constant cross-section assigned is a rectangular section with a width of 286 mm and a depth of 429 mm. The FEA results show that the strain energy is reduced from 5711.46 kN·m to 2660.66 kN·m, representing a reduction of 53.4% (Figure 5.f).

With FSO, the strain energy is reduced to 1917.53 kN·m after 378 iterations (Figure 5.f), which is 27.9% lower than the FDM solution. The lower strain energy of the FSO solution implies that the resulting gridshell makes more efficient use of material than the FDM solution. Figure 5.c presents the final geometry obtained by FSO. An interesting observation is that, instead of having a saddle point around X=25 m like the one in the FDM solution, the main exhibition area has positive Gaussian curvature. The structural height of the FSO shape is 28.47 m, which is 45.7% taller than the FDM solution whose height is 19.54 m. Although FSO takes more iterations to converge than the FDM-based optimization, the time FSO takes is 102.63 seconds, 6.49 times faster than FDM, which needs 666.28 seconds to converge.

3.3.3. Case 2: customized cross-sections

Customized cross-sections are assigned to the structural members in this case. The minimum sectional area is $A_{MIN} = 100 \times 150 = 15000$ mm^2. For FDM, the final geometry has a total strain energy of 18627.58 kN·m, showing a decrease of 62.7% from the initial value of 49927.71 kN·m. With the customized cross-sections, the FSO converges after 365 iterations and outputs a final strain energy of

11646.79 kN·m (Figure 5.f). Comparing the optimized strain energy values of both methods, the elastic stiffness-based solution is 37.5% lower. The form-found geometry of FSO has a height of 28.18 m and it is shown in Figure 5.d. This form-found geometry is different from the FSO solution in the constant-area case, as it manifests negative Gaussian curvature near $X = 25$m, which is similar to the FDM solution. However, the form-found geometry in this case is much taller than the FDM solution and its saddle geometry is not as significant as the one seen in the FDM solution. Regarding the computational time, the FSO takes only 96 seconds as opposed to the 662.28 seconds needed by the FDM-based optimization.

4. Discussions

A summary of the outcome of the experiments in the comparative study is provided in Table 1 where we include the optimized strain energy ratio, the maximum structural height and the optimization time needed. The optimized energy ratio is calculated by the ratio between the strain energy of the optimized structure and that of the unoptimized structure, which is used to quantify the efficiency improvement of the optimized structure in terms of material usage compared to the unoptimized one. Overall, assigning constant cross-sections yields designs with higher optimized strain energy ratio than those who have

cross-sections sized in a customized way in both form-finding methods. In a critical case (dome), the use of constant cross-sections makes the optimized strain energy ratio go up by 32.34% for FSO and 47.99% for FDM, compared to their counterparts with customized cross-sections. The lowest difference in the normalized strain energy ratio between constant and custom cross-sections for a single method is observed in the FDM-optimized barrel vault (0.5%).

Based on the assumptions outlined in Section 3.1 Scope and comparison framework, FSO with custom cross-sections consistently generates gridshell shapes that have the lowest optimized strain energy ratio. The FSO-optimized geometries reduce the total strain energy of the gridshells to at least a third of their initial, unoptimized values: 32.65%, 23.32% and 9.8% for the barrel vault, the gridshell with free-form plan and the dome structure, respectively. This finding is reasonable as FSO directly optimizes the shape of a gridshell for strain energy and activates the bending and shear capacity of the structural elements, unlike FDM-based optimization which minimizes total load path, a proxy metric for strain energy, and restricts the gridshell elements to bear load only under truss action.

Table 1 Summary of experimental results

	Strain energy ratio [%]				**Height [m]**			**Time [s]**		
	FDM		FSO		FDM	FSO		FDM	FSO	
	Constant	Custom	Constant	Custom		Constant	Custom		Constant	Custom
Barrel	34.91	34.39	34.05	**32.65**	**6.52**	8.25	9.68	36	**8.5**	12
Dome	58.03	10.04	42.03	**9.8**	**7.99**	11.97	11.21	**25.85**	65.76	63.84
Free-form	46.58	37.3	33.57	**23.32**	**19.54**	28.47	28.18	666.28	102.63	**96**

Nevertheless, FDM is an effective approach to reduce the material usage of a gridshell, on par with FSO when the elements of a gridshell are sized with custom cross-sections. In half of the experiments in the study, FDM produces shapes whose strain energy ratio is at most 2% higher than those of the shapes output by FSO. The average difference in the normalized strain energy ratio in this custom cross-section regime is 5.32% between these two methods. For example, the difference in the strain energy reduction between FDM and FSO was 1.76% for the barrel vault and only 0.24% for the dome. This difference increases by one order of magnitude in the constant cross-section regime: the strain energy ratios of the FSO solutions are 13.01% and 16% lower than the FDM solution in the free-form roof case and the dome case, respectively. These findings suggest that FSO is more suitable than FDM to reduce the strain energy of complex gridshells. In addition, for the gridshells whose members cross-sections cannot be sized proportionally to their internal force and thus cannot achieve a fully stressed state potentially due to fabrication constraints, FSO is more ideal. More experiments should follow to confirm this trend.

One of the trade-offs that FSO makes to minimize strain energy is to raise the height of the gridshell. In 5 out of the 6 experiments in the study, the gridshell geometries output by FSO are at least 40% taller than those generated by FDM. For the free-form gridshell, for example, the height of the FDM-optimized gridshell is 19.54 m whereas that of the FSO optimal is at least 28 m, irrespective of the use of constant or custom cross-sections. While tall gridshells are more structurally efficient than shallow ones in this study, their increased height can conflict with architectural requirements in practical applications, which often pose limits on the total height of a structure. Because of these limitations, it would be interesting to explore the effect of height constraints on the strain energy of the optimized gridshells for both FDM and FSO in more detail.

FDM is on average 2.46 times faster to optimize the shape of the dome than FSO in the example that leveraged radial symmetry to reduce the size of the optimization problem. However, calculating optimal gridshell shapes is in general more efficient with FSO in both cross-section regimes, taking only 1/4 and

1/6 of the optimization time elapsed with FDM for the barrel vault and the free-form roof, respectively. The connectivity of the barrel, the dome and the free-form gridshells in the comparative study have 1.86, 2.93, 2.76 times more edges than nodes. Hence, one plausible explanation for this difference in performance is that FSO solves optimization problems that are at least half of the size of those addressed by FDM in terms of number of design variables, thanks to its formulation which scales up linearly with respect to the number of nodes in the gridshell (FSO sets the Z coordinate of the gridshell as design variables). Another explanation for the difference in computational performance between FSO and FDM is that the latter solves a constrained optimization problem to fix the horizontal projection of the gridshells on plan, whereas the former only deals with an unconstrained optimization problem. One way to alleviate this computational cost in the future is to replace FDM with the thrust network analysis (TNA) [15], another geometric stiffness-based form-finding method which fixes the horizontal projection of the structure without resorting to constrained optimization.

The strain energy contribution from axial forces is further evaluated for the shapes output by FSO as illustrated in Table 2. For all the FSO-optimized structures, the vast majority of the strain energy is produced by axial stresses, irrespective of the cross-section assignment strategy used. This contribution has a minimum value of 97.91% and maximum value of 99.99%, illustrating the contribution of the bending is at most 2%. This result confirms that the FSO-optimized gridshells resist external loading predominantly via axial forces, demonstrating the underlying consistency of FSO and FDM despite the difference in the types of structural elements used in the form finding process.

Table 2 Contribution of the strain energy from axial action in FSO

	Strain energy - FSO			
	Constant		Custom	
	Value [kNm]	Axial [%]	Value [kNm]	Axial [%]
Barrel	9182.95	**99.92**	24490.72	**97.91**
Dome	12.82	**99.67**	43.45	**99.99**
Free-form	1917.53	**99.87**	11646.79	**99.93**

5. Conclusions

In this work, we compare the geometric stiffness-based FDM and elastic stiffness-based FSO in terms of finding the optimal form of gridshells that minimize the material usage as quantified by the strain energy. The results show that the load path minimization based on FDM is an effective approach in reducing the material usage though it is purely geometric. For FSO, as it incorporates the elastic stiffness, it performs better than FDM in terms of strain energy reduction for the optimized structures. The FSO-optimized structures are usually taller than their FDM counterparts. In terms of the computational time, FSO is usually faster as it solves an unconstrained optimization problem while the FDM-based optimization is constrained. There exist limitations in this work, and they lead to promising future research directions. For instance, finding a strategy to combine the merits of both methods to assist the inverse design problems is of great importance. Nevertheless, this paper provides insights on the strengths and weaknesses of two widely used form-finding methods, opening new research directions that will facilitate better design of lightweight shell structures that greatly benefit the built environment.

Abstract

Elastic gridshells are a sub-category of shell structures, covering long-span with high performance and low materiality using actively bent elements. Our literature review and previous studies revealed some difficulties in integrating spatial grid patterns with multiple purposes such as architectural, environmental, structural, etc. during the form-finding process. Additionally, the possibility of changing the initial parameters such as grid pattern during the form-finding may be helpful to increase the final form variation. Indeed, an approach based on multi-objective integration and the possibility of parametrical change may encourage architects to incorporate these structures more effectively into their designs. Inspired by weaverbirds' nest building strategies and variation in pattern topology, we propose a model as "cognitive form finding" that extracts surface curvature features to identify and apply suitable pattern topologies. Consequently, we link the generated pattern topologies with an interactive physics engine to generate the overall form. In this paper, we implement our proposed method and illustrate its potential in simple geometries. Case studies show the flexibility and impact of significant changes in early-stage decision-making on the final form while staying in a feasible range of structural patterns. Our proposed method aims to increase the influence and flexibility in the early design process of the gridshell and pave the way to increased variations in patterns and final forms.

1. Introduction to gridshell design and pattern arrangement

1.1. Gridshell design process

Shell structures are characterized by a curved, often doubly curved, surface. Gridshells, also referred to as lattice shells or reticulated shells, are structures that exhibit the shape and strength of double-curvature shells but are composed of a grid rather than a solid surface. As a result of the differences in the used material, differences in the construction and assembly processes arise. Elastic gridshells are a sub-category of shell structures, and gridshells respectively. They are long-span structures characterized not only by high performance and low material use but also by the continuity of actively bent elements. The generated patterns and the detailing of the intersections influence the visual appearance, the structural performance, and the final form of the gridshell. There are several approaches to designing gridshells [1]. Propose the following approaches a funicular approach, an analytic approach, a combined approach from the previous, and a construction-based approach that nowadays may include fabrication aspects. Funicular gridshells start from a predefined pattern and by inverting the shape of a hanging chain model under self-weight, a pure compression structure is obtained. From a designer's viewpoint [2], this method may restrict the varieties of shell geometries, as they are often resulting in dome-like structures [3]. In this approach, the predefined pattern has to be modified to adopt the surface curvature. The

analytic approach defines a grid as a pattern of nodes and lines on a pre-defined surface. Usually, form-finding is nowadays achieved using computers and the surface is defined and mathematically populated with a desired grid. Here, the needed immediate accuracy of the surface geometry and the selected grid may restrict the design freedom. A combined approach between the two approaches is possible and was used for example for the Weald and Downland gridshell. In this case, the gridshell was developed from the architectural concept using physical models. The form-finding of construction-based approaches and processes uses a flat grid and pushes the support nodes toward a desired support configuration, while also pushing the grid upwards. In a repetitive process, various parameters can be adjusted to modify the geometry, overall dimensions, or material limitations. In this approach, the pattern is related to a predefined surface type.

Designing gridshells is closely related to form-finding, which describes the process of defining the shape of a structure featuring a complex geometry. However, geometry and structural aspects are in a direct relationship, when dealing with form-finding processes of spatial lightweight structures. Usually considered a core competence of engineering, such approaches are mostly problem-solving-oriented, where results are evaluated by comparison with pre-defined requirements [4]. However, an increased variety in designs may be achieved, if early-stage parameters, including the pattern topology, can be considered and flexibly changed during the process of design. Based on our previous research on the relation between the surface curvature and the pattern in gridshell design, we can conclude that potentials/weaknesses of changing the pattern locally over the surface were not yet fully explored.

1.2 Morphology as a response to design criteria

In nature, birds more specifically weaverbirds, are fascinating craft experts who build their nests. Studies revealed that they have differentiation in their nest pattern morphology that helps them to be adapted to the environment (Figure 1). Male examples have low to no repeatability of the morphology [5] , because individual builders modify their behavior depending on their experience/environment [6]. The final surface geometry of the nest is roughly defined for the birds [7] and they construct it with various materials [8], arranging it in a specific order [9] based on cognitive selection [10]. Weaverbirds' nest-building method is hierarchical in a way that when a piece of material is failed to stick on the initial push they often shift to some other spot and try again [8]. The trial-and-error process of weaverbirds helps them to learn how to locally adjust the nest morphology while constructing it. This strategy of changing morphology as a response to reach adaptation is worth more investigation to be applied in architectural design. Gridshells as structural forms have great potential to implement the weaverbird's morphology change strategy responding to the design criteria.

Figure 1. Weaverbirds has cognition of the surface that they want to build and arrange the material to build the target surface [10].

1.3 Pattern morphology control

This research aims to provide a new method of gridshell design, inspired by weaverbirds' strategy, with the potential for local adjustment in the form-finding process. This method could result in an adaptive design. From a systematic point of view on the gridshell design process, starting from a shape so-called "shape-first" follows the top-down approach, while starting with a pattern of elements so-called "pattern-first" follows a bottom-up approach [11]. We are looking for a new method, which is a mixture of both of them in the design process. Naturally designed models are operationally neither formed entirely top-down nor bottom-up [12]. In our research, we hypothesize this mixture is a key point to achieving

adaptive form-finding. The mixed method of bottom-up and top-down results in a design process where the final form is the result of multiple sub-processes equilibrium that has converged internally and interacted with the whole afterward. Therefore, the formation of form follows the theory of systems having a micro-macro effect [13–19], which is not organized by itself like self-organizational models [19, 20]. The essential properties of such systems are the increase in order [15, 16, 19, 21], no external control, and adaptability [19]. Adaptability can find different target goals based on the design perspective such as sustainability, economics and etc. If we have a design concept that has characteristics of adaptation, as we propose here, then we can set various target goals and set up the design process. More potentials will be explained by examples in the last chapter. In order to reach the explained goal, we implemented multiple investigations that are presented in this paper. Firstly a deep computer vision [22, 23] method has been applied to our gathered dataset [11]. The possibility of pattern prediction based on surface curvature change and new pattern generation with a deep learning model has been investigated and is presented in the chapter3. The results of the experiments guided us to develop a smart computational design environment that we call pre-informed geometry modeling and is presented in chapter 4. Following chapter 2 presents some basic geometrical definitions and general terminologies before getting deeper into the investigations. Finally, the potential of our developed method and future vision is provided.

2. Surface morphology and pattern curves

As mentioned in the first chapter, gridshells are structural forms composed of continuous elements. Therefore, in computational geometry, their surface is often considered a smooth surface [24]. The changes in the surface curvature are mostly depending on the curves on it [25]. Individually evaluated curves on a surface can be analyzed by the coordination system of the curve direction vector as X direction, the surface normal vector as Z direction, and the third axis perpendicular to them as Y [25, 26]. Figure 2 represents the two principal curves on an exemplary surface, Kg, Kn, and Tg at a single point on the interaction of two curves. By evaluating a series of points on the domain of each curve on a surface, we can measure the geodesic torsion Tg, normal curvature k, and geodesic curvature T over the curve [27, 28]. Information of Tg, Kn, and Kg indicate that any deformation of the surface has a direct effect on the curves of the surface, and consequently on the pattern morphology and vice versa.

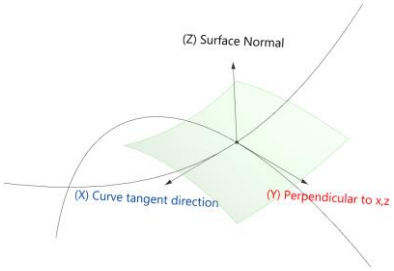

Figure 2. The local coordinate system of a certain point on a curve of a surface. Rotation of the curve around axis (Z), surface-normal direction, at an evaluated point, causes a change in geodesic curvature represented as Kg. Rotation of the curve around axis (X), Curve tangent, at an evaluated point, causes a change in geodesic torsion represented as Tg. Rotation of the curve around axis (Y), at an evaluated point, causes a normal curvature represented as Kn.

2.1 Surface types based on curvature

With the measurement of the Gaussian Curvature “K” and Mean Curvature “N” [29] of surfaces it is possible to divide surface types into three main categories monoclastic, synclastic, and anticlastic [30]. Figure 3 shows an example of these three surfaces. Synclastic surfaces have the same direction in both principal curvatures throughout the surface. For a synclastic surface, in a case where the surface curvature is constant in all points, the surface shape is that of a sphere dome (Figure 3-a). Monoclastic surfaces, also known as zero-Gaussian curvature surfaces, have zero curvature in one direction. Figure 3-b shows an example of half of a cylinder monoclastic surface. Anticlastic surfaces, in contrast, have

one positive and one negative principal curvature throughout the surface (Figure 3-c). Additionally, a surface is considered constant mean curvature (CMC) [31] when it has constant, equal principal curvature across all points. Minimal surfaces and sphere domes are examples of CMC surfaces. Figures 3-a and 3-c are members of CMC surfaces. Architectural designers do not necessarily want to have a form composed of only one surface type. In fact, sometimes design concepts are free-form surfaces that consist of multiple surface types. Figure 12 shows 4 free-form surfaces. Lacking attention to the designed surface curvature variation causes problems in realization. These problems are usually solved by changes in the concept design or additional support structures.

In the following explanation, we consider geometry modeling in centimeter metric with 4 decimal thresholds. In order to understand the surface type, we developed an algorithm that divides a surface by a distance of 1cm and evaluates the Gaussian curvature and mean curvature on each point. For a given surface the developed script calculates mean and Gaussian curvature for all evaluated points on a surface and generates two 1-dimensional vectors that we call respectively "Mean Curvature Vector", and "Gaussian Curvature Vector". If the Gaussian curvature vector of a surface is all zero it means the surface is monoclastic. If all of the Gaussian Curvature Vector values have a positive sign, the surface is synclastic. If the Gaussian Curvature Vector has a negative sign, then the surface is anticlastic. If the Mean Curvature Vector of a surface has a constant value the surface is CMC type. From this part of the paper, we consider three colors to show the surface curvature type; blue for synclastic surface, orange for monoclastic surface, and green for anticlastic surface type.

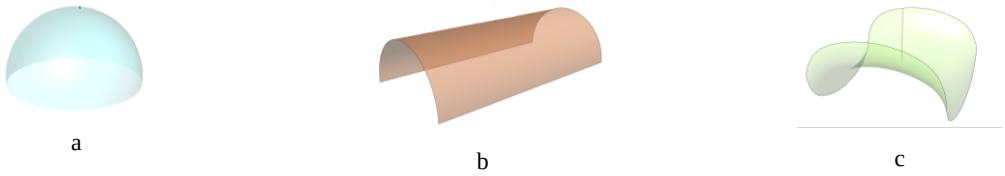

Figure 3. Three surface types based on curvature, a: sphere dome with Synclastic surface, b: Half of a cylinder surface with Monoclastic type, and c: Minimal surface with Anticlastic surface type.

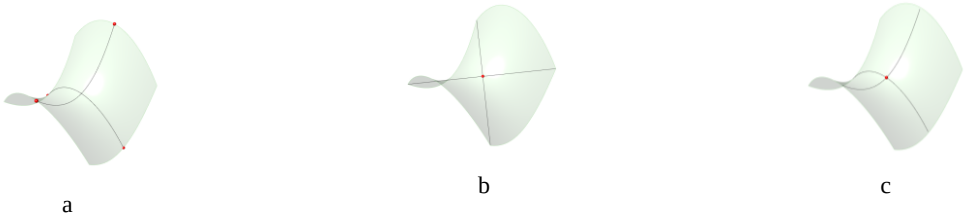
2.2 Curves on a surface

In this paper, we consider three categories of curves on a surface to generate a pattern:

A. Geodesic lines: Given a regular surface M, a geodesic curve x is the shortest path between two points on a surface, with constant geodesic curvature kg=0 [27, 28]. Geodesic lines apply to any type of surface (Figure 4-a)
B. Asymptotic curves: Given a regular surface M, an asymptotic curve is formally defined as a curve x on M with constant normal curvature kn= 0 in the direction of x tangent for all domains of x. Asymptotic curves only exist on Anticlastic surface regions [27, 28] (Figure 4-b).
C. Principal curves: Given a regular surface M, a principal curve is formally defined as a curve x on M with constant geodesic torsion Tg= 0 in all domains of x [27, 28]. Principal curves exist on all surface types (Figure 4-c).



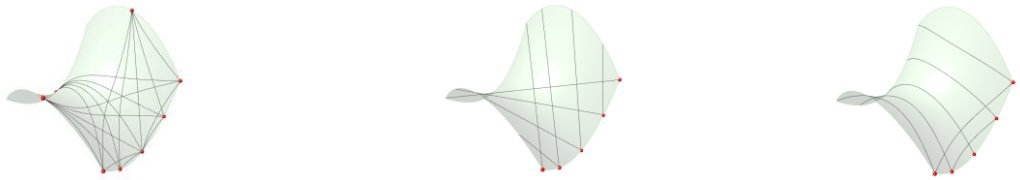


Figure 4. Three categories of curves on a surface, a: Geodesic lines from 2 pairs of points on a minimal surface, b: Asymptotic lines in 2direction of one point on the center of a minimal surface, and c: Principal lines in 2direction of one point on the center of a minimal surface.

2.3 Pattern of curves on a surface

For the sake of explanation, we assume an anticlastic surface (Non-Rational B-Spline Surfaces) M as a design concept geometry. With the evaluation of two pairs of points on the M domain, it is possible to generate geodesic lines in between them. The pair points coordination, the topology of start and end-points, and surface curvature affect the pattern morphology. Figure 5-a shows a sample pattern of geodesic curves on a surface with 5 points on one edge of each of them is connected to all individual points on the other edges. Because surface M is anticlastic, with an evaluation of a series of points it is possible to generate a pattern with asymptotic curves. Figure 5-b shows the pattern of asymptotic curves starting from 5 points on one edge of a surface. With the same series of points on M, it is also possible to create a pattern with principal curves. Figure 5-c shows the pattern of principal curves starting from 5 points on one edge of a surface. In both principal curves and asymptotic patterns surface curvature and point set coordination effects the pattern morphology.

2.4 Adding profile to curves

It is possible to numerically add a profile to a curve on a surface based on its curvature features (Kg, Tg, and Kn) following the ruled surface [26] method. For a given curve on a surface, evaluate a number of points on the curve, and equally move them on both sides along their local surface normal vector. The result is two series of points above and beneath the surface. Connecting each point series as a spline curve gives us the two edges of the profile. Figure 6 shows the point movements and profile edges generation for a segment of an exemplary curve. The change in the length of the normal vector changes the profile width. If the initial curve is a geodesic line then the edges must be rotated over the curve's tangent direction axis by 90 degrees to lie on the surface. For an asymptotic curve there is no need for any rotation, and the associated profile aligns with the curve´s surface normal. For a principal curve type, rotation over the curve must guarantee a torsion-free profile.

a b c

Figure 6. Generating profiles on a surface, a: select a curve on a surface, b: evaluate a series of points on the curve and move them on their local surface normal vector on 2 sides, and c: generate spline curve form each series of points and generate a ruled surface between them.

3. Data analysis for cognitive pattern setting

With the scope of this paper, we re-evaluated our previous dataset [11]. This data-set consists of 980 NURBS surfaces and a pattern of curves on them. We developed a local rendering pipeline to export the NURBS surface as a matrix of numbers, in four steps. (i) Orient all surfaces on the xy plane in a way each one has the maximum footprint that touches the XY plane. (ii) Generate a bounding box that contains all oriented surfaces. (iii) Divide the rendering frame into a grid of 128 rows and columns. (iv) Move each point of the grid point in the Z direction with the length of the bounding box height.

For bounding box generation, Figure 7-a shows all oriented surfaces on the XY plane and the bounding box contains them all inside. A face of a bounding box on the XY plane that includes all surfaces inside itself is the reference rendering frame. With regards to the Z direction, if a point intersects a surface, the distance between the intersection point and the grid point is the normal displacement value. Figure 7-b shows the rendering frame grid points. The arrow in Figure 7-b shows the direction vector to move points for the intersection. The points that have an intersection with a surface along the Z direction are displayed in green color. Otherwise, if there is no intersection for a point of a grid the normal displacement value is zero. The result is an array matrix with a size of 128*128*1 that represents a surface as a numerical value. We do the same process of orientation for the surface pair pattern curves as well. We divide curves into 100 segments, map the segment points on a reference rendering frame and find their closest point on the frame. The points of the frame that are selected gain a value of 1 and others take a value of 0. The result is an array matrix with a size of 128*128*1. Figure 7-c shows the pixelization of a pattern in a render frame. Both matrixes are remapped between a value of 0.0 to 255.0 to be represented as an image for visualization. Considering the data conversion as a custom rendering pipeline we can easily serialize the numerical data in JSON, PNG, or CSV format and export. We developed an automated code using Rhino.Compute to export all data as dictionary objects to the MongoDB database.

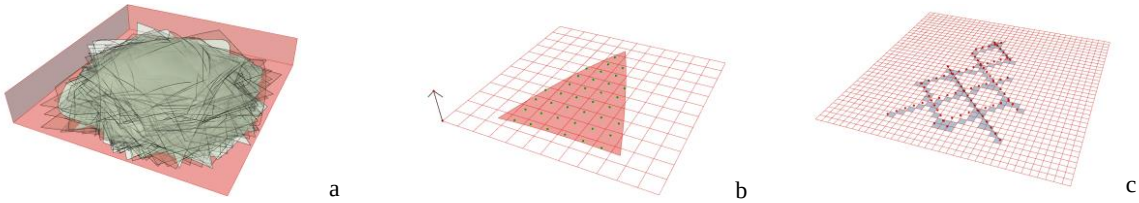

Figure 7. Data set for surfaces and patterns, a: the bounding box with all 980 oriented surface segments inside, b: the rendering frame grid points, c: the pixelization of a pattern in a render frame.

3.1. Deep exploration

Once we have geometrical data as numerical matrixes, it is possible to analyze them with computer vision methods. First, we use a mixed algorithm of a deep neural network and PCA [32, 33] to reduce the data dimensions and cluster them with K-Means clustering afterward. For the neural network, we use a pre-trained VGG-16 [23] network from tensorflow.keras backend. We check the feature maps of VGG-16's models each layer on several random pattern inputs and find that the first 12 layers are enough for the machine to understand the curves' direction and pattern. VGG-16 model converts the input pattern into a vector with the size of 40060 after 12 layers. Figure 8-b shows the feature maps captured from the network in layer 12. We then use the PCA model to find suitable potential features out of 4060. After some experiments with k-Means clustering, we find 200 features effective. As a result, we have a dataset with a size of 980 *200. The unsupervised k-Means clustering results in the three features curve orientation, free endpoints, and density. Figure 8-a shows the clustering results samples. In the second step, we trained a VAE [34] model to check if is there any potential in the provided data of the literature to have a new generation of the pattern out of it. VAEs have the potential to both generate new data and analyze the data [35]. The generated patterns of the trained model do not necessarily follow the curvature features suitable for a specific surface type.

cluster 0 oriented patterns with lower density and more free end points	cluster 1 mostly perpendicular patterns with low density and more free end points	cluster 2 oriented patterns with higher density and less free end points	cluster 3 mostly perpendicular patterns with higher density and more less end points

Figure 8-a. Clustering with a pre-trained VGG model and PCA with 500 features.

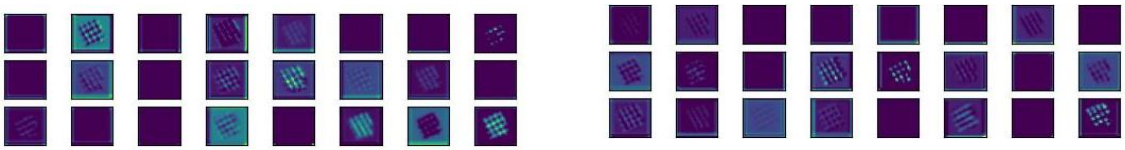

Figure 8-b. 48 feature maps of a pattern in layer 12th of the VGG-16 model.

Figure 9. shows the generated latent space in two dimensions. The point structure of the latent space of the VAE model represents a Fibonacci sequence, which could mean there is a hierarchical structure in the data, where each data point is composed of smaller sub-components. It means the patterns are a subset of each other and therefore it is hard for the machine to find significant differentiation to create new patterns from them.

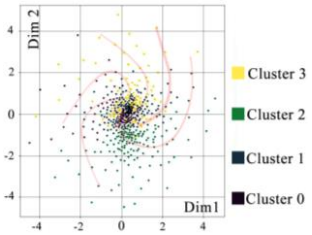

Figure 9: The latent space of the VAE model mapped on 2 dimensions.

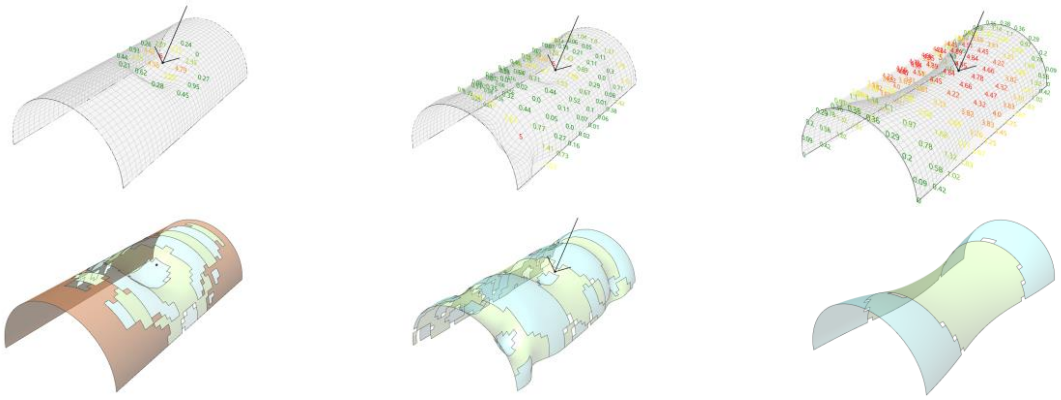
3.2 Result of the investigation

One of the main problems is the complexity of knowing how easy it is to fabricate the predicted pattern. Because the data input does not have curvature features related to the surface, results require post-evaluation. In post-evaluation, the curves will be checked if they work to align the surface curvature or result in large unexpected deformation. The process to make the model robust is as follows:

1) Combine the already gathered dataset with a collection of the elastic gridshells pattern images
2) Combine a new set of elastic gridshell surfaces and patterns with newly generated models
3) Train a model with newly added data with an additional evaluation engine to check the machine-generated data and add a new dimension to the latent space matrix to inform the system if the pattern is suitable or not.

Because in this research, we are looking for a method to reach results that are easy to be built and have standard features as an architectural geometry, the result of the experiments recommends us to a pre-informed modeling. In pre-informed modeling, we generate new data in a specific order that helps us to involve the curve and surface geometrical features in training. The next chapter explains the primary development of this method.



4. Smart pre-informed modeling

The pre-informed modeling environment is where not only the designer generates the surface geometry, but also can see the generated surface features, have design hints about patterns applicable on a surface, add physical behavior, and generates a form. In this chapter we first explain the method we used to make the design environment geometrically informed and afterward, we show some case studies of modeling in such a system, finally, we will discuss the potential of our developed model and what features we will add to it in the future. In our method we equipped the CAD environment with a smart assistant with the following features:

1) Identifies the surface geometry and gives the summary of the possible patterns that the surface locally can have.
2) Provides the utilities to deform the surface geometry precisely to have meaningful curvature variation.
3) Merges the patterns, adds profiles, and defines the final form.

4.1 Meaningful surface deformation

We developed a surface deformation workflow in grasshopper3d to change the surface Gaussian curvature vector. It is possible to evaluate several points on the initial surface and apply push or pull to them. The surface is sub-divided to generate grid points. It is possible to define the percentage of the grid points to be affected by the implied force and control the weighting of the force on the select points with a Bezier graph. Push means deformation is in direction of the surface normal at the evaluated point, otherwise, it is in the opposite of the normal direction. Figure 10 shows how changing push-force-vectors and weights result in various deformation. Figure 10 illustrates how the weight of the force and its distribution affects the numbers of unique curvature type segments, their size, and gradient changes in the generated free-form surface Gaussian curvature vector.

a b c

Figure 10. Deformations on a surface, a: pushing deformation on a low number of points but intense weight, b: pushing deformation on a higher number of points with cosine weighting distribution, and c: pushing deformation on a higher number of points with cosine weighting distribution.

After explained surface deformation the Gaussian curvature vector is updated. The Gaussian curvature vector matrix then is checked with the Density-Based Spatial Clustering (DBSCAN) model [36]. The DBSCAN is an unsupervised model of machine learning that based on element density checks a vector and makes sub-clusters. The Gaussian curvature vector consists of elements with negative (represents anticlastic region) and positive (reparents synclastic region) signs. Therefore, the result of the DBSCAN is a subset of regions of the surface with different curvature types. Checking the surface Gaussian curvature vector update, after deformation, gives us useful information. For example, a surface with multiple fluctuations on the curvature vector (previous figure middle) has a geodesic curve with various geodesic torsion and normal curvature. Various change in these two parameters results in the complexity to find a suitable profile direction for the strip for fabrication. Figures 11-a and b show the effect of surface deformation on a geodesic line in the middle of Figures 10-b and 10-c surfaces.

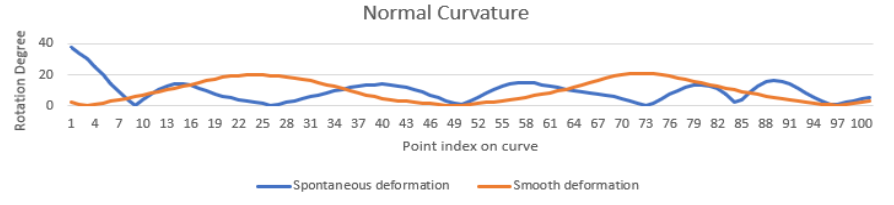


Figure 11-a. The changes of the normal curvature over a geodesic line in the middle of Figures 10-b and 10-c surfaces. The orange curve represents the curve in Figure 10-c and the blue curve is on the curve on Figure 10-b.

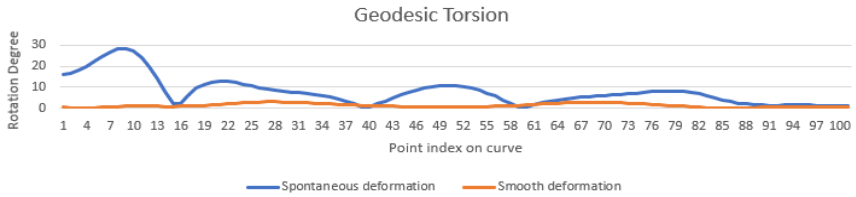

Figure 11-b. The changes of the geodesic curvature over a geodesic line in the middle of Figures 10-b and 10-c surfaces. The orange curve represents the curve in Figure 10-c and the blue curve is on the curve on Figure 10-b.

It is possible to split the deformed surface into multiple surface segments based on the DBSCAN results on the Gaussian curvature vector. Each segment has a specific curvature type with specific curve parameters. The segment numbers, outline, maximum/minimum curvature deviation, and sizes affect the pattern morphology and the final form. Integrating the deformation method with DBSCAN makes it possible to check the four aforementioned parameters in real time and visualize them. This visualization helps to be aware of the changes in surface curvatures and provides more control. Figure 12 shows an example of surface deformation on the original monoclastic and anticlastic surfaces that results in different segmentations. In this case, we can control surface regions' Gaussian Curvature Vectors to reduce the complexity in adding the profile.

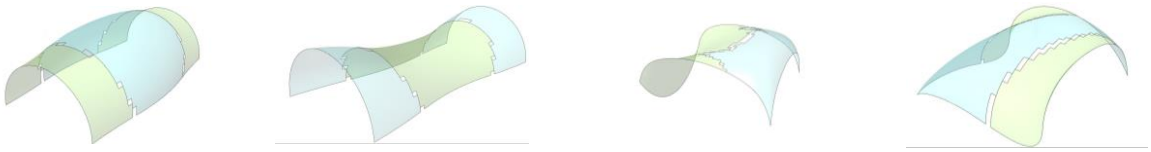

Figure 12. Surface deformations. 2 left figures are pulling and pushing deformation on a monoclastic surface. 2 right surfaces are pulling and mix of pull and push on an anticlastic surface.

Figure 12 illustrates how a simple change in direction of deformation changes the surface regions. The first two surfaces from the left in Figure 12 are generated by pulling and pushing the surface from the center. While pulling results in 1 synclastic and 2 anticlastic surfaces, pushing changes them to 1 anticlastic and 2 synclastic at the edges. Having an anticlastic region in the center means that we can have elements perpendicular to the surface and having synclastic makes it more relevant for elements tangential to the surface. Based on the geometrical theories explained in chapter 2, we can check the surface regions to understand the feasible patterns on them. Because of the parametric deformation and real-time feedback on the Gaussian Curvature Vector update, it is also possible to define preferred surface region changes as an objective for surface deformation and generate multiple variations. Figure 13 shows an example of controlling the surface deformation with a target of reaching 2 anticlastic at corners and one synclastic in the center with our developed method.

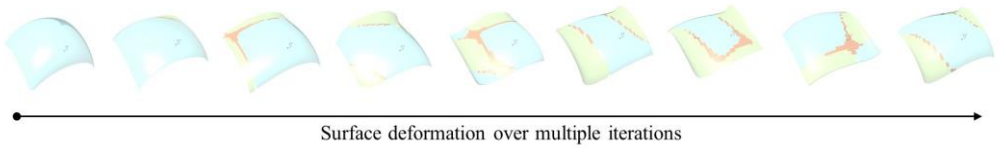

Figure 13. Unsupervised form-finding with an objective of having 2 anticlastic and one synclastic surface region.

4.3 Merging the patterns and final form-finding

Once we have finalized the surface based on each surface region's surface type, we can arrange their patterns. The final step is to merge the multiple region patterns to have continuous members on the surface. Figure 14 illustrates an example of a setting pattern on 3 regions of our deformed surface from Figure 13.

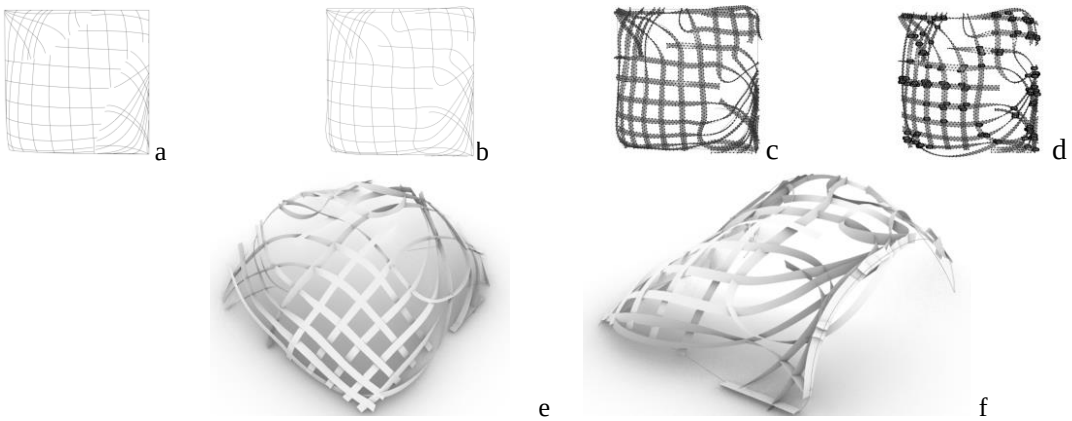

Figure 14. a. Set a pattern for each surface region. Here because two sides are anticlastic regions asymptotic curve is applied. In the center region simple grid pattern with geodesic lines is applied. b. merging different pattern curves to make continuous curve elements. c. adding a profile to curves based on their curvature properties. d. defines connection and anchor points for dynamic relaxation. e and f. finalized form-finding.

To merge patterns, we developed an algorithm that connects the different regions' pattern curve endpoints. If endpoints are in a distance of less than 3.5 cm they will be connected. Depending on starting from what region first, the order of connection will be different. Each node can select one neighbor. Therefore, the region that the connection is started from has more options in neighbor selection. Figure 15 b. shows a second possibility of merging the pattern on the surface of Figure 14. It is possible to add or remove connections afterward manually. Because after merging patterns curves' curvature will be modified, the rotation of the profile on them is not constant. Depending on which region of synclastic or anticlastic a part of the curve is its profile has a rotation of 90 degrees (geodesic line) or 0 degrees (asymptotic curve). We developed an algorithm to automatically find connections between mesh elements where pattern curves had intersected. It is possible to add and remove the connection afterward manually as well. Figure 14 d shows the connections between the profile meshes before dynamic relaxation. Kangaroo physics engine is used for dynamic relaxation.

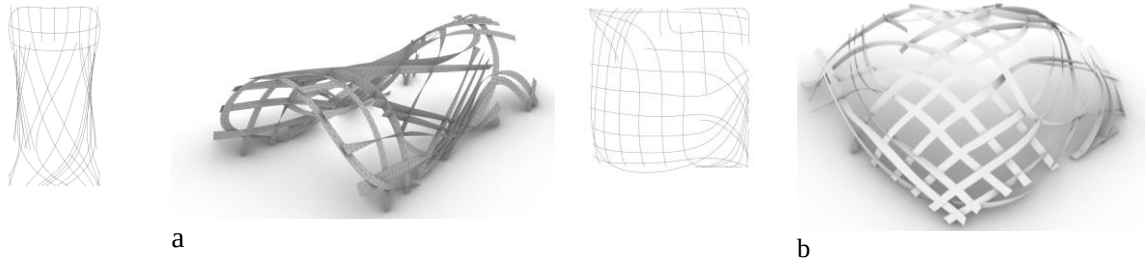

Figure 15. Multi-pattern form finding examples, a: application of method on a deformed monoclastic surface, b: change in pattern merge of the previous surface.

5. Discussion

Clearly, there are some technical issues, limitations, and errors we faced during this project so far. To control the surface deformation, we use an optimization approach that evaluates the deformation based on 2 parameters, the number of regions with different curvature types, and the area of each region. Therefore, the process is iterative and presently adds time and computational cost to the design process. With automated data generation, it is possible to generate a dataset of deformed surfaces based on set requirements. We are able to train a model based on the generated data to increase the speed and variation in this part. In order to split the surfaces, we consider surface curvature regions at the moment, while it is also possible to have segments with a mixture of curvatures to start from. We may develop an interactive space where designers either can select the region manually or have variations and/or a

mix of curvatures as well. The dynamic relaxation methods we used has some inaccuracies. The observed inaccuracy may be argued by the mesh segmentation that affects the bending behavior. The mesh segmentation also has an effect on the connection of elements as well. We will adapt our algorithm that connects the mesh elements to reduce the unexpected error of mesh crossover.

6. Potential of the cognitive method and future works

In this project, we set up the design process from a geometrical perspective. We created gridshells without repetitive geometry. When looking at the figures that are shown in Figure 14 and 15, it is obvious that we currently manage to generate and find geometrical solutions between different patches and their patterns. Usually gridshells are highly efficient spatial structures with optimized material use. Even though, they are generated by physics engines at least under gravity load, our geometries are presently neither structurally evaluated nor optimized. We are aware, that proposed geometries may not meet a grade optimization of a uniform mesh, which on the other hand comes at the cost of design freedom. As mentioned earlier, the proposed method creates a process with possibilities of adaptation and interactive workflow. The reverse of such a method is starting from the designers´ perspective and their design goals. In this case, the geometrical analysis and interaction have to be found and to be interactively proposed for the intended design concept. In our ongoing research, we are developing a model that learns from earlier experiments to provide geometrical and structural solutions that meet the design intent and purposes. In our future work, we will firstly clarify and improve the above-mentioned issues. Secondly, we will develop a model that learns from crafting similar to what weaverbirds do in their learning process. The benefit of such a model is to pave the use of gridshell for non-uniform concept designs. Indeed, architects will experience more design freedom and generate advanced geometrical forms through interactive design processes.

Abstract

Exploring a wide range of design options is crucial for every sound conceptual design process. In the conventional structural design workflow, optimization techniques are generally employed to generate well-performing design options. However, focusing only on performative criteria may result in a lack of design exploration and diversity, narrowing down the design brief too early and neglecting essential aspects beyond pure performance. In response, this paper introduces a new method for the generation of structural forms that emphasizes both performance and the exploration of a diverse set of design briefs. The method employs layout optimization in a new way and aims to find close-to-optimal yet diverse structures. First, a parametric ground structure is generated. Second, this ground structure is used to produce a structure in equilibrium based on different user-defined goals. By varying ground structures and balancing the different goals, the method produces a series of designs that are both diverse and well-performing. The applicability of the method is demonstrated through several case studies. Results show that this method allows for the real-time generation of multiple design options, including both well-known and less well-known, but not less valid, typologies. Using this approach, designers can move beyond the limitations of established typologies and explore a new variety of structural forms.

Keywords: computational design, design exploration, interactive design, conceptual design, layout optimization, form-finding

1. Introduction

Traditionally, the process of designing structures involved reliance on hand-sketches, physical models, and well-established typologies. With advancements in computational power this process was extended to include digital format. As a result, designers have been enabled to integrate geometric and performance metrics in the design.

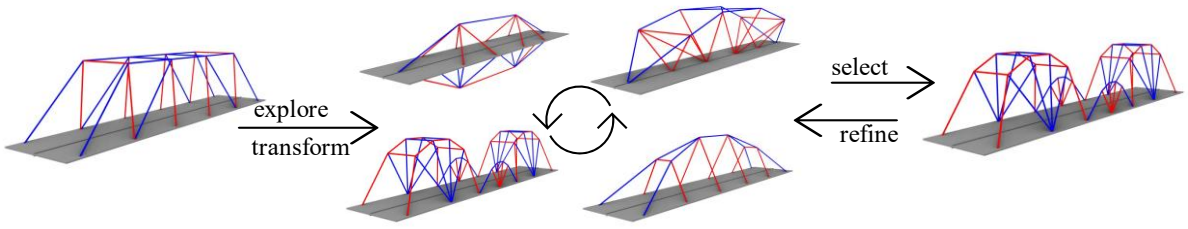

Figure 1. Designing structures by transformation operations and layout optimization

Computational design has opened up a new realm of design possibilities, where feedback on an intended design is instantly available, leading to an entirely new approach of exploring and designing structures. This also brought the benefit of generating a significantly larger number of design alternatives, thereby expanding the design space and promoting exploration. With these increased possibilities, the fundamental goals of conceptual structural design could be addressed more effectively – exploring structures beyond pre-defined catalog types while ensuring adequate performance.

1.1 Related work

In this regard, computational tools have been developed to assist designers in this task. Typically, so called meta-heuristic optimization methods, such as genetic algorithms, have been employed to explore structural forms. An early example is ParaGen [1] by von Buelow. This tool operates on structures whose topology is predefined. The evolutionary exploration mechanism controls nodal coordinates and imposes the nodes' relocation until specific design criteria are satisfied. Mueller and Ochsendorf [2] contributed to the development of performance-informed design, which resulted in the creation of StructureFit. This approach employs genetic algorithms to enable designers to investigate and enhance design candidates by selecting parents for crossover and mutation. The topology of the design candidates is determined by the designer's input, with the examples presented in a 2D format. Harding and Shepherd [3] worked on meta-parametric design, resulting in Biomorpher [4], a plug-in for Grasshopper that employs interactive genetic algorithms to explore and optimize any parametric definition created by the designer. Mirtsopoulos and Fivet [5] presented a generative approach based on grammar rules and combined it with the interactive genetic algorithms in Biomorpher. A major advantage of employing meta-heuristic optimization algorithms is their capability to handle a diverse array of problems due to their independence from differentiable (in-)equations. Nonetheless, a significant challenge associated with their use is that the underlying computations may lead to computationally expensive procedures. More recently, a generative structural design workflow has been proposed that integrates the Combinatorial Equilibrium Modelling form-finding method [6] with a machine-learning-based clustering technique to facilitate the exploration of multi-dimensional spaces of structural design solutions [7]. While these methods can provide good solutions, it is essential to carefully balance design constraints to ensure practical outcomes. If constraints are excessively rigid, it may hinder design exploration. Furthermore, the process of generating results is a black box, making it challenging to establish a clear link between input and output. Regarding performance only, mathematically sound optimization techniques are often used to generate well-performing structures. He et al. [8] have proposed a computationally efficient optimization framework, in which a linear programming truss layout optimization is employed to generate close-to-optimal designs. Park et al. [9] discussed the potential use of layout optimization at the conceptual design stage. Both methods utilize optimization routines as a primary means of generating design alternatives. However, relying solely on optimization techniques can lead to prematurely narrowed designs, without sufficient exploration of other alternatives. This can result in an excessive focus on optimization itself, which may be appropriate for pure engineering tasks, but may not allow for sufficient exploration of structural forms when other factors beyond performance are important, as it is the case in the conceptual design stage.

1.2 Contributions

Optimization approaches can still be beneficial if they are integrated as sub-routines within a broader design process. Therefore, this paper aims to showcase how optimization can be leveraged without being the primary driving force, but rather a helpful tool in generating structurally sound designs while simultaneously promoting exploration. The focus lies on connecting structural performance with individual design preferences by using layout optimization in a new way. This allows to generate a diverse set of close-to-optimal structural forms that are yet visually distinct. A significant advantage of the presented method is that it operates in real-time allowing designers to directly manipulate and transform design briefs, resulting in an intuitive and seamless workflow. The method achieves a balance between exploration and rationality by imposing customized node-placing in combination with discrete

layout optimization. To summarize, this paper's contributions are: (1) the introduction of a new feedback-driven design framework for exploring structural forms in real-time, and (2) the use of discrete layout optimization in a new application focused on typological exploration.

2. Method

The method presented in this paper can be employed in two distinct ways: (1) for the creation and exploration of structural forms from the ground up, or (2) for the refinement and local transformation of an already existing design brief. This is achieved by using discrete layout optimization to create strut-and-tie models in static equilibrium, as they are known from graphic statics [10] and used by many architects and structural engineers. Section 2.1 of this paper outlines the overarching framework of the method, while Section 2.2 delves into the customized ground structure approach. In Section 2.3, the mathematical formulation for the discrete layout optimization is presented.

2.1 General framework

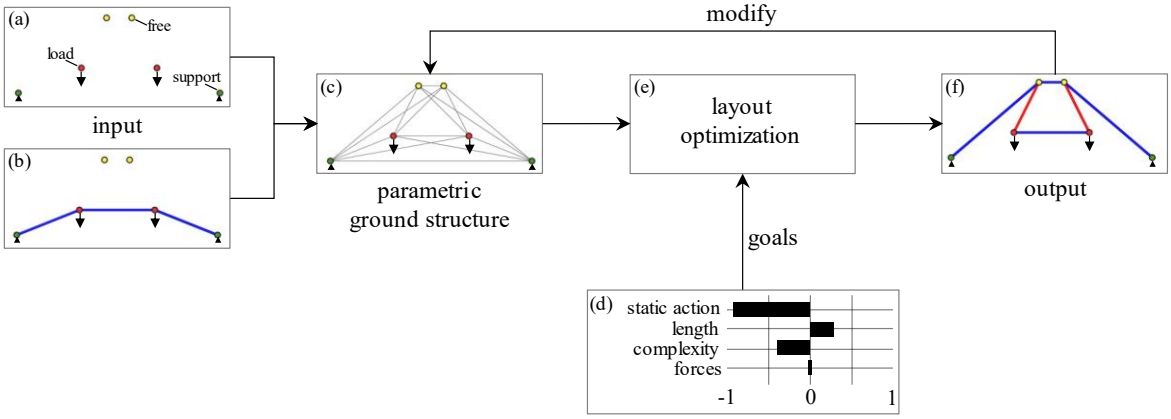

Figure 2. Workflow of the presented method

The general procedure of the method is summarized in Figure 2. The initial step in this process involves supplying input data. Figure 2(a) illustrates the three types of nodes that comprise the input data: support nodes (green), load nodes (red), and free nodes (yellow). Additionally, as illustrated in Figure 2(b), a pre-existing structure can be incorporated as needed. Once the input data is provided, a ground structure is generated by interconnecting all nodes (Figure 2c). It is important to note that the positioning of the nodes serves as one of two junctures where the designer can influence the resulting structure. The second point of influence is through the delineation of design goals, as shown in Figure 2(d). In this paper, these goals comprise four distinct categories: volume, length, complexity, and forces. However, additional, less trivial goals are available and would add even more relevance to the search process.

In order to weigh these design goals against each other, users can assign a real value between -1 and 1 for each of them, where a value of -1 represents a minimization, a value of +1 a maximization, and a value of 0 a neutral value indicating that the goal is not a priority for the optimization. When optimizing for volume, only values between -1 and 0 make sense since maximizing the volume of a structure is usually not desirable. However, for the sake of consistency, the range 0 to +1 can also be used. Regarding length, a value of -1 aims for shorter bars in the output structure, a value of +1 for longer bars. Complexity is derived from the number of bars and nodes existing in the output structure, where -1 aims for as less bars and nodes as possible and +1 for as many as possible. The 'Forces' input works slightly differently. A value of -1 requests all bars in compression, while a value of +1 requests all bars in tension. Values in between interpolate between both extremes. This means that a value of +0.8 tries to have most of the bars in tension but allows for some bars in compression. In summary, these goals influence the outcome of the layout optimization (Figure 2e) together with the custom ground structure

from Figure 2(c). Another peculiarity of the method used here is that instead of volume, the so-called static action is used:

$$\sum_{T} F_T L_T + \sum_{C} F_C L_C \tag{1}$$

Static action is calculated as the sum of the products of bar lengths by their force magnitude, separating bars in tension (T) from bars in compression (C). In early-stage design where no material has yet been decided upon, or where a constant material resistance in tension and compression is assumed throughout, static action can be understood as a substitute for volume. Thus, the terms volume and static action are used equally in this paper. Finally, the result of the process is shown in Figure 2(f). This result can be further modified by jumping back to step 2(c) i.e., by adding or removing nodes or by moving nodes to obtain a new custom ground structure. This enables designers to explore different kinds of structures for as many iterations wanted.

2.2 Extended ground structure approach

The discrete layout optimization used here is based on the ground structure approach, first proposed by Dorn et al. [11]. It consists in a fixed grid of nodes interconnected by bars. The optimal structure is found by only keeping a sub-set of all available bars and removing all obsolete bars. Over the years other strategies for discrete layout optimization were developed. Some start with a sparse structure and iteratively add nodes or bars to the structure. One well-known method, the growth method, was developed by Martinez et al. [12]. Instead of starting with a densely connected ground structure where all nodes are already available, it adds one node at a time to reduce computational cost. However, it can only deal with statically determinate 2D problems. The approach proposed here can be perceived as a combination of the two aforementioned strategies. Unlike the conventional ground structure approach that employs a predefined grid of nodes, the proposed approach allows the user to place nodes in desired locations, which are then interconnected to create a custom ground structure for the subsequent topology optimization. Therefore, the optimized ground structure is significantly influenced by the nodes selected by the designer. By this method, the designer has the ability to enforce their preferences and specify the locations where nodes and bars may or may not occur. The nodes that are placed beforehand can be altered or removed at any point during the process, and the designer can observe the effects on the final structure in real-time. This allows direct interaction with the design brief. Alternatively, the nodal positions could also be defined randomly in an automated way, which leads to the direct generation of a large set of diverse design outputs.

2.3 Layout optimization

The discrete layout optimization employed in this paper is formulated as an extension of the already mentioned ground structure approach by Dorn et al. [11] as a LP problem. Building on this, a mixed integer linear programming (MILP) formulation is proposed to allow for the definition of the goals explained in Figure 2(d).

2.3.1 Linear programming formulation

As already mentioned, the discrete layout optimization used here is based on the plastic layout optimization formulation for volume minimization. It consists of setting up a ground structure and solving the following LP problem:

$$\min_{\mathbf{a},\mathbf{q}} V = \mathbf{l}^T\mathbf{a} \tag{2a}$$

subject to

$$\mathbf{Bq} = \mathbf{f} \tag{2b}$$

$$\sigma_T \mathbf{a} - \mathbf{q}_k \geq 0 \tag{2c}$$

$$\sigma_C \mathbf{a} + \boldsymbol{q}_k \geq 0 \tag{2d}$$

$$\mathbf{a} \geq 0 \tag{2e}$$

where V is the total static action (≈ volume) of all members, **l** is a vector of all bar lengths, and **a** is a vector of all bar cross section areas. **B** is the equilibrium matrix containing the direction cosines of all bars. **q** is the vector of bar internal forces, and **f** the vector of external nodal loads. σ_T and σ_C are stress limits in tension and compression. The advantage of using this LP formulation is that it is computationally efficient which is an important feature for any interactive tool for the conceptual design stage. Design goals, as described in Figure 2(d), are not described yet in this formulation. Therefore, the current formulation needs to be extended.

2.3.2 Mixed integer linear programming formulation

One way to extend the previous formulation is to introduce additional constraints and variables. For this, binary assignment variables for nodes and bars are used, as they have already been used by Fairclough and Gilbert [13] and Brütting et al. [14]. The formulation used here is similar to the one of Fairclough and Gilbert. This extends the formulation to a MILP problem which can mean that computational complexity increases. However, it allows the addition of several goals, herein formulated as constraints:

$$M\mathbf{w} - \mathbf{a} \geq 0 \tag{2f}$$

$$Mv_j - \sum_{i \in N_j} a_i \geq 0 \tag{2g}$$

$$\mu_L \leq \sum_{i=1}^{n} w_i \leq \mu_U \tag{2h}$$

$$\vartheta_L \leq \sum_{j=1}^{m} v_j \leq \vartheta_U \tag{2i}$$

$$\mathbf{w}, \mathbf{v} \in \{0, 1\} \tag{2j}$$

Equation 2f denotes whether a potential bar in the ground structure is assigned to the final structure (w_i = 1) or not (w_i = 0), where **w** is the vector of binary assignment variables for each bar in the ground structure. *M* is a sufficiently large number which can be seen as an upper bound for cross section areas. Equation 2g denotes the existence of a node following the same principle. To provide this, the sum of the areas of all bars ($\sum a_i$) connected to the respective node is used. Here, N_j is the set of bar indices for all connected bars. **v** is another vector of binary assignment variables indicating the existence of a node j where $v_j \in \{0, 1\}$. μ_L and μ_U are lower and upper bounds for the number of bars and nodes, respectively. This allows to control the number of bars and nodes in the output structure.

3. Results

All examples in this section were run on an Intel Core i9-11900H @ 2.50GHz with 32.0 GB of RAM. To solve the MILP formulation, Gurobi 10.0.1 [15] was used. Sections 3.1 and 3.2 present a case study in 2D, where Section 3.1 demonstrates the exploration of structures generated from scratch with no additional input, while Section 3.2 demonstrates the local transformation of an existing structure to achieve structures with similar performance and appearance. Section 3.3 extends the study to 3D, highlighting the capabilities of the proposed method. Notably, all results presented in this section were obtained in real-time, taking only a few milliseconds to compute.

3.1 Structural exploration

Figure 3(a) shows the setup for this case study with three loads of value *F* and two supports. The design domain is indicated by the gray box and has a length of *L* and a height of *L/2*. Figure 3(b) shows the goals as black bars ranging from -1 to +1 (see Section 2.1). These goals can be changed to obtain different results. Support and load nodes do not move, while free nodes may move, vanish, or appear.

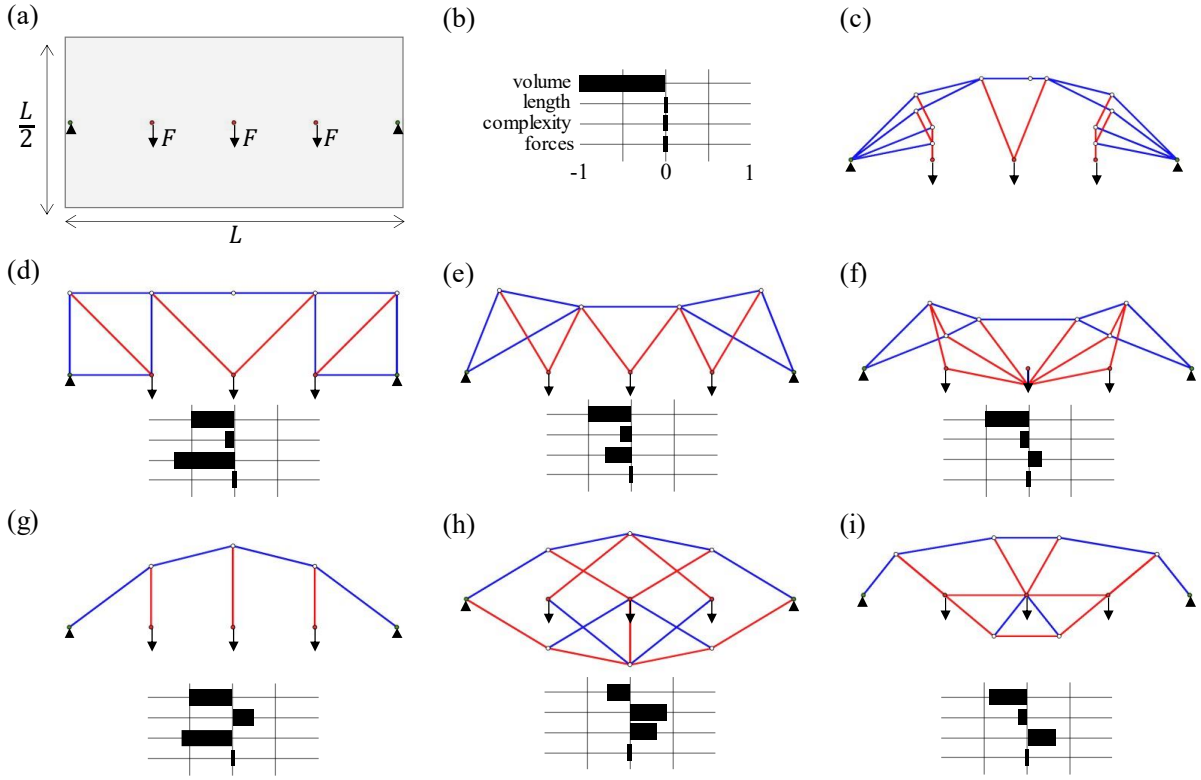

Figure 3. Case study for a structural exploration from ground up: (a) initial set up of load and support conditions; (b) input goals leading to (c) first iteration; (d-i) other results (top) resulting from other choices of input goals (bottom).

Table 1. Result metrics for the ground up exploration presented on Figure 3.

Name	Static action [FL]	Nodes [-]	Bars [-]	avg. Length [L]	Difference [-]
(c)	**21.3**	16	24	0.186	- 42%
(d)	**36.7**	10	14	0.280	± 0%
(e)	**26.1**	9	13	0.283	- 29%
(f)	**30.2**	12	20	0.211	- 18%
(g)	**21.7**	8	7	0.252	- 41%
(h)	**37.5**	11	17	0.284	+ 2%
(i)	**28.5**	11	16	0.208	- 22%

The obtained structures can be observed in Figure 3(c)-(i). Result (c) shows the 'optimal' structure if only the minimization of static action is a goal and a fully connected dense ground structure is available. It is rather a theoretical result used to benchmark results (d)-(i). Structure (d) denotes a 'classical' truss structure. Therefore, (d) is used as a reference to measure the difference of static action. The black bars underneath indicate the values chosen for the design goals. Table 1 shows the results belonging to the structures in Figure 3, containing their static action, normalized by *FL*, the number of nodes and bars,

the average length of the bars, normalized by *L*, and the difference of static action compared to the one of the reference structure (d), i.e. 36.7*FL*. All obtained structures perform similarly or significantly better than the truss in (d), while (c) performs best with 21.3*FL*. Except for (h) all structures perform 18% to 41% better. The amount of bars and nodes used is varying from 7 to 24 and 8 to 16, respectively.

3.2 Structural transformation

In this case study, the structure from Figure 3(g) is taken as a starting point and shown in Figure 4(a). Support and load conditions remain the same as in the previous example. Again, support and load nodes do not move, while free nodes may move, vanish, or appear. The intention is to transform Figure 4(a) to obtain similar arch-like looking results and explore the range of possibilities for a given type of structure. Figure 4(b)-(f) show the obtained transformed structures with the respective goals underneath. Table 2 shows the result metrics in the same way as Table 1 does.

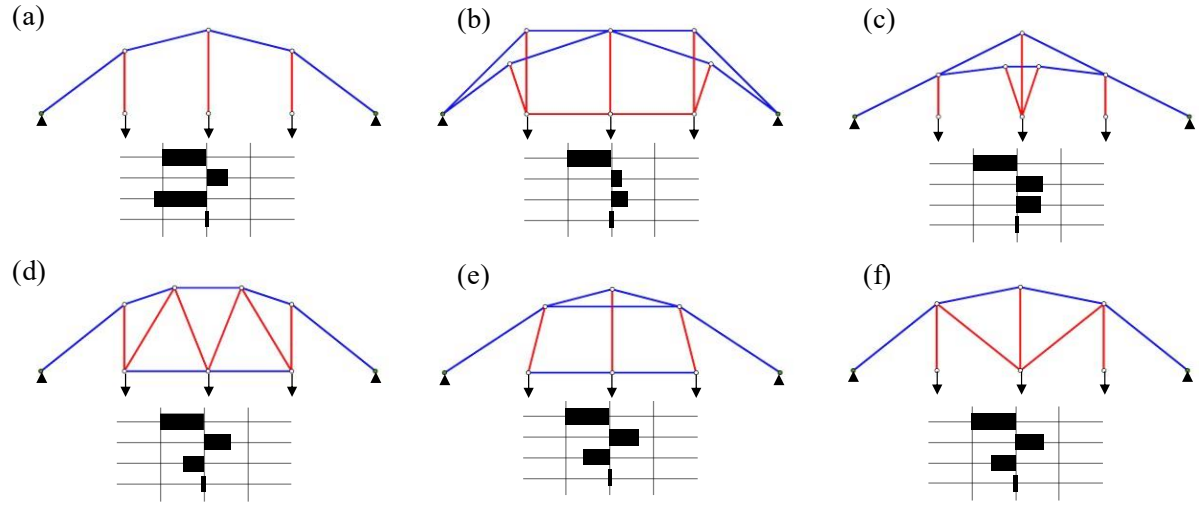

Figure 4. Case study for a structural transformation: (a) initial structure; (b-f) transformations (top) resulting from a change of input goals (bottom).

Table 2. Result metric for the structural transformation

Name	Static action [FL]	Nodes [-]	Bars [-]	avg. length [L]	Difference [-]
(a)	**21.7**	8	7	0.252	± 0
(b)	**22.2**	10	13	0.300	+ 2%
(c)	**25.9**	10	13	0.252	+ 19%
(d)	**22.2**	9	13	0.244	+ 2%
(e)	**24.1**	8	9	0.299	+ 11%
(f)	**21.9**	8	9	0.271	+ 1%

Moreover, all obtained structures perform similarly with static action deviations up to +11%, except for (c) deviating by +19% compared to the starting structure. Their amount of nodes and bars ranges from 8 to 10 and 7 to 13, respectively, while the average lengths ranges from 0.244 to 0.300.

3.3 3D bridge structure

This case study serves as an illustrative example of the extension of the introduced method to the third dimension, as demonstrated in Figure 5 where 40 different bridge structures of varying layout and

geometry are displayed. Underneath, a diverse selection of four structures for potential further investigations is shown.

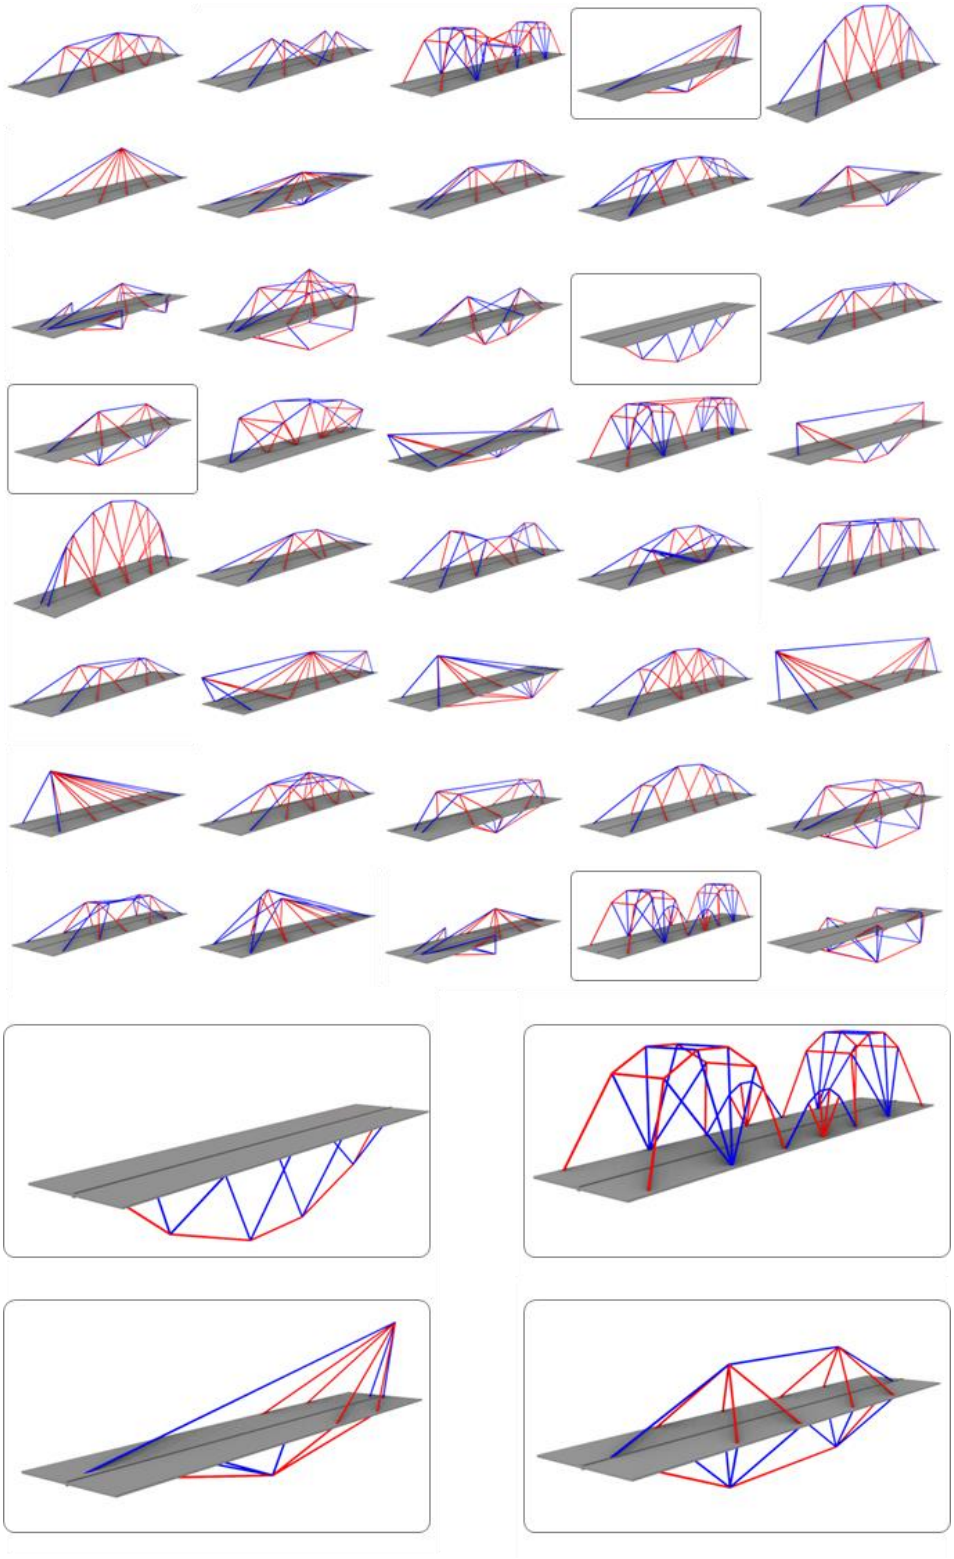

Figure 5. Sample of 40 generated structures with four selected structures to further investigate

4. Discussion

The present study reveals a diverse range of forms and types for spatial structures, as demonstrated by the case studies. These structures exhibit a variety of known types, such as arches and trusses, as well as new, uncategorized forms. Remarkably, the study finds that the diverse array of structures performs within a similar range in terms of static action. This suggests that designers may choose from a variety of forms and types for qualitative preferences without compromising performance. Moreover, the MILP problem introduced in this paper requires significantly less computational resources compared to similar MILP formulations in the literature, e.g. the one from Fairclough and Gilbert [13]. One explanation for this is that the current approach does not employ a densely connected ground structure, resulting in the utilization of fewer nodes and bars. However, there currently are several limitations and trade-offs. Form-active structures such as arches or cables are not always readily identifiable, as their nodes must be conveniently pre-positioned, which calls for combining current algorithms with complementary geometric search. Furthermore, more complex structures with a larger number of nodes and bars may pose challenges in control, and changing one node at a time only may not lead to a significant change. To address these limitations, the development of methods that bundle sets of nodes for efficient analysis and transformation is required. Also, even though this tool is meant for early-stage conceptual design, the integration of early stability checks and construction feasibility checks would make the transition to the next phases of the design process more straightforward. Finally, the development of additional goal parameters should allow users to gain control over more complex formal features and hence an even more straightforward control over the search process. These improvements will be the subject of future publications by the authors.

5. Conclusion

This paper introduced a new method for the generation and exploration of structural forms for the conceptual structural phase of the design process. The approach provides designers with the flexibility to choose between the unbridled exploration of various forms or the refinement of an already advanced design brief. The method uses layout optimization in a new way, which involves the creation of a parametric ground structure and the subsequent generation of structures in equilibrium based on different design goals. Primary advantages of this method are (1) its ability to navigate a solution space that is unrestrained from predefined typologies, (2) its ability to operate in real-time, enabling designers to modify their intended design interactively, and (3) its ability to only generate structural typologies that make sense from both points of views of static equilibrium and construction rationality or other custom goals.

Future developments of this method relate to the implementation of a geometry optimization step to allow for the generation of form-active structures and the implementation of additional design goals, hence allowing more design opportunities to tame the search of new structural typologies. The algorithms will soon be made available as a Grasshopper plugin for Rhino3D.

With this method, designers may break away from established typologies and explore a vast new set of sound structural forms. Furthermore, this method facilitates the simultaneous consideration of both performance and diversity, ensuring that the final design is not only well-performing but may also be distinctive and inventive. Therefore, this introduced method constitutes a valuable addition to the computational conceptual design process, providing designers with a persuasive tool for generating and exploring structural forms. The approach offers flexibility and adaptability to designers, empowering them to develop creative, high-quality designs that cater to the specific requirements of their projects.

Abstract

The 3D printing technology of mineral materials offers the possibility of manufacturing geometrically complex shapes. However, it is still difficult to integrate reinforcement into printed geometries. This production-related limitation results in a significant restriction in the load-bearing capacity of printed components. Therefore, the technology has been mainly used for decorative components so far. 3D-printed load-bearing structures should not be derived from conventional shapes of reinforced concrete but rather from their inherent functional and structural requirements. In this paper, we explore the strategy of combining large-scale 3D-printed, purely compression-loaded components with post-tensioned, unbonded tendons to generate statically and economically efficient systems. The separation into mineral, purely compression-loaded, and metallic, tension-loaded elements allows the advantages of the printing technology and the material's specific load-bearing behaviour to be exploited, as well as enabling better recyclability through the separation of construction materials. Using the example of large fluid containers, the form finding for systems under hydrostatic pressure and their construction with the described static system of separated compression and tension elements is investigated. These containers are considered highly relevant structures in the wake of the energy transition and climate change.

Keywords: form finding, 3d printing, post-tensioning, optimization, parametric design, concrete shells, lightweight construction, production-driven design

1. Introduction

1.1. Reason for investigation

3D concrete printing (3DCP) is developing into a competitive production method for a wide range of construction tasks, even in widespread use [1], [2]. However, current development aims more at substituting traditional construction methods and their associated shapes [3], [4]. The geometric design and structural potential of additive manufacturing technology remain largely untapped. So, the aim of this research project is twofold: first, to drastically reduce the required materials by optimizing structural shapes; and second, to avoid composite construction and thus allow for easy recyclability.

Our focus lies on construction systems for infrastructural buildings, especially liquid containers. In the infrastructure sector, more attention is paid to functional and economic aspects than to individual design aspects. Liquid containers are used in a wide variety of applications. In the course of the energy transition and the associated use of fluctuating renewable energies, an increased demand for such storage systems, both as water and heat storage, is to be expected [5], [6].

1.2. Used tools

The form-finding was developed entirely in the Rhinoceros 3D and Grasshopper [7] environment. For form finding, the Kangaroo 2 [8] solver was used, which works with the dynamic-relaxation method. We decided to use these tools because of the available APIs for Rhino and Grasshopper, as well as the comprehensive documentation of Kangaroo, which allows the implementation of self-programmed

'custom goals'. Through prior experience with programming in this environment, we were able to take the first steps quickly. Overall, an even more flexible form-finding tool with more possibilities (e.g., different load cases, envelope load cases) would be desirable.

1.3. Methodological approach

We are developing a specific form-finding setup for 3DCP structures in combination with unbonded, post-tensioned concrete containers based on the underlying static principles. From two-dimensional graphic statics, equations are derived to 'goal objects' for the digital form finding. With this procedure, the complexity of the system can be successively increased to gain a deeper understanding of the relationships between form and force and their corresponding shapes. In this paper, the investigation of the two-dimensional thrust lines and its conclusions are discussed. Afterwards, the principles are translated into three-dimensional space. These results are only a glimpse, as they have not been concluded yet. However, they give insights into the problems that still must be solved in this ongoing research project.

2. Form finding in two-dimensional space

In the following chapter, the applied loads and their derivation from the structure are briefly presented. The basic relationships between form and force are evaluated based on selected load combinations. Correlations between material consumption and container volume can be derived by introducing the evaluation criterion 'efficiency ratio'.

2.1. Dead load

The first load effect on the container wall is the dead load of the purely pressure-loaded (3DCP) shell, as described in figure 1a. The calculation of the dead load is realized with a discretized representation of the thrust line, represented by a polyline element. Loads are derived from each line segment of the polyline and applied to the segment's end points. The magnitude results from the product of the segment's length l and the length-related dead weight g_0 of the used material and wall thickness. Varying wall thicknesses within the container wall are not intended at this early stage, so the calculated line load can be uniformly distributed to each segment's end points. Dead load acts vertically in the global coordinate system (-Z) and is therefore applied in the positive Z direction (acting upwards) in the form-finding process [9], [10].

2.2. Hydrostatic pressure

The hydrostatic pressure is calculated analogously to the dead load. It derives from the length l of the polyline segments and the fluid-specific, length-related pressure p_v. In addition, the corresponding water level is included in the calculation, as shown in Figure 1b. The load is determined using two partial loads for each line segment of the discretized thrust line. The first part is a constant, uniform line load over the entire segment, corresponding to the pressure at the upper segment end, $p_1 * l$. The second part, the linearly increasing load component p_2, is calculated from the height difference over the segment's length (V[0]-V[1])/2 * l. These two load components are proportionally applied to the end points of the polyline segment. The force direction is normal to the surface or line, so care must be taken to ensure a consistent line direction in the 3D model. Otherwise, the calculated pressure direction can flip in the thrust line. Since the reference point for the water level can also depend on the shape of the thrust line (container height can also be part of the form finding, e.g., with a rolled support point on the top end, see figure 9), its coordinates can be bound to a control point of the discretized thrust line, which is calculated in the algorithm [9], [10].

The discretization of the geometry leads to a significantly higher discretization-related deviation for the hydrostatic pressure than for the dead load. Theoretically, the force components at a control point of the polyline from connecting segments should be equal. However, this is not the case due to the distribution of the increasing load component over the length of the discretized line segment. With sufficiently fine discretization, this circumstance can be considered. With an idealized discretization (lim l_0 → 0) and isolated hydrostatic pressure, a constant normal force in the entire thrust line can be expected.

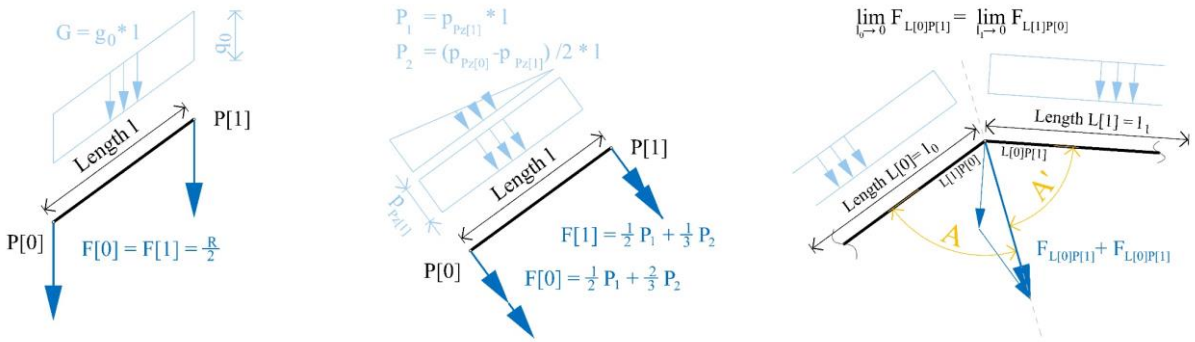

Figure 1. f.l.t.r.: (a) dead load calculation, (b) water pressure,
(c) constant normal force in thrust line under isolated hydrostatic pressure

2.3. Tension only elements

The load-bearing geometry in the form-finding process is calculated with spring elements. The spring force F is derived from the spring constant D and the length change Δl. At each line end point, half the spring force is applied coaxially to the spring axis, with the direction corresponding to the sign of the length change [9], [11].

To distinguish between purely compression-loaded and tension-loaded elements, the general spring equation was supplemented with a correction in the program. A pure tension element (e.g., post-tensioning elements) may only absorb compressive forces in the form finding process. It may therefore react to shortening (Δl < l0) with a corresponding counterforce, but not to lengthening (Δl > l0). This is realized in the program by a length-dependent correction. When Δl > l0 the calculated force will be reduced to zero. The force directions remain unchanged. Due to the reversal of the force direction in the form finding procedure, there is a risk of buckling with purely tension-loaded elements during the form finding procedure.

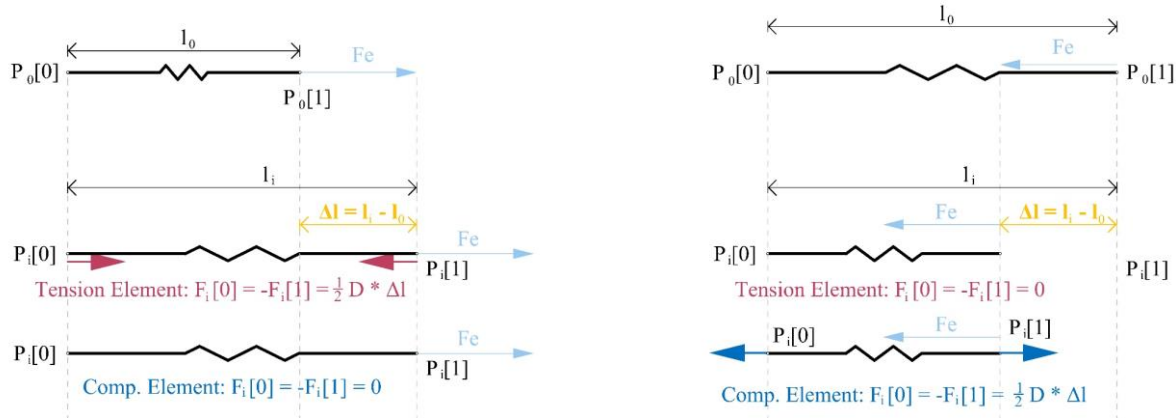

Figure 2. left: spring element under tension and corresponding reaction of tension and compression only elements; right: form-finding spring element under compression and corresponding reaction of tension and compression only elements

2.4. Compression only elements

A pure compression element (e.g., an unreinforced concrete container wall) may only absorb tensile forces in the form-finding process. A corresponding force will be applied to the line end points by lengthening ($\Delta l < l_0$). The applied forces are set to zero if the element is shortened.

2.5. Supports

Supports are calculated like a very strong spring element between its original point and the current point in the iterative solver, which always pulls it towards the origin. Support conditions (t_x, t_y, t_z) can be set by multiplying the vector's dimensions [12].

2.6. Different water levels

The forces of lower water levels can be dissipated within the thrust line of the maximum filling level in rotationally symmetrical containers. The missing dynamic pressure can be compensated with corresponding annular compression forces in the concrete shell. However, depending on the slope of the shell, these compensating annular forces can cause significantly higher internal compression forces than the load of a higher fill level, which is why these internal forces are also decisive for the dimensioning of the shell thickness. To calculate these internal forces, a new type of goal element is introduced.

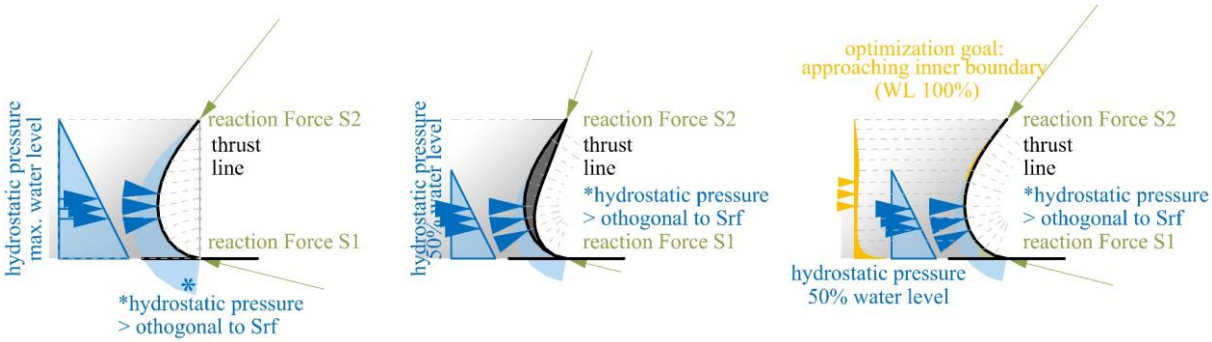

Figure 3. process of a form finding goal for lower water levels

Its mechanic is derived from the desired behavior of always approaching the thrust line geometry of a completely filled container. It is calculated in a second form-finding step after the initial one with a maximum water level. The behavior is achieved by applying additional, only horizontal-acting, concentrated loads to the control points of the thrust line. Its magnitude is derived from the horizontal distance to the thrust line of the first form-finding step. To prevent annular tension forces, the magnutude is corrected to zero depending on the acting direction of the concentrated loads (in our case, the -X direction will be corrected to 0).

2.7. Efficiency ratio

To enable an initial economic and ecological classification of different parameters and resulting shapes, we compare the resulting cross-section curves with a unitless "efficiency ratio". It is calculated from a predefined container volume in relation to the corresponding built volume of the container wall (m^3/m^3). For this purpose, the two-dimensional thrust line from the form finding is revolved around to determine the cylinder-equivalent radius b from its volume. This is supplemented with r to revolve the curve to the predefined container volume V. This results in the wall's area A, which is multiplied by the weight used for the wall's dead load in the form-finding process.

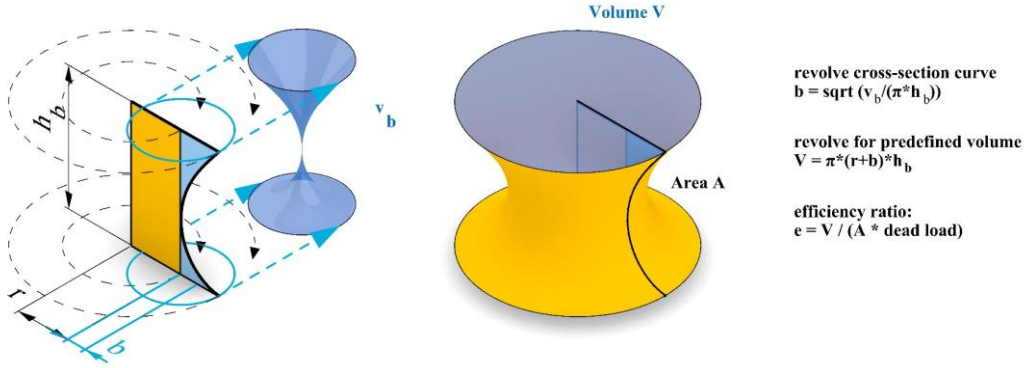

Figure 4. calculation steps of the described 'efficiency ratio'

2.8. Examples

Thrust lines for different input parameters are shown below. The ratio of dead load to hydrostatic pressure is mainly decisive for the shape of the thrust line. For this reason, only load proportions are given here (in %). A length- and height-based reference water pressure of 10 kN/m^2 and a reference dead load of 10 kN/m were assumed (100%). Loads are calculated as line loads, as described in paragraphs 2.1 and 2.2. These values were chosen for presentation in this paper to create a clearly perceptible variance and gain a better understanding of the dependencies. Real conditions for single extrusion walls would be sought near values of 100% water pressure (approx. $9.81kN/m^2$) and 20-30% dead load (approx. 3DCP wall thickness 7-8cm, $22kN/m^3$).

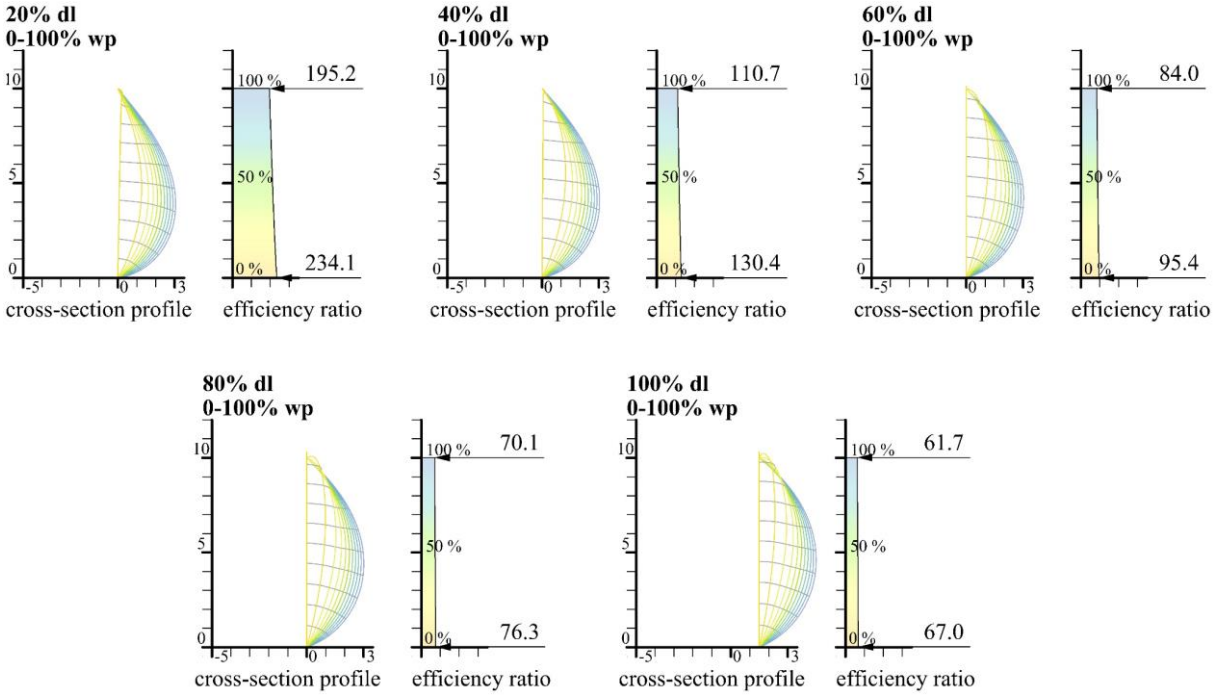

Figure 5. Thrust lines for different dead load factors (dl) with varying water pressure (wp), both ends with pinned supports.

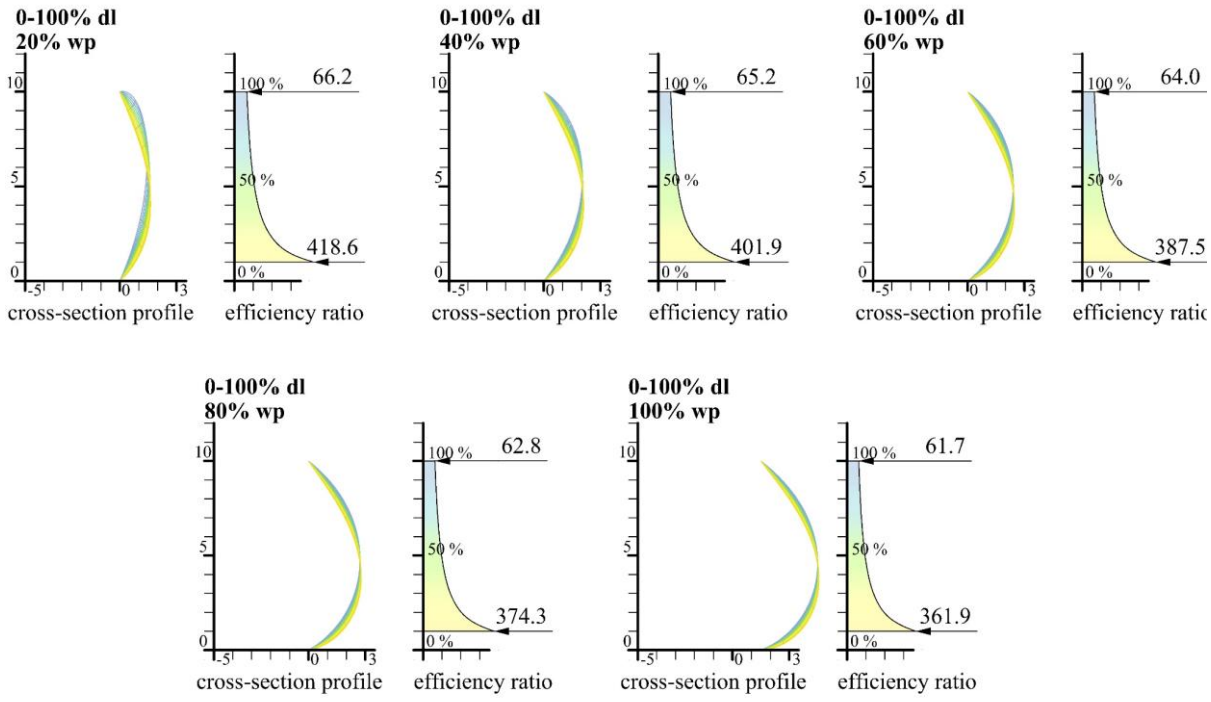

Figure 6. Thrust lines for different water pressure factors (wp) with varying dead load (dl), both ends with pinned supports.

As can be clearly seen in figures 5 and 6, the curvature shifts significantly upward due to a higher dead load. A slight reduction of the curvature can be observed. The efficiency ratio decreases significantly with increasing wall thickness, so the flatter thrust line with a higher mass in the container wall cannot compensate with a correspondingly higher container volume.

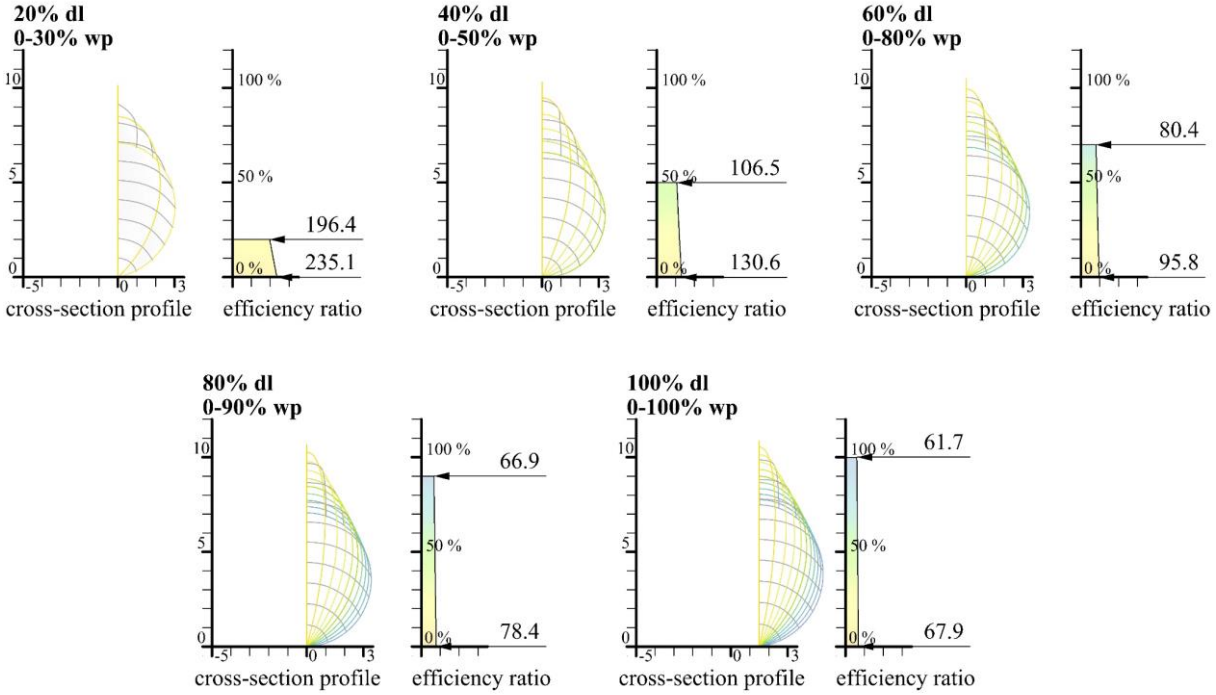

Figure 7. Different dead load factors (dl) with varying water pressure (wp), upper end with vertical roller support

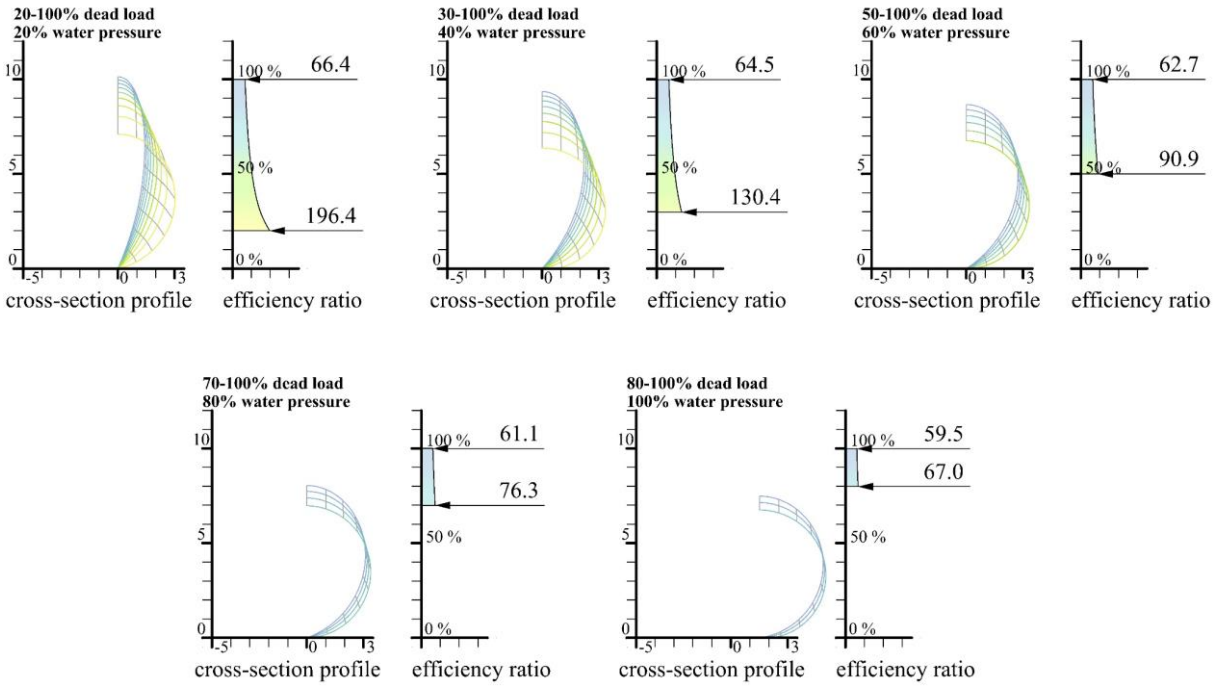

Figure 8. Varying water pressure (wp) with different dead load factors (dl), upper end with vertical roller support

Figures 7 and 8 show various support curves for load combinations with the upper support as a vertical roller support. With this support condition, all acting forces from the container are transferred to the ground through the purely compression-loaded shell without additional support structures. Annular tension forces are only short-circuited at the upper and lower edges of the container via post-tensioning tendons. The analysis shows that a certain dead load must always prevail as a prerequisite for a corresponding water pressure. For lower ratios of dead load to water pressure, no solution is found in the form-finding. This behavior is caused by the translation of the upper support point. It only absorbs vertical forces, so the support curve must always end exactly horizontally in the upper support. The higher the dead load component, the flatter the thrust line, and the higher the position of the upper support point. In this structural system, the efficiency of the container is reduced with increasing dead load (wall thickness). However, this effect becomes significantly smaller with increasing wall thickness.

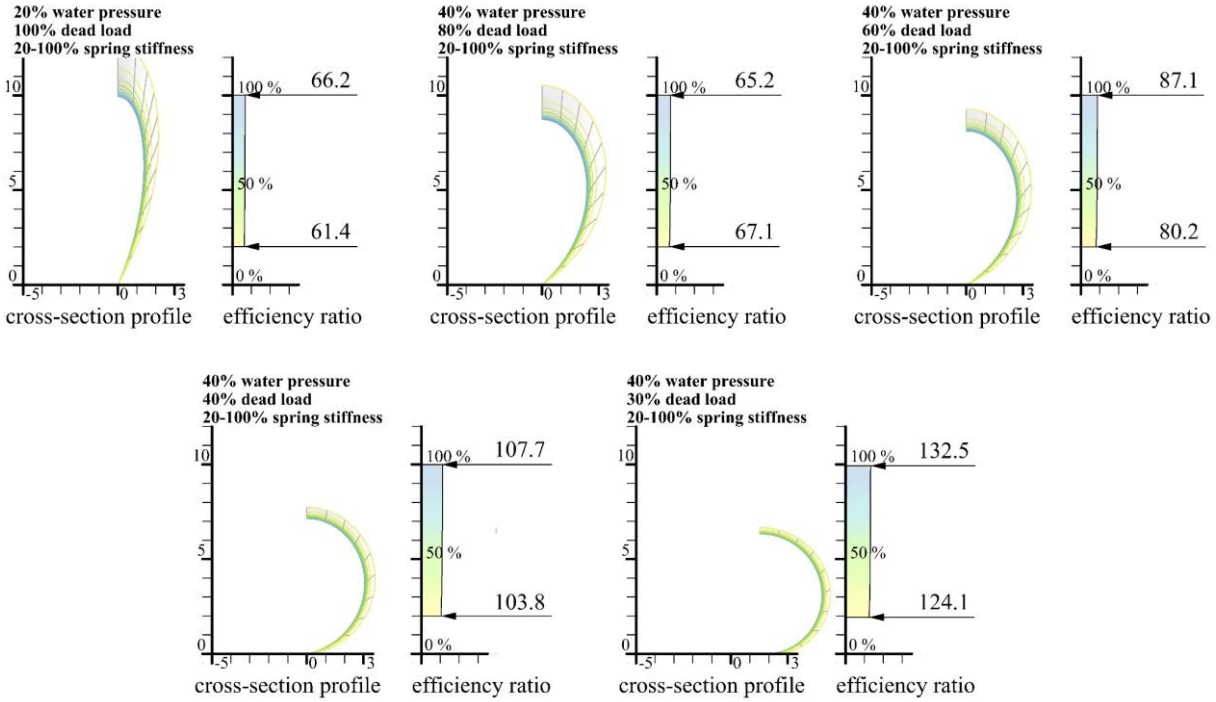

Figure 9. Varying spring stiffness with different dead load factors and water pressure, upper end with vertical roller support

Figure 9 shows the calculated spring stiffness's influence on the thrust line elements. Support conditions are derived from Figures 7 and 8. The stiffness value determines the resulting force density in the shell. The influence on the shape of the support curve and thus on the efficiency is relatively small because of the support conditions. It also decreases with higher load values. With a roller support on the top, the spring stiffness should therefore be selected accordingly high to utilize the load-bearing capacity of the shell as far as possible.

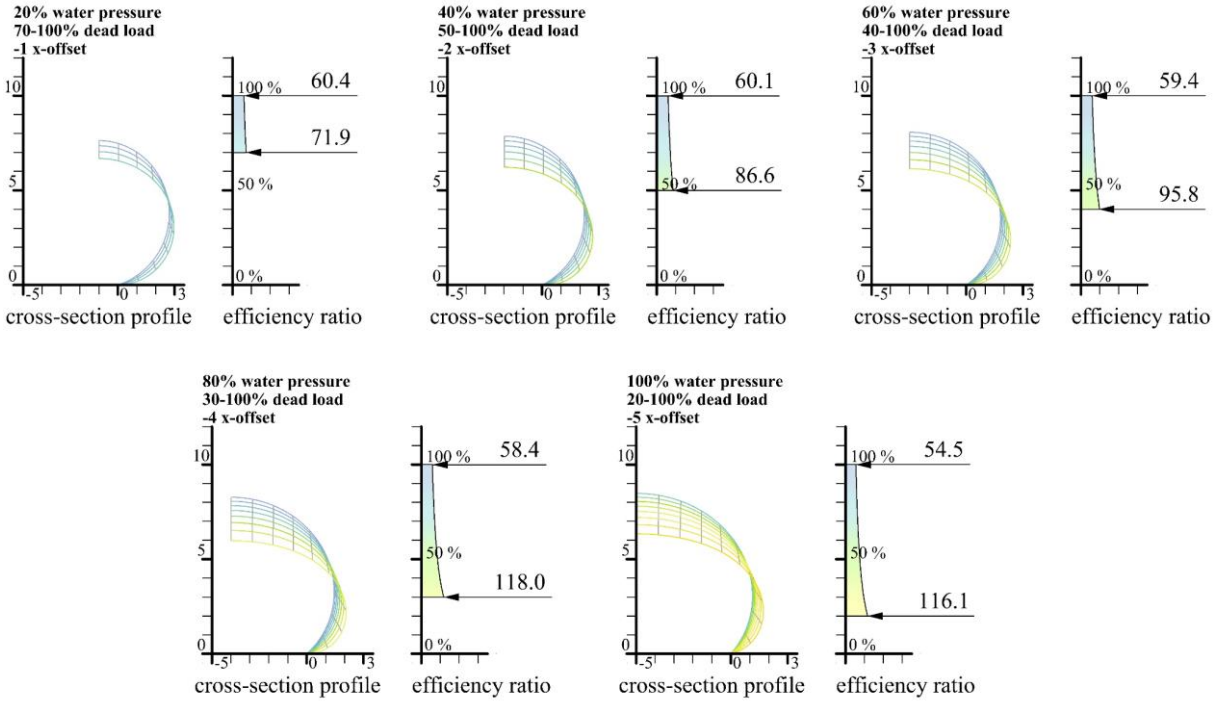

Figure 10. Varying dead load with different water pressure values, upper end with vertical roller support, different offset of upper support points

Figure 10 shows the thrust line with a pinned support at the bottom and a rolled support at the top. Based on historical examples of water tanks, the influence of a horizontal expansion over the height of the tank is examined. An increase in efficiency can be observed up to an opening angle of approx. 40°. A thicker tank wall continues to have a rather negative influence on efficiency.

2. From two-dimensional to three-dimensional space

The transfer of the principles from surface to space is associated with some difficulties. In the following, we briefly present our current state of work.

3.1. Dead load

The dead load in three-dimensional space is calculated by a corresponding discretized ‘thrust surface'. Mesh objects are most suitable; their geometric surface representation is determined by discretization via points (the so-called mesh vertices). To prevent anisotropy in rotationally symmetrical bodies and thus radial deformation in the shell during the form finding, it should be created as a uniform quad mesh, i.e., consisting of partial surfaces each described by four corner points. The problem with discretized meshes, however, is that the exact surface area is not defined by the representation of 3 or 4 surface corner points. There are an infinite number of surfaces that can be formed based on identical corner points. The area of them can always be different. Again, the finer the discretization, the smaller the deviation of the calculation algorithm gets. Our chosen approach determines the surface area with the surface area of the tetrahedron from the four corner points. The dead load is allied to each of the four corner points according to 1/8th of the tetrahedron area. The load direction remains the global Z-direction according to the two-dimensional calculation.

3.2. Hydrostatic pressure

Due to the maximum fine mesh, which is already required for the dead load calculation, the calculation of the 3D dynamic pressure was strongly simplified to save computing time. Our computational

approach is analogous to a homogeneous pressure on the mesh. The area of the mesh faces and the distribution of the force are calculated analogously to the dead load. Pressure values p(h) are calculated by the mesh area a times the area-dependent pressure force g (9.81 kN/m² for water) times the vertical distance to the maximum water level h. A differentiated consideration of the varying pressure within the mesh faces is not considered due to the required fine mesh.

3.3. Tension / Compression only elements, supports

These elements are also represented in three-dimensional space by linear, reticulated spring elements. Therefore, a dimensional adjustment of the used points and vectors is sufficient here. An adjustment of the calculation method is not necessary.

3.4. Examples of three-dimensional form finding for containers

The following shapes are results, or first attempts, at a more sophisticated design of the containers. The aim was to reduce the maximum inclination of the printed wall, as printing angles over 20° can cause layer adhesion problems during the printing process. From the 2D examination, it can be concluded that the primary lever to reduce the slope is the ratio of dead load to hydrostatic pressure. Unfortunately, studies have also shown that an increase in wall thickness is only associated with disproportionate volume gains. In the 3D models, new ways were examined to increase the vertical load component in the shell without increasing the overall wall thickness. These results are only glimpsed and not described in detail, as their investigation has not yet been completed.

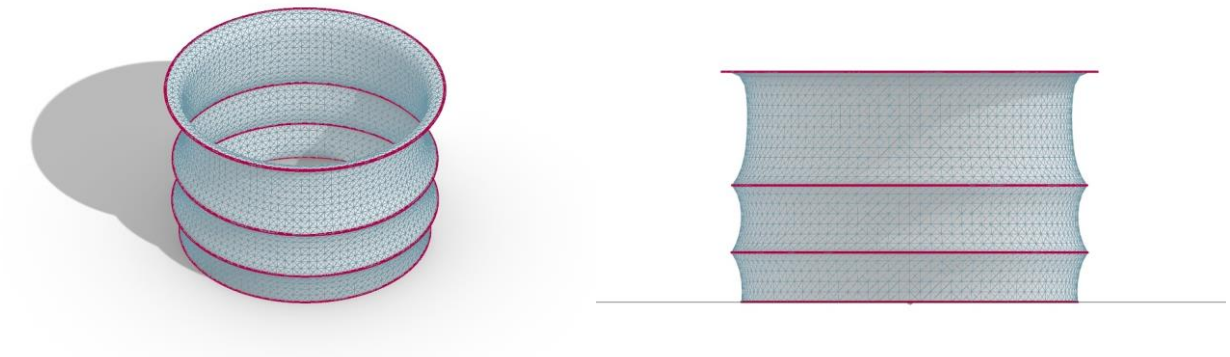

Figure 11. Container with various annular tendons, staggered according to the pressure curve
blue: pressure-loaded concrete shell, red: post-tensioning tendons.

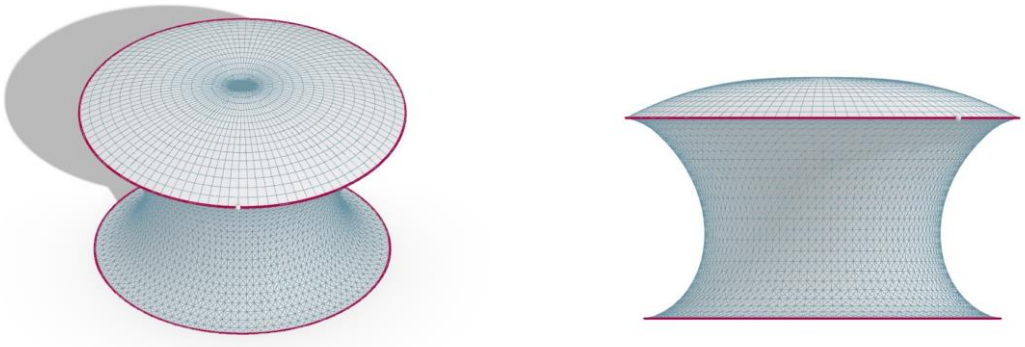

Figure 12. A roof on the container for additional vertical loads
blue: pressure-loaded concrete shell, red: post-tensioning tendons.

4. Conclusion

The implementation of the hydrostatic pressure in the form finding worked out quickly and purposefully with the available tools. The isolated results were always plausible and comprehensible. In combination with dead loads and different support conditions, however, a high level of complexity is quickly generated. By adding just a few components, the behavior of the form can only be predicted with difficulty. Even small variations in the boundary conditions can lead to completely changed results or even the failure of the form finding (no equilibrium state found). Further detailed studies of the relationships are therefore needed. Theoretically, the generated, rotationally symmetric, pressure-only shape can also derive different filling levels in the same cross-section by compensating ring forces. However, these are not directly part of the form-finding. The plausibility of the assumptions should be checked in the next step of the investigations by a complete structural analysis of the structure. The possibility of parallel simulation of different load cases in the form finding would be a helpful extension of the method to further increase the theoretical efficiency.

Abstract

Tensile membrane structures are becoming more popular day by day as more and more designers are opting for membrane structures due to their light weight, high material usage efficiency and their unmatched ability of spanning large areas. The designer has to undertake a methodology known as "form finding" as the form of the structure is unknown beforehand and depends on the given stress conditions and boundary conditions. In essence, the form finding aims to find a configuration of the structure that is in static equilibrium. However, mainstream form finding algorithms suffer from several issues such as selection of initial form, severe computational burden for high dimensional problems, parameter sensitivity, mesh distortion, etc. Hence, the authors propose a new method for form finding of TMS based on the theory of a general curved interface. This theory is conventionally applied to understand the contours of lipid vessels, cell membranes, etc. by solution to the general Laplace equation which is derived from the comparison of the mechanical and thermodynamical approach of describing the phenomena of curved interfaces. The proposed methodology involves the solution of a modified form of this equation by employing a newly developed method in the field of supervised learning known as Physics Informed Neural Network. The proposed meshless method is seen to be independent of dimensionality of the problem as well as the initial shape.

Keywords: tensile membrane structure, form finding, neural network, laplace equation, physics informed neural network, curved interfaces, machine learning

1. Introduction

Tensile membrane structures (TMS) have gained huge traction in recent years for permanent construction of important structural members. Constructed with the help of light-weight fabrics, they can be easily used to cover large areas. Hence, they are primarily used as roofing structures of airports, stadiums, shopping malls, parking spaces, etc. The fabric material employed for constructing TMS is incapable of resisting shear and flexure. The stability of TMS is primarily derived from the membrane action of in-plane prestresses and the anticlastic configuration. The intensity of the applied prestress should be such that the membrane does not face tearing or wrinkling failure. An important advantage of TMS is that they can be prefabricated, thus resulting in higher quality control than conventional structures like RCC, steel or masonry structures. Another advantage of such structures is the architectural freedom that flexible membranes can offer. TMS has been designed to obtain several aesthetically pleasing structures. The main design philosophy of TMS design stems from a procedure known as "form finding." The form of the TMS is not known in advance and is dependent on the

prescribed boundary and stress conditions. During this stage, the TMS is expected to be in stress equilibrium subjected to the prescribed boundary conditions by forming the double-curved anticlastic surface. The overall structural performance of the TMS depends on the form finding algorithm employed. It is expected that the form finding framework will produce optimal structural forms that meet the functional and durability requirements while also being affordable and aesthetically acceptable. [1, 2] provides a list of traditional form finding algorithms along with their criticisms. Some of these drawbacks include computationally costly calculation of stiffness matrix due to inclusion of material properties in stiffness-based methods, constructionally impractical results obtained from Force Density methods, and lack of clarity in choosing optimum hyper-parameters in Dynamic equilibrium based methods. Furthermore, various issues faced by mesh based traditional methods also include mesh distortion and floating meshes and computational burden for high dimensional problems. [2] explored Finite element based and DR based form finding for TMS and found that the obtained results are highly susceptible to convergence issues in case of an incorrect selection of initial shape. Furthermore, there is no unique solution of the mesh topology on the surface for a defined prestress in the mesh dependent methods, resulting in singularity concerns that must also be addressed. Additionally, a group of TMS researchers performed a round robin form finding exercise and observed that the results varied significantly across the different strategies employed and hence, underlined the importance of a method that gave consistent results.

This research proposes a new mesh-free algorithm for TMS form finding. This unique form finding strategy makes use of the theory of a general curved interface that is mostly used in the scientific domains of biophysics and colloidal sciences in conjunction with the 'Physics Informed Neural Network' (PINN) [3], which is an exceptionally convenient yet conceptually straightforward technology in the domain of data-driven solutions of partial differential equations (PDE). In this study, the theory of general curved surfaces and its relation to the form finding of TMS are explored. A more suitable equation specialized towards TMS is derived and this equation is solved using the PINN. The proposed methodology involves the solution of a modified form of this equation by employing a newly developed method in the field of supervised learning known as Physics-Informed Neural Network (PINN). It is seen that, unlike the first PINN-based method developed by the authors for TMS form-finding [2] for minimal TMS, the method proposed here can handle anisotropically prestressed TMS (non-minimal) as well. The proposed meshless method is seen to be independent of the initial shape, mesh distortion, and material properties. Different numerical form-finding case studies are presented to show the validity, accuracy and advantage of the proposed meshless form-finding method.

The rest of the manuscript is organized in the following order. Sec. 2 introduces the theory of a general curved interface and its relation to the form finding of TMS. A brief discussion on the framework of PINN is given in Sec. 3. The proposed methodology of the form finding of TMS is described in Sec. 4 followed by the form finding case studies in the subsequent chapter (Sec. 5). The manuscript ends with some concluding remarks in Sec. 6.

2. Theory of curved interfaces and its relation to form finding

There are two broad ways in which the theoretical and mathematical description of a general curved interface is approached. The first approach comes from a mechanical stand of view arising from the Kirchhoff-Love theory of plates and shells [4]. Although a benchmark in mechanical sciences, this theory is often applied to describe the surface of bio-membranes and lipid bilayers owing to its strong mathematical foundations based on two dimensional continuum mechanics, differential geometry, and tensor analysis. The second approach originates from Gibbs theory of capillarity [5] which is based on thermodynamics and is frequently cited in the domains of physical chemistry and surface sciences. [6] provided a detailed literature review of these two approaches and pondered on the relationship between the two widely different approaches used to describe the same phenomena. They came to the conclusion that the two approaches were actually equivalent and complemented each other and discovered the form of an elegant Generalized Laplace Equation. They suggested that this equation can be used to describe

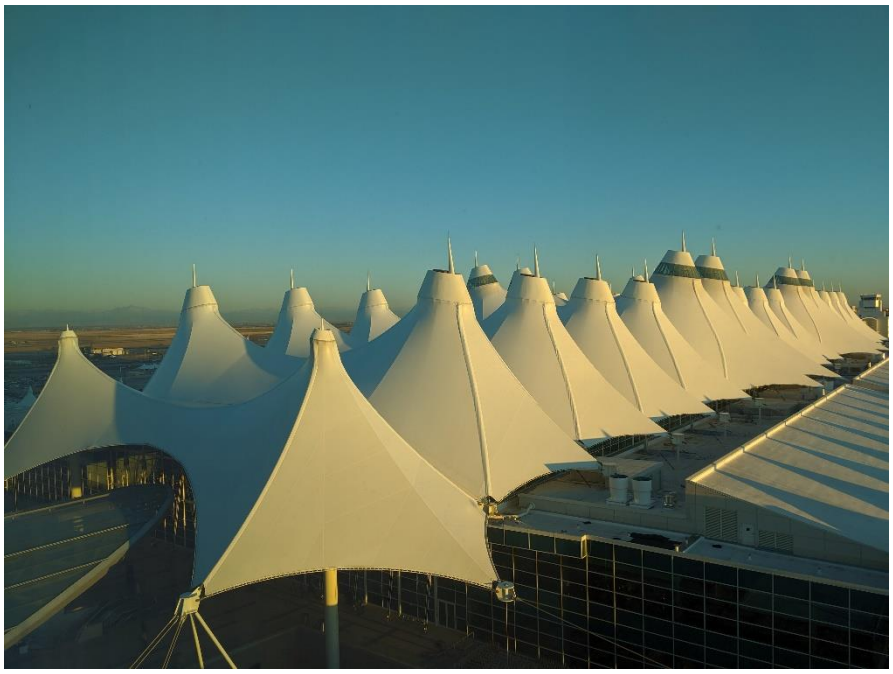

Figure 1. TMS example: Denver International airport [Wikimedia Commons]

the surface of any curved surfaces, thin films or membranes. The Generalized Laplace equation as derived in detail by [6] is given by:

$$2H\sigma + 2D\eta - 0.5\left(a^{\alpha\beta}B + q^{\alpha\beta}\Theta\right)_{\alpha\beta} = P_{II} - P_I \tag{1}$$

where,

$$\begin{aligned} \sigma &= 0.5\left(\sigma_x + \sigma_y\right) \\ \eta &= 0.5\left(\sigma_x - \sigma_y\right) \\ B &= M_1 + M_2 \\ \Theta &= M_1 - M_2 \end{aligned} \tag{2}$$

H and D are mean curvatures and deviatoric curvatures [7] at a point on the surface respectively. P_I, P_{II} are the pressures in the bulk phases. σ_x, σ_y are the eigenvalues of the surface stress tensor. M_I, M_{II} are the eigen values of the surface moment tensor. $a^{\alpha\beta}$ is the surface metric tensor and $q^{\alpha\beta}$ is the deviatoric curvature tensor. It is known that tensile membrane structures cannot resist bending stresses. Therefore, M_I , M_{II} are equal to zero. Hence, $B, \Theta = 0$. Additionally, no external loading is considered during form finding. Therefore, Eq. 1 can be reduced to the form found surface equation of TMS and can be written as:

$$H\sigma + D\eta = 0 \tag{3}$$

Due to the $\pm$ sign in the expression of $D = \pm\sqrt{H^2 - K}$ [7], where, K is the Gaussian curvature, it becomes tricky to solve Eq. 3 directly for form finding purpose. Furthermore, the square root term may also cause different numerical instabilities. Instead of solving Eq. 3 directly, $H\sigma - D\eta$ (analogous to the weight function in Finite element analysis) is multiplied on both sides of the equation and the integral given by Eq. 4 is solved (using Monte Carlo integration with N_f number of collocation points) as:

$$\begin{aligned} &\int_{\Omega}\left(H\sigma+D\eta\right)\left(H\sigma-D\eta\right)=0 \\ &\sum_{i=1}^{N_f}\left[\left(H\sigma\right)^2-\left(H^2-K\right)\eta^2\right]=0 \end{aligned} \tag{4}$$

3. Physics-informed neural network

Physics informed neural networks (PINNs) [3] are a type of neural network architecture that can learn from physics-based constraints. These constraints can be incorporated into the network's architecture as additional terms in the loss function. The general form of the loss function for a PINN is:

$$\mathrm{L}=\frac{1}{N_u}\sum_{i=1}^{N_u}\left|z(x_i)-\tilde{z}(x_i)\right|_2^2+\frac{\lambda}{N_f}\sum_{j=1}^{N_f}\left|f(x_j)\right|_2^2 \tag{5}$$

where N_u and N_f are the number of training points (for boundary/initial conditions) and physics-informed points, respectively. $\tilde{z}(x_i)$ is the predicted solution at the input x_i, and $z(x_i)$ is the true solution at the same point which is typically in the form of boundary constraints. $f(x_j)$ represents the residual of the governing equations at the input x_j, and λ is a hyper-parameter that controls the relative importance of the data (boundary/initial conditions) and physics terms in the loss function. PINNs can be used to solve a variety of physics problems, such as fluid dynamics, solid mechanics, etc. [2,3]. They are particularly useful when analytical solutions are not available or are difficult to obtain, as they can learn to approximate the solution directly from data and physics-based constraints. Overall, PINNs represent a promising approach for combining machine learning and physics-based modeling, and have the potential to revolutionize the way we approach complex physics problems.

4. Proposed approach

The approximate partial differential equation that governs the shape of the form found shape of TMS subjected to a general initial prestress condition is given by Eq. 4. This section introduces a framework for finding the solution of this equation with the help of PINN, thus finding an approximate equation of the form found shape while respecting the given boundary conditions within a low tolerance value. The basic idea of the proposed framework lies in finding the unknown solution, $z(x,y)$ of the Eq. 4 by approximating the solution of the partial differential equation using a neural network, $\tilde{z}(x,y)$. The proposed algorithm for form finding of TMS is elaborately described below:

Step 1: Boundary collocation points, $\left(x_u^i, y_u^i, z^i\right)_{i=1}^{N_u}$ and domain collocation points, $\left(x_f^i, y_f^i\right)_{i=1}^{N_f}$ are generated using Uniform distribution and Latin Hypercube sampling [8] respectively, where the x and y co-ordinates of the boundary collocation points are given by x_u^i and y_u^i respectively and z^i are the corresponding z coordinates which are to be dictated by the prescribed boundary conditions. x and y coordinates of the domain collocation points are represented by x_f^i and y_f^i respectively.

Step 2: The weights (W) and biases(B) of the neural network, $\tilde{z}(x,y)$ are initialized using Xavier Initialization [9]. The input layer of the neural network consists of two neurons and the output layer consists of just one neuron. The vectors of x and y coordinates of the collocation points are fed into the two input neurons which finally yields the vector of the unknown z coordinates of the form found shape.

Step 3: Using auto-differentiation, determine H, D [7] and find f as discussed in Sec. 3. In this case, Eq. 4 is to be approximated by f. To be specific, let's define f as f_{GLE} given by

$$f_{GLE} = \left[(H\sigma)^2 - \left(H^2 - K\right)\eta^2 \right] \tag{6}$$

Step 4: Update W and B of $\tilde{z}(x, y)$ by minimizing the loss function, E (Eq. 7) i.e. the sum of the MSE (Eq. 8) and standard deviation of the squared errors (Eq. 9).

$$E = MSE_u + MSE_f + STD_u + STD_f \tag{7}$$

$$MSE_u = \frac{1}{N_u}\sum_{i=1}^{N_u} \left| \tilde{z}\left(x_u^i, y_u^i\right) - z^i \right|^2 ; MSE_f = \frac{1}{N_f}\sum_{i=1}^{N_f} \left| f\left(x_f^i, y_f^i\right) \right|^2 \tag{8}$$

$$STD_u = \sqrt{\frac{\sum_{i=1}^{N_u} \left(|\, \tilde{z}(x_u^i, y_u^i) - z^i \,|^2 - MSE_u \right)^2}{N_u - 1}} ; STD_f = \sqrt{\frac{\sum_{i=1}^{N_f} \left(|\, f(x_f^i, y_f^i) \,|^2 - MSE_f \right)^2}{N_f - 1}} \tag{9}$$

MSE_u and STD_u are the error functions to be minimized for enforcing the boundary conditions whereas MSE_f and STD_f are minimized for enforcing the physical law defined by Eq. 4. The addition of the standard deviation in the error function improves the accuracy of the final solution [2]. In this study, the L-BFGS-B optimizer [10] is used for the training process as was suggested in [3].

Step 5: Once the convergence criteria of the optimizer is met, the PINN can be used as an approximate explicit analytical equation of the form found shape which can be subsequently used to generate the z coordinate of any given set of the x and y coordinates within the prescribed domain. Therefore, the coordinates of the form found shape of the TMS under the given boundary conditions and the initial stress conditions can be found from the ordered triplet (x, y, z).

5. Numerical study

This particular example deals with a frame supported non-minimal TMS $(\sigma_x \neq \sigma_y)$. The domain of x and y have been taken as [-2.5,2.5] m and [-5,5] m respectively. The height of the high points relative to the lower vertices is taken as 1 m. The boundary collocation points are shown in Fig. 2 (a). The final shape obtained using 2 hidden layers and 20 neurons per hidden layers [2] for $(N_u, N_f) = (30000,120)$ using the proposed PINN framework are shown in Fig. 2 (b) and Fig. 2 (c) for (σ_x, σ_y) = (4,3) kN/m and (2,4) kN/m, respectively. The prediction error at the boundaries are calculated as a percentage of the maximum TMS dimension and are found to be 0.36 % and 0.47 % respectively which signifies that the proposed PINN is able to accurately simulate the prescribed boundary conditions. The unbalanced residual forces calculated as shown in [2] are found to be 9.86×10^{-5} kN and 3.93×10^{-4} kN respectively which shows that the proposed method yields form found TMS that are in static equilibrium (acceptable tolerance 10^{-2} kN [12, 13]). The time required for convergence is 15 seconds on a 16 GB RAM standard work station (GPU is not used in this case).

6. Conclusion

This study explores the applicability of a general form of the Laplace Equation for the form finding exercise. This equation originates from the theory of general curved surfaces which is usually characterized by the mechanical approach and the thermodynamical approach. Based on this theory, an equation for form finding of TMS is proposed. This partial differential equation is solved using a

recently introduced algorithm in the domain of supervised learning known as Physics Informed Neural networks. It is seen that the proposed framework can be used for both isotropic (formulation reduces to [2] in this case i.e. $\sigma_x = \sigma_y$) and anisotropic initial prestress conditions and forms a robust tool for the form finding exercise unlike the PINN based method proposed in [2] which is only applicable for minimal TMS. Furthermore, the proposed framework has all the advantages of PINN-based framework proposed in [2] with respect to conventional mesh-based form finding frameworks like independent of the initial shape (since initial PINN parameters are initialized randomly) and material properties while also being immune to mesh distortion issues (as it is mesh-less). The proposed method does not require any discretization and the boundary can be enforced at discrete point similar to what is done in point collocation methods even for very complex frame-supported TMS. However, this manuscript presents an initial study to test the applicability of this novel mesh-less approach and needs to be tested on a larger variety of TMS case studies in the future. Furthermore, the proposed method is not applicable for cable-supported TMS as the boundary in such cases is not fixed as in frame-supported TMS. So, this PINN based form finding method needs to be explored further so as to increase the applicability to more general cases of TMS.

Abstract

Tensile membrane structures (TMS) are efficient, sustainable, and aesthetically pleasing structures. These structures are made up of a membrane fabric that has negligible bending stiffness. The membrane structures resist external loading due to the stiffness provided by the internal membrane prestress and anticlastic curvature. The initial equilibrium shape of these structures is a function of the initial prestress and boundary conditions and is not known beforehand. This shape has to therefore be found by a process called form-finding. Most mesh based form-finding methods depend significantly on the definition or choice of the initial shape; e.g., the dynamic relaxation method requires an initial starting solution to initialise the form-finding process. Other geometry based approaches such as the recently developed optimisation-based updated weight method, also requires the weights to be defined with respect to an initial reference configuration that gets updated. The choice of the initial shape is therefore crucial as it affects the final solution and overall convergence. This study proposes the choice of the initial solution using a transfinite interpolation function derived from the initial boundary conditions. This approach is applied on both dynamic relaxation and updated weight methods for demonstration. Form-finding solutions using the interpolated initial shapes are compared with the results of those that use simplified starting points, in terms of efficiency and convergence metrics. The comparison is done for both frame and cable-supported TMS.

Keywords: form-finding, transfinite interpolation, optimisation, tensile membranes

1. Introduction

The appeal of tensile membrane structures (TMS) lies in their affordability, minimal weight, eco-friendliness and visually appealing design [1]. TMS comprise of flexible membranes that are supported by cables or rigid frame structural elements. These structures are efficient because of their ability to span large distances with minimal material use. The membrane structure is flexible and resists external loads through the action of the internal in-plane forces and the curvature of the surface. The fabric comprises of orthogonal fibres weaved along the ‘warp’ and ‘weft/fill’ direction. The initial shape of these structures is unknown and must be found through a process known as form-finding. TMS are flexible and take an initial shape depending on the internal prestress and boundary condition. The objective of form-finding is to find the equilibrium shape having the target design prestress distribution. Physical form-finding methods have been mostly replaced by numerical form-finding methods with varying approaches. [2] categorised different form-finding methods into the dynamic equilibrium methods [3], geometric [4] and stiffness-based methods [5]. A recent optimisation-based approach, the updated weight method was also developed for the form-finding of both frame and cable supported TMS

[6]. Because form-finding methods, such as the dynamic relaxation method, are highly nonlinear, an initial solution is required as a starting point. In the updated weight method, an initial reference configuration is required to define the weights. The choice of the initial shape is usually assumed at the mid-height or a as planar configuration. However, this initial solution can influence the overall convergence and final solution.

In this study, a transfinite interpolated function is used to find the initial shape for a predefined boundary condition. The interpolation function is constructed with respect to the values imposed at the boundary points. This initial shape is used for popular form-finding methods such as the dynamic relaxation method (DR) [3] and the updated weight method (UWM). Different numerical case studies using the proposed approach are preformed and compared with the standard initial shapes to show the overall advantage of the proposed formulation.

The paper is organised as follows. Sec. 2 gives an introduction to the dynamic relaxation method and the updated weight method. The theory of the adopted transfinite interpolation and its implementation in form-finding is detailed in Sec. 3. Numerical studies are then presented in Sec. 4. Final concluding remarks are given in Sec. 5.

2. Form-finding techniques

2.1. Background

In form-finding, the membrane continuum is discretised into finite elements. The use of constant strain triangle elements (CST) is a popular choice to discretise the membrane domain [7]. Another popular method is to represent each triangular membrane element by pseudo-cable elements having side length L_j for each j th side (j=1, 2, 3). The membrane thickness is included in the membrane prestress (which is expressed in kN/m). In the pseudo-cable representation of the membrane element, the natural side force vector $\mathbf{t}$ force due to the internal stresses, along each element side t_j is given as

$$\mathbf{t} = AL^{-1}\mathbf{G}^{\mathrm{T}}\boldsymbol{\Phi}^{-1}\boldsymbol{\sigma} \tag{1}$$

where A is the area of the element, $L = diag\left(L_1, L_2, L_3\right)$, $\boldsymbol{\sigma} = \begin{bmatrix} \sigma_w & \sigma_f & 0 \end{bmatrix}^T$ is the target stress along the warp and fill directions. The transformation matrix $\boldsymbol{\Phi}^{-1}$, rotates the initial prestress from the material fibre (defined globally with respect to the fabric properties) to the local basis direction (defined locally for an element). The matrix $\mathbf{G}$ transforms the stresses defined in the local basis to the natural stress vectors along the triangular element side lengths [1, 8].

Cable elements are discretised by line elements having length l with n denoting the target internal cable force.

2.1. Dynamic relaxation method

In the dynamic relaxation method (DR) [3, 8]**,** a pseudo dynamic problem having fictitious mass and damping properties is considered. The method is based on the principle that any system subjected to an out-of-balance force will only come to rest when it is in equilibrium. The out of balance forces, due to the member forces, causes this lumped mass system to oscillate about an equilibrium position. The oscillations reduce to an equilibrium state under the action of damping or by monitoring the kinetic energy. The equation of motion of an unconstrained node m at time t is [3]

$$\mathbf{R}_m^t = \mathbf{M}_m^t \ddot{\mathbf{u}}_m^t \tag{2}$$

where $\mathbf{R}_m^t$ is the residual force at node m at time t in all the components, $\mathbf{M}_m^t$ is the assumed nodal lumped mass and $\ddot{\mathbf{u}}_m^t$ is the acceleration at the node at time t. Using a central difference form for $\ddot{\mathbf{u}}_m^t$, Equation (2) then become

$$\dot{\mathbf{u}}_m^{t+\Delta t/2} = \dot{\mathbf{u}}_m^{t-\Delta t/2} + \frac{\Delta t}{M_m}\mathbf{R}_m^t \tag{3}$$

where $\dot{\mathbf{u}}_m^{t+\Delta t/2}$ and $\dot{\mathbf{u}}_m^{t-\Delta t/2}$ are the velocities at different time increments. $\mathbf{R}_m^t$ is the residual force due to internal prestress force at $\mathbf{x}_m^t$, and a single mass M_m is taken for all components at node m. The geometry is updated in the next time increment using the following equation

$$\mathbf{x}_m^{t+\Delta t} = \mathbf{x}_m^t + \Delta t\, \dot{\mathbf{u}}_m^{t+\Delta t/2} \tag{4}$$

The residual $\mathbf{R}_m^t$ at a time increment t is found from the summation of the residual forces due to the natural side forces $\mathbf{t}$ and cable forces n, due to the target prestress and cable forces at the current configuration. M_m is taken as the maximum of the mass components at the node.

$$M_m^t = \max\left(\mathbf{M}_m\right) = \max([M_{mx}\ M_{my}\ M_{mz}]) \tag{5}$$

where the mass M_{mx} of node m in component direction x is found according to [8]. Kinematic damping is used to dampen the oscillation motion towards an equilibrium state by monitoring the value of the kinetic energy of the whole system. At each peak in the kinetic energy, the process is restarted, while maintaining the current nodal positions and setting the initial velocity and kinetic energy equal to zero.

2.2. Updated weight method

In UWM, the weighted function of the geometric shape is minimised. The objective function for UWM is defined as

$$f_{UW} = \sum_{i=1}^{N_m}\sum_{j=1}^{3} W_i^{\,j}\left(L_i^j\right)^2 + \sum_{i=1}^{N_c} w_i (l_i)^2 \tag{6}$$

where L_i^j and $W_i^{\,j}$ are the side length and corresponding weight of the j th side for the i th membrane element, w_i and l_i define the cable weight and length respectively for the i th cable element. The weights are found with respect to a reference configuration $\mathbf{x}_{ref}$ as

$$W_i^{\,j} = \frac{t_i^j}{2\left(L_i^j\right)_{ref}} \quad \text{and} \quad w_i = \frac{n_i}{2(l_i)_{ref}} \tag{7}$$

where $\left(L_i^j\right)_{ref}$ and $\left(l\right)_{ref}$ are the pseudo-cable length of the membrane and cable length respectively in $\mathbf{x}_{ref}$. This reference configuration is initially taken as a flat planar configuration. The form found shape for a particular set of weights is given by the given standard optimisation formulation given as

$$\mathbf{x}^* = \min\ f_{UW} \tag{8}$$

The equilibrium solution after solving each optimisation step is used as the next reference configuration $(\mathbf{x}_{ref} = \mathbf{x}^*)$. The corresponding weights are recalculated, and the optimisation process is repeated until convergence. The detailed implementation and algorithm of UWM is given in [6].

3. Implementation of transfinite initial shape

3.1. Transfinite interpolation

TMS are usually either frame or cable supported. Frame supports comprise of linear line elements that are rigid. In cable-supported TMS, the boundary edge of the membrane is supported by cables that are fixed at boundary points. The transfinite interpolation in this study makes the use of approximate distance functions defined with respect to any boundary element [9]. In this section, the distance functions for the line segment and boundary point are given.

Line segment: The approximate distance function $p(\mathbf{x})$ at any point $\mathbf{x}$ with respect to any line segment joining any two points $\mathbf{x}_1 = (x_1, y_1)$ and $\mathbf{x}_2 = (x_2, y_2)$, having a length, $L_R = \sqrt{(\mathbf{x}_2 - \mathbf{x}_1)^{\mathrm{T}} \cdot ? \mathbf{x}_2 - \mathbf{x}_1)}$ is given as

$$p(\mathbf{x}) = p(x, y) = \sqrt{b^2 + \frac{(a-c)^2}{4}} \tag{9}$$

where the parameters a, b and c are given as follows:

$$\begin{aligned} a &= \sqrt{b^2 + c^4}; \\ b &= \frac{1}{L_R}\left[\left(\frac{L_R}{2}\right)^2 - \sqrt{(\mathbf{x} - \mathbf{x}_m)^T . (\mathbf{x} - \mathbf{x}_m)}^2\right]; \\ c &= \frac{(x - x_1)(y_2 - y_1) - (y - y_1)(x_2 - x_1)}{L_R} \end{aligned} \tag{10}$$

where the mid-point of the line segment is defined as $\mathbf{x}_m = \frac{\mathbf{x}_1 + \mathbf{x}_2}{2}$.

Boundary points: The function $p(\mathbf{x})$ at any point $\mathbf{x}$ with respect to any boundary point $\mathbf{x} = (x_p, y_p)$ is given as

$$p(\mathbf{x}) = p(x, y) = \sqrt{(x - x_p)^2 + (y - y_p)^2} \tag{11}$$

3.2. Initial shape implementation

In DR, the standard initial starting solution is usually taken at the mid-height. as the starting solution. In the case of UWM, a flat configuration is used to as the initial reference configuration. In this study,

however, we use the transfinite interpolant function to interpolate the initial shape for DR and the reference configuration for UWM. The interpolated initial shape is defined as

$$N(\mathbf{x}) = N(x, y) = \sum_{i=1}^{N_{BC}} N_i^W(\mathbf{x}) z_i(\mathbf{x}) \tag{12}$$

where $z_i(\mathbf{x})$ is the value of the imposed boundary. The interpolating weights $N_i^W(\mathbf{x})$ is given as

$$N_i^W(\mathbf{x}) = \frac{p_i^{-1}}{\left(\sum_{j=1}^{N_{BC}} p_j^{-1}\right)} \tag{13}$$

for all N_{BC} number of boundary elements. The initial solution satisfies the imposed boundary condition. In both DR and UWM, a meshed domain is defined and the z co-ordinate of all the nodes of the mesh is found using Equation (12) and used as the initial shape.

4. Numerical study

In this section, a numerical study of the use of the transfinite interpolation is done for both DR and UWM. The case studies consist of both a frame and cable supported hypar having a width and breath of 6 m, with the maximum height at 2 m. An isotropic desired prestress of 3 kN/m and cable force of 30 kN (in the cable supported example) is taken. In both the studies a comparison of the solutions by using the conventional and transfinite interpolated shape are shown. DR converges when the maximum absolute residual force is less than 10^{-3} kN with a time step of t=1 s and the mass calculated according to Sec. 2.1. In UWM the weight update converges when the maximum standard deviation of the equilibrium stress is less than 10^{-2} kN/m. The numerical problems are implemented in *MATLAB* on a Windows 11 system.

4.1. Frame-supported hypar

A frame supported hypar is taken with all the boundary edges fixed (Figure (1)). The standard initial starting solution for DR is shown in Figure (1a), while the initial reference solution for UWM is shown in Figure (1b). The transfinite initial starting point using Equation (12) is shown in Figure (1c). It can be seen from Figure (2a), that the mesh is highly distorted in the final form-found shapes using DR using the standard initial shape. Using the transfinite initial shape, however leads to a much more uniform looking mesh (Figure (2b)). This is helpful especially in a method such as DR where mesh distortion can occur and the solution convergence can get stuck. The form-found shapes for UWM, between the transfinite and standard approach are however very similar (Figure (3a) and (3b)). This is because of the fact that in UWM, a planar initial reference configuration allows for a homogeneous distribution of initial weights, resulting in a well distributed mesh in the equilibrium configuration. The stress distribution (along the 'warp' and 'fill') on the equilibrium shape for UWM after the first weight update is shown in Figure (4) for both the cases. The median is shown by the horizontal line, with the top and bottom box edges representing the 75th and 25th percentile values respectively. The whiskers represent the maximum and minimum values. It can be seen that the stress distribution after the first weight update is relatively slightly better in the transfinite interpolated case. The number of iterations for convergence for both DR and UWM is shown in Table 1. It can be seen that the number of iterations is significantly reduced for the case of DR.

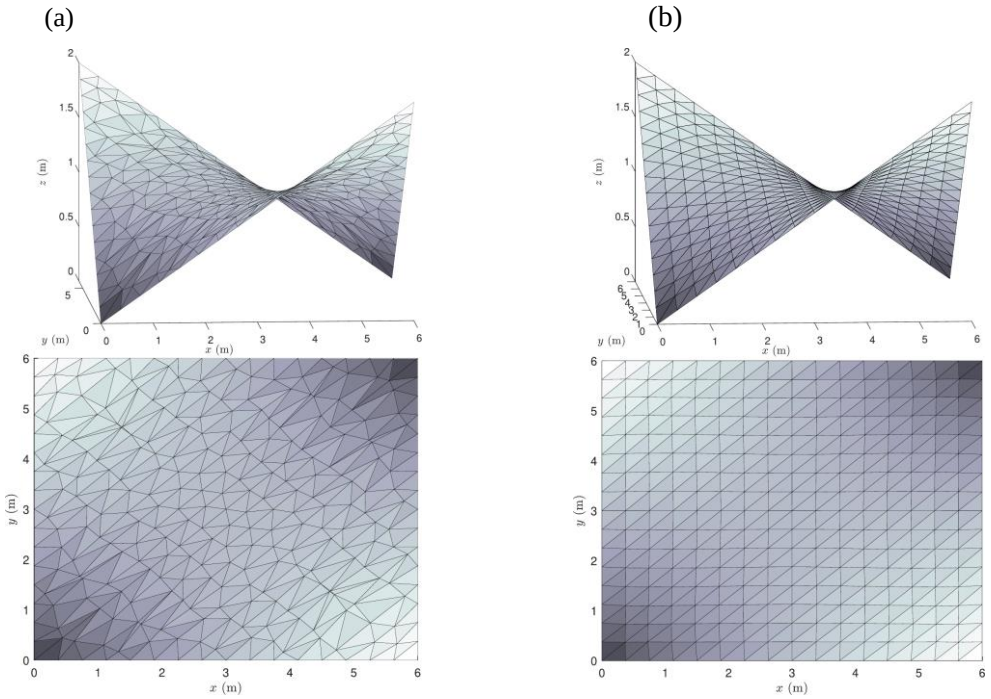

Figure 2. Form-found shape for DR for (a) Standard (b) Transfinite interpolated initial shape for frame supported hypar

Table 1. Number of iterations for convergence

	DR		UWM	
	Transfinite	Standard	Transfinite	Standard
Frame-supported	25	232	2	2
Cable-supported	394	431	4	5

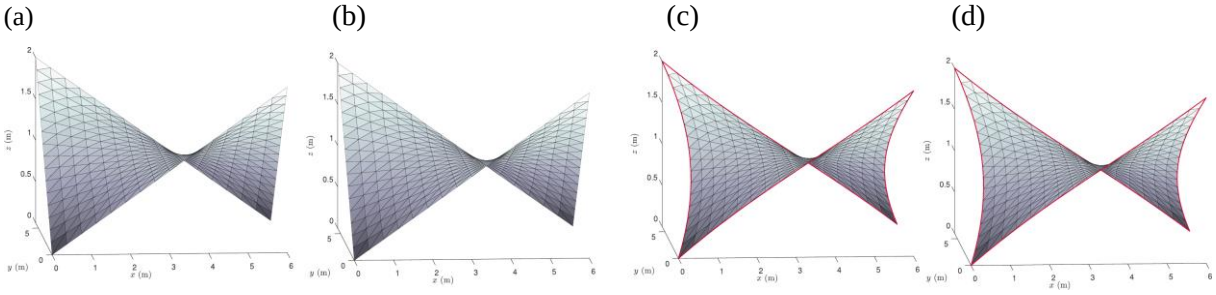

Figure 3. Form-found shape for UWM for frame supported using (a) Standard (b) Transfinite interpolated initial shape; for cable supported using (c) Standard (d) Transfinite interpolated initial shape

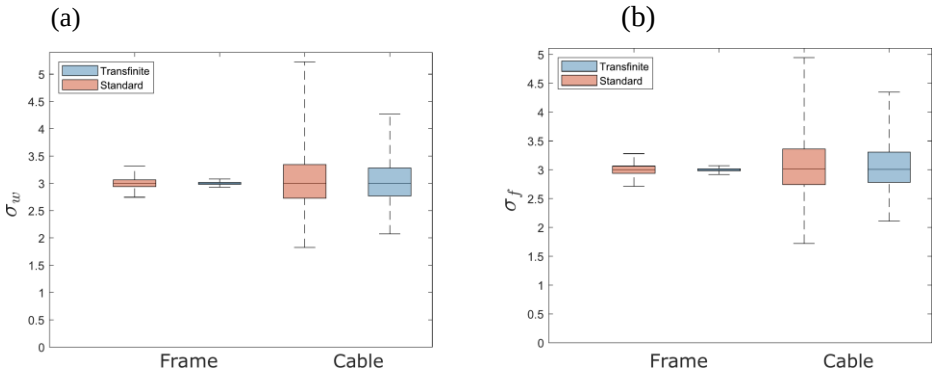

Figure 4. Stress distribution after first UWM weight update iteration for (a) σ_w (b) σ_f

4.1. Cable-supported hypar

The cable-supported hypar is shown in Figure (5) with the boundary cables fixed at four boundary points at the vertices. Figures (5a) and (5b) show the standard initial shape for DR and UWM respectively. Figure (5c) shows the transfinite interpolated shape generated by using the four boundary points in the distance function in Equation (12). In the case of DR, it is seen from Figures (6a) and (6b), that an improvement in mesh distribution is seen for the transfinite interpolated case. Similarly, to the previous section, there is no significant improvement for the form-found shapes using UWM as the final mesh in the standard solution is already well distributed (Figures (3c) and (3d)). However, it can be seen from Figure (4) that the stress distribution after the first weight update is significantly better for the transfinite interpolated case. At the first weight update iteration, the maximum standard deviation in the stress distribution in the standard case is 0.56 kN/m and 0.45 kN/m for the transfinite case. Table 1 shows that the number of iterations is reduced in the transfinite interpolated case for both DR and UWM.

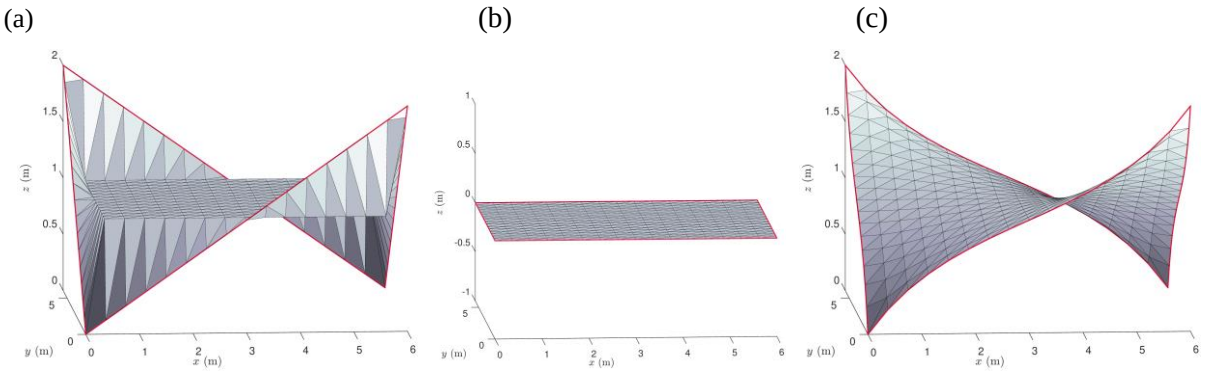

Figure 5. (a) Initial solution shape for DR; (b) Initial reference shape UWM; (c) Transfinite interpolated initial shape

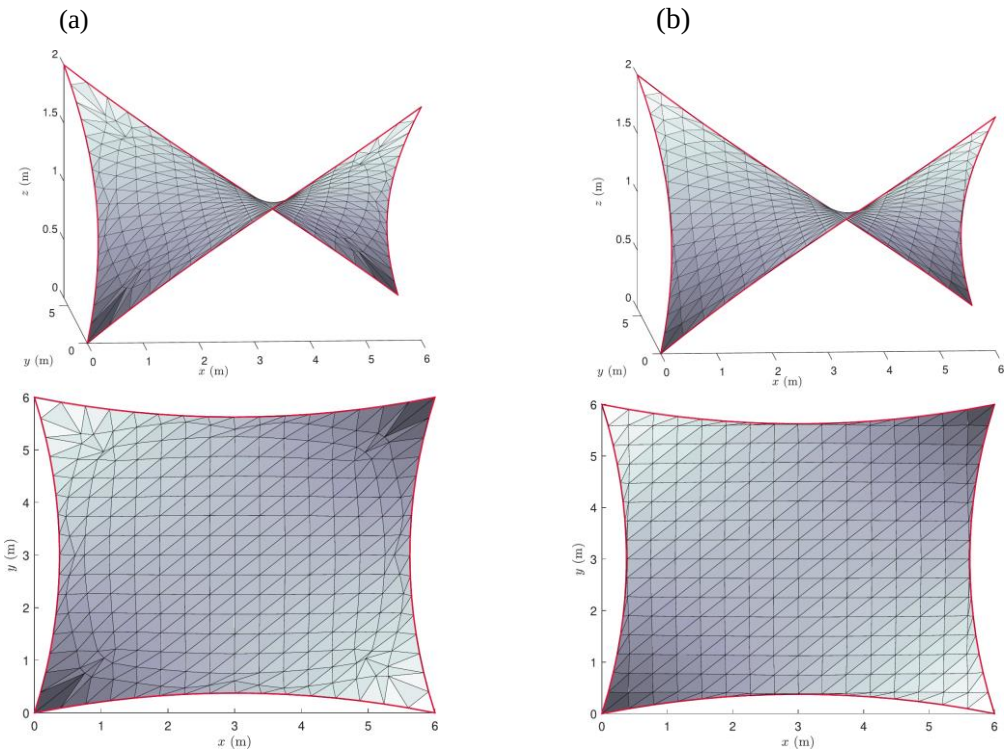

Figure 6. Form-found shape for DR for (a) Standard (b) Transfinite interpolated initial shape for cable supported hypar

5. Conclusion

The success of the form-finding process depends on the form-finding method employed and various hyper parameters. One such step is in defining the initial starting solution. In this study, the initial shape is found using the transfinite interpolation. The function can be constructed with respect to defined boundary line segments and points. The initial shape is used as the starting solution in DR and the initial reference configuration in UWM. It is seen that the proposed approach is advantageous and brings improvements in mesh uniformity, convergence and stress distribution. The method is highly effective for DR where the mesh in the final solution is highly improved along with a reduction in the total number

of iterations. Overall, the proposed method is expected to provide a more robust initial shape selection for different form-finding methods.

Abstract:

This paper presents a robust form-finding method by implementing algebraic polyhedral graphic statics to generate compression-tension combined beam structure. Compared to iterative graphic statics modeling, the advanced algebraic method can define the inputs and constraints of complex geometries rapidly and precisely. The previous development of the undulating beam system relies on manipulating the Geometric Degree of Freedom (GDoF). The transforming process of GDoF is only operated in form diagram, same force diagram is utilized for finalizing the design with the combination of both form modules. Indeed, investigating these steps from the procedural implementation is not an evident process. In contrast, applying the algebraic method will provide a clearer direction for the user to modify the initial design parameter without extra manual adjustment easily. Moreover, different from the existing algebraic method that needs non-intersected planar surfaces as the potential input to construct the cells, the proposed method is to convert intersected geometries to convex polyhedrons that share the same planar surface as the input. The cells will be flipped by changing the force diagram's normal direction. The presented approach allows for a comprehensive understanding of equilibrium and constraint requirements in form and force diagrams.

Keywords: form-finding, graphic statics, beam design, algebraic 3D graphic statics

1. Introduction

The pursuit of efficient and innovative structural designs has driven the development and exploration of a wide range of form-finding methods. Graphic statics, a well-established technique, has consistently proven invaluable for designers and engineers over a hundred years [1–3], offering a clear understanding of the relationship between form and forces. The visual and intuitive nature of graphic statics has made it particularly effective for analyzing planar systems.

As an extension of the conventional graphic statics method, 3D Graphic Statics (3DGS) explored the possibilities of designing complex spatial structures. The method allows for the simultaneous analysis of multiple forces acting on the structure, making it easier to consider different loading scenarios and optimize the design accordingly [4, 5]. By understanding the force distribution and equilibrium within the structure, designers can optimize the structural members for material efficiency, minimize weight, and maximize structural performance.

The majority of 3DGS implementations depend on procedural techniques [6] or iterative algorithms that use local node operations [7, 8]. Procedural methods can be time-consuming and difficult to generalize across various inputs, while iterative algorithms based on node operations provide a unified solver,

controlling edge lengths, vertex locations, and face areas under a single framework. However, these algorithms require an input angle tolerance for terminating iterations, leading to some deviation in the output and longer runtimes for more complex geometries. Furthermore, they cannot construct reciprocal diagrams for non-convex polyhedrons representing combined tension-compression systems, limiting the solution space exploration.

On the other hand, algebraic formulations of reciprocal diagrams offer an alternative perspective for implementing polyhedron-based 3DGS. These formulations provide more robust and faster numerical processes than existing methods, enabling greater flexibility, reduced computation time, and higher accuracy when manipulating reciprocal diagrams.

1.1. Related work

1.1.1. Computational implementations of 3DGS

Integrating computational methods and digital tools has expanded the scope and potential of polyhedral graphic statics, enabling more efficient analysis and optimization of three-dimensional structures. The properties of polyhedral forms can be combined with various fabrication techniques, such as 3D printing and origami, to create spatial frame systems with diverse design features [9–11]. Moreover, polyhedron-based 3D Graphic Statics can produce cellular solids featuring unique micro-architectures. Current studies demonstrate that subdividing force diagrams by subdivision can change these structures into highly efficient, low-density shellular funicular configurations [12]. These studies illustrate the versatility and effectiveness of polyhedral graphic statics in addressing the challenges of contemporary structural design.

1.1.2. Algebraic graphic statics

Alongside the traditional graphical approach in 2D graphic statics, researchers have explored incorporating algebraic methods, which streamline the analysis and design process for two-dimensional structures by formulating and solving equilibrium equations. Micheletti [13] introduced the concept of algebraic duality in reciprocal diagrams of self-stressed frameworks, which was then termed algebraic graphic statics by Van Mele and Block [14]. This tool calculates internal force distribution using connected lines as input and derives edge lengths by ensuring the 2D closeness of polygons. This method allows for obtaining internal and external force magnitudes. Alic and Å kesson [15] later extended this to a bi-directional approach, enabling manipulation of both force and form diagrams and updating reciprocal diagrams instantly, making it an effective interactive form-finding tool in 2D.

1.1.3. Algebraic 3D graphic statics

Building upon the principles of graphic statics, the methodology has been developed to incorporate three-dimensional systems, leading to the establishment of algebraic 3D graphic statics. Hablicsek et al. [16] developed an algebraic framework for 3D Graphic Statics, where reciprocal polyhedral diagrams are represented by a linear system of equations ensuring planar closeness of polyhedron faces. This method computes dual diagrams with high accuracy and allows for user input to control edge lengths, offering flexibility in exploring the solution space [17]. However, it lacks precise control over vertex location and edge lengths. Akbarzadeh and Hablicsek [18] proposed a quadratic formulation that can handle assigned area and edge lengths, enabling manipulation of force diagrams with desired face areas and exploration of various equilibrium states.

1.2. Problem statement and objectives

As previously discussed, 3DGS has demonstrated significant potential for diverse applications across various materialization strategies. However, current implementations have yet to take full advantage of the capabilities that 3DGS has to offer. For instance, the iterative method is limited to compressive

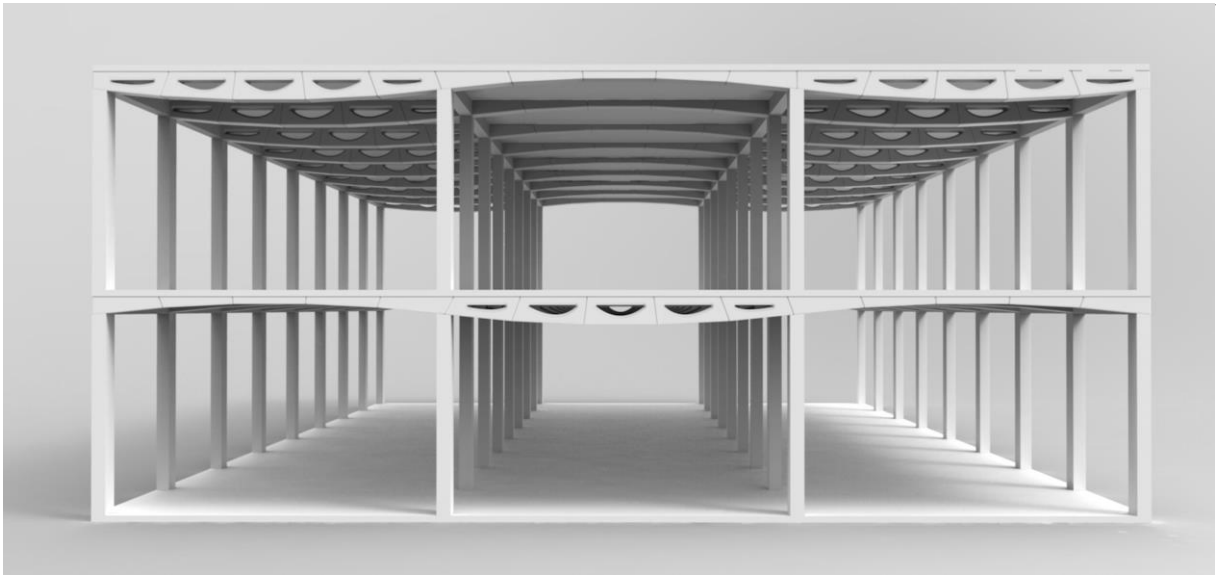

Figure 1. Undulating beam structure with potential porous materialization for all the modules.

form finding, which is usually utilized for the compression-dominant structure and is computationally demanding for intricate geometries.

While the algebraic formulation of 3DGS allows for a comprehensive exploration of the solution space, it needs to have the same precision in controlling edge lengths in reciprocal diagrams that the iterative method provides. This is a crucial aspect that needs to be addressed to maximize the potential of 3DGS for practical applications.

The other challenging part of the method is to develop an efficient and robust way for form-finding to further determine an updated force diagram and generate a corresponding form diagram that satisfies these constraints. This process should apply to a wide range of complex three-dimensional structures, facilitating the analysis and optimization of form and forces in spatial systems. To address the problem stated above, the following objectives have been identified:

- Check the property of the geometric relationships that define the force groups, including global, compression, and tension.
- Develop an algorithm that uses algebraic edge constraints to update the force diagram and generate a corresponding form diagram that adheres to these constraints.
- Demonstrate the effectiveness and versatility of the proposed method through the case study of an undulating beam structure that represents the compression and tension combined loading scenarios.

To tackle these issues, this paper aims to present an enhanced algebraic formulation of 3DGS that incorporates edge constraints. This advanced formulation offers precise control over edge lengths without compromising the inherent advantages of flexibility and accuracy. A more detailed explanation of vertex constraint can be found in the research of Lu et al. [19].

2. Methodology

In this section, we present the methodology of algebraic 3DGS, specifically focusing on the utilization of edge constraints to design structures that incorporate both compression and tension nodal groups. As the continuation study of the previous research [20], we will demonstrate the design process through the

example of the same repeatable undulating beam structure shown in Figure 1.

In 3DGS, polyhedral reciprocal diagrams play a crucial role in representing both form and force diagrams. These diagrams feature a well-defined topological and geometrical hierarchy, including vertices (v), edges (e), faces (f), and cells (c). The unique arrangement within these diagrams ensures that each edge shares a common vertex with its adjacent edges. The edges and faces in reciprocal diagrams exhibit specific directions, which are essential for maintaining the structural integrity of the diagrams. The right-hand rule is applied to achieve consistency, guiding the alignment of face normals and edge directions [16]. This rule ensures that face orientations remain consistent within each cell and maintain cell orientations throughout the diagram. As a result of this structure, neighboring faces in the reciprocal diagrams share two versions of the same edge but with opposing directions. Similarly, adjacent cells exhibit two versions of an identical face, each with contrasting normal directions. This detailed arrangement showcases the intricacies of the polyhedral reciprocal diagrams in 3DGS and their significance in both form and force representation.

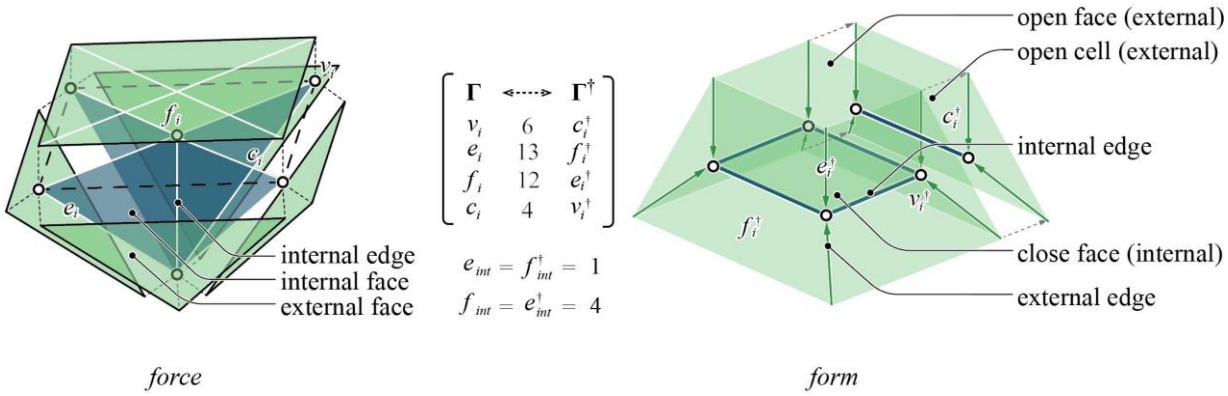

Figure 2. Left: force diagram; Right: form diagram.

A four-applied loads example is illustrated to show the topological relationship between polyhedral diagrams (Figure 2). The starting diagram or the first input is called *primal*, Γ, which can either be a form diagram or a force diagram and the reciprocal diagram is called *dual*, $\Gamma^\dagger$. The ones of the dual are identified as a dagger symbol (†). In general, both two diagrams share a reciprocal relationship, with the primal diagram's elements—vertices v, edges e, faces f, and cells c—mapping to the corresponding elements in the dual diagram—cells ($c^\dagger$), faces ($f^\dagger$), edges ($e^\dagger$), and vertices ($v^\dagger$). This reciprocity leads to an equal number of dual elements in both diagrams, such as the primal's edges (e) matching the dual's faces ($f^\dagger$) and the primal's vertices (v) matching the dual's cells ($c^\dagger$). Additionally, adjacency is preserved between the corresponding elements in both diagrams and each edge (e_i) in the primal is perpendicular to its corresponding face ($f_i^\dagger$) in the dual.

The force diagram's external faces correspond to the external edges in the form diagram that represent applied loads and reaction forces, typically depicted in green. While all elements in the force diagram are closed, the form diagram contains open elements. External edges in the form diagram have vertices at only one end, making them open-ended, and any faces or cells with open edges are also considered open. In contrast, closed faces in the form diagram are deemed internal and correspond to the force diagram's internal edges.

2.1. Analysis of form and force diagrams

The previous IASS paper presented an initial form generated using 2D graphic statics, which was then manipulated geometrically to increase design freedom for constructing updated modules. Detailed force distribution was also utilized to locate the column when merging the two units together. Figure 3 shows the extruded version of single force diagram connecting two modules that are generated from GDoF. The applied loads are evenly distributed at the top, and the supports are illustrated to identify the merging locations.

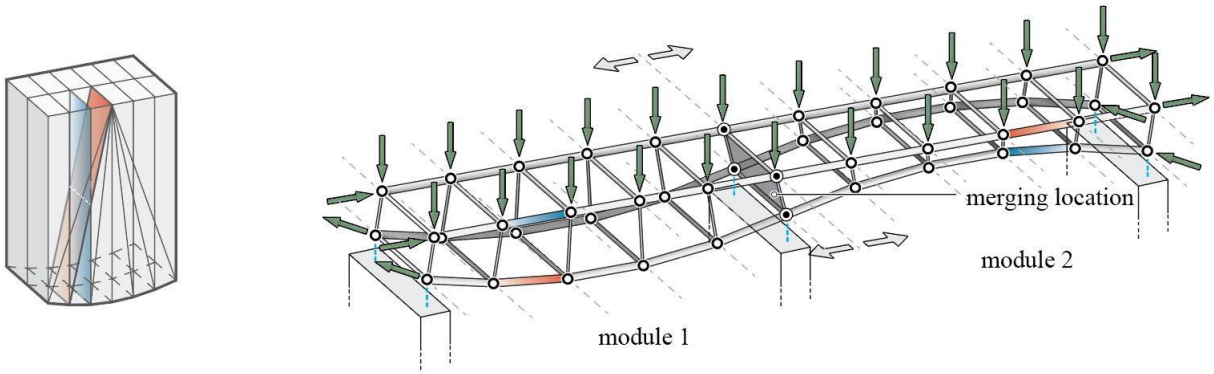

Figure 3. Left: single force diagram of two modules combined; Right: its corresponding form diagram shows the undulation of the geometry and the merging location.

Considering the current limitations of the algebraic graphic statics method, which does not allow intersected faces as input parameters, it is essential to analyze the geometric relationship of the initial force diagram. This analysis enables designers to gain a deeper understanding of structural behavior, paving the way for the development of improved methods and approaches that address these limitations. The key idea focuses on transforming intersected cells into non-intersected convex cells. Investigating this transformation process can help uncover potential strategies to overcome the existing constraints. Importantly, the geometric data is contained within the individual elements. The original relationship is preserved as long as the geometry remains unaltered by adding or subtracting faces, allowing for the free manipulation of moving locations. This approach offers a promising avenue for enhancing the applicability and effectiveness in solving complex geometric problems.

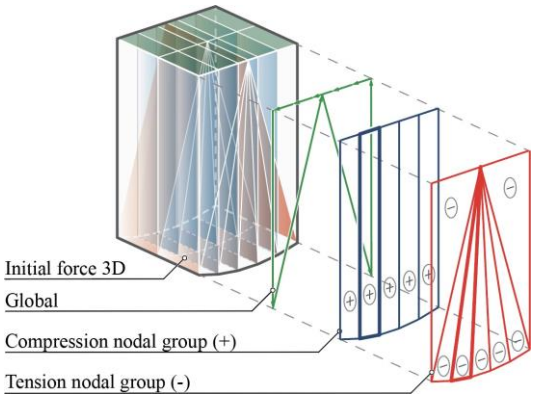

Figure 4. Analysis of different nodal groups in the tension and compression combined force diagram.

Figure 4 presents a detailed representation of the various nodal groups within the force diagram, effectively dividing it into global, compression, and tension forces. To classify these groups based on the connection to the global forces, a positive (+) value represents the compression that shared the edges with applied loads, and the negative (-) is for tension cells that have the same edges with reaction forces. The force diagram effectively demonstrates the intricate relationships in 2D, describing the connections between the edges. In the case of the 3D version, it is essentially a simple extrusion from the 2D representation, maintaining the same relationships between the elements. The global forces, denoted by the color green, remain unchanged throughout the process.

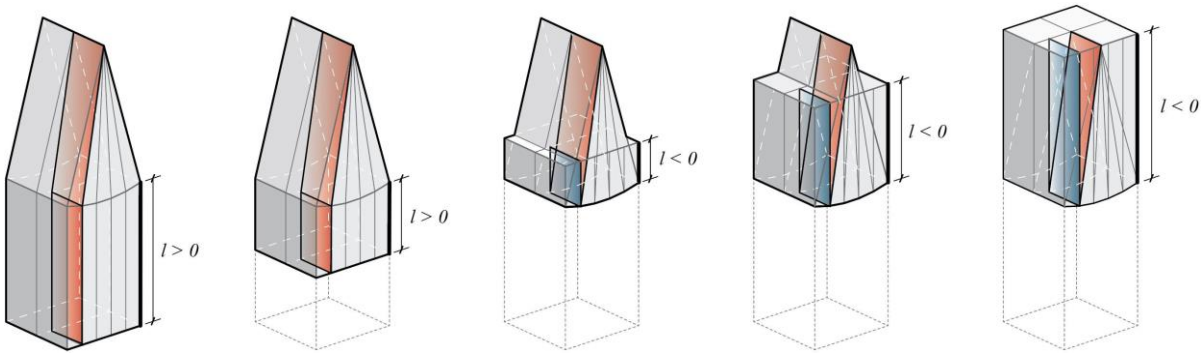

Figure 5. Edge length switched from a positive number to negative to finalize the form diagram.

2.2. Algebraic form-finding

In this section, the equilibrium equation of algebraic implementation will be explained. Firstly, each edge of the force diagram is perpendicular to its corresponding face in the form diagram, resulting in the unit direction vector of edge $e_i^{\dagger}$ in the form diagram being equal to the unit normal vector of face f_i in the force diagram. Then define $\mathbf{N}x$, $\mathbf{N}y$, and $\mathbf{N}z$ as [$f_{int} \times f_{int}$] diagonal matrices with diagonal entries representing the x-, y-, and z- coordinates of the unit normal vectors of the internal faces in the force diagram, respectively. Based on prior research in the algebraic method, the [$e_{int} \times f_{int}$] connectivity matrix $\mathbf{C}_{e_{int} \times f_{int}}$ displays the relationship between faces and edges in the form diagram. Consequently, the closeness can be expressed accordingly:

$$\begin{aligned} \mathbf{C}_{e_{int} \times f_{int}} \mathbf{N}_x \mathbf{q} &= \mathbf{0} \\ \mathbf{C}_{e_{int} \times f_{int}} \mathbf{N}_y \mathbf{q} &= \mathbf{0} \\ \mathbf{C}_{e_{int} \times f_{int}} \mathbf{N}_z \mathbf{q} &= \mathbf{0} \end{aligned} \tag{1}$$

Combing the above equations to an equilibrium matrix multiple by the potential edge length as shown here:

$$\mathbf{A}\mathbf{q} = \mathbf{0} \tag{2}$$

so $\mathbf{A}$ is a [$3e_{int} \times f_{int}$] equilibrium matrix can be represented as

$$\mathbf{A} = \begin{pmatrix} \mathbf{C}_{e_{int} \times f_{int}} \mathbf{N}_x \\ \hline \mathbf{C}_{e_{int} \times f_{int}} \mathbf{N}_y \\ \hline \mathbf{C}_{e_{int} \times f_{int}} \mathbf{N}_z \end{pmatrix} \tag{3}$$

Every solution for $\mathbf{q}$ represents a potential combination of edge lengths in the form diagram that ensures the closeness of all internal faces within the form diagram.

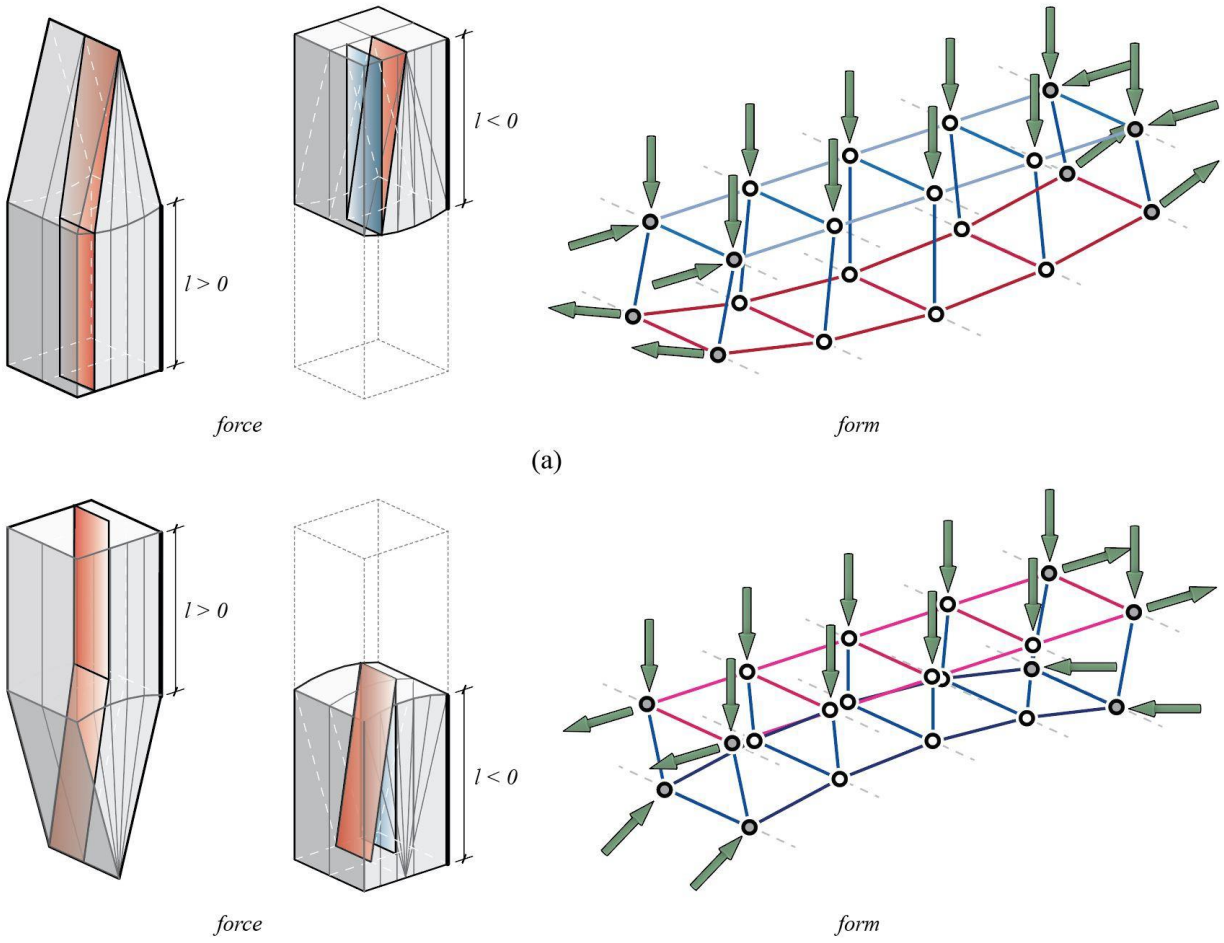

Figure 6. The transition from compression/tension only to intersected force diagram and corresponding form diagram. (a) the reciprocal polyhedral diagrams of the first module (b) mirrored force diagram as the input to generate the second module.

2.3. Additional edge constraints operation

Edge constraints set target lengths for the internal edges in the form diagram, and each constrained edge requires one additional constraint equation. For example, if the i-th internal edge $e_i^\dagger$ is constrained to a target length l, its constraint equation may be written as

$$\mathbf{b}_i^\top \mathbf{q} = l \tag{4}$$

where $\mathbf{b}_i$ is the $[f_{int} \times 1]$ column vector with all entries zero (0) except at the index of $e_i^\dagger$ where it's one (1). For a total number of b constrained edges, all b edge constraint equations may be assembled in the matrix form as

$$\mathbf{Bq} = \mathbf{l} \tag{5}$$

where the rows of the $[b \times f_{int}]$ edge constraint matrix $\mathbf{B}$ are the row vectors $\mathbf{b}_i^\top$, and $\mathbf{l}$ is a $[b \times 1]$ column vector with the entries being the target lengths.

2.4. Constrained solutions

All equilibrium equations, edge constraint equations, and vertex constraint equations are assembled as a system of non-homogeneous constrained linear equilibrium equations written as follows:

$$\mathbf{Mq} = \mathbf{t}. \tag{6}$$

Here the $[(2e_{int} + b + 3(p - 1) + 2l + n) \times f_{int}]$ matrix **M** is named the constrained equilibrium matrix, obtained by vertically stacking the equilibrium matrix **A** and the edge constraint matrix **B**

$$\mathbf{M} = \begin{pmatrix} \mathbf{A} \\ \mathbf{B} \end{pmatrix}. \tag{7}$$

The $[(2e_{int} + b + 3(p - 1) + 2l + n) \times 1]$ column vector **t** is obtained by vertically stacking the $[2e_{int} \times 1]$ zero vector, the vector **l**, and the vector **d**. Each solution of **q** represents a set of edge lengths of the form diagram that satisfy all equilibrium requirements and constraints.

The form diagram may face issues of over-constraining when constraints conflict with planarity or compete with each other, leading to overdetermined equilibrium equations with no solution. In these cases, the least-square solution offers the closest possible solution by minimizing the Euclidean norm while still attempting to satisfy all equilibrium and constraint requirements.

Figure 5 describes a process by which the final force diagram for the structure can be generated. This is achieved by assigning negative values to specific edges, allowing the structure's bottom part to merge with the top part. The decision to assign negative values is based on the changeable edge length, which affects the force distribution in the structure. It is important to note that the IDs of the fixed edges must be determined to ensure that the structure shifts within the predefined boundary conditions. This is necessary to prevent the structure from moving beyond acceptable limits.

3. Conclusion and future work

In conclusion, this research presents an analysis of the topological relationship between reciprocal polyhedral diagrams. The connectivity matrix and equilibrium matrix are used to express the closeness between the force diagram and its corresponding form diagram. Additional linear equations are introduced to account for edge constraints, resulting in a system of non-homogeneous constrained linear equilibrium equations. The least-square solution is utilized to find the closest solution in cases of over-constraining or incompatibilities among constraints (Figure 6). This approach enables a comprehensive understanding of the equilibrium and constraint requirements in form and force diagrams, paving the way for further exploration and optimization in structural design.

Abstract

This paper presents a method for optimizing the structure of a railway station. In contrast to traditional techniques that manipulate the structure's geometry using a single optimization method, the approach proposed in this paper employs a multi-strategy solution. Specifically, it utilizes two structural optimization design tools, namely BESO and graphic statics. By combining these two methods, the truss structure in a railway station can be effectively optimized. The algorithm implementation of the graphic statics component primarily relies on vector-based graphic statics. This approach tackles the discretization issue in topology optimization and significantly enhances the efficiency of design iterations.

Keywords: performance-based design, structural optimization, graphic statics, topology optimization

1. Introduction

The architectural design process needs to be further digitalized due to the increasing complexity of building functions and the diversification of architectural design objectives. The convergence of computer science, material science, mechanical engineering, architecture, and other disciplines, along with the advancement of digital architecture, has given rise to performance-based design thinking as a prominent approach in digital design. This approach has replaced the traditional focus on pure "formalism."

Structural performance-based design is a crucial aspect of performance-based design. In recent years, numerous structural design tools have emerged, leading to active intervention of structural design in the architectural design process [1]. Additionally, architects have expanded the application of structural design tools beyond mere structural performance-based design, aiming to facilitate the mutual integration of structure and form. Among these tools, graphic statics and topology optimization play vital roles in structural performance-based design.

1.1 Graphic statics

Graphic statics, formally established in the second half of the nineteenth century, combines both constructive and generative aspects. The foundations of graphic statics were laid by James Clerk Maxwell in his article published in 1864 [2]. It consists of a form diagram and a force diagram that are reciprocal, enabling simultaneous control of form and force flow.

Swiss engineer Robert Maillart pioneered the application of graphic statics to explore new materials for reinforced concrete. He designed several elegant and efficient bridges and roof systems using graphic statics, including the Tavanasa Bridge (1906) [3], the Chiasso shed (1924) [4], and the Salginatobel Bridge (1930) [5], among others. Graphic statics enabled Robert Maillart to efficiently explore the balance between the aesthetic and efficiency aspects of architectural form. Architect Christian Kerez

and structural engineer Joseph Schwartz collaborated on projects such as the Apartment Building on Forsterstrasse, the House with One Wall, and the School Building in Leutschenbach [6], utilizing graphic statics to construct their architectural free forms in a rational manner.

With the increasing digitization of architectural design, complex arithmetic processes can now be delegated to computers, leading to a resurgence of graphic statics in structural design. In contrast to numerical computational methods, graphic statics is preferred for its ability to seamlessly integrate form and structure. In recent years, researchers have dedicated significant attention and effort to the development and advancement of graphic statics.

There are currently two primary research directions in graphic statics, one based on vectors and the other on polyhedra. Several software tools have been developed for graphic statics form-finding based on these approaches. Andrei Nejur et al. introduced Polyframe [7], a 3D graphic statics tool utilizing polyhedra, but it is limited to calculating purely compressed structures. Lee developed COMPAS3gs [8], a set of 3D graphic statics tools based on polyhedra; however, it does not support automatic optimization based on constraints. The VGS tool (Vector-based 3D Graphic Statics) developed by Pierluigi D'Acunto et al. solves graphic statics using a vector approach [9], enabling iterative optimization. Nevertheless, one limitation of graphic statics is that it requires a thorough understanding of structural principles on the part of the designer.

1.2 Multi-material BESO

Topology optimization is a vital method for achieving performance-based design in structures. Compared to graphic statics, topology optimization offers advantages in material layout optimization. Presently, the prominent topology optimization techniques include the Solid Isotropic Material with Penalization (SIMP) method [10], the Level Set method [11], and the Bi-directional Evolutionary Structural Optimization (BESO) method [12]. Among these methods, the BESO method is favored by architects and engineers due to its user-friendliness and fast calculation. Mature commercial software tools, such as Ameba [13], are already available for implementing the BESO method.

However, most of the previous methods, including the classical BESO method, have been developed based on a single material and do not consider the optimization of structures with multiple materials possessing different tensile and compressive properties [14]. Recently, Li and Xie [15], [16] extended the single-material BESO method by dividing the structure into tensile and compressive regions during the topology optimization process. They assigned different materials to these regions based on the tensile or compressive state of the finite element analysis (FEA) elements, enabling the topology optimization of structures composed of two materials. Subsequent research and applications have demonstrated the excellent practical value and potential of this method in the design of large-span and composite structures [17].

1.3 Motivation

BESO is a powerful and widely recognized technique used to determine optimal geometries for designing efficient systems. However, one challenge with BESO is that the structure it generates is typically continuous, which means that it needs to be discretized into multiple parts for construction in later stages. This discretization process can sometimes make it difficult to interpret the resulting discrete structure.

Graphic statics is an exceptionally effective tool for the structural design of truss structures. It relies on reciprocal graphical relationships between the form diagram and force diagram, enabling the quick determination of force magnitudes for each component without the need for complex structural calculations. This efficient approach significantly reduces the time required for design and simulation. However, it is important to acknowledge that obtaining the initial form using graphic statics requires significant structural experience.

We propose an integrated approach to structural optimization. Unlike traditional techniques that manipulate the structure's geometry using a single optimization method, our approach utilizes a multi-strategy solution. In this paper, we present a method that combines two structural optimization design tools, namely BESO and graphic statics, to address the problem. By leveraging both of these tools, we aim to enhance the effectiveness of structural optimization.

2. Method

Given the distinct advantages of graphic statics and BESO, this paper adopts a two-stage approach, employing topology optimization and graphic statics at different design stages to leverage the strengths of both methods. The topology optimization is applied initially to generate a form, which is then transformed into a graphic statics representation by extracting the primary force flow. This enables the overall structural design, as depicted in Figure 1.

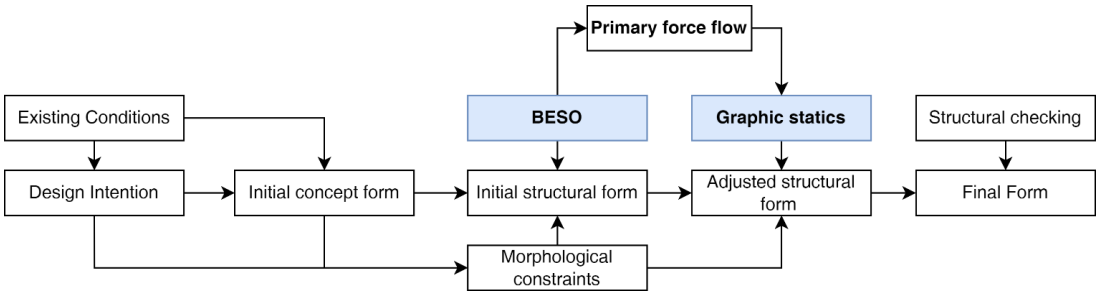

Figure 1. Structural design process of this paper

2.1. Conceptual form-finding stage

Form creation holds immense significance in architectural design. Within the field of architecture, practitioners are continually engaged in developing architectural forms and exploring various approaches to form creation. This exploration has given rise to the concept of "form-finding," which involves analyzing external conditions and responding to the design intentions of the architect. Form-finding, therefore, represents a systematic design strategy and method employed to achieve specific design goals within given constraints. It encompasses both rational reasoning and perceptual judgment. In the context of this paper, the conceptual stage refers to the architect's initial conception of form during the early proposal phase, setting the foundation for subsequent structural form-finding endeavors.

2.2. Initial structure form-finding stage

In recent times, the division between architects and structural engineers has resulted in a certain level of detachment between the form and structure of buildings. A sufficient understanding of structural principles is crucial for architects in order to develop structural concepts. Therefore, the collaboration between architects and structural engineers is often necessary to create distinctive building structures. The approach presented in this paper can, to some extent, assist architects in formulating preliminary structural concepts and expedite the initial process of generating such concepts.

The development of the initial structural concept primarily relies on the multi-material BESO algorithm. By specifying the initial design domain, loads, supports, and relevant parameters, we can readily obtain the structural form. However, adjusting the solution using the multi-material BESO algorithm is not straightforward, especially when dealing with complex building designs. Additionally, the computational speed of existing computers is inadequate for running this algorithm efficiently. Consequently, if we solely rely on this method for structural solutions, the time required for design iterations would significantly increase. As a result, we utilize the multi-material BESO algorithm for the formation of the initial concept, allowing us to generate the initial concept scheme in a single operation (see Figure 2).

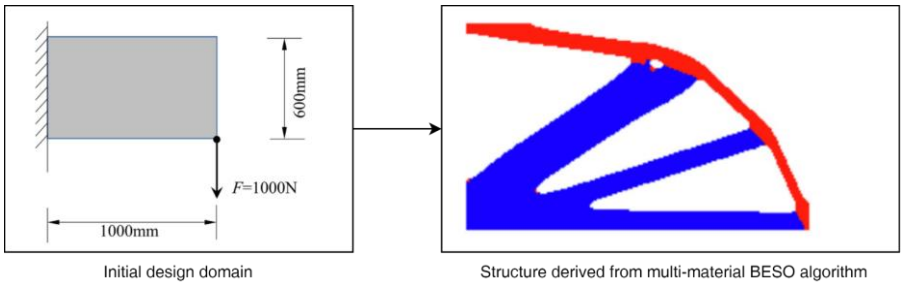

Figure 2. Initial structure form-finding stage, Modified from [15]

2.3. Conversion from BESO to graphic statics

The force flow method is a structural design approach that clarifies and analyzes the transfer mechanism of forces within a member. It conceptualizes force transfer as force flow and depicts the path of force flow through force lines. The density of force lines corresponds to the intensity of force flow, which directly correlates to stress magnitude. By utilizing the BESO (Bi-directional Evolutionary Structural Optimization) technique, we can efficiently ascertain the primary flow direction of the main force flows. This allows us to quickly identify the principal force flows required to achieve the desired design objectives in structural design.

CEM (Combined Equilibrium Modeling) [18] is a graphic statics tool that utilizes topological diagrams. It is based on the Plasticity Theory and its Lower Bound Theorem [19]. This theorem primarily aims to fulfill the structural limit states (ULS), with particular emphasis on static equilibrium conditions [20]. CEM's objective is to facilitate the active and consistent generation of discrete network models that differ in terms of topology and combinations. These networks should not necessarily be perceived as physical structures but rather as spatial representations of equilibrium forces [21]. By focusing solely on the balance between external and internal forces, CEM allows for the analysis, visualization, and integration of the relationship between geometry and structural behavior in a comprehensible manner using graphic statics.

The CEM tool is employed to convert the primary force flows into the necessary topological diagram. Subsequently, by adjusting the lengths of pertinent components or the magnitude of internal forces, we obtain the force diagram using graphic statics (refer to Figure 3).

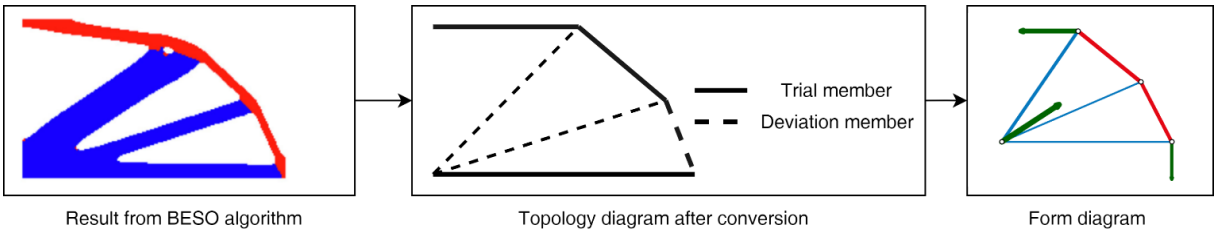

Figure 3. Conversion from BESO to graphic statics, Modified from [15]

2.4. Form adjustment stage

With the above method, we can obtain the form and force diagrams solutions for tuning. With the vector-based graphic statics tool, we can pass various constraints and optimization objectives and quickly obtain the desired optimization model. The constraint in this step generally refers to the morphological constraint we need to reach rather than the mechanical concept of constraint. In this way, we can optimize the structural form of the remaining parts of the structure while keeping some parts' shape and achieving a more efficient form within the tolerances (Figure 4).

We can use V as an indicator of the efficiency of the structure:

$$V = \sum_{i=0}^{n} L_{Fi} \times L_{F^*i} \quad (1)$$

where L_{Fi} refers to the length of the i-th component of the shape diagram solution, L_{F^*i} refers to the length of the force diagram's line segment corresponding to the form diagram's i-th component.

By employing this evaluation index, we can enhance structural efficiency through two approaches: firstly, by reducing the lengths of members in the form diagram, and secondly, by minimizing the lengths of members in the force diagram. However, as the aforementioned method revolves around optimizing a single operating condition, it is essential to validate the structure to ensure its reliability.

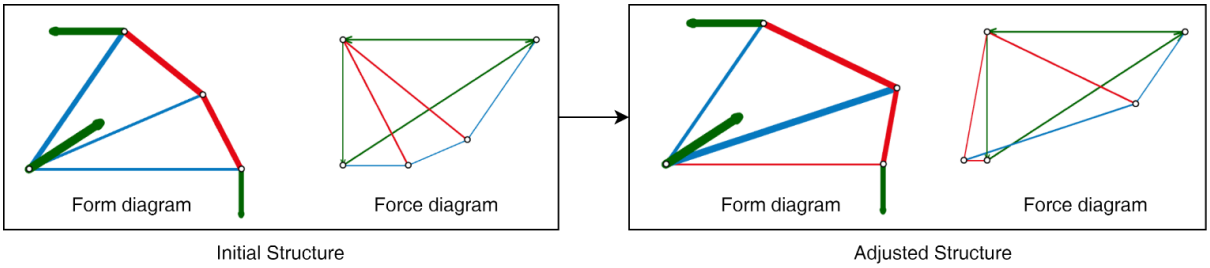

Figure 4. Form adjustment stage

3. Case Study

3.1 Background of the case

The project is situated in Chongming, Shanghai, which is an alluvial island located at the mouth of the Yangtze River in the eastern part of the Yangtze Delta. Chongming Island is the third-largest island in China and holds the distinction of being the largest estuarine alluvial island as well as the largest sand island in the country. The island features a flat, fertile landscape with abundant forests, making it renowned for its agricultural productivity and being recognized as the land of fish and rice. Given Chongming's significant agricultural foundation, the proposal aims to reconnect with the island's ecological roots by constructing a high-speed railway station amidst the fields. The underground placement of the public transportation system allows for substantial public space to be reclaimed on the surface. This approach seeks to bring nature back to the residents and visitors, creating a green urban center within Chongming.

The project's concept is called "The Tail of the Yangtze River," drawing inspiration from the meandering shape of the Yangtze River, which is the longest river in China. The design incorporates wings that unfurl along both sides of the station building, and the overall form features simple and sleek horizontal lines. At the main entrance, these lines are subtly elevated, symbolizing the entrance and creating a welcoming gesture for passengers arriving from various parts of the world (refer to Figure 5).

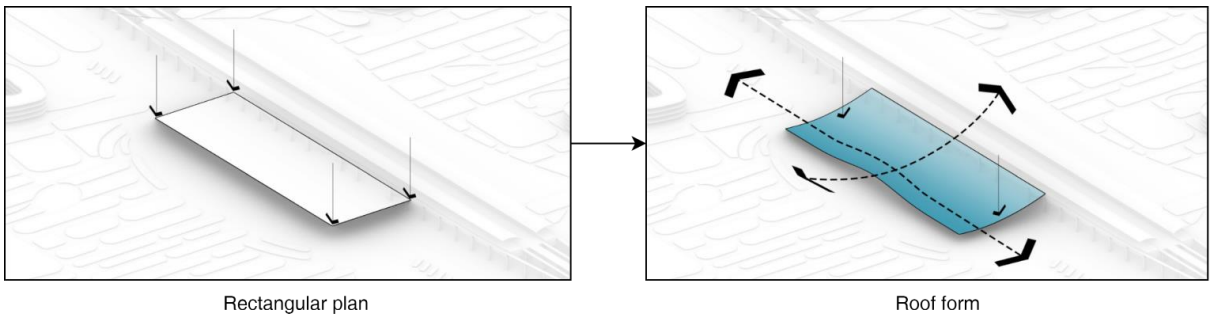

Figure 5. Concept Form Generation

The subject of this study is a railway station hall characterized by a rectangular floor plan. The structural system consists of multiple trusses that are arranged parallel to each other. Figure 6 illustrates the cross-sectional view of the structure. As the trusses exhibit a high degree of similarity, the project can be simplified to a 2D planar structure. The prominent feature of the design is a substantial overhang measuring 16 meters in length.

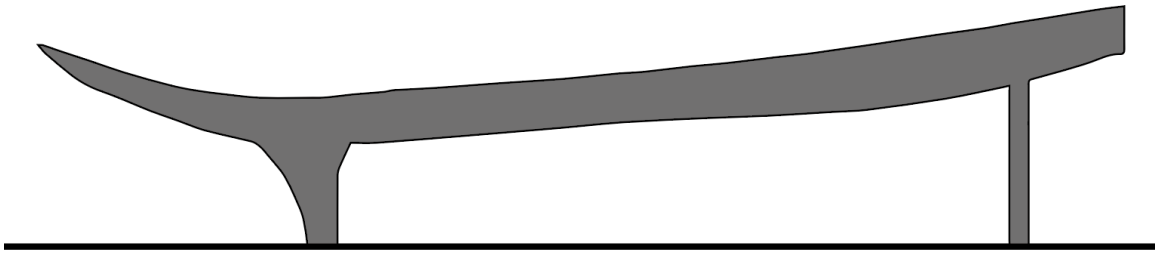

Figure 6. Initial section of the train station hall.

Initially, the design of the roof structure followed a traditional approach as depicted in Figure 7. The primary load-bearing structure of the roof consists of plane trusses and columns. The roof load is transferred to the main truss through secondary beams and further transmitted to the ground via linear and curved columns. However, this solution presented two challenges. Firstly, the roof windows were unable to be opened, limiting the amount of sunlight that could enter the interior space. Secondly, the presence of columns on the façade resulted in a segmented glass curtain wall, which compromised the heat insulation efficiency. As a result, it became necessary to introduce two additional support columns on the front elevation to ensure continuity in the curtain wall.

Additionally, due to the minimal presence of equipment ducts on the roof, there is no need to enclose the ceiling structure. Therefore, a redesign of the roof structure is required.

Figure 7. Roof structure designed using conventional methods

3.2 BESO form-finding process

The simplified design domain is shown in Figure 8, where the roof section is simplified as a curve and set as a non-design domain with a specific thickness on which the uniform load is distributed. The region under the roof is set as the design domain. On the north side of the building, due to the space limitation, only one row of columns is kept, which is also set as the non-design domain.

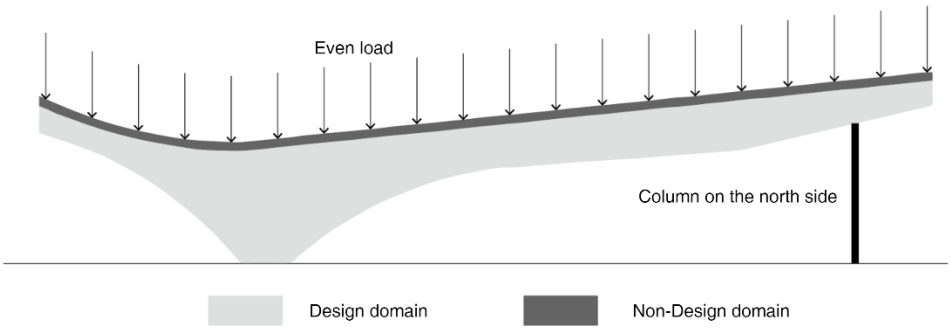

Figure 8. Design domain for topology optimization of the hall

The design domain undergoes multi-material topology optimization, even though the primary structural material intended for use is steel. It is important to note that the mechanical properties of steel may vary between tension and compression. The target volume for the topology optimization is set to 0.4, indicating that the final structure's total volume will be 40% of the volume of the original design domain illustrated in Figure 8. Figure 9 provides an overview of the crucial steps involved in the optimization process.

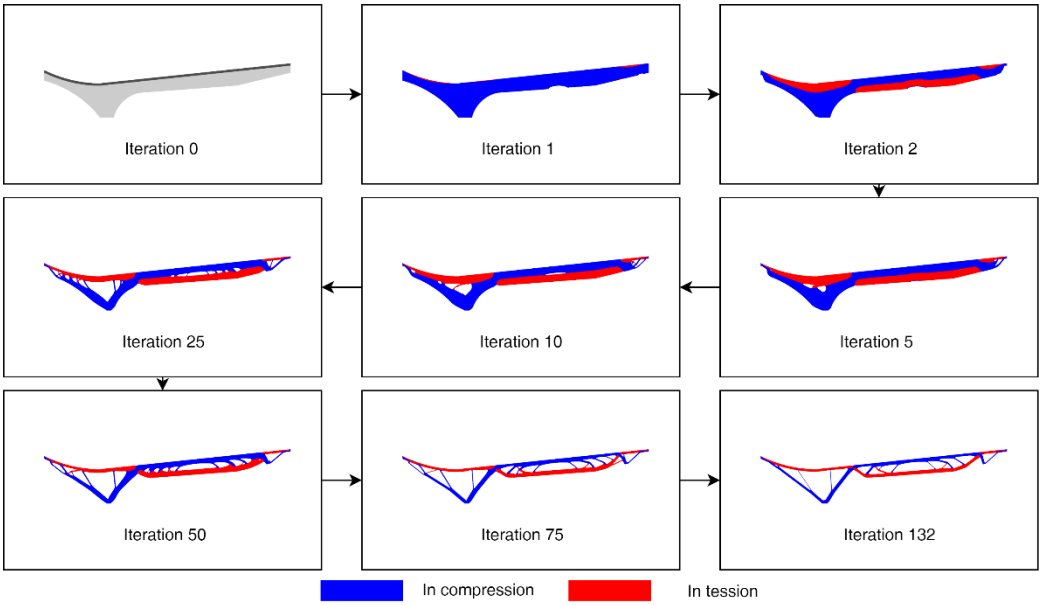

Figure 9. The process of topology optimization

After 132 iterations, the structure eventually converges to its optimized form. In the right span of the structure, the upper side experiences compression, while the lower side is subjected to tension. The topologically optimized structure necessitates additional refinement for further design. This structure comprises three primary components: the main compressed members, the secondary compressed members, and the tendons. Together, they form a stable and interconnected structural system.

By following the aforementioned method, we have obtained the initial solution for the structural design using the multi-material BESO approach. The structure exhibits an approximate triangular form on the left side. However, the inclination of the inner members is excessive, which adversely affects the utilization of the interior space. Additionally, a weak point is identified in the middle of this frame, potentially resulting in structural instability under different operational conditions. Consequently,

further adjustments and modifications are necessary to address these issues and enhance the overall design.

3.4 From BESO to graphic statics

The results obtained through the multi-material BESO algorithm reveal the presence of two primary force transfer paths within the structure. One path is predominantly subjected to compression, exhibiting a shape reminiscent of an arch. The other path is primarily subjected to tension (see Figure 10).

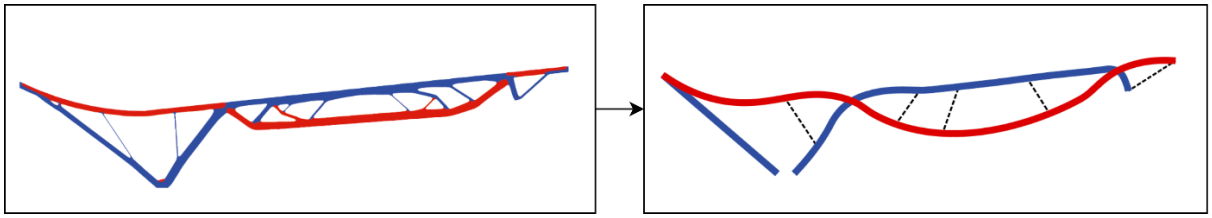

Figure 10. Extraction of force flow

To convert the two identified force transfer paths into graphic statics, we create corresponding topology diagrams. Figure 11 displays the topology diagram, which is based on a truss-like triangular structure for stability. Two trials represent the primary force flows obtained from the multi-material topology optimization, while the third trial represents the required column on the right side of the project. Several deviation members connect these three trials. In the CEM approach, the trial members can have adjustable lengths, and the deviation members can determine the magnitude of the internal forces (as shown in Figure 12). The lengths and positions of these members are crucial factors that influence the final form of the structure.

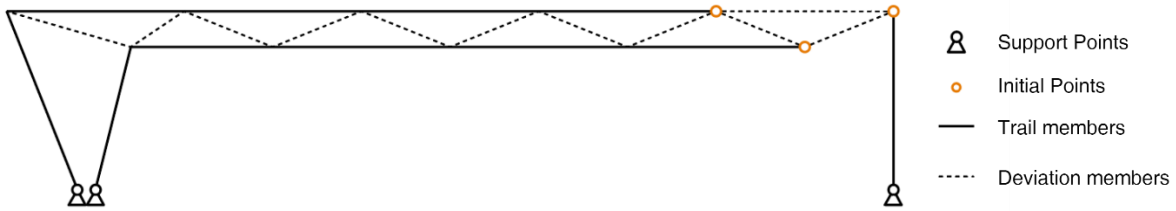

Figure 11. Constructing topological diagrams from force flow results

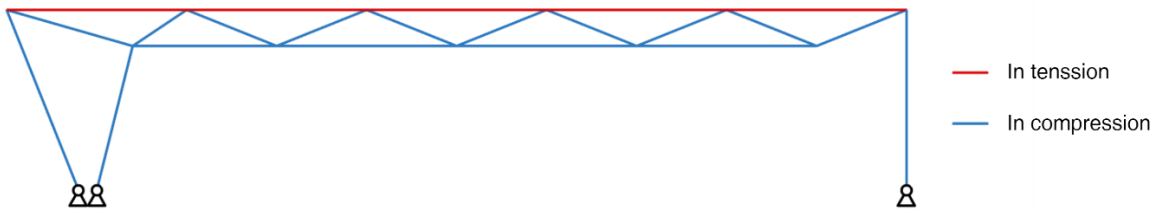

Figure 12. The set tensile-pressure relationship

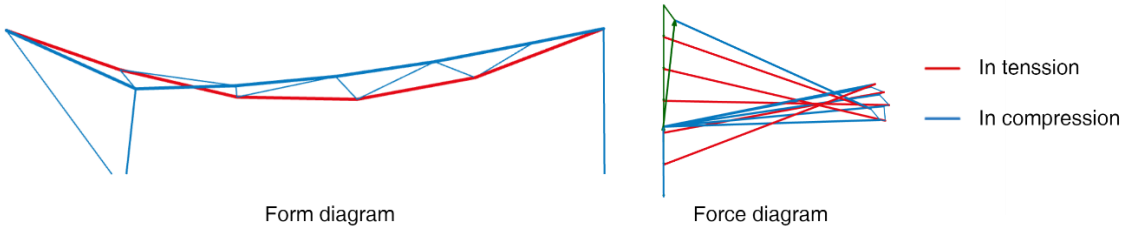

Figure 13. Generated initial graphic statics form diagram and force diagram

Following the CEM calculations, we acquire the initial form and force solutions. Figure 13 illustrates that the force flow within the structure, constructed using this method, aligns with the force flow obtained from the topology optimization. In contrast to the bars within the interior calculated through previous topology optimization, the existing structure no longer encroaches upon the interior space. However, some members in the model still possess excessive length-to-slenderness ratios, indicating room for further enhancement in terms of their efficiency.

3.3. Adjustment process based on graphic statics

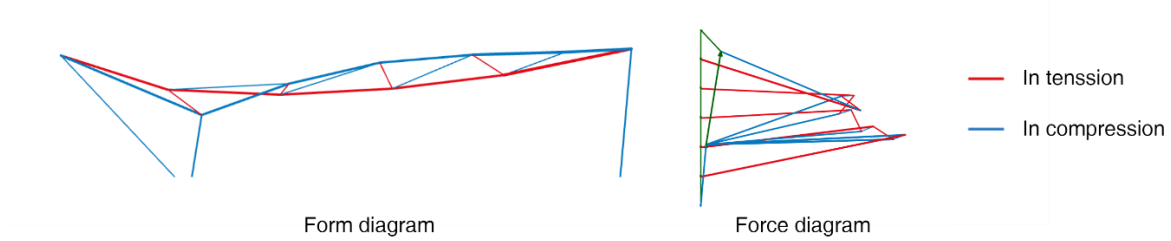

Figure 14. Adjusted structure

The existing shape and force diagrams are input into VGS (Vector-based Graphic Statics) for further adjustment and analysis. By controlling the overall form and fine-tuning the entire structure, we aim to enhance its efficiency. During the adjustment process, certain constraints are applied to specific aspects of the design. Firstly, the façade, being a crucial element of the project, is constrained to minimize the impact of efficiency optimization on its form. Consequently, it undergoes minimal changes. Secondly, the position of the supports is related to the interior area and is therefore also constrained. Lastly, the size of the interior space needs to be ensured, so the lower part of the roof is constrained as well. Taking these constraints into account, we optimize the structure by modifying the tension-compression relationship of the web members. As a result, the V decreases by 14.2%. The optimized structure exhibits a slight upward raise in the form of the roof. This alteration has a minimal impact on the building's appearance and is thus deemed acceptable (refer to Figure 14).

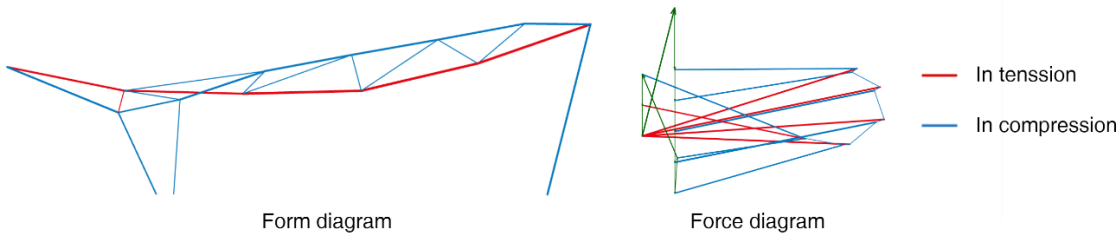

Figure 15. Adjustment of components on the façade

Nevertheless, the columns in the overhang direction were observed to be excessively long and slender, requiring further adjustments. To address this issue, we made additional modifications to the columns on the façade, taking into account the original form diagram. Simultaneously, we slightly increased the thickness of the roof to enhance structural efficiency. As a result, the final outcome successfully reduces the length of the columns on the façade while maintaining the same V value (Figure 15).

3.4. Post-design process

To enhance the overall structural strength, a modification was made to the tension beam by dividing its upper chord into two sections, ensuring out-of-plane stability (as shown in Figure 16). This configuration also allows for the inclusion of a sunroof. Additionally, certain nodes in the structure were reinforced to improve stability. In the final design, the number of web members was increased to reduce the length-to-slenderness ratio of the members, further optimizing structural efficiency (Figure 17).

Furthermore, for aesthetic purposes, the supporting columns on the façade were replaced with curved columns (Figure 18). These design adjustments collectively contribute to the final structure's strength, stability, and visual appeal.

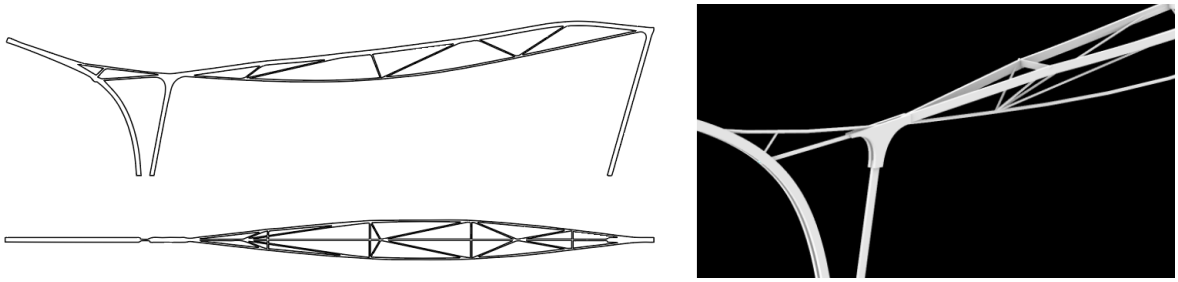

Figure 16. Post-processed structure

Figure 17. Interior effect of the railway station hall

Figure 18. The effect of the façade of the railway station hall

4 Discussion

By implementing the approach described above, the final structure successfully addresses the initial challenges while preserving the desired architectural design. The separation of the two sets of columns in the façade ensures the integrity of the curtain wall, thereby improving the building's insulation properties. Additionally, the structural design allows for the inclusion of skylights, enhancing natural lighting within the interior space. The case study serves as evidence that the method proposed in this paper is both rapid and effective in designing structural forms for buildings with multiple objectives.

Indeed, the present method does have certain limitations that should be acknowledged. Firstly, it is currently confined to two-dimensional structural design, and the transition to three-dimensional design is achieved through post-processing techniques. Further research and development are required to extend the method to three-dimensional structures. Secondly, the conversion from the multi-material BESO algorithm to graphic statics heavily relies on human observation, which may introduce subjectivity and limitations. There is a need for further exploration and investigation into automated extraction methods to enhance objectivity and efficiency in this process.

5 Conclusion

The proposed integrated design approach that combines the multi-material BESO algorithm and graphic statics offers a novel and efficient method for coupling building form and structural design. By utilizing the multi-material BESO algorithm, the initial structural solution is obtained, leading to the generation of an efficient initial structure form. The force flow patterns derived from this initial form serve as a foundation for further structure refinement using graphic statics. The effectiveness of this approach is demonstrated through its application in the design of a railway station hall. Overall, this integrated design approach showcases the potential and benefits of combining these two methods to achieve optimized and well-integrated building structures.

Abstract

The research focused on the conceptual development of innovative architectural forms that meet both aesthetic and practical criteria by combining physical experimentation with computer simulation. The physical form-finding technique was employed in the experimental approach, utilizing models generated from pretensioned fabric as a membrane and various glued-on grid patterns as stiffeners. The relaxation of the prestressed fabric resulted in the formation of anticlastic surfaces. The influence of different patterns of rigid elements, prestress intensity, and direction were investigated. Tensegrity structures were also examined using the same method. The results of the physical experiments were utilized as a basis for parametric modelling in the Grasshopper add-on for Rhino3D. The optimization of the final shape was achieved by varying the parameters, such as the configuration of the stiffeners and membrane strength. The transfer of designs to the digital environment allowed for more accurate shaping of the elaborated structures, and subsequent optimization and development of a detailed model. The resulting prestressed stiffened membrane structures exhibit great potential for practical application as pavilions, roofs, and awnings.

Keywords: conceptual design, form finding, membrane structures, parametric modelling

1. Introduction

Nature has long been a source of inspiration for various fields of science and design, including architecture. Bionics, the study of living organisms and their structures, has been used as a design concept for developing structures that are both aesthetically pleasing and functionally efficient. Bionic architecture aims to mimic the harmonic shapes and structural principles of living organisms [1]. In this study, we focus on the exoskeleton of insects as a design concept.

Insects possess a complex system of support and movement, known as the exoskeleton. This cuticle consists of an elastic membrane supported by a network of rigid rods or plate-shaped segments, known as sclerites. The muscles, tendons, and apodemes within the insect body work together to stretch the membrane, which returns to its initial configuration when the tension is released. This interaction of rigid and flexible elements of the exoskeleton affects the position and movement of the insect body [2].

By exploring the complex interplay of rigid and flexible elements in these natural systems, architects and engineers can develop new materials and construction methods that are more sustainable, efficient, and aesthetically pleasing. Torres and Borenstein [3] further investigated the structural analysis of insect exoskeletons and proposed that their complex hierarchical structure could be used to develop new materials and structural designs for use in architecture. When applied to architecture, the structure of insect exoskeletons can be compared to pretensioned stiffened tensile membrane structures. Sclerites

are equivalent to rigid edges and stiff elements such as rods or beams, while the muscle work of stretching the membrane can be calculated using structural analysis. By changing the pattern of stiffness and characteristics of pretensioning, various variations of shapes and reliefs can be obtained.

Tensegrity structures offer a potential solution for prestressed and locally stiffened membrane structures. Tensegrity systems are defined as "a system in a stable self-equilibrated state comprising a discontinuous set of compressed components inside a continuum of tensioned components" [4] (p.19). Wang, Zhang, and Wu [5] reviewed the applications of tensegrity structures in architecture, highlighting their versatility and adaptability in a variety of contexts. In this article, the case is considered when the membrane serves as the continuous tensioned component, while rigid struts and rods act as the compressed elements. Such a structure is in a state of spatial equilibrium and offers broad potential for inspiration and experimentation.

1.1. Structural behaviour

Generally, lightweight membrane surface structures are classified as form-active structures, which are characterized by loading with only tensile or compressive stresses in the axial direction [6]. The membrane is in a pure state of tension, and the geometry of the structure must follow the flow of forces [7]. The stress state in the edge details depends on the type of elements, i.e., flexible or rigid. Rigid elements are loaded in compression and may be stressed in bending [8].

The stiffness of a membrane structure is influenced by various factors, such as the surface curvature, the value of prestress, and the characteristics of the materials used [9]. In general, prestressing acts as a uniformly distributed load perpendicularly to the rigid elements and causes compressed elements to bend. The elements resist bending to maintain their original shape through their stiffness. This can also be recognized from the internal tensile forces, which depend on the value of the prestressing force and the spans [6].

External loads are transferred from the membrane to the supports and foundations through rigid elements. The ratio of external loads to their weight is significantly higher for lightweight structures than for typical building structures. Therefore, it is essential to carefully consider the design of such structures because external loads such as wind, snow, and rain have a significant effect on the deformation of the structures. Structural analysis should be performed with loads without partial safety factors to account for large deformations of membrane structures. Self-weight and prestressing loads must be taken into account for all load combinations. However, pretensioning may not affect the maximum forces in the calculations for the structural system as it can largely dissipate under the total design loading [10].

In theory, the stiffness of tensegrity structures can be achieved independently of any external loads by self-stress, which allows the system to keep itself in equilibrium, which was illustrated from linear to three-dimensional systems with struts and cables [4]. However, in practice, appropriate support systems and bracers are needed for better stability.

1.2. Execution

According to Ochsendorf and Filippi [11], a membrane structure is made of a flexible material with a thickness that is much less than its surface area. The material must be resilient and able to protect against environmental influences. Textiles, polymers, and even thin metal plates can be used as membrane material. The material must also have mechanical strength, fracture toughness, light transmittance, protection from weather and fire, and be suitable for enclosing and economical. However, there is no single material that meets all requirements, and the choice of material depends on the specific function, location, and application requirements. For mechanically pre-tensioned structures, coated textile materials such as PVC-coated polyester fabric and PTFE-coated glass fabrics are generally used [12].

Rigid elements are subject to compressive forces and bending, as described before. Steel profiles, glued wooden beams, or metal tubes are usually used for this purpose [12].

The design phase is the most time-consuming part of building membrane structures. On the other hand, assembly is the fastest part of the process. One of the main advantages of membrane structures is that with good quality, almost no maintenance is required, and often only a visual examination is sufficient [13].

2. Materials and methods

2.1. Physical form finding

To investigate forms that are suitable for implementation in architecture, such as roofs, awnings, and shells, several models were constructed. These models were composed of an elastic nylon fabric with orthogonal weave orientation to simulate a textile membrane and a rigid frame of flat wood sticks.

The fabric was attached to the cork backing using nails hammered along the edge of the backing and stretched in one or two directions. A grid of wooden sticks was then glued onto the stretched fabric while the rods remained unconnected. After the glue was allowed to dry, the fabric was removed from the fixers, leading to the deformation of the entire structure. The fabric surface bends in each "cell" due to the opportunity of the tissue to relax only within the closed contour of the framework. The rods rotate until the deformation of the fabric is complete, changing their original horizontal position so that one end forms a high point and the opposite end forms a low point, which serves as the anchor point. The rotation stops when the fabric is relaxed. This process results in the formation of rigid elements that create a frame of minimal surfaces, leading to the generation of an anticlastic hyparic surface.

The final shape is influenced by the geometry of the rigid bar mesh and some parameters, such as the direction and intensity of the pretension.

2.2. Parametric modelling

To advance the exploration of prestressed and locally stiffened membranes, their models were integrated into a digital environment. This was achieved through the utilization of the Grasshopper plugin, which is designed for use with the Rhino3D software. The integration of Kangaroo 2 into the Grasshopper plugin provides the capability to model form-active systems parametrically [14]. This allows for the simulation of various form-active structures with prestressed and locally stiffened membranes, thereby enabling the exploration of their behaviour under different conditions and the optimization of their design parameters.

3. Results

3.1. Physical form finding

3.1.1. Intensity of pretension

In this study, the effect of pretensioning intensity on the final geometry of a membrane structure was investigated through the physical examination of five specimens. A rigid frame in the shape of a square with a side length of 115 mm was glued onto a piece of the fabric. The perimeter along which the fabric was stretched was kept the same for all samples at 205x270 mm.

The intensity of tension was determined by the degree of elongation, which is calculated as the ratio between the change in the length of the fabric and the original length.

Once the fabric was removed from the nails, it relaxed inside the rigid frame, resulting in the formation of a saddle surface, which caused the opposite ends of the rods to rise. The final shape of the structure was a parabolic hyperboloid, as shown in Figure 1.

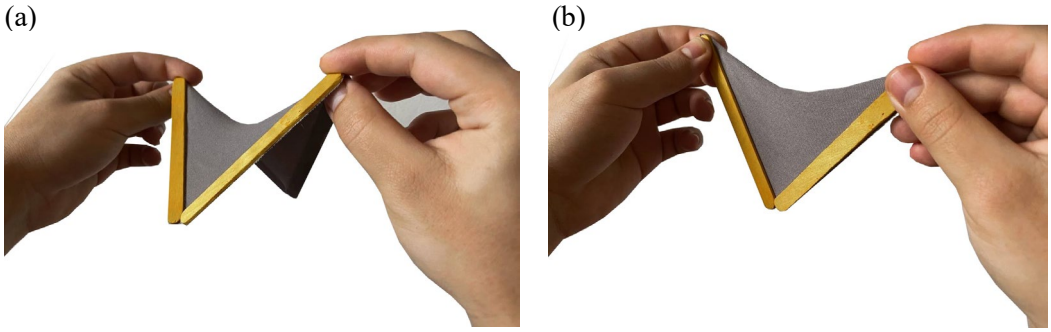

Figure 1. Parabolic hyperboloid surface: (a) unfolded state; (b) folded state.

To quantify the lift height of the rod ends, a perpendicular line was dropped from the upper ends of the rods to the level of the lower ends, using a metric ruler with a precision of +/-0.6 mm. The lift height *H*, as shown in Figure 2a, was measured and recorded for each specimen. Table 1 presents the results of this measurement, which vary depending on the level of pretension. The change in length of the fabric *Δl* was calculated as the difference between the original length of the fabric and the base on which it was stretched. The strain of the fabric, indicating the level of pretension, was calculated as the ratio of the change in length *Δl* to the original length *L*.

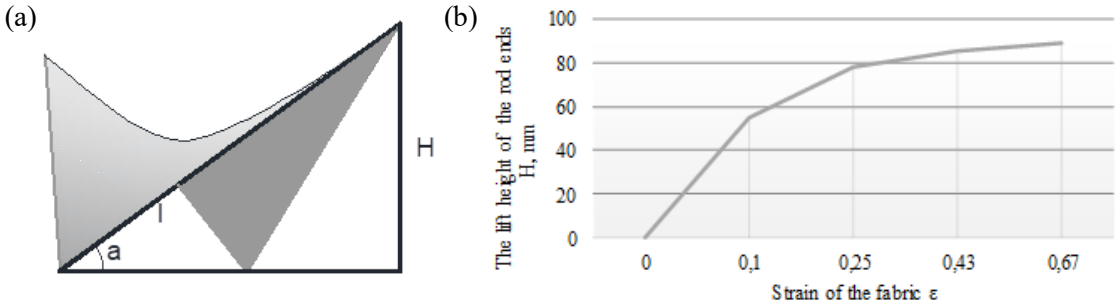

Figure 2. (a) scheme of the resulting parabolic hyperboloid with notations, (b) relationship between strain of the fabric and the height of lifting the rods ends.

The relationship between the fabric elongation during pretensioning and the amount of lifting of the rod ends in the final position was examined by plotting the results shown in Table 1 on Figure 2b. The results indicate that the intensity of pretensioning is greater when the original dimensions of the fabric are smaller because of the greater strain of the fabric. As the prestress intensity increases, the angle *a* between the base level and the rod, which determines the slope of the structure, also increases.

Table 1. Results of the experiment with different intensity of pretension.

Sample	Original length of fabric L, mm	Length of base l, mm	Change in length of fabric Δl, mm	Strain of fabric ε	The lift height of the rod ends H, mm
1	270	270	0	0,00	0
2	243	270	27	0,10	61
3	216	270	54	0,25	78
4	189	270	81	0,43	85
5	162	270	108	0,67	89

3.1.2. Direction of pretension

Two membrane structures were fabricated for physical examination in this study. One was made with uniaxial initial tensioning, while the other was fabricated with biaxial prestress. Both specimens were constructed with a square rigid frame of 65 m in side length, which resulted in a parabolic hyperboloid after relaxation. The green specimen was stretched in only one direction, while the red specimen was tensioned homogeneously, i.e., with equal tension in both directions (see Figure 3).

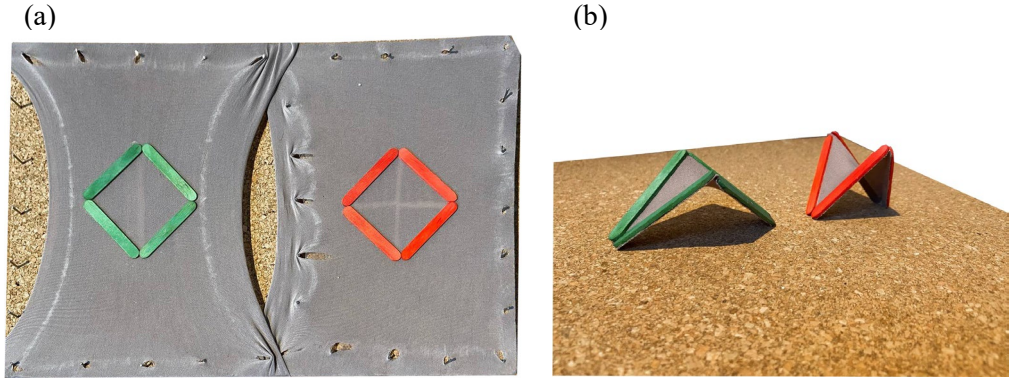

Figure 3. Specimens in the initial and final stages: (a) pretensioned fabric with a glued frame, (b) final geometry after relaxation and cutting out.

It was observed that different prestressing of the same rigid elements led to the same geometry but with different heights and curvature. The rod ends of the biaxial pretensioned membrane lifted less than those of the uniaxial pretensioned membrane. In the latter, the main curvatures were identical.

During the formation of the final geometry of the hyperbolic paraboloid, the rod ends rose at the nodes where the membrane was first relaxed. Furthermore, the highest nodes of the shape could also be inverted manually in a symmetrical manner.

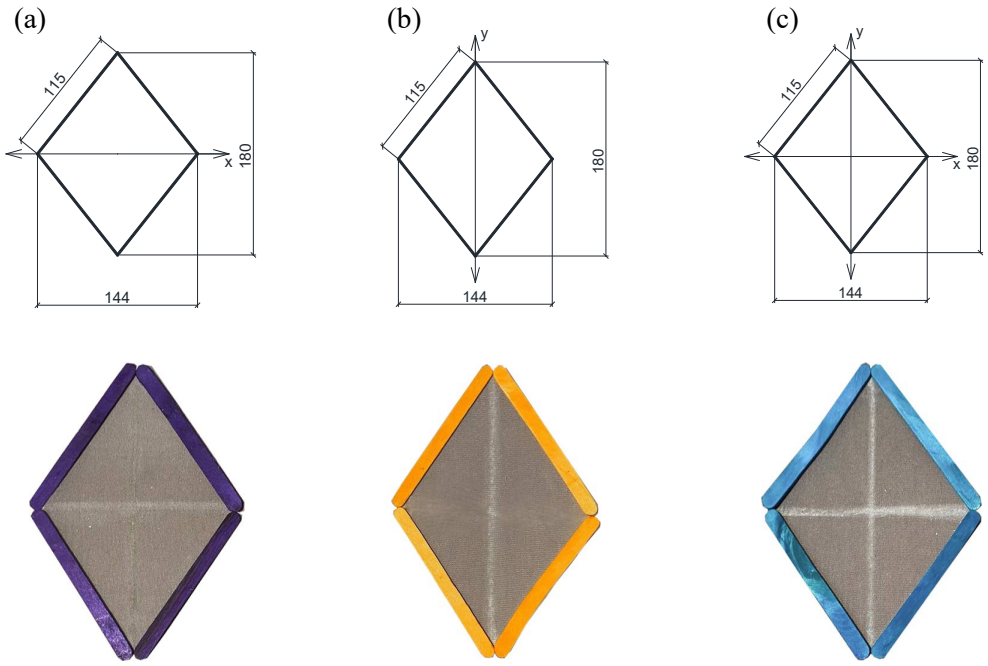

Figure 4. Specimens under tension with a glued rhombus frame and their drownings. Direction of pretension is pointed by a line: (a) with transverse pretension, (b) with longitudinal pretension and (c) with biaxial pretension.

To investigate the effect of geometry on the principal curvatures, three specimens were fabricated with a rhombus as the rigid element. The purple specimen was prestretched along the x-direction, the orange one along the y-direction, and the blue specimen biaxial prestressed (Figure 4).

The rod ends were lifted higher when prestressed in the direction of the long diagonal than when prestressed in the short diagonal, resulting in a flatter and more elongated shape. The curvature ratio remained proportional to the original dimensions with uniform preload, and the blue sample was a mixture of the others (Figure 5).

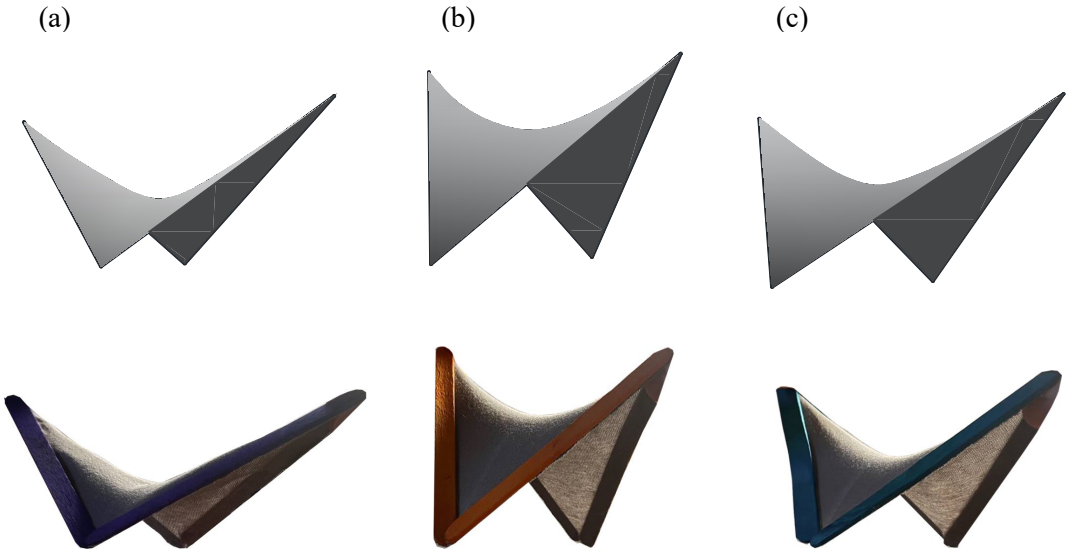

Figure 5. Final geometry of specimens with a rhombus frame and their drawings: (a) with transverse pretension, (b) with longitudinal pretension and (c) with biaxial pretension.

3.1.3. Stiffening patterns of cell structures

The geometry of the rigid members was found to be the most critical factor influencing the geometry of the entire structure. Therefore, changing the relative position of the stiffeners enabled the production of a variety of architectural forms. In this work, several experiments were conducted, and all structures were constructed with homogeneous pretensioning along the main orientation axes of the fabric weave.

Initially, a simple model (№1) was constructed, which comprised of identical parallelograms having equal side lengths (= 115 mm) and angles of 60º and 120º (Figure 6). This model can be inverted and employed on either side depending on the desired nodes of the high points.

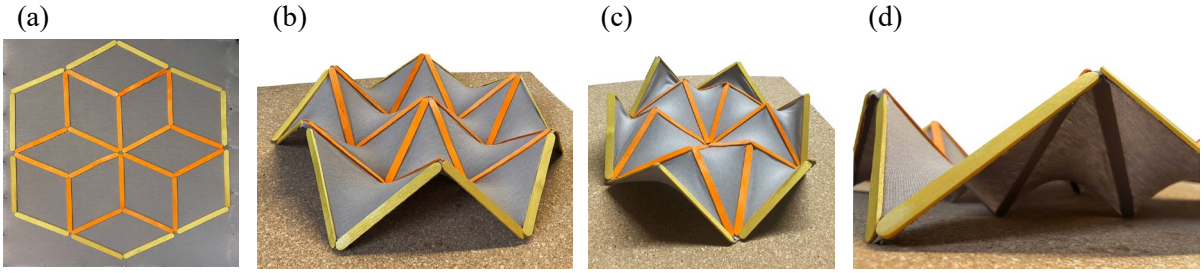

Figure 6. Specimen №1: (a) before relieving pretension, (b) after relieving pretension, (c) After turning and (d) side view.

A wide range of designs can be produced by merging rectangles and parallelograms. Pattern №2-5 were developed using 65 mm sticks, with parallelograms featuring angles of 45º and 135º (Figure 7).

Although these structures can be used for diverse purposes, they do possess a notable drawback, namely that additional internal supports might be required in the lowest nodes to bear external loads. In contrast, tensegrity structures do not face this issue.

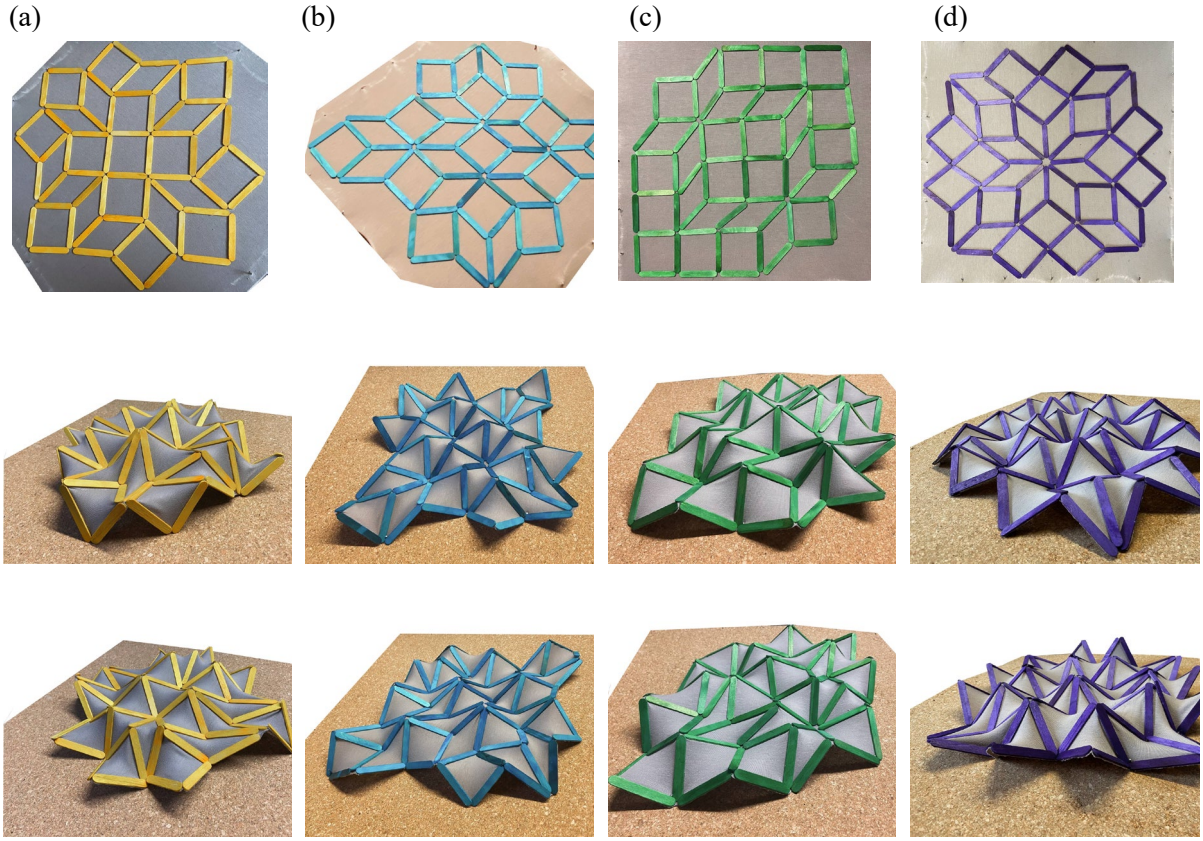

Figure 7. Specimens before and after relieving pretension and after turning out: (a) specimen №2, (b) specimen №3, (c) specimen №4 and (d) specimen №5.

3.1.4. Tensegrity structures

Tensegrity structures are a class of efficient structures that are composed of a combination of compressive and tensile elements in a state of self-stress, providing stability and equilibrium. The distinguishing characteristic of tensegrity is that the rigid struts are not directly connected to each other, but are instead supported by a network of tensioned elements. [4]. One specific type of these structures is membrane tensegrity, which replaces the tensioned cables with a continuous tensile membrane. It is based on the idea that the tensile elements should be a continuum of tensile components [15].

Physical prototypes of membrane tensegrity structures have been implemented in various ways. The common method involves connecting thin rods to the membrane at their ends, causing local stretching [16]. However, this method can be difficult to implement. An alternative approach involves using a connection fabric and rods along their entire length, as described before, which simplifies the process.

To construct a membrane tensegrity structure using this method, a symmetrical pattern of individual flat wooden sticks is glued to the prestressed fabric. The pretension is released and the ends of the outer wooden sticks are fixed as supports. The prestress is then transferred to the wooden rods as compressive forces, resulting in pure internal compression [17]. The model with sets of simple straight lines (Figure 8) is based on the the MOOM Pavilion project, a similar structure on a large scale [18].

(a) (b)

Figure 8. Pavilion with straight beams: (a) before relieving pretension and (b) after relieving pretension.

The use of rigid elements composed of a few sub-elements with different directions and locations relative to each other can result in various configurations, such as I-beams, crosses of beams, and others (Figures 9-11).

(a) (b) (c)

Figure 9. Pavilion with cross beams: (a) before relieving pretension, (b) after relieving pretension and (c) side view.

(a) (b) (c)

Figure 10. Pavilion with I-beams: (a) before relieving pretension, (b) after relieving pretension and (c) side view.

(a) (b) (c)

Figure 11. Pavilion with V-beams: (a) before relieving pretension, (b) after relieving pretension and (c) side view.

This method of form finding has the potential to generate multiple forms that can be effectively employed in architectural practice. A significant advantage of this method is its high degree of variability, which is attributable to the alteration of prestressing parameters and the pattern of rigid elements. Another advantage is the low cost of equipment required to perform experiments, which facilitates the creation of tensegrity systems, in particular.

Finally, this approach offers a simple and efficient way to construct membrane tensegrity structures in the stage of form finding using available materials and straightforward construction techniques.

3.2. Parametric modelling

3.2.1. Cell structures

The whole algorithm is shown in Figure 12a. Figure 13 demonstrates the resulting models of structures, based on the physical models.

The modelling of rigid elements and membrane behaviour is achieved using a combination of components in the Grasshopper plugin. The Length component, based on Hooke's law, is used to represent the rods and their stiffness, while the Angle component defines the geometric stiffness of the substructure (see Figure 12a, a red block). In addition, a reduction of rod's stiffness to 15% is applied to mimic the natural behaviour of rods compressed by the tension of the stretched membrane, which cause rod's shrinkage along their length, and to take into account an initial assumption of spring behaviour [18].

The behaviour of a membrane is realized by a mesh of springs with certain stiffnesses (a light blue block). The Mesh from Lines component in the Weavebirds plugin creates a mesh without binding to rods. The combination of the List Item, 4Point Surface and Mesh Brep components results in a mesh in each cell. Afterward, the Line components are applied again. The upper component in a purple block has a high value of strength and a stiffer interaction of the mesh with rods. The lower component in a blue block has a strength close to one, simulating the flexibility and mobility of the membrane surface.

Based on the experimental physical models, two lists of nodes were introduced to constrain points to the ground through the AnchorXYZ component so that our structure remains on the surface while we restrict the movement only along the z-axis. Changing between the sheets allows to create two different shapes, one from the other by rotating them (a green block). The Floor component is used to support the formation of the structure above ground level (a violet block). Components of a yellow block serve to apply forces to the structure.

The central part of the algorithm involves integrating all the components and obtaining the final result through the Solver component (outside blocks). The final output is visualized (see dark blue blocks).

3.2.2. Tensegrity structures

The algorithm for tensegrity structures is demonstrated in Figure 12b, while Figure 14 displays the parametric models of tensegrity with straight lines, crosses, I-beams, and V-beams based on physical models.

The first part of the algorithm contained in an orange block allows for the configuration of the struts in simple structures to be changed. The input consists of multiple elements, such as lines, crosses, I-beams, and others, which are sub-elements of the entire structure. Geometric parameters such as the angle of rotation of the elements, the number of columns and rows, and the distance between them can be modified, creating a network of sub-elements. A pink block corresponds to a red block in the previous example.

The second significant difference is the use of a special Delaunay mesh to simulate the membrane as a cable, with the endpoints of the struts serving as vertices (a purple block). This enables the natural structural behaviour of the membrane in tensegrity structures to be largely mimicked. The approach of using a Delaunay mesh to simulate the membrane is also supported by previous studies [19, 20].

The violet block contains the same procedure as in Figure 12a. A dark violet block corresponds to the yellow block. Other steps of the algorithm are identical to the previous one.

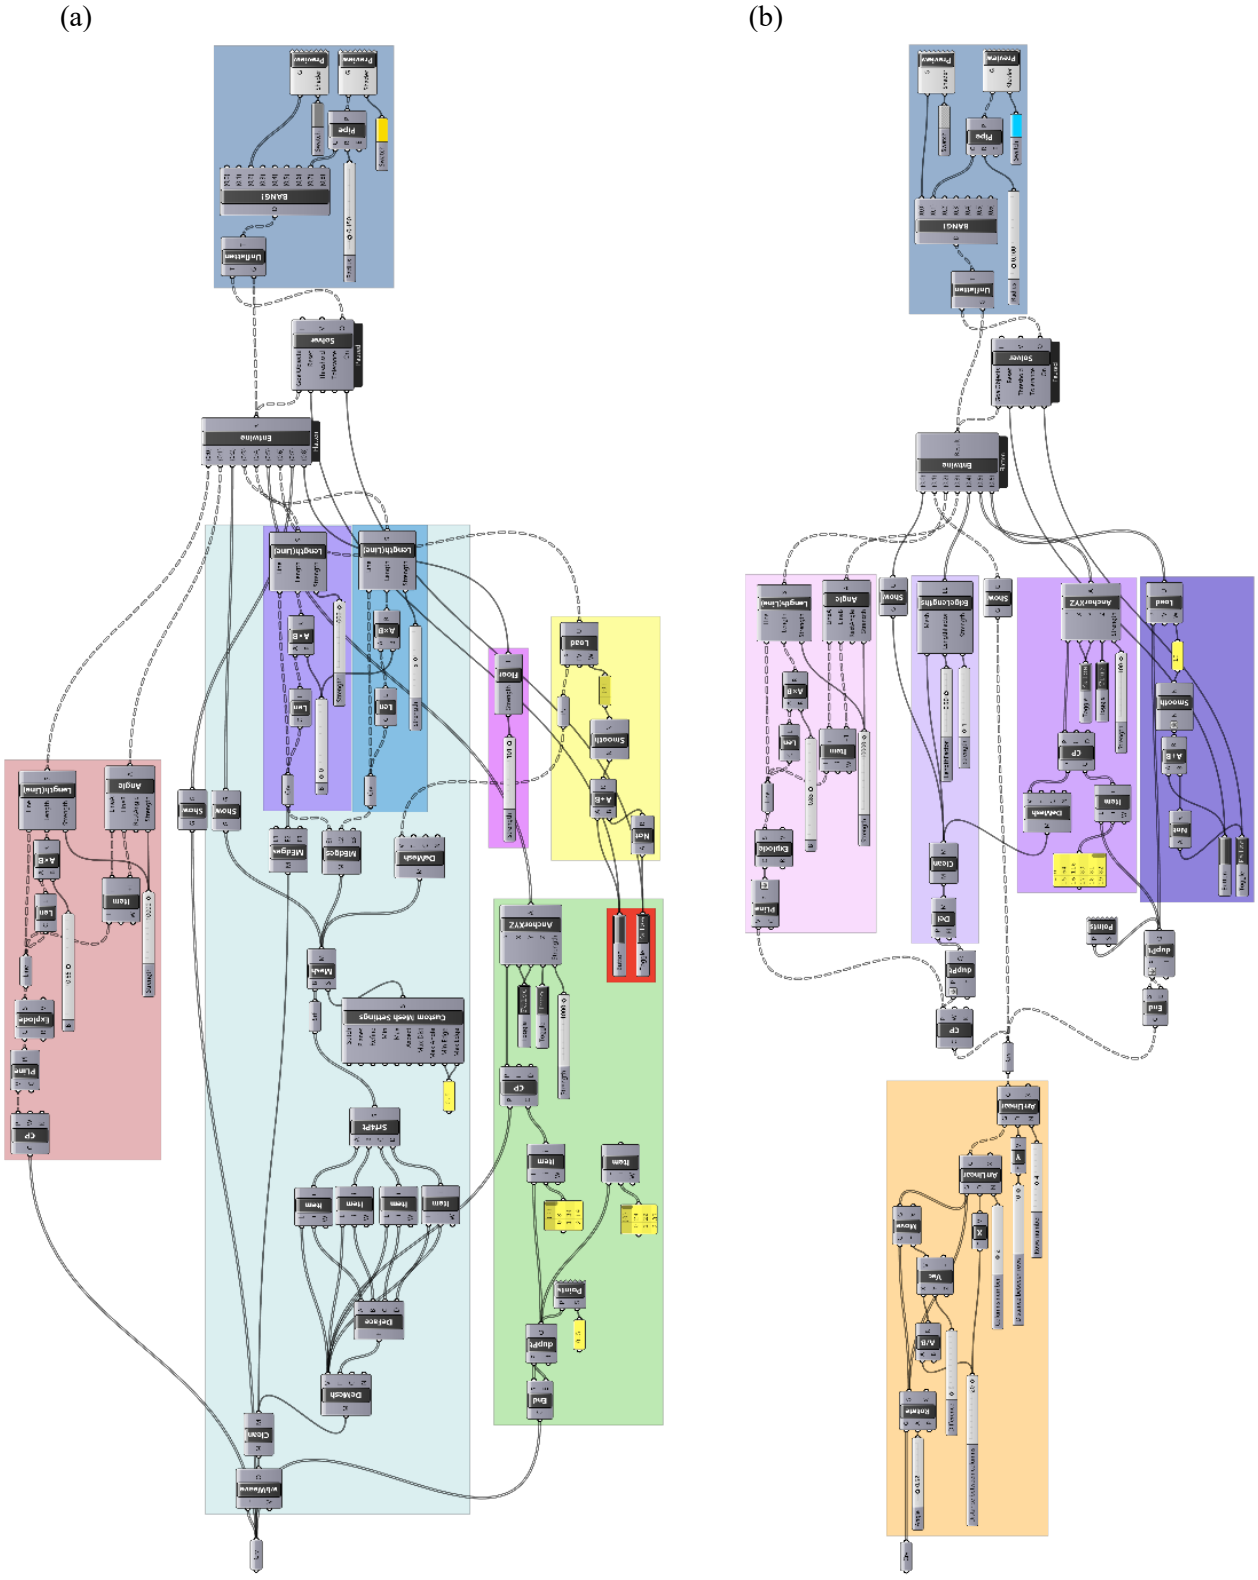

Figure 12. The algorithm in Grasshopper: (a) for cell membrane structures, (b) for tensegrity structures. (The pictures are rotated 90° to make them more readable.)

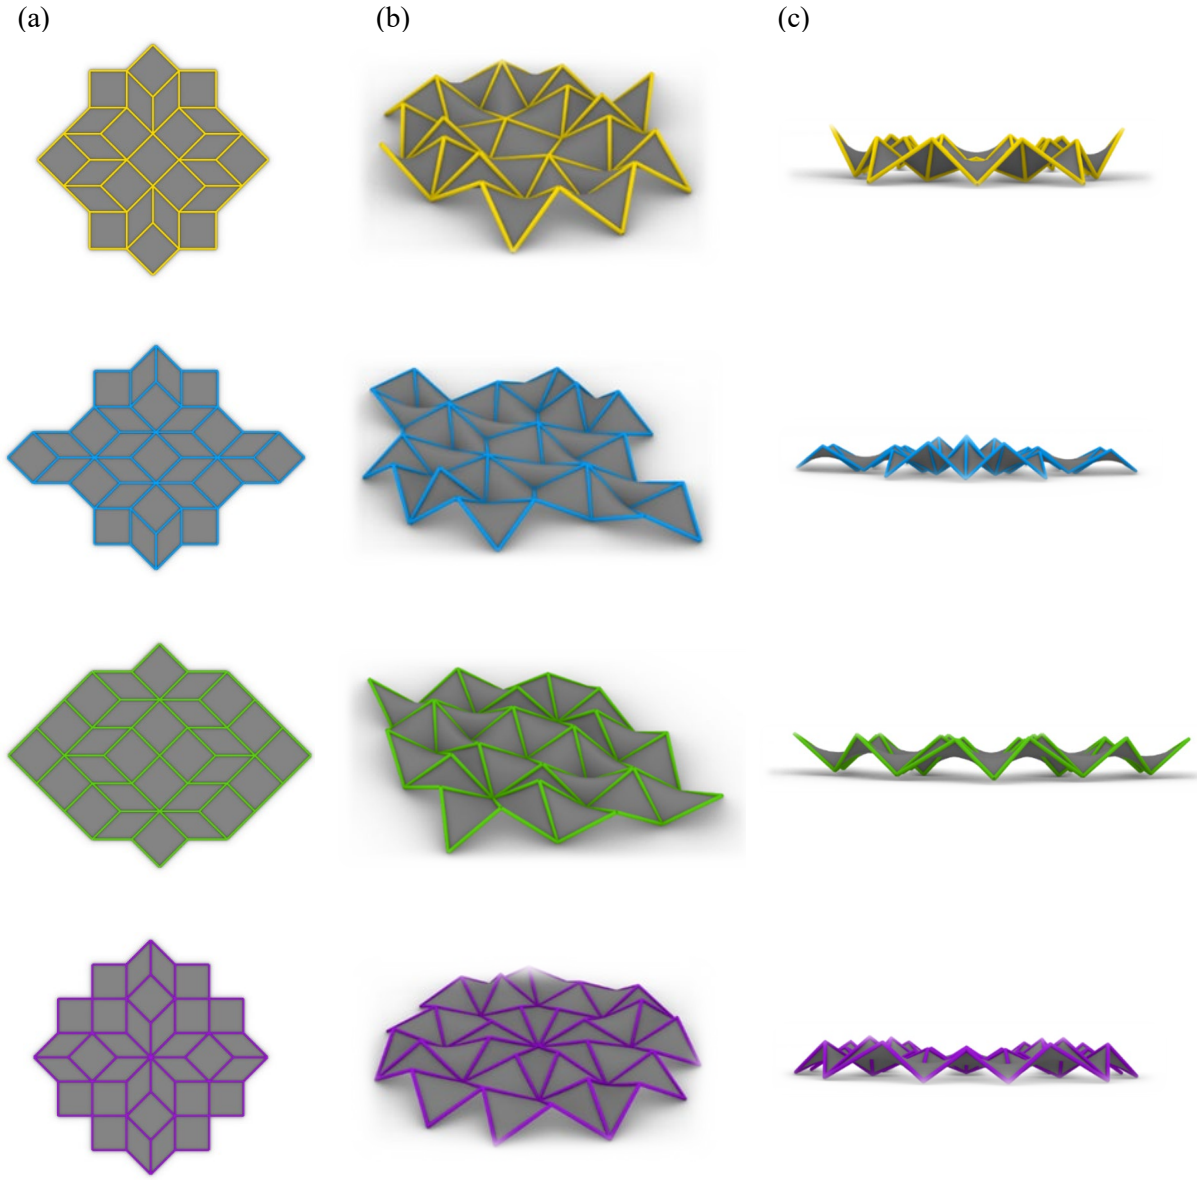

Figure 13. Parametric models of cell structures: (a) before relieving pretension, (b) after relieving pretension, (c) side view.

Many different layouts of strut configurations by Wang and Li serve as the source of inspiration for modelling these tensegrity structures [21]. In this work, such prototypes were utilized for modelling tensegrity in Grasshopper (Figure 15).

To conclude, parametric modelling is a suitable choice for digital form-finding. This method allows for the intended shape to be simulated and the properties of parts to be easily modified, helping to optimize geometry and find the ideal shape. Modelling in Grasshopper offers extensive possibilities for the required simulation of structures.

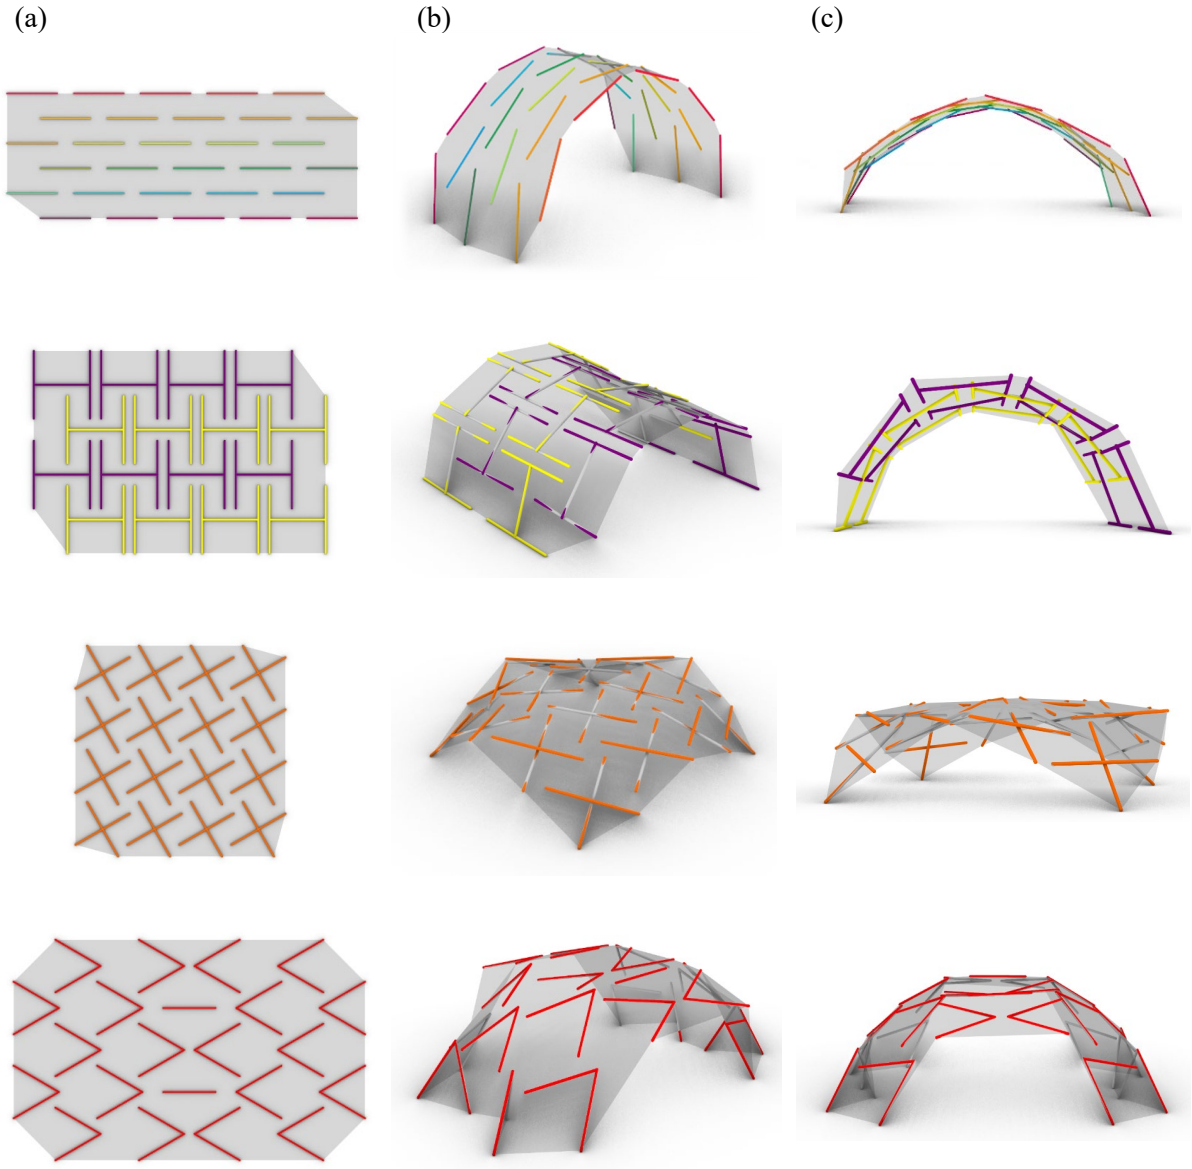

Figure 14. Parametric models of tensegrity structures: (a) before relieving pretension, (b) after relieving pretension, (c) side view.

4. Discussion

In this study, a prototype method for shape modeling was introduced based on existing types of forms and methods of finding them. The experiment involved a pretensioned fabric with a glued grid of wooden sticks, where the relaxation of the prestressed fabric contributed to the forming of specific anticlastic surfaces by energy release. The influence of the pattern of rigid elements, intensity, and direction of pretensioning on the final shape was investigated. The results showed that increasing pretension intensity results in a greater inclination of the entire structure. Hyperbolic curvature also depends significantly on the direction of prestress – uniaxial or biaxial. The overall geometry of the structure is changed by the relative position of rigid elements, resulting in a wide variety of possible shapes that can be applied in architecture. Samples of tensegrity structures were built using the same form-finding method, which simplifies the modeling process compared to the conventional method for creating tensegrity.

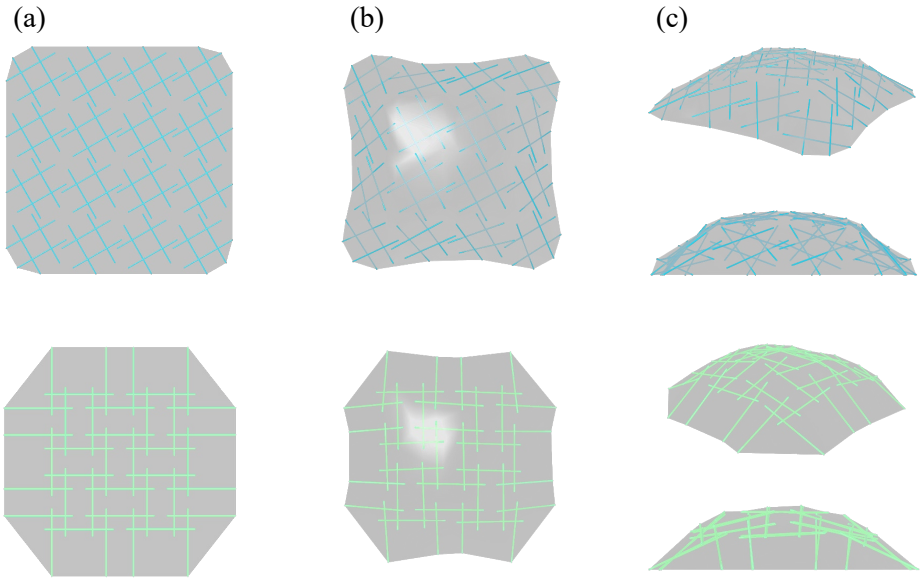

Figure 15. Parametric model of tensegrity according to layouts from [13]: (a) before relieving pretension, (b) after relieving pretension, (c) side view.

Furthermore, the experiments were digitized and simulated using Rhino6 and Grasshopper software, which offers even more options to optimize the final shape by changing the stiffening configuration, membrane strength, and deformability. This digital approach produces correct forms corresponding to physical shapes, leading to successful modeling and rationalization of the considered structures.

The final algorithms developed in this study can be extended to more detailed models, further structural analysis, and implementation in BIM. The resulting designs of the pretensioned and stiffened membrane structures have great potential for application in practice as pavilions, roofs, and awnings. These structures can demonstrate effective structural behavior and can be very spectacular from an architectural point of view. Overall, this study highlights the effectiveness of the physical and digital form-finding methods used in the design of pretensioned stiffened membrane structures. The results provide valuable insights into the factors that influence the final shape and geometry of such structures, paving the way for their practical application in various architectural contexts.

Abstract

This paper is the structural design proposal for a bridge-like observatory with a spiral stairway. The building is located on a top of a mountain. Moreover, the site is undulating and complex ground containing many rocks. The main issues in the structural design were as follows:1. Design of forms considering both architectural aesthetics and structural rationality; 2. Implementation of systems which properly resist seismic forces on undulating ground; and 3. Reduction of underground rock excavation in foundation construction. The authors proposed a structural system with a L-shaped beams on inclined pillars. It effectively uses the pillars as seismic elements. This system was achieved by using slender pillars to provide sufficient horizontal stiffness, while minimizing the amount of rock excavation by using fewer foundations.

Keywords: structural design, L-shaped beam, inclined pillars, undulating ground

1. Introduction

With the development of technology, it has become possible to realize any form of structure. Under such circumstances, it would be important for structural engineers to consider structurally reasonable systems, not by brute force, but by structural design ingenuity. The authors have focused on the relationship between the curved structures and pillars, have been studying effective structural systems that combine them for complex forms [1]. The authors also studied a frustum shaped structures with diagonal members and ascertained its effectiveness [2].

This paper presents the structural design of the Senkoji Peak Observatory, which appears to float atop the mountain. This observatory, called “PEAK”, has a total length of 63m. While most observatories extend above the ground into the sky, this project is unique in that it is in the form of a horizontal bridge.

The building consists of three elements: an observation platform, a spiral stairway, and a vertical elevator shaft, as shown in Figures 1 and 2.

The ground is undulating and interspersed with numerous granite formations. These require high costs to excavate. Furthermore, the area below the observation platform is used as a park. In order to obtain a sufficient view from the park and to ensure the integrity of the park, the support structure was required to be free of many members so as not to become an obstacle. To solve the issues, the authors proposed a new structural system that effectively uses inclined pillars.

2. Building overview and issues

2.1. Building overview

Senkoji Peak Observatory was completed in 2022, in Onomichi-city, Hiroshima Pref., Japan. Table 1 summarizes the overview. The city faces the Seto Inland Sea, is characterized by mountains on its back and few flat areas, and is known as a city of slopes. Figure 3 shows a view from the seaside; the building is located at the top of the mountain. Figure 4 shows a view from right above.

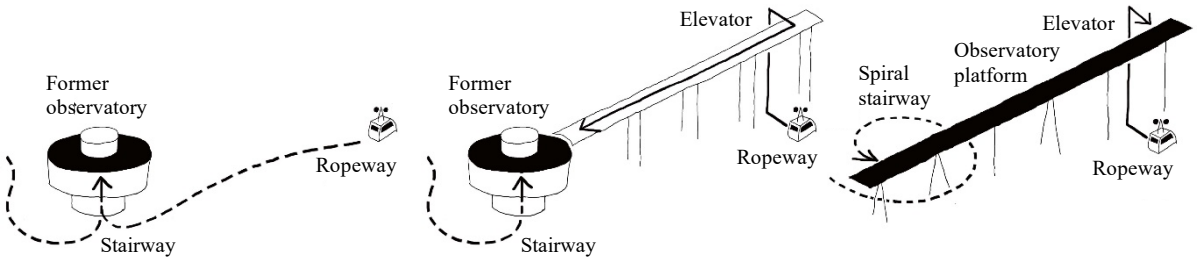

Figure 3. View from the seaside.

Figure 4. View from above.

This is a project to reconstruct an observatory and ropeway station at the top of Mt. Senkoji. Figure 5 shows the diagram transition of this project. The former observatory did not have an elevator and was not accessible, as it was on a different level from the ropeway station building, requiring a climb up the hill. In the schematic design phase, a bridge-type structure was proposed for the approach from the station to the existing observatory for accessibility. Later, the former observatory was demolished due to insufficient seismic resistance, however the view from the bridge-type approach was retained. The authors sought a simpler form, aiming for a horizontal deck floating at the top of the mountain. A spiral stairway was built where the former observatory was located.

Figure 8. Site condition.

The site is the precincts of the Senkoji Temple, located near the top of Mt. Senkoji, and is used as a park. As shown in Figures 6 and 7, the ground level is undulating; Figure 8 shows that it interspersed with numerous granites. The former observatory stood on the western edge of the site, and the former ropeway station was to the east.

The building consists of two parts: one on the east side with a ropeway station, elevator shaft and observation platform; the other on the west side with an observation platform and a stairway. The platform level of each building is the same, however the east wing is one story deeper than the west wing, depending on the topography. The east wing is a three-story building, including the penthouse for the elevator, while the west wing is a one-story building.

In order to preserve the environment and atmosphere of the park, buildings above the ground were to be kept to a minimum such as the platform of the observatory; the elevator shaft on the east side and the stairs on the west side were installed as a connection path to the platform. The platform is flat and straight, the elevator shaft on the east side is rectangular prism, and the stairs on the west side are spirals with a large circular diameter and a constant slope.

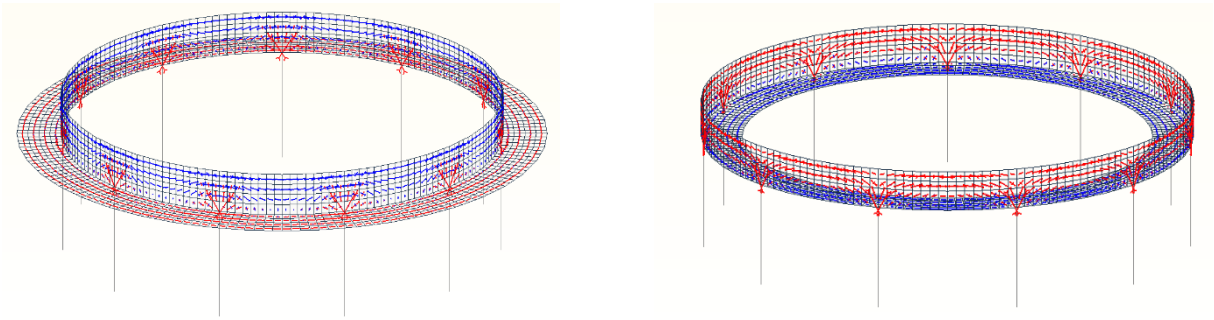
The entire platform is 63m long, of which the east side is 18m and the west side is 45m. The width of the platform is 3.64m. For the ropeway station, the length of the longitudinal direction is approximately 22m; the length of the transverse direction is approximately 12m; the elevator shaft is approximately 3m square. The spiral stairway has the inner diameter of approximately 15m and the path width of 1.5m.

The building is made of RC, with the platform and spiral stairway supported by steel columns; the main girder of the platform is made of SRC.

2.2. Issues

The key to the structural design was to build the observatory, especially the spiral stairway, on top of this complex ground, while maintaining unobstructed atmosphere below the platform as a park. The main issues in the structural design were as follows:

1. The architectural form is a combination of geometrically simple shapes: an elongated platform, a rectangular-prism shaped shaft, and a spiral stairway. The site also functions as a park, so it was necessary to minimize the number of pillars and other obstructions. Therefore, it had to propose a system that would minimize the number of support members and effectively resist horizontal forces, while taking the form into account in the architectural concept.
2. Because the site is located on a mountaintop, the ground surface is highly undulating, which causes variation in column length. However, a rigid frame structure is not efficient because horizontal forces are concentrated on the short columns. Therefore, it should be proposed a system to enhance horizontal stiffness for the topography and height differences of the structure.
3. The site is densely covered with rocks, mainly granite, scattered throughout the ground. Because of the high cost of rock cutting, the challenge was to minimize the amount of rock cut when constructing the foundation.



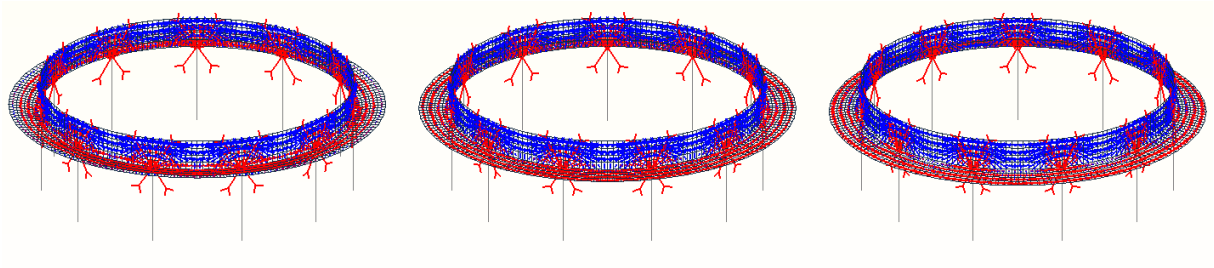
3. Analysis

3.1. Model

The building was analysed by using an FEM. Slabs and walls were modelled plane elements with in-plane and out-plane stiffness; columns, beams and footing beams were modelled beam elements. The model was considered during the design of the whole structure, and was analysed by considering dead loads, live loads, snow loads and seismic forces. This project, especially the spiral staircase, generates bi-directional axial forces and bending moments in plane elements. For the proportioning of member sections, the design method was used to design plane elements with in-plane and out-of-plane bending moments that take into account the movement of the neutral axis.

3.2. Structural behaviour

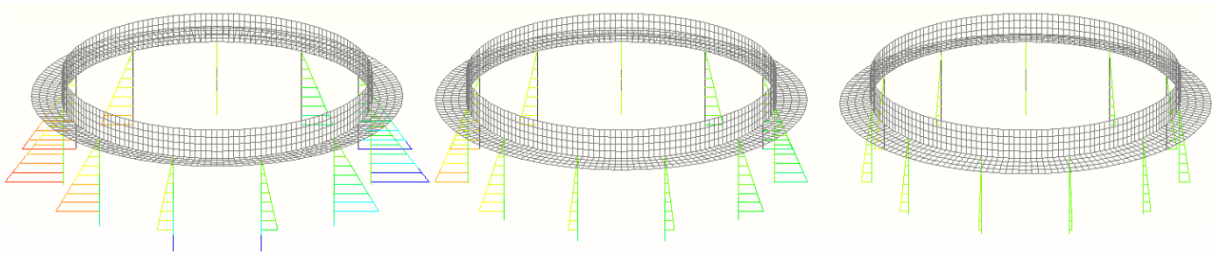
Prior to the analysis of the characteristics of the spiral stairway, this section will focus on a ring structure with an L-shaped disk composed of plane elements at the top and supported at equal intervals by pillars at the corner of the L-shape. In general, L-shaped frames are unstable when the shape is straight rather than circular because of the torsional behaviour of the L-shape around the supported point. However, if it is curved, it is stable because the torsional stress, i.e., the radial bending stress, is balanced by the circumferential bending stress. Here, although a circular shape is shown in Figure 9, etc., it does not have to be particularly closed.



a. Supported on the inner side.

b. Supported on the outer side.

Figure 9. Axial force diagram.

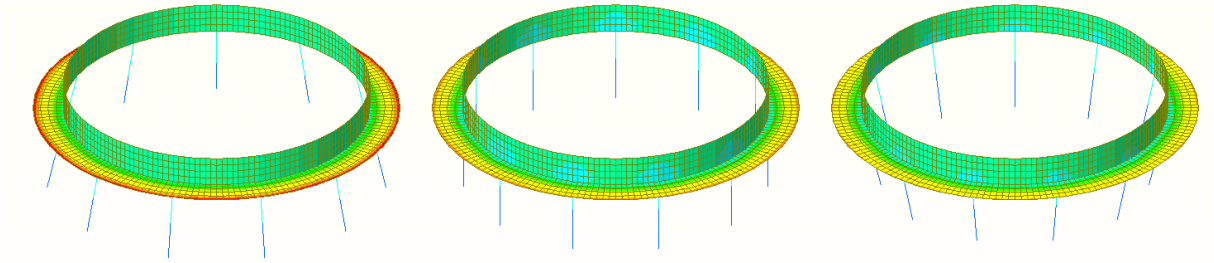


Firstly, consider the location of the supports. The L-shape assumes RC slabs and walls, and a frame supported by steel pipe pillars. The pillars are rigid at the bottom and pinned at the top. Figure 9 shows the axial force diagram under dead loading. Figure 9.a shows a structure supported on the inside with a cantilever slab on the outside, and Figure 9.b shows a structure supported on the outside. Red and blue in the figures indicate compressive and tensile forces, respectively. In this project, the L-shaped portion is assumed to be of RC. Considering the shear force transition of the slab by seismic forces, the system shown in Figure 9.a, where the slab is subjected to compressive forces under dead load, is preferable.

Secondly, the radial slope of the slab face of the L-shaped frame is discussed. Figure 10 shows the axial force diagram of plate elements and Figure 11 shows the bending moment diagram of pillars under dead load. The slope of the slab in each figure is: 'a' is higher on the outer edge, 'b' is flat, and 'c' is higher on the inner edge. Due to the difference in the slope of the slab, a tension ring is occurred at the slab edge in Figure 10.a and a compression ring in Figure 10.c. This means that near the top of pillars, compression and tension occur, respectively, opposite to the slab periphery. The top of pillars is deformed inwardly as a result of the L-shaped torsional deformation, as can be seen in Figure 11.b, where bending stresses are induced in the bottom of pillars. By varying the radial gradient on the disk, the stresses on the columns are increased or decreased in Figures 11.a and 11.c. Although it is effective to radially slope the slab so that the outside is lower for a more efficient structure, the slab is not radially sloped in this project because it is a staircase, so it is radially stepped for ease of use.

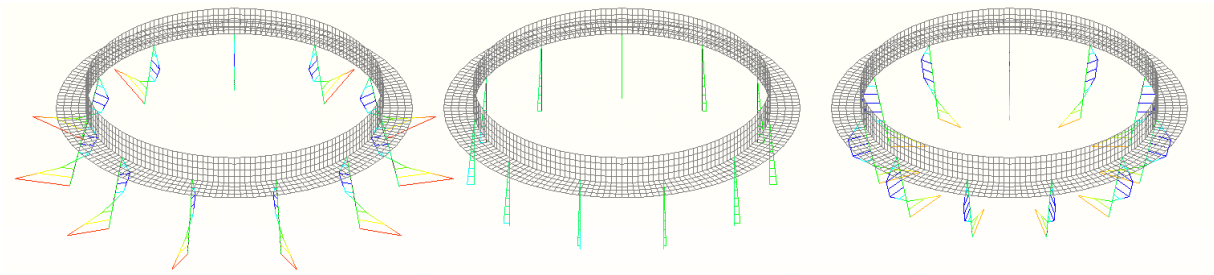
a. Higher on the outer edge. b. Flat. c. Higher on the inner edge.

Figure 10. Axial force diagram for difference in radial slope of slab.



a. Higher on the outer edge. b. Flat. c. Higher on the inner edge.

Figure 11. Bending moment of pillars for difference in radial slope of slab.



Thirdly, the inclination of the columns is discussed. Figure 12 shows contour diagrams of the vertical displacement of the slab under dead load, and Figure 13 shows bending moment of the pillars. In each figure, the columns are tilted in the following three forms: 'a' shows the bottom of pillars spread outward, 'b' shows vertical, and 'c' shows the bottom of pillars narrowed inward. Each column is tilted in a radial direction. In Figure 12, red indicates greater displacement. In other words, in Figure 12.a, the vertical displacement of the slab edge is large, and in Figure 12.c, the displacement is small. Figure 13 shows that the tilting of the column increases the bending moment due to the eccentric bending effect caused by the dead weight of the L-shaped portion. As mentioned with respect to Figure 11, even in the vertical case, as shown in 13.b, there is a bending moment that causes tension in the outward direction

of the circle due to the torsion of the L-shape. This effect is added to the eccentric bending effect for inwardly tilted pillars and subtracted for outwardly tilted pillars. Therefore, it seems structurally reasonable to support vertical loads with outwardly tilted pillars.

a. Inwardly tilted pillars. b. Vertical pillars. c. Outwardly tilted pillars.

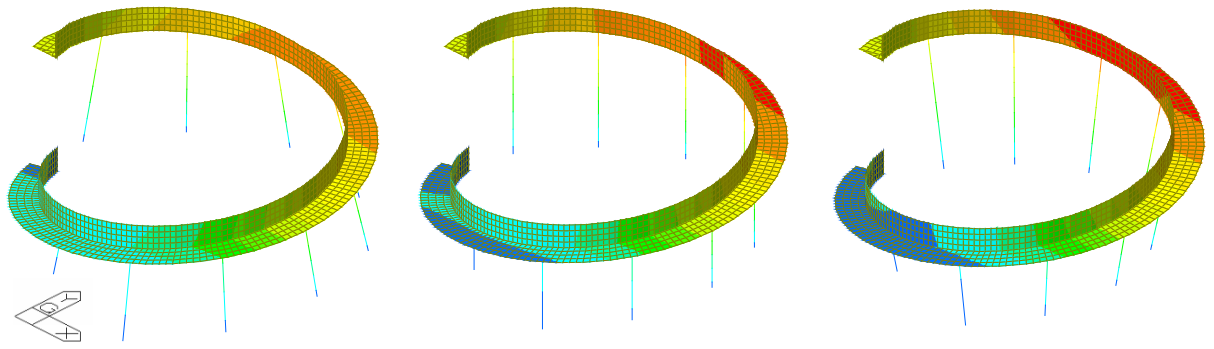


Figure 12. Vertical displacement for difference in pillar inclination.

a. Inwardly tilted pillars. b. Vertical pillars. c. Outwardly tilted pillars.

Figure 13. Bending moment of pillars for difference in pillar inclination.

Finally, considerations are made for the spiral shape. In the spiral shape, the pillar length is shorter and the horizontal stiffness is higher in the area closer to the ground, causing the pillar to behave in a twisting behaviour by seismic forces. In such a case, it would be effective to install circumferential walls or braces, however this is unsuitable for this project because of the openness required under the structure. The effect of horizontal deformation caused by tilting the pillars in the radial direction is shown in Figure 14. This contour plot represents the horizontal displacement of the slab due to seismic forces. Red indicates large displacement. The X direction in the figure is the direction of seismic force application. The models assume this project, and the pillar lengths are set according to the actual ground level. In Figures 12 and 13, tilting the columns outward was more advantageous, however in Figure 14, tilting outward is not necessarily more advantageous due to greater torsional deformation; the relative difference in horizontal displacement at low and high levels differs by about 17% between Figure 14.a and 14.c. Therefore, sufficient attention should be paid to the inclination in the actual design. In this project, the pillars were tilted inward in consideration of architectural aesthetic.

4. Structural design

4.1. Design and realization

While most observatories extend above the ground into the sky, this project is unique in that it is in the form of a horizontal bridge. Through the design process, the search for a simpler form led to the consolidation of columns to create the expression of a horizontal platform floating above the mountain. In addition, the distinctive spiral staircase was also required to be a light structure. The spiral stairway and platform each feature L-shaped structures. Figure 15 shows the structural organization of the entire building.

Due to the unique nature of the massive rock formations scattered throughout the site, it was an important issue to consolidate the pillars to reduce the amount of excavation as much as possible. In order to reduce the cost of rock excavation, the former building locations were followed as much as possible to minimize excavation for new foundations. The spiral stairway was excavated to reduce the amount of excavation by decreasing the foundation beam size.

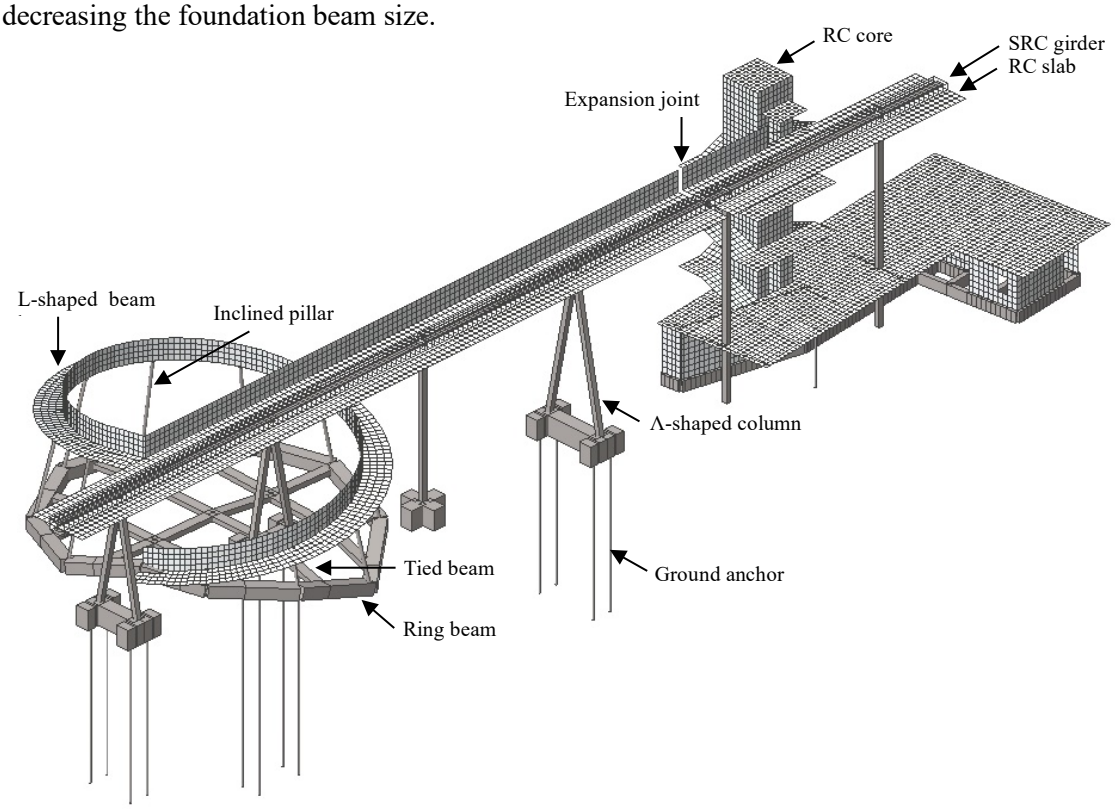

Figure 15. Structural arrangement.

4.1.1. Platform and shaft

In the schematic design phase, the structural system was envisioned to be a light structure, such as a tree-like structure, with two rows of columns with canes and beams composed of small size members that would be easy to transport, taking into account that the building is located on a mountain top.

As shown in Figures 16 and 17, the platform consists of an SRC main girder with 750 x 1,000, that is provided at the centre of the bottom of the L-shape, and a 200mm thick cantilevered slab floor. The uneven distribution of the load is resisted by the torsional stiffness of the SRC girder. Because of the long bridge geometry, there was a high degree of freedom in the location of support points. Column locations were designed to minimize the amount of framing and rock cuttings while avoiding localized depressions and exposed rock, with a span of11m. The length of the columns varies with the difference

in elevation of the ground, with a height to the platform of about 6.7m at the western end, about 9.2m near the centre, and about 12.5m at the eastern end. If the columns are designed to rigid frame system, horizontal forces will be concentrated on the short columns. Therefore, Λ-shaped columns, made of 300 mm square steel pipes, were used to resist axial forces in the direction of the applied force, regardless of the length of the member. They are arranged in a balanced manner. The columns were made thinner as an axial force resisting system, and an attempt was made to realize a floating observation platform.

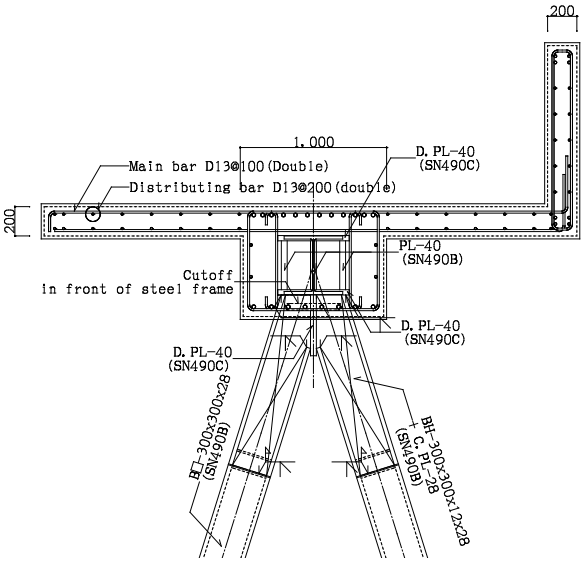

Figure 16. Detail of platform.

Figure 17. Construction of platform.

The elevator shaft, which is the starting point of the approach from the station, is constructed with RC walls. An artificial ground consisting of a 400 mm thick RC slab was provided on the middle floor to gently connect with the ground on the west side. The RC core could be used as a seismic core. The seismic wall thickness was set at 200-300 mm. Considering the overall horizontal stiffness balance, the stiffness of the RC core, which is located on the east side, is too high, causing the entire structure to cause eccentric behaviour. Further, the shaft side is also one story deeper on the elevation due to the undulating topography, so it is unbalanced in the elevation. Therefore, of the total length of 63m, 18m on the shaft side was constructed of RC and the other 45m was constructed of steel, structurally separated and functionally connected using expansion joints. As shown in Figures 18 and 19, The expansion joints are made with fluoroplastic sliding bearings attached to the steel frame of the SRC girders, and the east side is placed on the west side. In addition, since the frame is exposed as it is, the temperature fluctuation of the frame due to solar heat and other factors is significant. By dividing the building into separate buildings, seismic elements with high horizontal rigidity in the longitudinal direction can be concentrated in each building, and the effect of thermal distortion is also controlled.

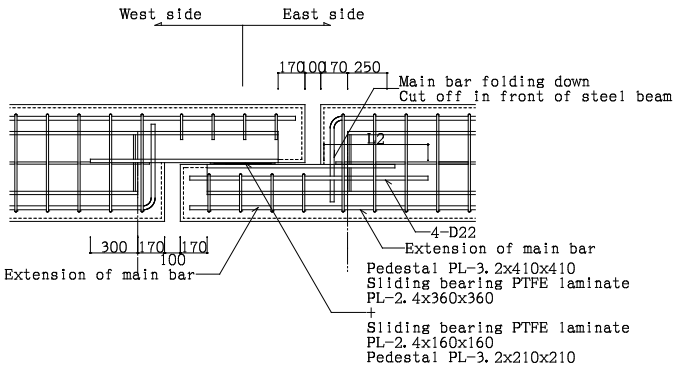

Figure 18. Detail of expansion joint.

Figure 19. Construction of expansion joint.

In the west building, the Λ-shaped steel columns are designed to resist the horizontal forces, and two are placed at both ends and one in the centre in the long direction. Torsion due to eccentricity in the longitudinal force is resisted by Λ-shaped columns in the shortitudinal direction. The columns are made of square steel tubes and are designed so that buckling will not occur on the compression side even under horizontal forces that are expected to occur in an earthquake with ground acceleration of 600 gal. Because the Λ columns of the platform have large variable axial forces due to horizontal forces in relation to the dead loads, the ground anchors were used to resist the foundation uplift.

4.1.2. Spiral stairway

A spiral stairway with a steep slope and a small diameter could be constructed without pillars due to the effect of the spiral, but in this plan, the slope is shallow, and the inner diameter is large to ensure the necessary depth dimensions for the dance floor at each level. Due to the greater influence of out-of-plane bending and torsion actions under dead load, the structure was supported by pillars with a pitch of approximately 4.6 m. Figures 20 to 22 indicate that steel capitals were provided at the top of pillars to account for stress transfer through punching. Inside the stairway has an RC beam that also serves as a handrail, enhancing bending and torsional stiffness. Horizontal stiffness is enhanced by an RC cantilevered slab that serves as a stepped floor. These form an L-shaped structure. The L-shaped beam, one side of the L-shape is about 1.5m, made of RC were 200 mm thick, and the steel inclined pillars were φ200 in diameter.

In the seismic design aspect, instead of transmitting the inertia force of the entire stairway to the platform, the supports are designed to resist the inertia force of about half of the stairway's load-bearing area. Inertia forces are transferred to the columns via stud bolts in the steel plates of the capitals. The radial arrangement of inwardly inclined pillars is expected to have the effect of suppressing torsional deformation during horizontal loading.

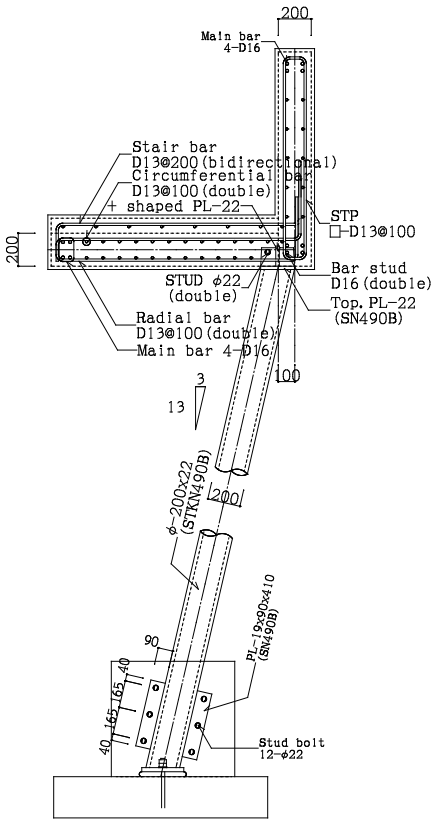

Figure 20. Structural arrangement.

Figure 21. Construction of stairway.

Figure 22. View from below.

4.3. Foundation design

The stratigraphic composition is composed of a dense concentration of hard rock, mainly granite, topped by 1 to several meters of fill. A direct foundation with rock as the support layer was designed, and soil improvement was designed to cope with the unevenness of the support layer.

In the spiral stairway, the 700mm height foundation beams were arranged in a ring shape to connect the pillar bases while adjusting to the undulations of the ground in order to resist thrust from the inwardly inclined columns. The 300mm height foundation beams are arranged in a grid pattern to serve as tie-bars. Consideration is given to reducing the amount of rock cuttings by minimizing the beam size. Moreover, as shown in Figure 23, 3D scans were made to determine the existence of rocks and landforms, and the point cloud data was shared among the parties involved to rationalize foundation planning and rock cutting areas. Using point cloud data, the foundation beams were planned so that they would not interfere with the rock to minimize the extent of rock removal as shown in Figure 24.

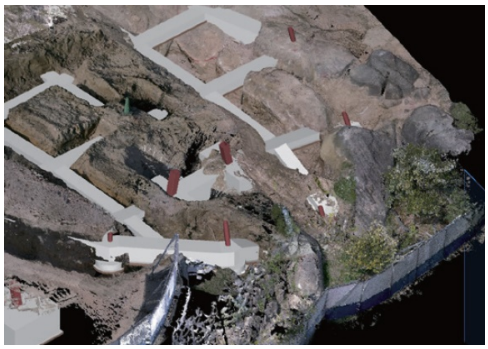

Figure 23. Point cloud data of the site by 3D scan.

Figure 24. Construction of foundation.

5. Conclusions

This paper describes the structural design of an observatory built on the mountaintop with complex ground condition.

Focusing on the spiral stairway, it was analysed the structural characteristics of a circular structure with L-shaped corners supported by columns. In order to apply the structure to the actual structure, it is supported by inwardly inclined columns, and about half of the inertia force is resisted by the columns.

In the platform, a girder is provided at the centre of the bottom of the L-shape, and a structural system with axial force resisting Λ-shaped columns is used to accommodate the different column lengths caused by the undulating ground. The platform was divided into two buildings to balance the stiffness of the entire building and to take thermal stress into consideration.

The foundation was designed to minimize the amount of rock cuttings using point cloud data obtained from a 3D scan of the ground.

Acknowledgements

We would like to thank everyone involved in the planning, design, and construction of this project. Figures 1 to 7 and 23 were provided by AS.

A Group-Theoretic approach for constructing spherical-interlocking assemblies

Abstract

A topological interlocking is an assembly of blocks constrained by a fixed frame such that each set of blocks is kinematically constrained. Estrin et al. [3] provide a recent overview of progress in the study of topologically interlocking assemblies. Using a group-theoretic approach, we construct interlocking assemblies of different polygonal surfaces. Given such a polygonal surface, we can compute its automorphism group and check for identified faces, i.e., faces that are identified under the symmetry of the given surface. The number of classes of identified faces corresponds to the number of different types of blocks in the resulting assembly. Next, we deform faces to obtain an interlocking structure. In this paper, we give examples of interlocking assemblies which form platonic solids or tubular interlocking structures. For our examples we use an algorithmic approach that can be easily generalized to arbitrary tessellations of spheres and tubes.

1. Introduction

Since antiquity Stereotomy (lit. the art of cutting solids) has been employed to design structures which are aesthetically pleasing and structurally sound by employing gravity and the design of a stone. Perhaps best summarised in the words of Perrault (as cited in [14]), Stereotomy is based on the principle of using *the weight of the stone against itself by making it hover in space through the very weight that should make it fall down*.

While most applications employ this principle to exploit the force of gravity to a construction's advantage, the idea of underlying Abeille tiles and the modern idea of topological interlocking [2] go beyond this: they use Stereotomy to design blocks that can be assembled inside a fixed frame such that

each block is not only constrained by its neighbouring blocks in one direction (towards the ground) but in all directions.

In recent years, many topological interlocking assemblies have been proposed and have been shown to have many advantageous properties (see e.g. [3] for an overview). The osteomorphic blocks proposed in [10] are very versatile and can be arranged in different ways to form 3D structures. Others have proposed blocks that can be assembled to form a tubular structure fixed by frames at either end, see [8].

We propose several new blocks that facilitate spherical and tubular interlocking assemblies. We modify a group-theoretic method introduced in [4] to design blocks that facilitate a planar interlocking assembly to the case of spherical or tubular structures. It turns out that in designing blocks for non-planar assemblies another problem arises: While each individual block may be constrained when its neighbours are fixed, it might be possible to move all blocks simultaneously, each in a different direction, thereby rendering the assembly less stable.

One example of such an assembly is that of a sphere, where each block is obtained by the group-theoretic method described above. When assembled into a sphere, all blocks can simultaneously be moved away from the centre of the sphere along the line to its centre of gravity. This problem may also arise in a tubular interlocking assembly, where it may be possible that all blocks are simultaneously moved away radially from the central line of the tube.

Depending on the applications of these structures, these problems may influence their performance. While a tunnel may experience mostly gravitational forces and forces directed towards its interior, a pillar in the shape of a hollow tube might be subjected to different forces. For example, during seismic activity it is possible that all blocks are subjected to an outwards force.

We give some examples of spherical and tubular interlocking assemblies which display this weakness and present methods for designing blocks which overcome this problem.

2. Topological interlocking

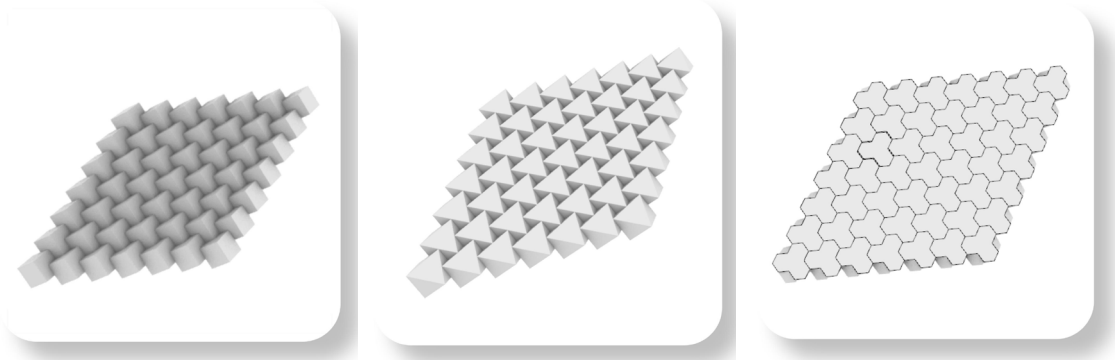

Figure 2. Left: Topological interlocking assembly of cubes [1]. Middle: An assembly of compressed octahedra (obtained by truncating cubes) Right: Filling the gaps or using the Escher-Trick (see [4])

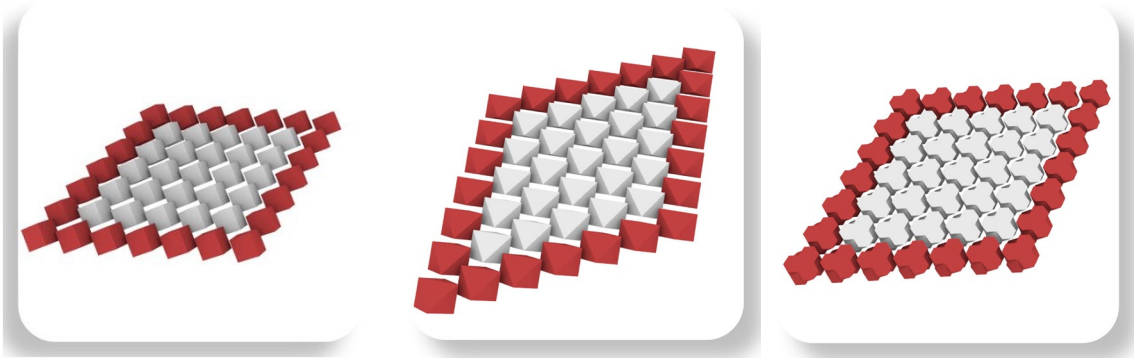

Figure 3. Exploded views of the assemblies given in Figure 2 with frame marked in red.

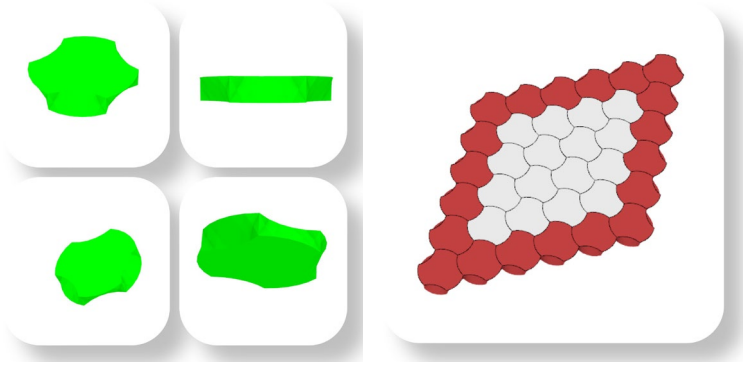

Figure 4. In [8] the authors give a smooth version of the block from the assembly in Figure 2 (right).

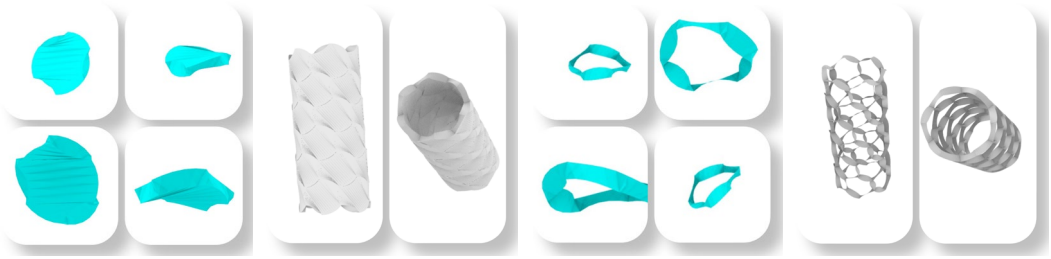

Figure 5. Deforming the block from Figure 4, we obtain a tubular interlocking assembly (see [8])

A topological interlocking (short TI) assembly consists of several blocks which are in loose contact with each other such that fixing a subset of blocks, called the "frame", restrains any motion of any arbitrary set of blocks in the assembly. The term and concept of TI assemblies were first introduced by Dyskin et al. in [2].

Before making this definition more precise we will give some examples of TI assemblies and shed light on methods that yield candidates for TI assemblies.

In [1], the authors give an assembly of cubes arranged in a hexagonal fashion, see Figure 2, such that the middle section is given by hexagons. By truncating the cubes, we obtain another interlocking assembly consisting of compressed octahedra, see Figure 2. By closing the gaps between blocks and thus enlarging the pairwise contact surfaces of any two blocks we obtain another assembly shown in Figure 2. The latter assembly can be obtained by the methods presented in [4] via the Escher-Trick. For all those assemblies we can select the outer most blocks as part of the frame (marked in red in Figure 3), to obtain a TI assembly.

A similar approach to obtaining candidates for TI assemblies starts with a hexagonal prism. Next, side faces of the prism can be paired, and a part is removed from one face and this exact part is added onto the paired face. Starting with a tessellation of hexagonal prisms, the pairing of the faces corresponds to orbits under the action of a crystallographic space group (see [4]).

In [8], the authors use this approach to obtain a smoothed version of the block (Figure 4) which can be deformed to obtain a TI assembly which has the shape of a cylinder, see Figure 5. In [8], the authors use the CAD system Rhino [9] to map this block onto a cylinder (tube). In [13], the authors further investigate generalizations of this block and constructed 3D-printed prototypes.

The assemblies in Figure 2 all use a frame consisting of the most outer blocks, see Figure 3 for an exploded view with frame marked in red. In the following sections tubular shaped assemblies with a frame consisting of the top and bottom blocks and thus two non-connected frame components are shown.

Motivated, by these examples we can state the definition of a TI assembly, taken from [4].

A pair $((X_i)_{i\in I}, J)$ consisting of an assembly $(X_i)_{i\in I}$ *of blocks* with an index set I and a subset $J \subset I$, called "frame", is called a *topological interlocking assembly* or *topological interlocking* (TI for short) if all the blocks given by $I \setminus J$ are kinematically restrained, that is we **cannot** find a finite non-empty subset $\emptyset \neq S \subset I \setminus J$ and for all $i \in S$ non-trivial continuous movements $\gamma_i: [0,1] \to SE(3)$ with $\gamma_i(0)$ is the trivial motion in the set of all three-dimensional rigid motions $SE(3)$ such that the family $\left(Y_i^t\right)_{i\in I}$ with $Y_i^t = \gamma_i(t)X_i, i \in S$ and $Y_i^t = X_i, i \notin S$, is an assembly for each $t \in [0,1]$.

In the definition above, the blocks $X_i \subset \mathbb{R}^3$ are three-dimensional subsets of the set $\mathbb{R}^3$, where in the examples shown in Figure 3 and 5, the blocks are all congruent to each other. However, the stated definition also allows assemblies of non-congruent blocks, see for instance [7]. In [6], the authors give a method for proving the interlocking property using infinitesimal motions. In [5], the authors analyse interlocking blocks from [4] as a basic unit for large shells and show that they possess favourable properties relative to their density.

In the following sections, we will give further examples of tubular interlocking assemblies and spherical assemblies and take a first step in the direction of a mathematical generalization of this concept.

3. Construction of spherical and tubular interlocking blocks

In [4] a method is introduced to construct topological interlocking blocks by deforming fundamental domains of planar crystallographic groups. The next goal is to generalise this method to construct blocks, whose topological interlocking assembly forms surfaces such as a sphere or a cylinder. Starting from a tessellation of a sphere or a cylinder, it is natural to ask whether topological interlocking blocks for these surfaces can be constructed by deforming tiles of the given tessellation.

Here, a tessellation is an arrangement of 2D-geometric shapes covering the whole surface, without gaps and intersections. For example, mapping the edges of a platonic solid onto the surface area of a sphere gives rise to a tessellation of the sphere.

For simplicity, we formulate the generalized construction for polyhedral surfaces whose vertices all lie on the unit sphere or a cylinder of radius one. The spherical and tubular case then follow by considering polyhedral surfaces with spherical and tubular faces instead of planar faces.

Let P be a convex polygonal surface with faces $f_1, \dots, f_m$ and vertices $V_1, \dots, V_n$ satisfying $\sum_{i=1}^n V_i = 0$ and $\| V_i \| = 1$ for all $1 \leq i \leq n$. Since the faces of P can be viewed as a tessellation of the polygonal surface, we aim to construct interlocking blocks by deforming these faces into tiles of a polygonal surface that arises from scaling the vertices of P with a non-negative real number.

Let therefore $\{t_1, \dots, t_m\}$ be another tessellation of the polygonal surface P with simple polygons t_i for $1 \leq i \leq n$, such that the vertices of the face f_i lie on the boundary of t_i. For a real number $a \in \mathbb{R}$ with

$a > 1$ the scaled polygonal surface aP can be tessellated by $\{at_1, \dots, at_m\}$. We now aim to construct blocks $X_1, \dots, X_m \subseteq \mathbb{R}^3$ such that $\{X_1 \cap bP, \dots, X_m \cap bP\}$ is a tessellation for any polygonal surface bP with $b \in [1, a]$. A set of blocks $X_1, .., X_m$ satisfying this condition can be realized by continuously deforming the tile f_i into the tile at_i. We then obtain a candidate for a TI block that can be assembled to reconstruct the polygonal surface.

The package [11] contains functions to compute blocks to realize a given polygonal surface whose faces consist of regular polygons as an assembly of TI blocks. The blocks used in this construction have piece-wise linear boundary and are constructed by the following deformation:

Let $(V_1, \dots, V_l)$ be the ordered vertices of a face f that forms a regular polygon and $f_1, \dots, f_l$ be the neighbour faces of f, so that f and f_i are both incident to the vertices V_i and V_{i+1}. Furthermore, let $m_i, n_i \in \mathbb{R}^3$ be vectors so that m_i is contained in the plane placed at the origin parallel to f, the vector n_i is contained in the plane placed at the origin and parallel to f_i and

$$\langle m_i, V_{i+1} - V_i \rangle = \langle n_i, V_{i+1} - V_i \rangle = 0. \tag{1}$$

We then obtain a continuous deformation of f by the following geometric shape:

$$(V_1, w_1^1, w_2^1, w_3^1, V_2, \dots, V_n, w_1^n, w_2^n, w_3^n), \tag{2}$$

whereby for $1 \leq i \leq n$ and $t \in R_{\geq 0}$ the vectors w_1^i, w_2^i, w_3^i are given by

$$\begin{aligned} w_1^i &= V_i + \frac{1}{4}(V_{i+1} - V_i) + tm_i, \\ w_2^i &= V_i + \frac{1}{2}(V_{i+1} - V_i), \\ w_3^i &= V_i + \frac{3}{4}(V_{i+1} - V_i) + tn_i. \end{aligned} \tag{3}$$

In Figure 6 the described deformation is applied to a triangle, a square and a pentagon that lie in the plane.

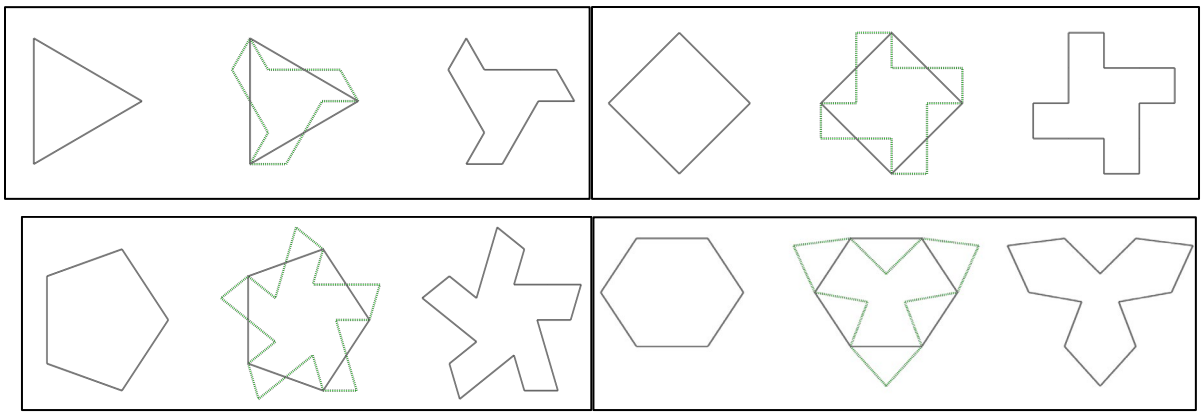

Figure 6. Deforming different regular polygons to construct a new tile of a polygonal surface

Note, by using suitable parameters to describe the above deformation we can limit the number of different blocks needed for this assembly to the number of orbits of the automorphism group of P on

its faces. Figure 7 shows the blocks that are obtained by applying the described construction to the surface of a tetrahedron, cube or dodecahedron.

Figure 7. Interlocking blocks that arise from the deformation of an equilateral triangle (left), a square (middle) and a pentagon (right)

By assembling copies of the constructed blocks, we can realize the platonic solids as an TI assembly, see Figure 8.

Figure 8. Platonic solids constructed by an assembly of interlocking blocks

Note, the tetrahedron can be realized as an TI assembly with an empty frame. The assembly of blocks that realize the octahedron or the dodecahedron forms a TI assembly by choosing the top and the base block as the frame. The constructed icosahedron and octahedron on the other hand are not that stable. In Figure 6 these two structures are held together by gluing together the different blocks.

3.1. Examples of spherical interlocking blocks

In this section we present interlocking blocks based on the platonic solids that allow us to realise spheres by assembling copies of an interlocking block.

Let therefore P be the surface of a platonic solid and S a sphere both centred at the origin so that P is fully contained in S . As mentioned above, mapping the edges of P onto the sphere leads to a tessellation of S consisting of spherical faces. By continuously deforming the faces of P onto the spherical faces of S , we obtain the interlocking blocks presented in Figure 9.

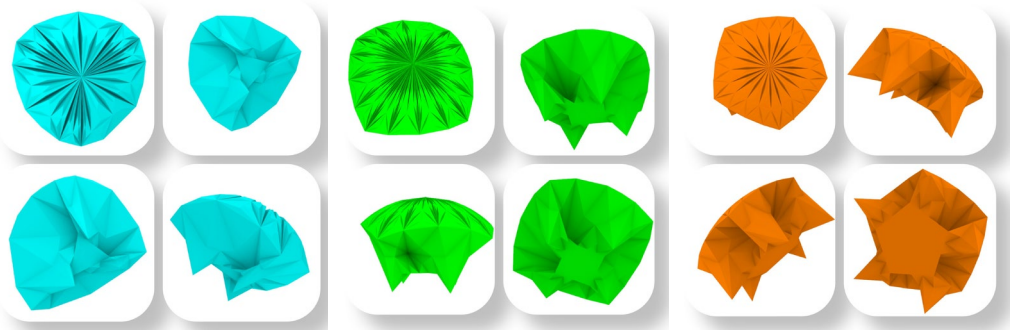

Figure 9. Various views of interlocking blocks based on the tetrahedron (left), the cube (middle) and the dodecahedron (right)

Assembling copies of the introduced blocks gives rise to topological interlocking assemblies in the shape of the platonic solids, see Figure 10.

Figure 10. Spheres realized as an assembly of constructed blocks

Note, the above assemblies based on the tetrahedron, cube and dodecahedron do not require any additional binders to stabilize the whole structure whereby the blocks in Figure 8 of the octahedron and icosahedron are glued together.

3.2. Examples of tubular interlocking blocks

In this section we discuss the construction of blocks that form tubular structures. Moreover, we illustrate the problem of creating TI blocks, introduced in Section 1, that do not allow disassembling the tube

constructed from copies of a block by simultaneously moving all copies radially from the central line of the tube.

In [4] a topological interlocking block for a planar assembly is constructed by placing a rectangle with side lengths 1 and 2 and a square with side length $\sqrt{2}$ in two parallel planes and continuously deforming the domains into each other. Algebraically the rectangle and the square form fundamental domains of a certain wallpaper group. Here, we call the process of deforming one fundamental domain into another the *Escher Trick,* as this method has been applied by M.C. Escher to create his artwork. In [7], the authors give an alternative approach for generating tubular structures using this block by introducing additional angle blocks. The above procedure can be modified by transforming three different fundamental domains for the same wallpaper group placed in three parallel planes into each other. We call this the *double Escher Trick.* A planar TI assembly yields a tubular TI assembly by mapping a section of the planar assembly onto a cylinder. Using the described double Escher Trick and mapping the resulting assembly onto a cylinder, yields the blue block in Figure 11 that can be assembled as a tube as shown in the same Figure.

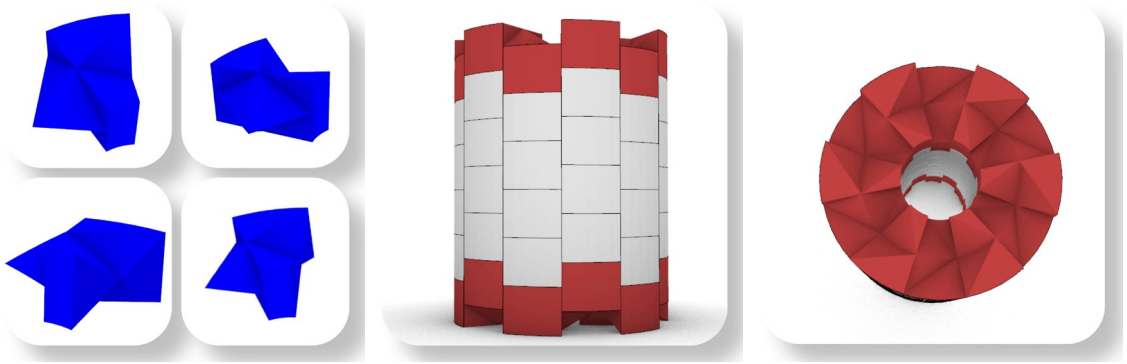

Figure 11. Various views of the interlocking block with a base and top tubular rectangle and a tubular rectangle in the middle with the corresponding assembly; frame is coloured in red

Now, assume that the frame of the assembly shown in Figure 11 is chosen to be empty. This assembly does not form a TI assembly because moving all blocks radially outwards from the central line of the tube is a set of continuous movements that does not result in non-trivial intersections of copies of the constructed block in the assembly, see Figure 12. For practical applications this might be problematic.

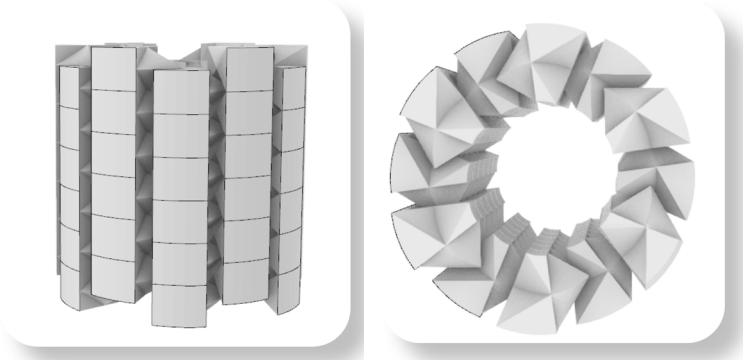

Figure 12. Various views of TI assembly forming a tower with blocks moving radially

It is well known that the load capacity of columns can be significantly increased by spiral reinforcements. This indicates that it is important to design tubular structures where the interlocking property of the assembly itself prevents the movement of collections of blocks radially outwards. For

example, without preventing radially outward movement, seismic motions may dislocate a frame that solely fixes the assembly at the top and the base, whereby the whole column could collapse.

A block whose assembly prevents the described outward movements can be created by examining the brick wall tessellation of the Euclidean plane, see Figure 13.

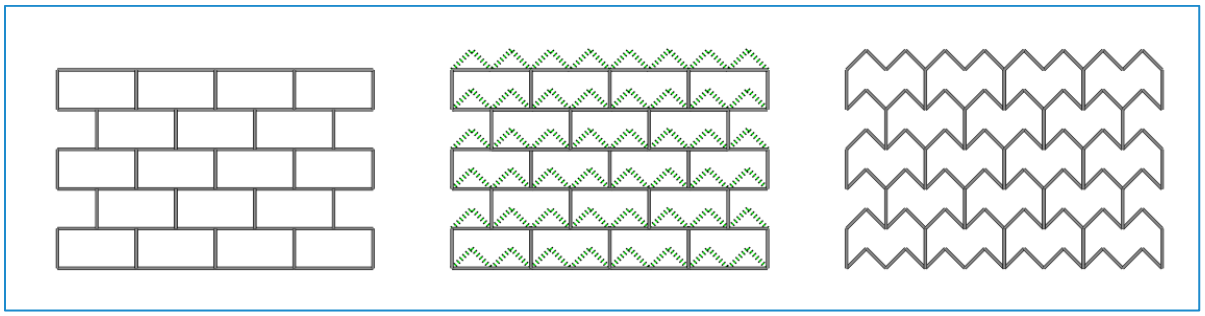

Figure 13. Deforming the brick wall tessellation of the Euclidean plane into another tessellation of the plane

Up to translation, a tile of the brick wall tessellation can be described by the following ordered list of 2D coordinates:

$$[(0,0)^t, (2,0)^t, (2,1)^t, (0,1)^t]. \tag{4}$$

Let a be a real number with $0 \leq a \leq 1$. Deforming the above tiles using the Escher Trick yields the polygon given by the following list of ordered 2D coordinates

$$\left[(0,0)^t, \left(\frac{1}{2}, a\right)^t, (1,0)^t, \left(\frac{3}{2}, a\right)^t, (2,0)^t (2,1)^t, \left(\frac{3}{2}, 1+a\right)^t (1,1)^t \left(\frac{1}{2}, 1+a\right)^t, (0,1)^t\right], \tag{5}$$

which gives rise to a new tessellation of the Euclidean plane. By placing these two tessellations in two different parallel planes and continuously deforming each tile into another, a TI block, that allows planar assemblies, is created, see Figure 14.

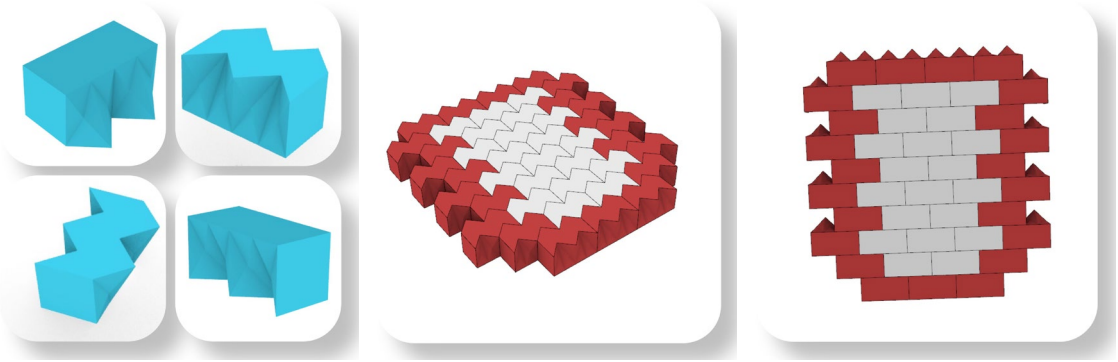

Figure 14. Various views of a TI block based on the brick wall tessellation and the corresponding planar assembly; frame is coloured in red

If we then deform the block as presented in Figure 15, it is possible to assemble angular tubes. Varying different parameters such as the diameter of the block and number of blocks that form a ring of the assembled tube, we obtain different angular tubes.

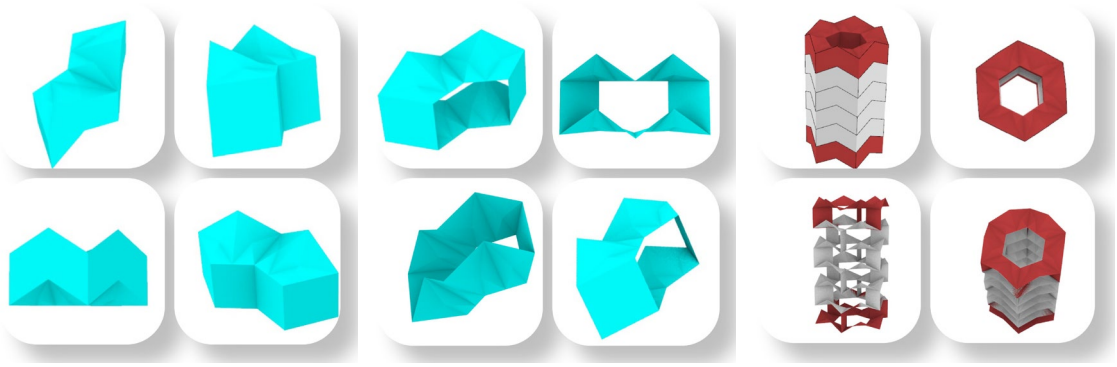

Figure 15. Various views of a TI block based on the brick wall tessellation (left), Various views of the TI block with outer and inner faces removed (middle), Various views of the corresponding topological interlocking assembly; frame is coloured in red

We can also apply the double Escher Trick and map the corresponding planar TI assembly onto a cylinder to obtain another TI block. With the tessellations shown in Figure 13 we can create the TI blocks and the tubular assembly shown in Figure 16.

Figure 16. Various views of a TI block based on the brick wall tessellation and the corresponding assembly to form a tube

As shown in Figure 17, the presented blocks prevent the simultaneous radially outwards movement of all blocks of the assembled tubes.

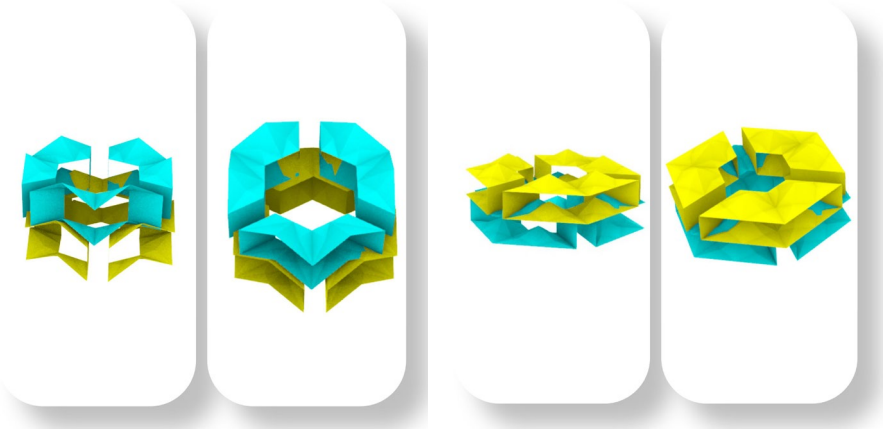

Figure 17. Various views of the TI assembly based on the brick wall tessellation with all blocks moving radially outwards

4. Conclusion

Building on a method to construct planar interlocking assemblies by modifying fundamental domains of planar crystallographic groups, a method for constructing topologically interlocking assemblies for spherical and tubular structures has been developed. An additional complication in designing good interlocking assemblies for these cases is that some assemblies might allow radially outwards simultaneous movement of all blocks. We give an example of a tubular interlocking allows for such movements and another which prevents such movements. In a forthcoming paper, proofs of the interlocking properties of the given assemblies will be given and the behaviour of tubular and spherical interlockings will be further investigated.

Abstract

Amongst the additives in cementitious mortar, biochar is popular as a green material that enhances engineering properties. Its ability in densifying the microstructure is responsible for these improvements. Meanwhile, literature reveals that supplementary materials (e.g. silica fume), which densifies the microstructure, increase the impact resistance of concrete. However, such elaborations are unexplored for biochar. Meantime, alkali-activated slag (AAS) is known to be a sustainable replacement for Portland cement. Thus, it is of interest to assess the feasibility of supplementing biochar in AAS composites in terms of strength and impact performance. The effects of the biochar type, biochar replacement level and Na_2O content were considered in the mix design optimization using the Taguchi method. It was found that the 2% rice husk biochar (RB) increased the early strength by 16.5% while the 5% RB enhanced the 28-day strength by 27.5% compared to the control specimen. The impact resistance of the alkali-activated slag concrete (AASC) samples with 10% Na_2O and with 0%, 2%, 4% and 6% RB was measured using a drop weight test. In comparison to the biochar free sample, 6% RB improved the impact number at the first crack and the failure by 185% and by 180% respectively. Moreover, 6% RB improved the 28-day strength of AASC by 44.6% compared to the control mix. These improvements are due to the water absorption property and internal curing effect of biochar.

Keywords: alkali-activated slag composite, compressive strength, impact resistance, rice husk biochar, sewage sludge biochar, Taguchi method

1. Introduction

Alkali-activated materials (AAMs) are considered as excellent sustainable replacements for ordinary Portland cement (OPC) [1, 2]. AAMs are produced by activating an aluminosilicate precursor by an alkaline activator. Since the majority of aluminosilicate materials (e.g. fly ash and slag) are industrial waste products, the production emits low level of greenhouse gases and that result in environmentally and economically sustainable outcomes [1, 2]. Meanwhile, Alkali-activated slag (AAS) is recognized for its ability to attain considerable strength at ambient temperatures. However, some alkaline activators such as sodium silicate are carbon intensive as they are normally manufactured by the 1200–1400 ^{0}C fusion of sodium carbonate and sand [3]. Therefore, the use of alkaline activators with low carbon footprint (e.g. sodium carbonate) is highly encouraged [1, 2, 4].

Over the recent past, biochar gained considerable attention as an additive in cementitious mortar due its ability in improving the sustainability and mechanical properties. Porous biochar can absorb and sequester CO_2 without affecting the properties of mortar [5, 6]. In addition, biochar is reported to

improve the mechanical properties of cementitious mortar, especially the compressive strength. Gupta and Kua [7] reported an increment in compressive strength of cementitious mortar at the ages of 1- and 28-days by 20-25% due to the addition of 0.5-1 wt.% mixed wood sawdust biochar. Chen found that 2 wt.% sewage sludge biochar could enhance the compressive strength of OPC mortar by 29.3% and 5.8% at the ages of 1-day and 28-days, respectively. Moreover, an increment in the 28-day compressive strength of cementitious concrete by 20.4% with the addition of 5 wt.% rice husk biochar (RB) is reported by [8]. However, further increment of RB content up to 10% reduced the compressive strength by about 13%. These strength enhancements are due to the high-water absorption and retention properties of porous biochar. It absorbs a portion of the added water to the mix, reducing the effective water to binder ratio (w/b), thus densifying the microstructure [9, 10]. Moreover, the absorbed water is retained in biochar, maintaining healthy internal moisture. This favours the hydration mechanism, which can result in enhanced formation of hydration products, leading to further densification of the microstructure [5, 11, 12]. Even though numerous studies evidenced by the success of biochar as an additive in cementitious mortar, limited attempts have been taken to identify the suitability of biochar as a supplement in AAM mixes [13, 14]. However, because of its potential to absorb and retain water, biochar could also have an ability to improve the performance of AAM mixes as well. Therefore, it is of interest to study the feasibility of using biochar as a supplement in AAS mixes.

In the meantime, the impact resistance of cementitious concrete has been reported to be improved by the addition of supplementary materials like silica fume, which can densify the microstructure. Gupta [15] reported an increment in the number of impacts required (drop hammer impact test) for the failure of OPC concrete from 65 to 67 and 72 respectively when the silica fume dosage was increased from 0% to 5% and 10%. Similarly, Nili [16] observed an improvement in the number of impacts for the first crack and failure of the cementitious concrete, by 6.9 and 6.5 times, respectively, with the addition of 8% silica fume by the cement weight. Moreover, Ameri [17] discovered that in OPC concrete, replacing natural sand with 60% of copper slag (CS) could improve the impact energy at the initial crack level by 42% and at the failure by 50%, compared to the non-CS mix. The densified microstructure resulting from the CS addition is responsible for these improvements. In this context, it is possible to expect that biochar would have the ability in improving the impact resistance of concrete as well. However, no studies have been carried out to verify this hypothesis. Moreover, improved impact resistance is highly beneficial for concrete structures subjecting to vehicular crashes, terrorist attacks and collisions due to earthquakes. Exploring the biochar's possibility in improving the impact resistance, would widen the application of biochar supplemented alkali-activated slag concrete (AASC) even in structures subjecting to impact forces as well. Therefore, this research study was further extended up to investigate the effect of biochar on the impact resistance of the AASC.

First part of the study focused on the identification of the feasibility of supplementing biochar in alkali-activated slag mortar (AASM). Three major affecting factors (Biochar type -BT, replacement level of biochar with slag -RL and Na_2O content by the weight of the binder -Na_2O-E) were considered in identifying an optimum AASM mix in terms of flow and compressive strength. Taguchi design of experimental method was used for the mix design optimization [18, 19]. Second part of the study was developed to understand the influence of biochar on the strength and impact resistance of the AASC. Thus, based on the identified optimum values of the selected parameters (BT and Na_2O-E), four different AASC mixes were cast with 0%, 2%, 4% and 6% biochar content. Each mix was tested for slump, 28-day compressive strength and the impact resistance. Drop hammer impact test based on the ACI 544 committee was used to evaluate the impact resistance of the AASC mixes.

2. Methodology

2.1. Materials

2.1.1. Ground granulated blast furnace slag (GGBS), alkaline activators and aggregate

GGBS was collected from the Siam City Cement (Lanka) Limited. The median particle size (D_{50}) of GGBS was measured using a laser diffraction particle size analyzer and found to be 6 µm. The chemical composition of slag assessed by the X-ray fluorescence (XRF) spectrometry is shown in Table 1. Analytical grades of Na_2CO_3 (99.9% purity) and NaOH pellets (98.5 – 100.5% purity) were dissolved in distilled water to prepare the alkaline solution. Saturated surface dry coarse aggregates were used in this study. Both coarse and fine aggregates were graded according to ASTM C33 (particle size distribution curves are shown in Figure 1). The maximum size of the coarse aggregates was 12 mm. The specific gravities of coarse and fine aggregates were 2.75 and 2.65 respectively.

Table 1. Chemical composition of GGBS (%)

Oxide	CaO	SiO_2	Al_2O_3	MgO	Fe_2O_3	K_2O	Na_2O	SO_3	MnO	P_2O_5	LOI
Percentage (%)	40.39	35.35	12.19	6.18	0.75	0.3	1.09	0.1	0.13	0.05	1.4

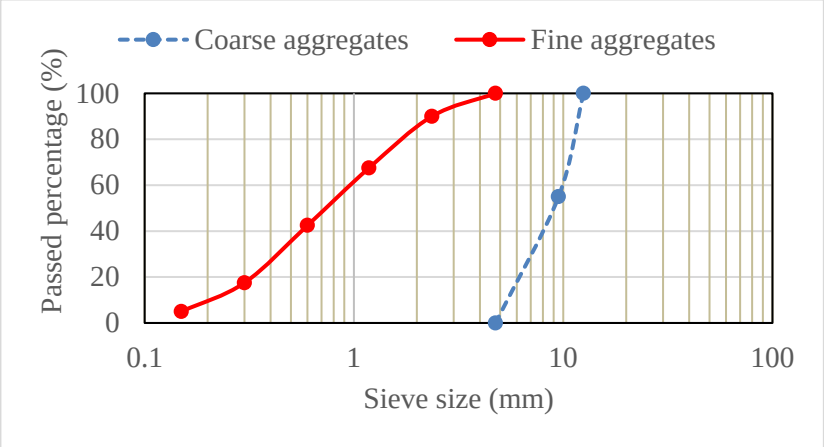

Figure 1. Particle size distribution of fine and coarse aggregates

2.1.2. Preparation of biochar

Three different biochar types, prepared from Rice husk and sewage sludge (gathered from two different treatment plants) were considered in this study. Before pyrolysis, the rice husk was cleaned with tap water, after that oven-dried at 80 ^{0}C for 48 hours. Similarly, sewage sludge samples were oven-dried at 105 ^{0}C for 24 hours until the weight became constant. Following that, sewage sludge was crushed into fine particles and passed through a 5 mm sieve in order to increase the pyrolysis efficiency. Prepared biomasses were filled into sealed crucibles separately, after which the crucibles were placed inside a Yamato FO-310 muffle furnace for pyrolysis. Pyrolysis was conducted at 500 ^{0}C as low temperatures conserve energy and the amorphous silica content [9]. However, as temperatures less than 500 ^{0}C can retain toxic substances available in sewage sludge, those temperatures were not used in this study to avoid ecological risks [9, 20]. The heating rate and the residence time were selected as 10 ^{0}C/min and 60-minutes respectively. Low heating rates and high residence times (slow pyrolysis) can smoothen the volatiles and organics release, thus enhancing the micropore fraction of biochar [5, 21]. Moreover, the yield of biochar becomes high and flammability is less in the slow process [21]. However, prolonging

the residence time beyond 60-minutes requires more energy, thus it is not economical. Finally, biochar was well-ground using a mortar and pestle, after which it was sieved through a 75 µm sieve.

2.2. Methods

2.2.1. Characterization of biochar

pH of all the biochar types was determined by mixing biochar and distilled water at a mass ratio of 1:10 [22]. After stirring the solution for 30-minutes, it was stabilized for 1 hour, after which the pH was assessed using a pH meter. pH values of the biomasses before and after pyrolysis are listed in Table 2.

Table 2. pH values of biomasses before and after pyrolysis

Biomass	pH	
	Before pyrolysis	After pyrolysis
RH	-	8.02
SSA	6.55	6.77
SSB	6.37	7.00

RH – Rice husk, SSA – Sewage sludge collected from wastewater treatment plant A, SSB - Sewage sludge collected from wastewater treatment plant B

The chemical compound compositions of biochar determined by X-ray fluorescence are tabulated in Table 3. SiO_2 was the major chemical compound found in all the three biochar types. In RB, SiO_2 content was 35.61%, which was the highest silica content among all the biochar types used in this study. The particle size distribution (PSD) of only RB and GGBS particles (Figure 2) were measured using a particle size analyzer, as RB was selected as the optimum biochar type (discussed in section 3.1). It was found that the median particle size of RB was 7.9 µm, while that was 6 µm for GGBS. This shows that RB did not impart an effective filler effect in this study as it was reported in the previous studies [5, 11].

Table 3. Oxide composition of biochar

Oxide composition (%)	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	K_2O	Na_2O	P_2O_5	ZnO	Mn_2O_3	LOI
RB	35.61	0.03	0.02	0.33	0.14	0.57	0.05	0.1	-	0.06	62
SBA	32.99	14.67	15.84	4.06	1.15	0.66	0.82	-	-	-	30
SBB	23.94	15.58	6.05	2.06	2.17	0.99	1.01	3.76	0.07	-	45

SBA – pyrolyzed SSA, SBB – pyrolyzed SSB

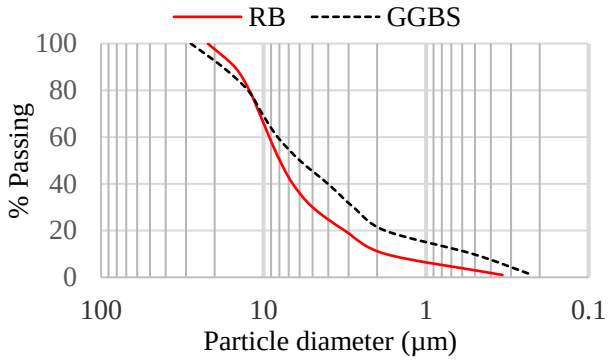

Figure 2. Particle size distribution of GGBS and RB

The water absorption capacity of biochar was measured using the 'tea bag method' [10, 11]. A quantity of 5g of dry biochar was placed inside a tea bag after which it was fully submerged in a water beaker.

Along with that an empty tea bag was also immersed in the water beaker to determine the water absorption only by biochar. The weight of the tea bags was measured at regular time intervals until there was no change in the mass. The water absorption capacity of RB, SBA and SBB was found to be 2.02 g/g dry biochar, 1.08 g/g dry biochar and 1 g/g dry biochar, respectively.

2.2.2. Mix proportion, mixing and curing

An optimum AASM mix design was selected using the "Taguchi method" based on the flow, 3- and 28-day compressive strength [18, 19]. In the mix design optimization, the considered parameters and levels of those are shown in Table 4. These parameters and their levels were selected depending on the trials and the data collected from previous studies [2, 4, 8, 9]. In both mortar and concrete preparation, the w/b and Na_2CO_3 to NaOH molar ratio were maintained as 0.5 and 10:15, respectively [4]. For mortar mixes, the sand to binder ratio was 3 [23], while for concrete mixes the coarse aggregates to total aggregates ratio was 0.57 [24]. Based on the optimum mix design identified for AASM (section 3.1), the biochar type and Na_2O content used in the AASC mixes were RB and 10%, respectively. For AASC mixes, the biochar replacement level was increased up to 6% by 2% intervals, to determine the maximum biochar replacement level in terms of improved impact resistance and the 28-day compressive strength. In [6], Praneeth reported an increment in the 28-day compressive strength of cement (80%)-fly ash (20%) composites when increasing the biochar content up to 6%. However, a reduction in the compressive strength was observed with the enhancement of the biochar dosage beyond 6%. The response of the AASC with the increased biochar content beyond 6% needs to be explored in the future. In concrete mixes, the required coarse and fine aggregates proportions were calculated using the absolute volume method. The mortar mix proportions based on the Taguchi orthogonal array are listed in

Table 5. The concrete mixture details and the slump values are given in Table 6.

2 hours prior to starting both mortar and concrete mixing the alkaline solution was prepared in order to ensure that the solution is at room temperature before adding to the mix [25]. To mix biochar well with slag, those were manually mixed before mortar mixing and subsequently mechanically mixed in the Hobart mixer at low speed for 4-minutes. Next, the alkaline solution was added and continued mixing for another 2-minutes at the same speed. Finally, sand was added to the mix and mixed at a high speed for 3-minutes [23]. Standard steel moulds (50 x 50 x 50 mm^3) [26] were used to cast mortar and then it was vibrated for a maximum of 45 seconds by placing it on a vibrating table. Until 3-days, the samples were cured inside the sealed bags, after which they were demoulded. After demoulding, the samples were continuously cured inside the sealed bags until the testing age.

In concrete mixing, coarse and fine aggregates were dry mixed for 2-minutes in a 120 L concrete mixer. Then the manually mixed slag and biochar mixer was added to the mixer and mixing was continued for another 3-minutes. Then the mixing was continued for further 4-minutes after adding the alkaline solution [27]. At the completion of the mixing, the concrete was poured into cubic and cylindrical steel moulds (100 x 100 x 100 mm^3 and 150 x 300 mm) [28] and vibrated for 1-minute using a vibrating table. Curing process was similar to that with the mortar samples.

2.2.3. Testing procedure

The compressive strength and the flowability of the mortar samples were determined according to ASTM C109 [26] and ASTM C1437 [29], respectively. In concrete mixes, the compressive strength and slump were measured conforming to BS EN 12390-3 [30] and ASTM C143 [31], respectively. The compressive strength testing was performed using a 3000 kN compression testing machine. The loading rate for the mortar samples was 1.5 kN/s while that for the concrete samples was 6 kN/s. The average result of three samples was considered as the compressive strength for both mortar and concrete samples.

The impact resistance of the AASC samples were tested as per the guidelines of ACI Committee 544 [32]. For each concrete mix, a 150 x 250 mm cylinder was cast and at the age of 28-days, it was cut into three 64 mm height discs for subjecting to drop weight impact test. As illustrated in Figure 3, the concrete disc is placed on the steel base plate with four positioning lugs. A weight of 4.54 kg was dropped repeatedly from a height of 457 mm on the steel ball (63.5 mm diameter) placed on top of the sample. The number of impacts till the first visible crack (L_1) and the failure (L_2) were noted. The total impact energy, depicted in Eq. (1), determines the impact resistance.

$$\text{Impact energy} = n \times m \times g \times h \quad (1)$$

Where n is the number of impacts for the first crack and failure, m is the mass of the drop weight (4.54 kg), h is the drop height (457 mm) and g is the gravitational acceleration (9.81 m/s^2).

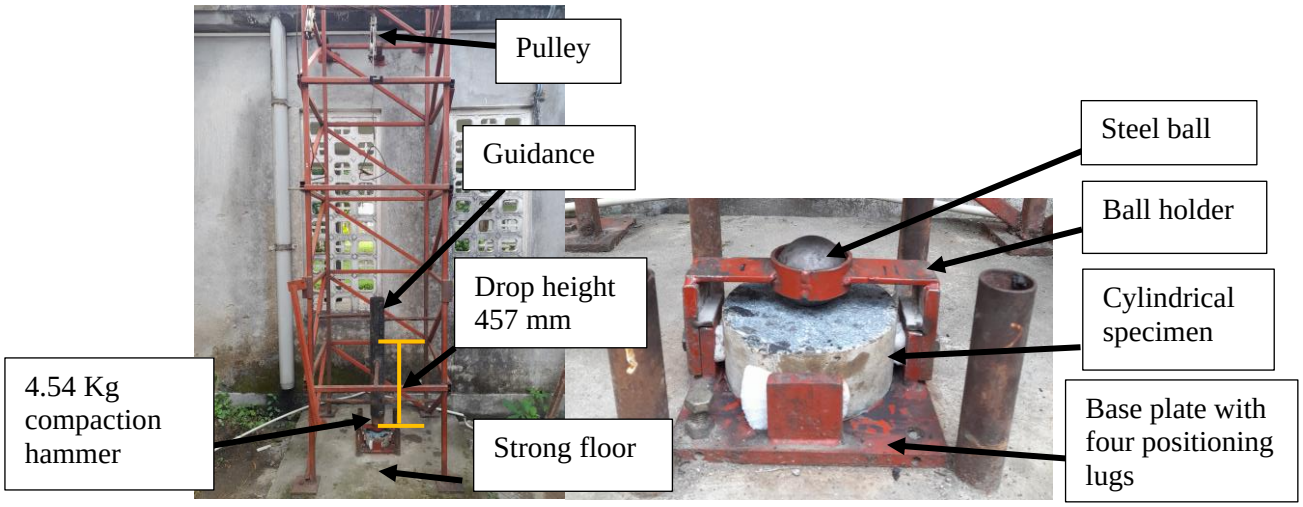

Figure 3. Drop weight test apparatus

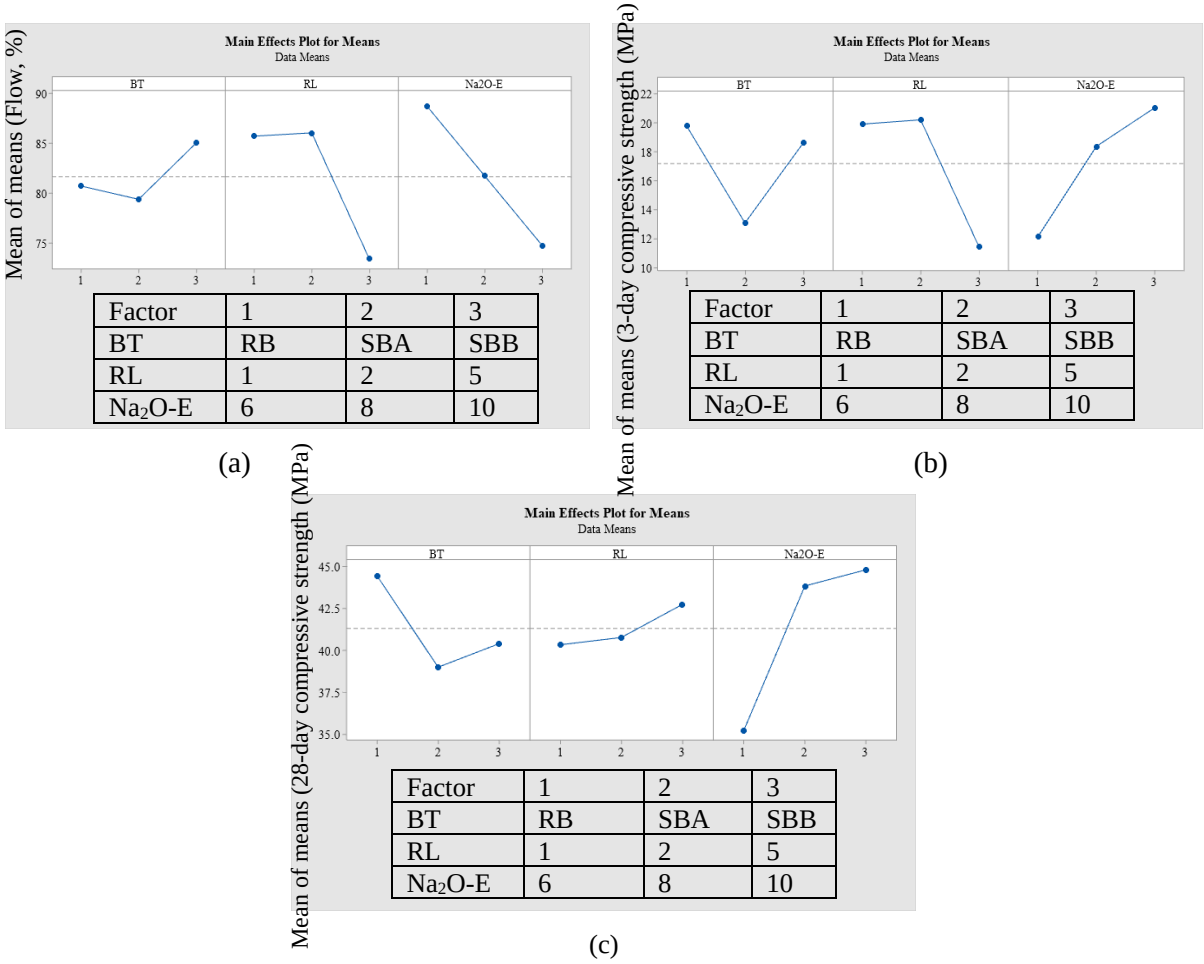
3. Results and discussion

3.1. Determination of optimum mortar mix design



The average flowability, 3- and 28-day compressive strength of the AASM mixes cast according to the Taguchi method are shown in Table 7. Minitab software was used to analyse the results and the resulting main effect plots are given in Figure 4.

According to Figure 4(a), the highest flow is yielded by SBA2-6. Increasing biochar replacement level from 2% to 5%, caused a reduction in the flow. However, it is limited to 13 mm. Similarly, raising Na_2O content from 6% to 10% dropped the flow by 14 mm. Moreover, the response of flow to the change in biochar type is very low. Figure 4(b) illustrates that RB2-10 achieves the highest 3-day compressive strength. This is in agreement with the previous studies mentioning the ability of biochar in improving the early compressive strength when the biochar content is around 2% [5, 9]. The sensitivity of the 3-day compressive strength to the biochar replacement level is considerably higher (increasing biochar content from 2% to 5% reduced the 3-day compressive strength by about 44%). In consideration of the 28-day compressive strength, RB5-10 exhibits a better performance (Figure 4(c)). Considering the overall performance, the RB2-10 combination seems to be more promising towards the early strength improvement. However, while looking at the latter compressive strength development, RB5-10 seems to perform better than RB2-10.

Table 7. Flow and compressive strength results

Run	Flow (%)	Compressive strength (MPa)	
		3-day	28-day
R1-RB1-6	94	18.0 (0.2)	37.6 (0.8)
R2-RB2-8	83	21.7 (0.2)	43.8 (0.9)
R3-RB5-10	65	19.7 (0.3)	52.0 (0.9)
R4-SBA1-8	83	18.8 (0.3)	43.2 (1.5)
R5-SBA2-10	79	20.5 (0.1)	42.2 (0.9)
R6-SBA5-6	76	0.0*	31.7 (1.0)
R7-SBB1-10	80	22.9 (0.3)	40.3 (0.3)
R8-SBB2-6	96	18.4 (0.2)	36.4 (1.1)
R9-SBB5-8	79	14.6 (0.5)	44.6 (0.2)

3.2. Effect of biochar on the compressive strength of AASM

As both RB2-10 and RB5-10 combinations seemed to improve the compressive strength of the AASM, 3- and 28-day compressive strength of those mixes were compared with a biochar free AASM mix with 10% Na_2O content (RB0-10). The results are illustrated in Figure 5. In comparison to the RB0-10, 2% RB improved the 3-day compressive strength by 16.5% while 5% RB decreased it by 12.1%. In terms of 28-day compressive strength, RB2-10 combination showed a limited increment of 7.4% relative to RB0-10. However, 5% RB showed a significant improvement of the 28-day compressive strength by 27.5% compared to the biochar free mix. These results, agree with other studies where the lower replacement levels of biochar (around 2 wt.%) increased the compressive strength, especially at the early ages [5, 9]. Meanwhile, Zeidabadi et al. [8] observed an increment in the 28-day compressive strength of cementitious concrete by 20.4% with the addition of 5 wt.% biochar. Porous biochar tends to absorb a portion of the alkaline solution, declining the solution/binder ratio of the mix [14]. This results in a reduction in the capillary porosity and the alkali content of the mix. Declining the capillary porosity densifies the microstructure, improving the compressive strength [9, 10]. However, lowering the alkali content leads to a reduction in the compressive strength [33]. Therefore, a combined effect of these two determines the observed compressive strength values. This might be a reason for the reduced 3-day compressive strength of the RB5-10. Together, the internal curing action of biochar, contributes to enhancing the compressive strength. The ability of biochar to act as an internal curing agent has been reported in the previous studies [5, 12]. Choi [12] reported that the weight loss over time for mortar samples with biochar due to moisture evaporation is low compared to that of the biochar free mortar sample.

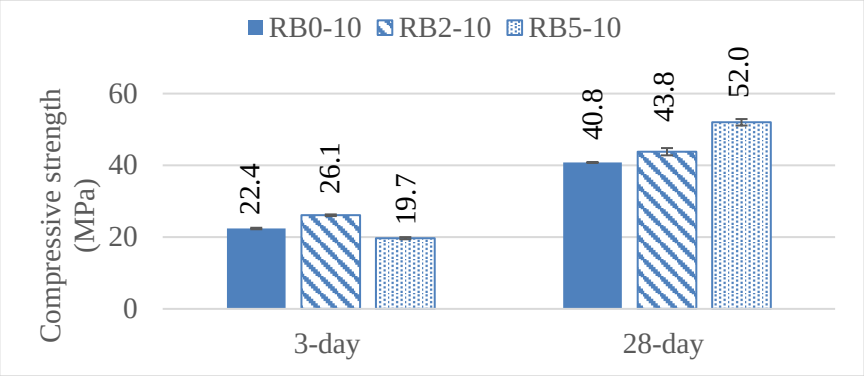

Figure 5. Compressive strength of AASM at 3- and 28-days

3.3. Effect of biochar on the compressive strength of AASC

The 28-day compressive strength results of AASC with different RB dosages are shown in Figure 6. Similar to the AASM mixes, increasing the biochar dosages enhanced the 28-day compressive strength of the AASC. The strength enhancement with the addition of 2%, 4% and 6% RB was 20.1%, 31.5% and 44.6%, respectively compared to the biochar free concrete samples. As previously discussed, biochar's ability to absorb and retain the solution is responsible for these improvements.

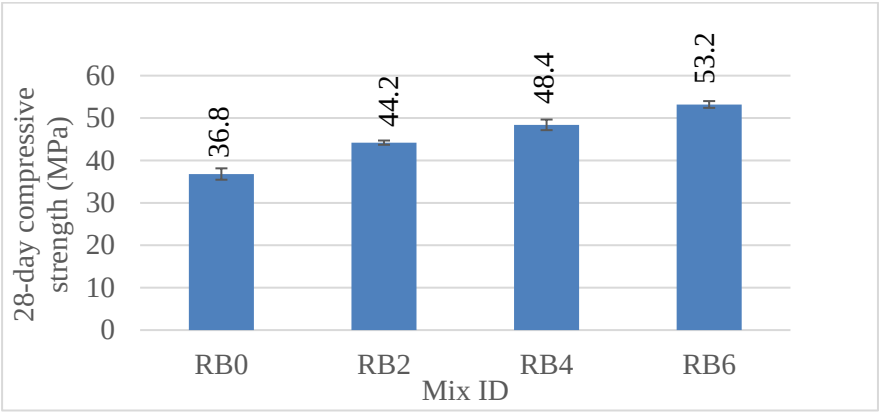

Figure 6. 28-day compressive strength of AASC with different biochar dosages

3.4. Effect of biochar on the impact resistance of AASC

The impact energies of the biochar supplemented AASC mixes at the age of 28-days are shown in

Table 8 and Figure 7. Increasing biochar dosage from 0% to 2%, 4% and 6% demonstrates an increasing trend in the impact resistance. It is visible that RB6 has gained the highest impact resistance where the impact energies at the first crack and failure are increased by 184.5% and 180.4%, respectively compared to the RB0. As anticipated, this increment in impact resistance is due to the densification effect caused by RB on the AASC. Reduction in the capillary pores of the mix and enhanced formation of the hydration products due to the addition of RB, leads to densifying the concrete mix. Egodagamage et al. [34] revealed the ability of RB to densify the microstructure of the AASM. In addition, previous studies observed the contribution of biochar to densify the microstructure of mortar [9, 10]. Similarly, enhancements in the impact resistance of concrete due to the densification effect caused by different supplements such as silica fume have been reported previously [15, 16, 17].

Table 8. Drop weight test results of AASC specimens

Mix No	Impact Numbers (L1/L2)				L1	L2	Impact energies (J)	
	S1	S2	S3	Mean	SD	SD	First crack	Failure

4. Conclusions

Considering the early age compressive strength development of the alkali-activated slag mortar (AASM), the combination with 2% rice husk biochar (RB) and 10% Na_2O was more promising. The mix increased the early compressive strength by 16.5% in comparison with the biochar free mix (RB0-10). The 28-day compressive strength increment was limited to 7.4%. Meanwhile, 5% RB with 10% Na_2O combination (RB5-10) reduced the early age compressive strength by 12.1% relative to RB0-10. However, this mix gained a considerable 3-day compressive strength of 19.7 MPa. In addition, a significant compressive strength increment of 27.5% was shown for the RB5-10 at the age of 28-days. Therefore, depending on the application, both 2% and 5% RB are suitable to be supplemented in AASM. RB's high-water absorption and retention properties are attributed to these strength improvements.

In terms of impact resistance of alkali-activated slag concrete, 6% RB with 10% Na_2O yielded the largest impact energy, which is higher by around 180% compared to the mix without biochar. Biochar's ability to densify the microstructure resulted in this impact resistance enhancement. In addition, RB6-10 achieved a 28-day compressive strength of 53.2 MPa, which is 44.5% greater than the biochar free concrete mix.

Acknowledgements

This project is funded as part of the CRC project "upcycling solutions for hazardous claddings and co-mingled waste". The assistance provided by the Siam City Cement (Lanka) Limited and the Materials/Environmental Laboratories of the Civil Engineering Department of the University of Peradeniya is also greatly acknowledged.

Abstract

Research on shell structures has been pursued by many in the AEC industry. Looking at contemporary precedents of shell designs - from subdivided vaults to continuously 3D printed, to discrete assembly -, we argue that they all rely on high precision and therefore have very low tolerance to construction errors. Whilst high precision is a manageable concern in controlled, accessible sites, we argue that a different approach is needed for remote sites like the Moon. As an alternative approach, we propose a construction system that is anti-fragile - a term coined by mathematical statistician Nassim Nicholas Taleb to describe a quality that gains from disorder and randomness instead of losing. As a result, the project proposes an aggregation system of hexapods as a radiation protection shell for Lunar Habitats. This approach offers a construction system that is anti-fragile to a notable degree of randomness; allowing low tolerance in how the aggregates are placed as the system is highly flexible in its interlocking mechanism. Although we use a pre-optimized, continuously smooth shell geometry to guide the hexapod aggregation process, no aggregate on its own has a crucial role in the integrity of the overall structure. This presents a novel shell design with its embodied carbon distributed evenly across its aggregates that can shrink, grow or be reconfigure the structure for future needs of human habitation on the Moon.

Keywords: anti-fragility, aggregation, randomness, dome structures, hexapod, interlocking, reconfigurability, low precision, disorder, regolith, shell structures, radiation protection

1. Introduction

1.1. Background

1.1.1. Case-study project

The research discussed on this paper is born out of a project Hassell is working on as part of the ESA Open Space Initiative Platform (OSIP) research grant. Titled as Lunar Habitat Framework, the project is looking at creating a framework for designing a scalable Lunar Habitat system that can grow to accommodate from 6 to 144 people.

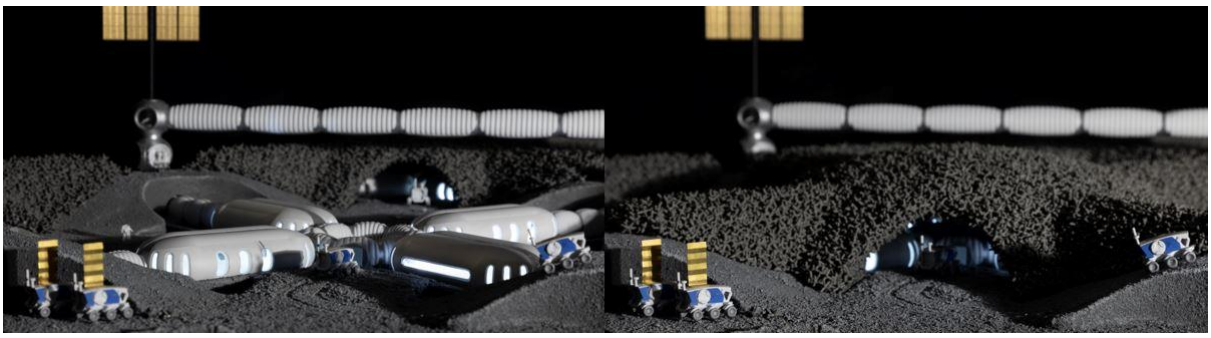

Figure 2. Physical Model of a segment from the Hassell Lunar Habitat Framework for ESA. The pair of photos highlight what sits beneath the radiation protection shell as inflatable habitats. Credit: Hassel

1.1.2. Lunar context & materiality

The location for the project is on the South Lunar Pole near the Shackleton Crater. The Moon is a highly extreme site for human habitation & construction. With no atmosphere, humans will need novel, infrastructure to access to water & oxygen whilst being subjected to high degrees of radiation. In our Lunar Habitat Framework, we propose a variety of systems to establish material cycles within pressurized, inflatable modules in which most of the human activity shall take place. Yet, these inflated habitat systems do very little when it comes to protecting from the Sun's radiation. As a solution to this problem, we propose radiation protection shell structures built with aggregates that are made of sintered Lunar Regolith; relying on in-situ material reutilisation as a means of sustainable construction growth.

2. Methodology

The design process for this research relied heavily on digital simulations. Hassell used advanced visual effects software HoudiniFX to simulate how aggregates behave in collision in a highly efficient manner in computational terms.Using HoudiniFX has allowed to have a good understanding on how hexapods - which have a geometry with concave characte -, interlock as a system of aggregates. The software is able to compute their concave form with minimal loss of information by using solvers such as Bullet and Rigid Body Dynamics. This approach makes our simulation a closer approximation to the reality than other methods like Particle-Based Simulations that treat each aggregate as a particle or a convex

form such as sphere which could have created deceptive results as the aggregates would not interlock but rather touch each other at certain points [1].

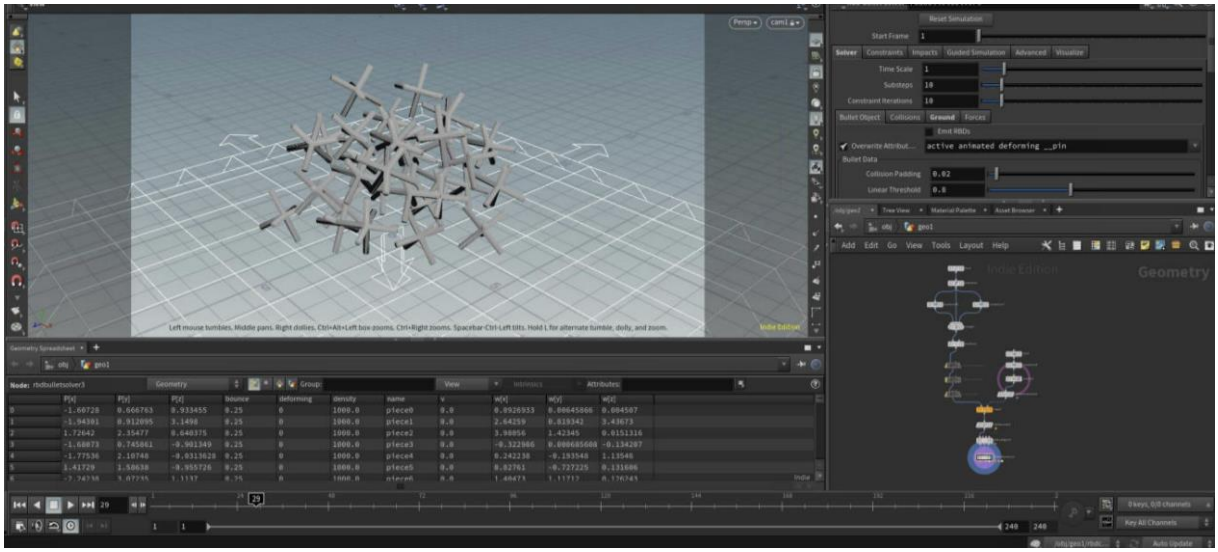

Figure 3. Houdini interface showing the procedural / algorithmic nature of where the designer is asked to create algorithmic procedures with node trees on the bottom right and their relevant parameters on the top right as a means of design. Credit: Hassell

3. Shift in design thinking

3.1 Key principles

In the last decade, there has been a significant number of precedents for continuously 3D printed, monolithic shell structures as a protection layer for habitats on the Moon & Mars [2]. The design we present here is radically different from this approach as we associate numerous concerns of scalability, sustainability and maintenance within a framework that is to grow to accommodate 144 people. Constrained to the material availability on the construction site, continuous 3D printing requires a high degree of precision with a low degree of tolerance for error for the shell to be pressure-retaining and watertight. Furthermore, a monolithic approach would lock fully the embodied carbon in its construction and does not offer any flexibility for repair / reuse due to its fixed / continuous nature. The construction would also require complex scaffolding / formwork systems. Each shell would be fixated to the form of their initial design without the ability to grow or to be reconfigured [3]. When it comes to breaking the continuity in the construction of shell structures, there is numerous novel examples on earth with both bespoke as well as the discrete approach. Although the discrete offers a great potential in reducing the amount of part typology, it nevertheless requires high precision in assembly. Therefore, our research started with the two following requirements in mind: singularity in building block and as low precision as possible for the assembly: a novel, modular aggregation that gains from disorder. This way not only the the embodied energy of a large volume is broken down, but the system is less fragile to error and adaptation to a future reconfiguration. In summary, we seek to establish a true bottom-up thinking like

the historical context of the use and development of bricks on earth-based construction systems (Figure 4) which offer a great degree of variation on the architectures it can produce (Figure 5).

Figure 5. Use of brick for vault applications. Mapungubwe Interpretation Centre by Peter Rich Architects (Left), Mortuary Chapel for the Soriano Manzanet Family by Vegas & Mileto Architects (Right). Credit: Peter Rich Architects (Left) Vegas & Mileto Architects (Right).

As a departure point, we present the following key principles for our design: discrete assembly with a single type of pieces, a high degree of flexibility in orientation of the piece during assembly, lower requirements for manufacturing precision and an aggregation-based system rather than a subdivision / grid based one. Our main inspiration comes from tetrapods which are used on Earth - particularly in Japan - as wave-dissipating blocksto prevent erosion caused by weather and to enforce coastalstructures like seawalls and breakwaters (Figure 6). Whilst tetrapods work well on being stack around simple forms, we augmented the design module to hexapods to allow for more interlocking around curved geometries that shell design will need as a compression only structure. A novel precedent that uses hexapod aggregate systems is the ICD Aggregate Pavillion 2018 [4].

Figure 6. Aerial View of tetrapods being used as coastal barriers. Credit: Institution of Civil Engineers

3.2. From order (grid / subdivision) to disorder (aggregation)

There has been a considerable number of precedents for shell designs in outer space as well as on Earth applications. We present an in-depth look in key examples under three categories: (1) Vaults with Subdivided Elements, (2) Continuous 3D Printing, (3) Discrete Blocks. (Figure 7).

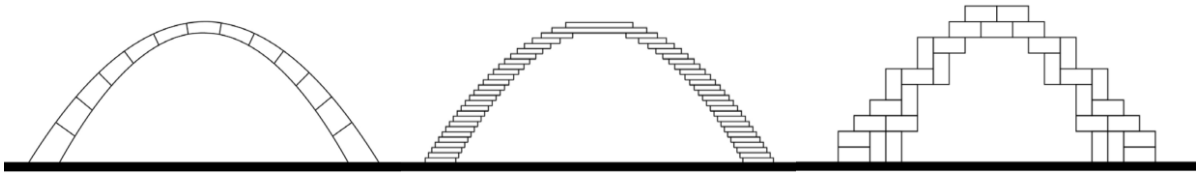

Figure 7. Three contemporary approaches to shell design: Subdivided Elements, Continuous 3D Printing, and Discrete Blocks. Credit: Hassell

3.2.1. Vault with subdivided elements

This category refers to shells as compression structures built by sub-division of an optimised global geometry into smaller parts. Key examples include Armadillo by Philippe Block [5] and Hyperbody Studio Foam Shell by TU Delft [6]. Both examples achieve great spans and open spaces and are built with high precision parts with novel assembly.

3.2.2. Continuous 3D printing

These structures are continiously 3D printed as monolithic structures, using local resources like Regolith on the Moon or Mars. In the case of Hassell's Mars Habitat [7], there are swarm of different robots building simultaneously different parts of a continious structure. In contrast, the Olympus project, a proposal by ICON, BIG & Search+ looks at continious 3D printed shells by a singular, large robot. [8]

3.2.3. Discrete blocks

Contrasting from the first two categories where global geometries dictate towards a single, optimised solution, here we see examples of bottom-up assembly discourse where parts define the whole. Notable work in this discourse to look at are Regolight by Liquifier Systems [9] and Discrete Assembly Concept by Foster + Partners [10].

Although each of the above mentioned precedents are of novel form and construction techniques, we nevertheless argue that an aggregation system acts as the best option to mitigate uncertainty and low precision tolerance within the lunar environment. The main advantage of an aggregation system is that it allows for both extra pieces as well as removal of some existing pieces. This is an approach where the piece is decided first, and the final global geometry is derived from this piece. In this case our piece is a hexapod and although it is 3D modelled as a smooth and simple Euclidean geometry for design, simulation and analysis purposes, in reality each piece can be manufactured with low precision with certain degree of roughness (Figure 8).

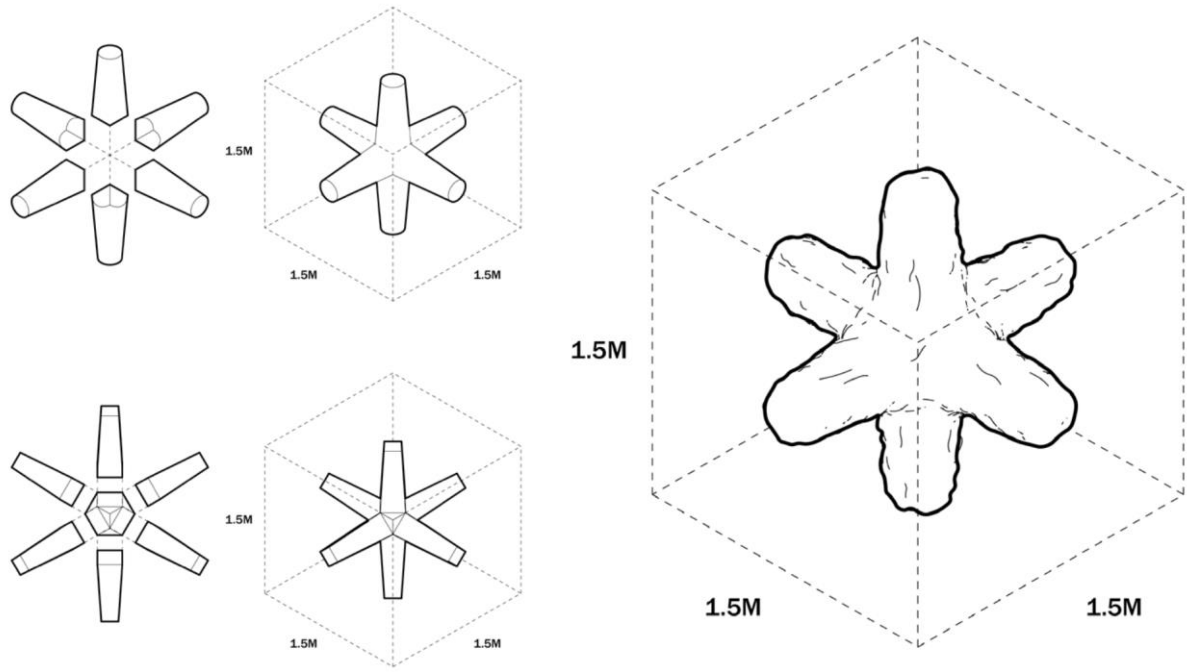

Figure 8. Different modelling of the hexapod design. Top left is used for Houdini Simulations, bottom left for structural analysis in Karamba and the version on the right is to induce how a hexapod could look like in reality as an aggregate made with sintered Regolith. Credit: Hassell

Overall, random aggregation approach differentiates itself from the above mentioned category of Sub-divided Vault Elements where it is the global geometry that is decided first and the piece(s) are subdivisions of the global geometry, allowing only a fixed number of pieces to create the structure and making each one of them necessary for the overall integrity of the structure. Our design process relies heavily on simulations as a means of calibration as for each design iteration we start with the piece first and try to populate a target surface or volume in a similar fashion to how it would be constructed. Therefore, the core of the construction method directly derives what the final design is. The design of the protection shell has evolved extensively by testing varying modes of construction, size, and form of the aggregate piece as well as the global geometry. The final state of the design relies on an inflatable formwork to build a central dome shape which then expands into an X shape by the diagonal contour slicing of four legs. Each hexapod fits inside a 1.5m x 1.5m x 1.5m bounding box

4. Design process & simulations

4.1. Conic structures

Prior to the final design and construction sequence we present later, we started our research in the hexapod aggregation by simple concentric build-ups of straight and curved - section cones. This set of exercises were useful to understand the key parameters that derive the success or failure of a design iteration: size of the hexapod, size of the target geometry (cone), and steepness (height of the target geometry divided by its radius). All the three parameters need to work together as in isolation there is no ideal value for any of them but ideal combination as a set of three. As the system has an inward / concave tendency for collapsing inwards rather than outwards, the structures would naturally become ever more stable during their construction process (Figure 9).

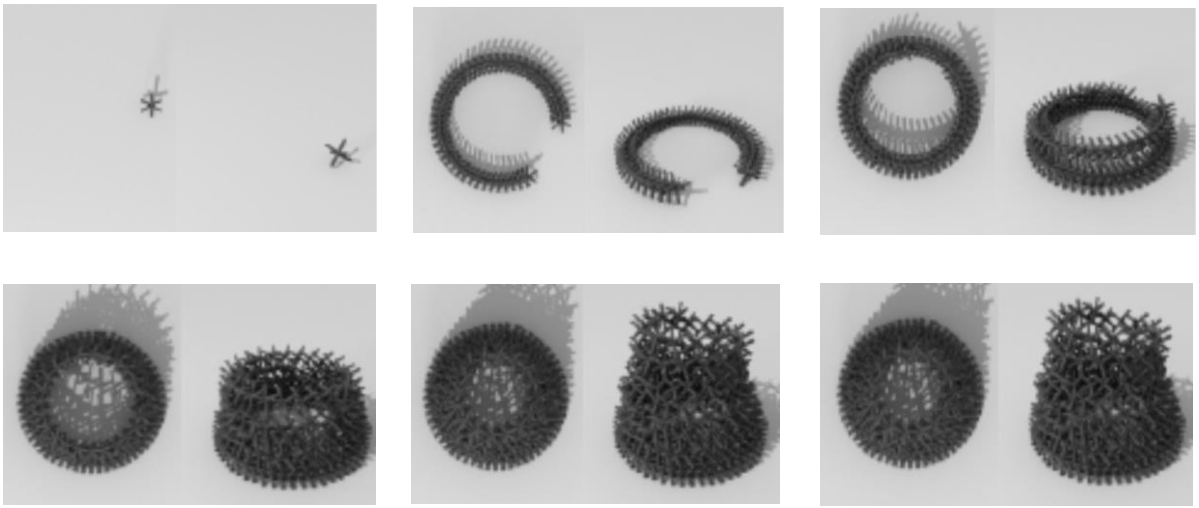

Figure 9. Key frames of the conic array drop test. Credit: Hassell

4.2. X shape / 4-legged vault

As a next step and to be able to test the effect of different values for each of the parameters mentioned above, we developed a more efficient system of simulating the collapse of non-intersecting aggregates. Instead of dropping the aggregates piece by piece, we project a large, non-intersection collection of the aggregates right above the formwork. In doing so each one of the aggregations have a different orientation vector.The algorithm loops over this logic to populate the target geometry as quickly as possible by dropping collections of aggregates instead of one by one. This reduces the overall computational time required as one does not to wait for each aggregate to drop and rest one by one. (Figure 10).

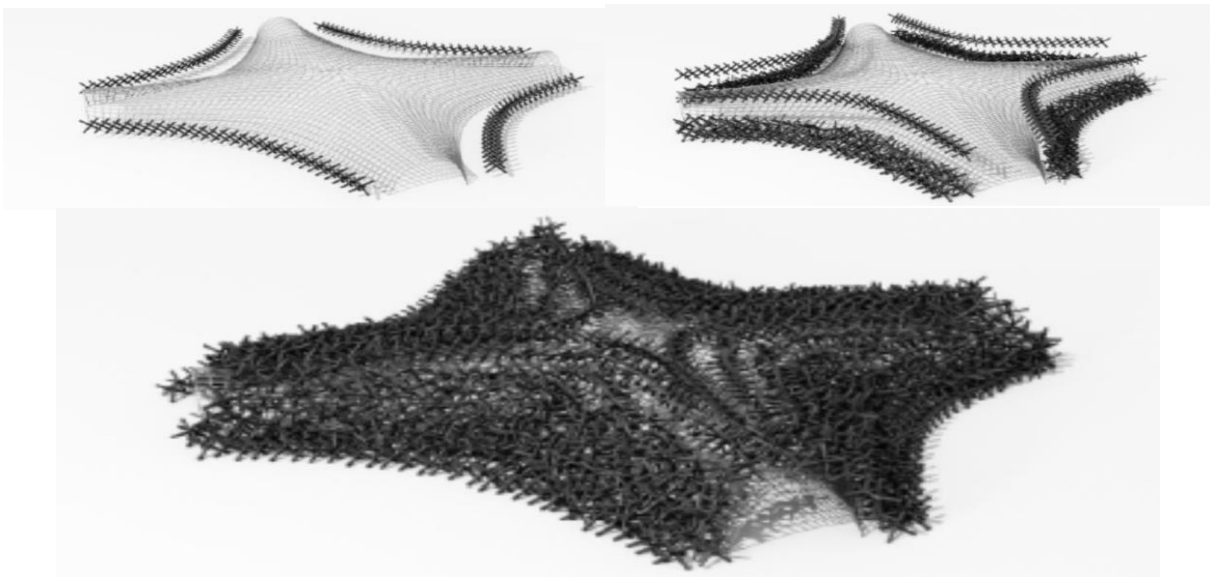

Figure 10: Aggregations collectively dropped on an X shape formwork.

As the design of the rest of the habitat framework evolved simultaneously it became clear that the next stage of evolution for the protection elements was to form an X shape on top view - as a vault with for legs. The initial set of simulations imagined a wireframe like formwork in the shape of the target geometry. This way one could rely on the formwork and simply populate the hexapods on it without any pre-engineering of a stacking sequence for the hexapod aggregation. This meant however that for each build-up of protection element, there is a need for a highly bespoke metal formwork, diminishing the true structural potential of the hexapods by making them merely insulation-like elements. Unlike the cone geometry, when an X like shape is contoured inwards the pieces stack in a convex manner, in other words they try to fall into the wrong side of the arbitrary contour they follow in construction. This results in the need for at least a temporary formwork structure holding the pieces until the construction is finished after which the formwork can be removed. Yet if we rationalize the X shape into 4 legs coming out of a vault, then the required formwork could be eliminated or reduced in size. In this approach the dome would be built prior to the legs so that the legs cannot influence the dome anymore. Here we rationalize the concave sides of the X shape to be generated by deletion of 4 sides of a uniform dome (Figure 11). What is not deleted at the perimeter of the dome is then extended outwards to create the legs. This way the dome and the legs are derived from two separate but clear structural thinking, whereby the dome is built prior to the legs and works without the legs as well if needed. To build the dome stage, we use a temporary inflatable formwork with 8 bending-active steel arches rest on it. The aggregate pieces are then populated on the inflatable formwork, with the steel arches acting as a formwork for the 8 openings. Once this is complete, 4 of the 8 openings are treated as the start of the extended legs. The contour slicing therefore follows the same profile as the opening to create the legs, built diagonally layer by layer.

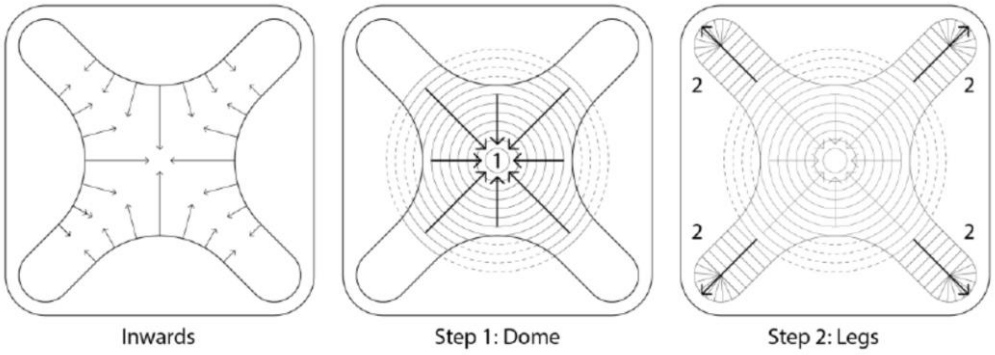

Figure 11: Dome to Legs approach explained. Credit: Hassell

5. Construction sequence

After evaluating both approaches to the general construction logic, we further developed the Dome to Legs strategy into a full construction sequence. At this point in time, the method of stacking up the aggregates is ballistic shooting with robots on site - which is the core focus of the research for Lunar

Modular Robotics project -. Figure 12 explains the key steps of the construction and do not detail out the technology for stacking-up the aggregates around the formwork and the inflatable modules:

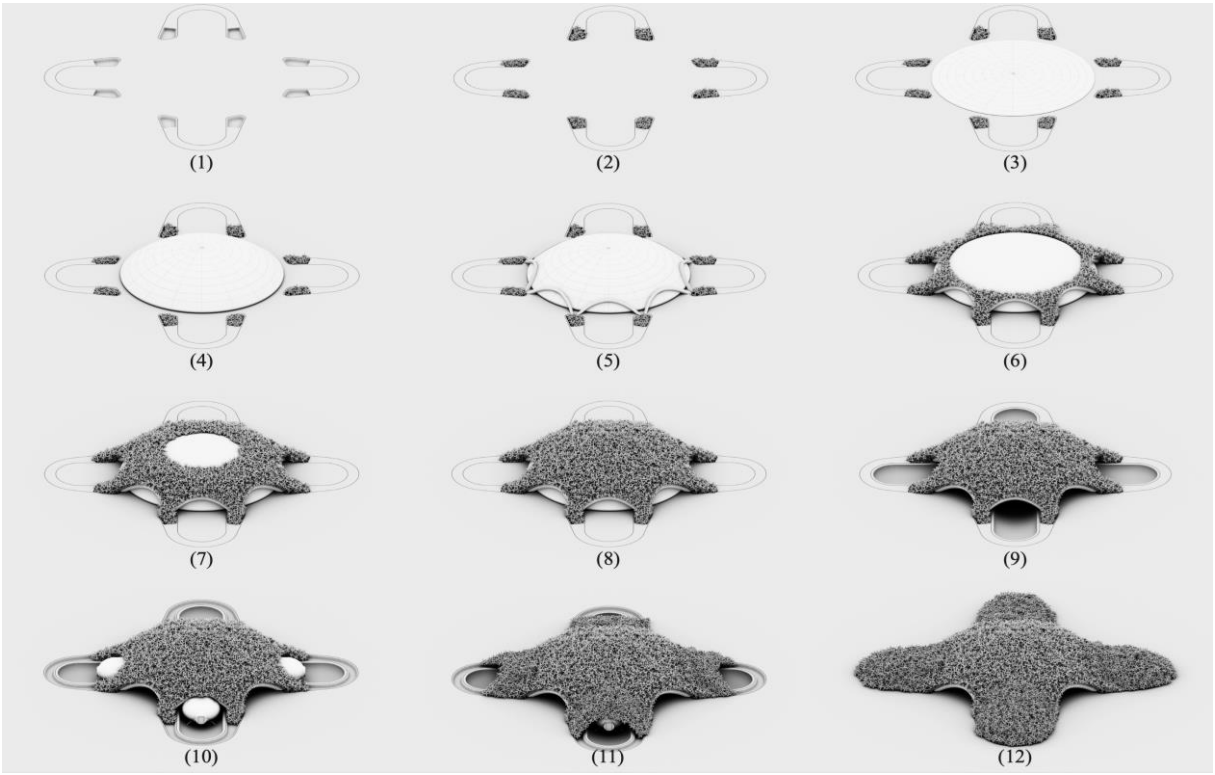

Figure 12: (1) First part of the pit dug out, (2) first layer of foundation aggregates placed, (3) inflatable formwork placed, (4) formwork inflated, (5) bending-active arcs positioned on formwork, (6-7) dome structure in construction with aggregates, (8) dome structure completed, (9) inflatable formwork removed, (10) habitats positioned under dome structure, (11) further aggregation to complete legs branching out from the dome, (12) construction completed. Credit: Hassell

6. Structural parameters

The structural understanding presented in this repor have mainly relied on digital simulations.Working closely with Format Engineers on finding an optimum design for the shell structure's guide geometry, we treated the central dome structure as compression shell and the legs acting as shear connection. In the absence of any wind forces on the Moon, where "moonquakes" are rare occasions, the digital simulations did not need to incorporate additional forces to lunar gravity. How the hexapods that do not interlock will behave; to what degree they will fall down and get damaged as a result of that will be a key question to answer with physical testing. In the final construction sequence discussed in this report, we propose that the inflatable habitats would only be placed after the dome is complete. For the legs, the habitats could be over-pressurized to act as a formwork during the construction. Integration of physical testing will be carried out on our next ESA – OSIP project titled as "Lunar Modular Robotics" on which we are working with University of Toronto. This next chapter will focus on the physical fabrication and performance analysis of the structure. As a replicant of regolith, we will be using voxel-based sand 3D printing as a fabrication method. Manufactured in different scales, the 3D-printed hexapod prototypes will then be tested for structural performance and interlocking behaviour. Below we present a collection of key details about the guide form and the structure derived from Format's report which will also play an instrumental role in setting out the physical testing in the next ESA-OSIP project.

6.1. Horizontal dimensions

The X shape shell sits on a 75m x 75m rectangle which is the reconfigurable grid cell for the Lunar Habitat Framework. Whilst the radiation protection shell stays fixed, what is underneath it as habitat modules are reconfigurable; from 1 big greenhouse to a combination of 4 medium or large habitable modules. The dome part of the X shell spans for 49 meters and has 8 openings, 4 of which is then closed with the leg part. The remaining 4 opening allows visual connection for the habitants inside with the outside world.

6.2. Form finding

The cross section of the guide shell will have an impact on defining the forces within the structure. Minimizing bending in the shell geometry will result in the thinnest required depth. The shape of the cross section will be ideal when no bending is carried under its own weight. In that sense, we isolate the dome part within the overall structure and use a inverted chain model to come-up with the compression only under moon gravity - which is around %16.5 of Earth gravity -. The results showed that arc geometry is more efficient than catenary due to the stress around openings of the dome geometry.

6.3. Height

The dome part of the guide shell is a revolved arc with openings. The height of the dome will determine the curvature of its geometry; the height of the dome will have a direct impact on material usage as well. Based on the horizontal dimensions discussed above, we found that 13m is an optimum height for the dome based on its Area / Buckling value.

6.4. Thickness

Using the same guide shell geometry, we can obtain the inflated formwork geometry by offsetting it inwards. Furthermore, to achieve an optimum thickness for the shell structure itself, we scale X/Y and Z dimensions of the guide shell independently to create a target volume for the aggregates to populate. This way, the target volume could be thicker at the bottom and thinner and the top.

6.5. Inflatable formwork

The inflatable formwork will create a closed volume, with additional surfaces along the floor being required for support. Its double curvature global form geometry will be created by using cutting patterns. This makes the fabric itself singly curved - develop from flat pieces - and the number of splits in fabric will determine: (1) how smooth inside of the shell is, (2) how consistent the thickness is at each height.

6.6. Edge support

Support conditions are vital for the edge of the shell structure, where it touches the ground. Here, lateral and vertical forces must be resisted. Notch cut into ground will be useful as a shear key and can putt horizontal forces into the ground. Furthermore, openings of the dome must be properly detailed to provide safe boundary conditions for the shell to work. In that sense, additional structure may be required to support the dome construction temporarily in these areas. Two options that can be applicable

are planar 3D trusses that are prefabricated on Earth or arches created with bags filled with Lunar Regolith (Figure 13).

Figure 13: A close approximation of arches that could be done with bags filled with Lunar Regolith. In this Earth application the bags are filled with sand.

6.7. Legs

Although the dome structure was based on revolved arcs, the legs are optimized into catenary section with no openings except the connection to the dome structure. Apart from the end cap of the legs the rest of its guide geometry is singly curved. Due to the aggregation nature of the system the transition from catenary form of the legs to the arcs of the dome is handled smoothly as low accuracy of the interlocking blends them. Figure 14 gives an overall idea on how the stacking up sequencing for each part works.

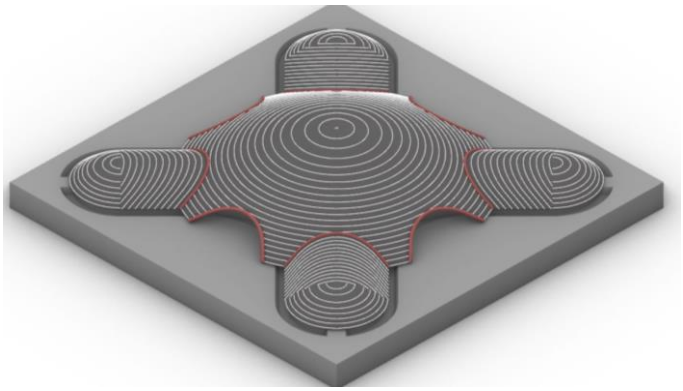

Figure 14: Guide paths for each section of the X shell. The legs are two stages; starting with a diagonal contour approach that is than finished off with horizontal stacking.

7. Conclusion

The paper offers an insight into a shift away from highly controlled design & construction methods into systems that gain from low-precision and disorder. When designing for extreme environments, we often see over-engineered control as the sole means to success of long-term survival of the building. With this paper, we propose an alternative way where disorder is not only tolerated (robustness) but more importantly is used to the overall design's advantage (anti-fragility). We position the research behind shell design as a balancing act between bottom-up module - fabrication oriented designing & top-down optimization / brief oriented designing. On the one hand, the final shell design is a direct multiplication

of a single type aggregate, making qualities like performance, aesthetics or thickness a direct product of quantity. On the other hand, how the quantities of aggregates are distributed relies on the pre-engineered, continuous shell geometry which is used to organize the randomly positioned aggregates around a more defined area than in the case of coastal barriers. Leveraging both ways of designing, we make the design as optimized and yet also as flexible as possible at the same time.

Abstract

Cast glass is an excellent candidate for achieving fully transparent arch, vault and dome structures. By casting, voluminous, free-form glass components can be produced that fulfil the complex geometry requirements, offer increased compressive strength and maximize the incoming sunlight. Nonetheless, the application of cast glass in such structures is seldom seen; manufacturing challenges, uncertainties over the strength of the material, missing guidelines on the assembly methods of the components, lack of engineering norms, and the associated research and development costs to overcome those barriers, are some of the key discouraging factors. This paper explores several realised case studies of small-scale, cast glass arches, vaults and domes, where the TU Delft Glass Research group was involved in the R&D process, as well as unrealised case studies developed by the group (Fig. 1). The main challenges and developed solutions for each project are described, focusing on three main aspects: (i) the manufacturing challenges linked with achieving the desired curvature, (ii) the assembly method and mechanical validation of the system, and (iii) the construction ease of the system. Based on the comparative study of the selected projects, the paper aims to provide a design methodology for future projects employing cast glass curved structures.

Keywords: structural glass, cast glass components, cast glass shells and arches, glass casting and post-processing, adhesive bonding, interlocking components, adaptive moulds

1. Introduction

With the Industrial Revolution enabling the use of cast and wrought iron in building structures, large-span, glazed vault and dome structures were made possible, significantly increasing the incoming daylight in public buildings of the Victorian era (Fig. 2a, b). Ever since, transparent roofs fascinated the architectural world, sustaining continuous engineering developments that refined their typology (Fig. 2c). Nonetheless, in essence, the same structural model is being reproduced over the years: a metal load-bearing structure, cladded with glass. Technological developments in the field of structural glass during the last three decades, however, showcased in smaller scale structures, the functional and aesthetical benefits of maximized transparency and light income (Fig. 2d), as these result from employing float glass as the structural element and minimizing, if not omitting, the use of steel. This can be achieved by taking advantage of the high compressive strength of glass, yet the two-dimensionality of float glass imposes buckling-related limitations and shaping challenges, which prevent the realization of larger-span all-glass curved structures. In this context, cast glass could be an excellent candidate for achieving compressive, fully transparent curved structures of larger spans, as with casting, robust components of complex geometry and considerable thickness can be achieved. Yet, the use of cast glass as a structural material is still in an experimental phase; lack of manufacturing, quality control and engineering norms coupled with a lack of design data, prevents its use in structural applications. Therefore, its suitability in such structures has been so far tested in small-scale realized projects, and with prototypes that evaluate the casting ease, mechanical performance and assembly method of the cast components. This paper explores several realised case studies of small-scale, cast glass arches, vaults and domes where the TU Delft Glass Research Group was involved, addressing the following main points:

(i) manufacturing challenges: in this case, the strategy for achieving the desired curvature of the structure is addressed in relation to the shaping limitations of cast glass, the resulting number of different component shapes and moulds, and the requirements for post-processing.

(ii) assembly methods: the choice of a permanent or temporary adhesive bonding versus a dry-assembly solution by using interlocking components and dry-interlayers is discussed. Where applicable, the output from the mechanical validation of the assembled glass system is provided.

(iii) construction ease: insights on the assembly method and sequence are provided, covering a range of solutions from scaffolding and layer-by-layer building, to rotating frames and robotic arms.

2.1. Crystal Houses Façade

The Crystal Houses façade in Amsterdam, designed by MVRDV, is a reinterpretation of the original 19th century brick façade in cast glass. As such, 12 architraves, 10 to be placed over the windows (1.26m span) and 2 larger ones over the doors (1.89m span) were designed, following the same structural system of the cast glass façade (Fig. 3d). This system comprises cast glass components (produced by Poesia) bonded brick by brick on site, using a stiff, transparent UV-curing acrylate of 0.25mm thickness [1]. The selected adhesive, due to its low viscosity, was applied at the horizontal brick surfaces only; vertical application would lead to non-homogeneous results due to the downward flow of the adhesive prior to curing. In addition, due to the adhesive's minimum optimum thickness, extreme dimensional precision had to be met, dictating, among others, the CNC grinding and polishing of the bricks to meet the desired tolerances [1]. Realizing the architraves was therefore an additional challenge, as (i) the cast glass bricks had to be tapered and bonded to precision to reproduce the exact curvature, (ii) the top side of the architraves had to be perfectly straight –within the 0.25mm tolerance range- to accommodate the glass brickwork above, and (iii) the adhesive could not be applied on site, as this would imply its vertical application. To solve the above challenges, 54 different steel moulds were required to achieve the desired geometry of the tapered bricks (544 pieces in total), and the vertical surfaces of the bricks were further CNC-post processed to meet the tolerances. The architraves were then prefabricated at the TU Delft Glass lab, using a rotating steel frame that allowed the horizontal application of the adhesive at every brick layer, and the creation of a straight line at the top side of the architraves (Fig. 3a,b). The prefabricated components were then craned on site, and special corner brick pieces (five per side) were adhesively bonded one by one to the side of the architraves to keep it in place (Fig. 3c). To ensure that the architraves could withstand their own weight before becoming incorporated in the wall system, a destructive 4-point bending test was conducted in a door architrave specimen. The specimen failed at 6.7MPa [2], withstanding 41.6KN which was more than double of the service load specified by the project engineers (abt).

2.2. Glass Masonry Bridge

The Glass Masonry Bridge (Fig. 4a, non-realized project) is a pedestrian bridge designed for the TU Delft campus [3]. The arch-formed bridge consists of cast, interlocking glass components, dry assembled with a polyurethane (PU) rubber interlayer inbetween. One main component (Fig. 4b) is used -of a slightly tapered geometry to achieve the desired curvature- while two different corner components are designed to connect the bridge with the foundations. To reduce the complexity and costs of the production process, the post-processing of the glass surfaces is avoided, and dimensional deviations are expected to be absorbed by the rubbery interlayer. Several interlocking geometries were tested based on their interlocking performance [3, 4] but also on the complexity of the casting process and the compatibility of the geometry to the glass properties (e.g. sharp angles were avoided). A smooth, curved interlock was opted and validated by testing kiln-cast specimens (1:2 scale) in shear [5] (Fig. 4c) and compression [4]. These experiments indicated that poor contact between the interlocking surfaces can lead to the generation of point loads and subsequent fracture. A larger specimen (1m span), comprising components (1:2 scale) that were waterjet cut out of cast glass bricks, was tested in bending (Fig. 4d), showing satisfactory shear resistance, yet further testing involving a larger span and different load combinations is required [6]. For the assembly of the Glass Masonry Bridge, a secondary Glass Truss Bridge has been constructed below, to serve as scaffolding [7].

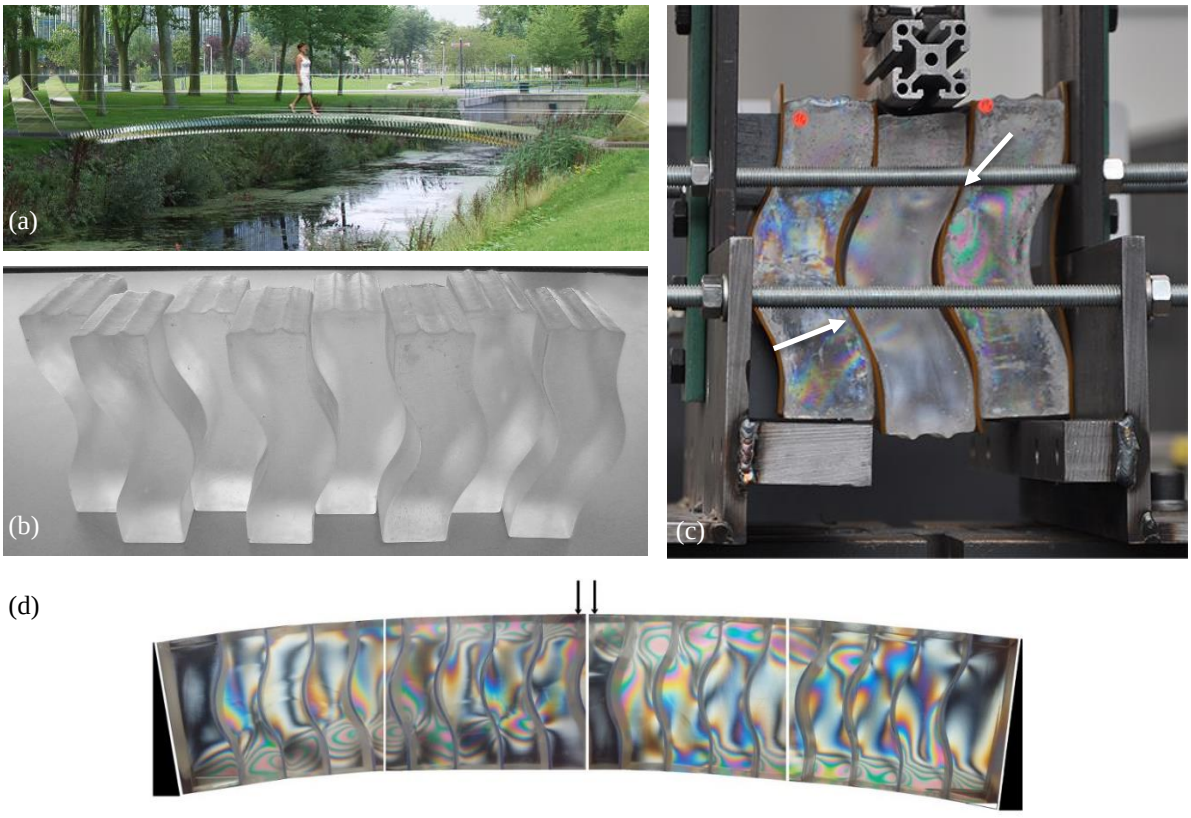

Figure 4. Cast Masonry Bridge: (a) 3D-visualization of the bridge, (b) kiln-cast glass components in 1:2 scale, showing the interlocking principle, (c) testing in shear combined with photography using cross-polarized light indicated the generation of point loads instead of the full cooperation along the interlocking surface, (d) photograph using cross-polarized light of a loaded 1m arch segment made from waterjet-cut components out of cast glass bricks.

2.3. LightVault

The LightVault, designed by SOM and Princeton University c.r.e.A.te lab and Form Finding Lab, is a double curved glass brick vault following a herringbone pattern [8]. It was designed to be built without the use of scaffolding, but with the aid of two robotic arms that would place the bricks in the precise location (Fig. 5a). The structure is realized in its majority with the use of one type of rectangular, non-tapered cast glass brick (309 pieces, produced by Poesia) that is not post-processed after casting, while a small number of half-sized bricks (29 pieces) are strategically inserted to reduce the occurring gaps in the structure. Nonetheless, due to the use of one rectangular geometry and taking into account the dimensional deviations occurring from casting, wedge-shaped gaps of significant thickness between the brick interfaces were created, the majority of which were optimized to be below 17.5mm [9]. A fast curing Epoxy Patty of 20mm gap-filling capability was selected as the intermedium [9, 10], minimizing the time the robotic arm would hold the brick in place to 12-15min (25min for the middle arch) [11]. Several prototypes were constructed to evaluate the assembly order, suggesting that the building of a broader brick wall section at the base, would enhance the temporary stability of the system (Fig. 5b, c).

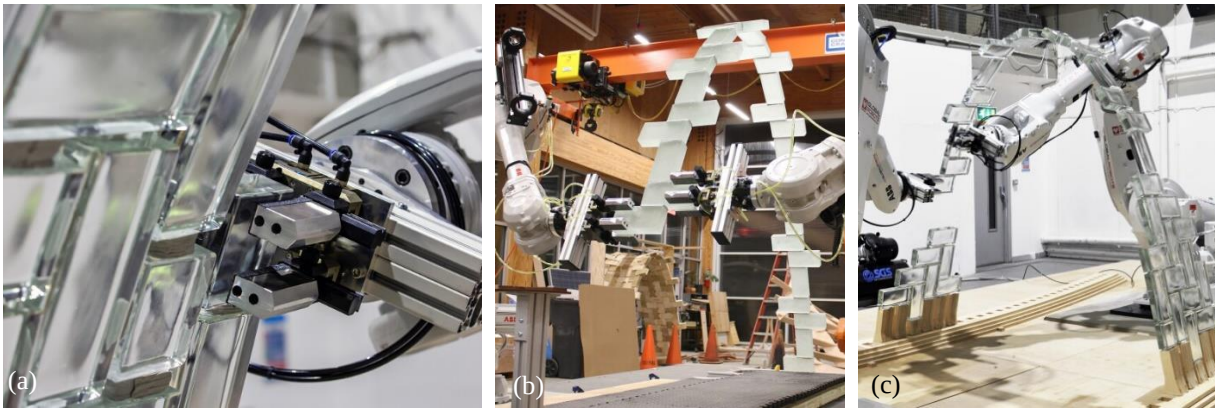

Figure 5. Robotically assembled cast glass vault: (a) robotic arm placing a half-sized glass brick (image credits: M. Grzeskowiak/SOM), (b) unstable assembly configuration (image credits: I. X. Han/ Princeton University), (c) redesigned assembly order to ensure the temporary stiffness of the system (image credits: I. X. Han & E. Bruun, Princeton University).

2.4 Qaammat Pavilion

The Qaammat Pavilion in Greenland, designed by Konstantin Arkitekter, comprises two semi-circular, perforated walls that follow a frustum shape (Fig. 6a, c). The walls were constructed with the use of a basic rectangular cast glass brick (1100 pieces) and a limited amount of half-sized bricks for the edges (bricks produced by Wonderglass). The bricks were not post-processed and were adhered with two different types of 2-component adhesives. At the bottom rows, where larger gaps between the bricks occur due to the developed geometry, a clear polyurethane of high stiffness, >3.7MPa shear strength and 1mm gap-filling capacity was selected [10, 12]. For the middle and top rows, where less stresses are developed but also higher deviations are built up from the occurring variations at the bricks' height due to casting, a more flexible, white structural silicone of 2-3mm gap filling capacity and circa 1MPa shear strength was applied, developed by DOW specifically for this project [13]. The bricks were laid row by row with the aid of CNC-cut PVC templates that would control their placement (Fig. 6b). The use of scaffolding was avoided by selecting 2-component, fast curing adhesives, which reach their set-time within 4-20min. To ensure the temporary fixing of the bricks until the set-time is reached, double-sided tape spacers were placed between the bricks, holding them in position and securing the desired thickness of the adhesive layer.

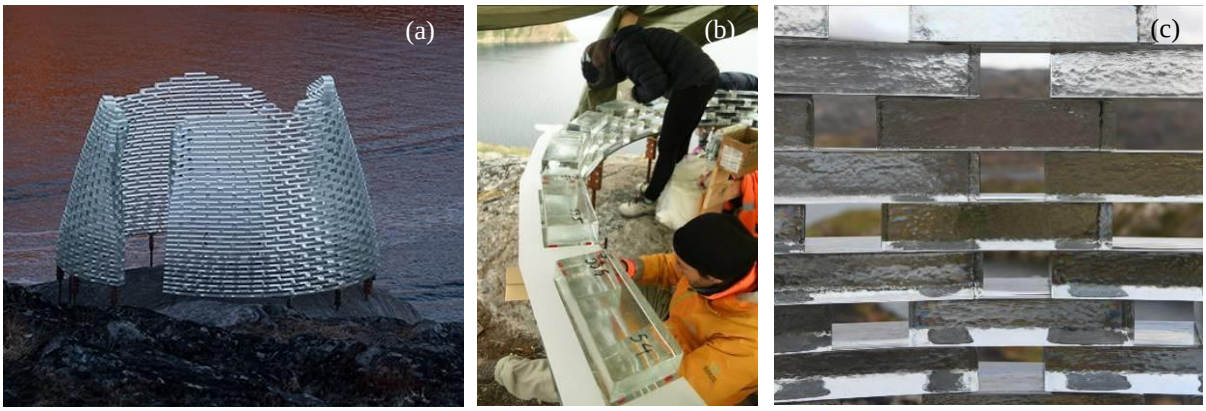

Figure 6. The Qaammat Pavilion in Greenland: (a) Aspect of the finalized project (Image credits: Julien Lanoo), (b) row by row brick laying on site, using PVC templates, (c) detail of the perforated cast glass wall.

2.5 Geodesic cast glass dome

This dome is a theoretical study on how to achieve the minimum number of different components to realize a 20m span cast glass dome [14]. The components should not overly exceed a maximum mass of 10kg, to ensure a realistic annealing time during casting, and to facilitate the assembly process. To fulfil the above criteria, Buckminster Fuller's Geodesic dome configuration was preferred versus a horizontal ring division. Using a geodesic dome frequency of 22, 20 different pieces are required; 19 hexagons and 1 pentagon. To further reduce the mass, the pieces were divided in half, and a ribbed geometry was preferred instead of a constant thickness (Fig. 7a, b). The pieces were slightly tapered and adhered together with a UV-curing acrylate that could accommodate up to 1mm tolerances. A scaffolding would be required for the construction of the dome. Prototyping of the components in 1:5 scale was conducted, to evaluate the suitability of the designed shape in relation to the casting process (Fig. 7b). Larger bevel angles are advised for the rib edges.

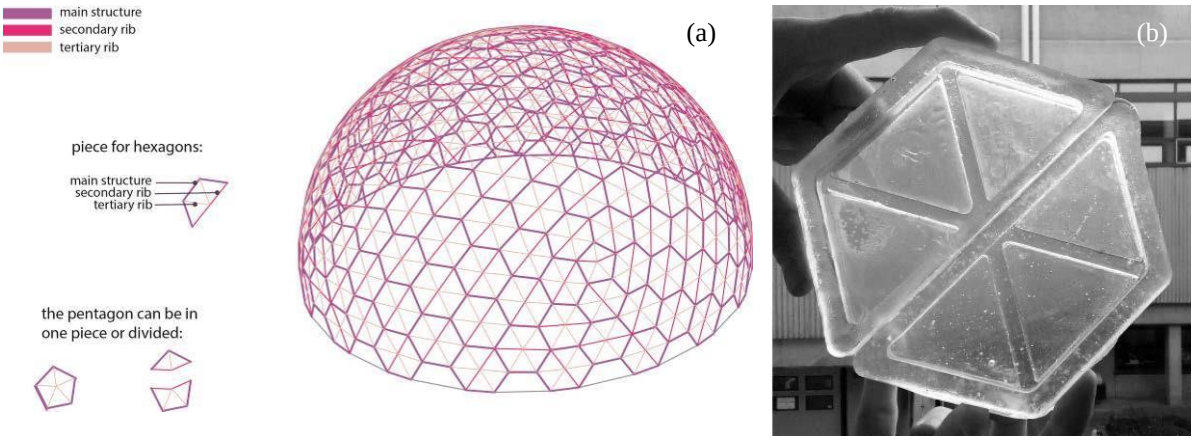

Figure 7. Concept for a cast glass geodesic dome: (a) division of the components and distinction of rib thicknesses, (b) 1:5 kiln-cast glass mock-up.

2.6 Glass Vaults

This project studies the realization of free-form transparent shell structures, by employing interlocking cast glass voussoirs [15, 16]. The voussoirs interlock thanks to their tongue or groove -shaped side surfaces, and the pieces are dry-assembled with the use of a rubber interlayer in between. Node components are also introduced at the intersection points of the voussoirs. To achieve such a complex system, voussoirs of distinct geometries are required. Adjustable moulds in triangular, quadrangular and hexagonal configuration (Fig. 8a) are therefore devised that adjust the length and angles of the components' edges, and the type and angle of the interface geometry (tongue or groove). As a proof of concept, a shell roof structure is designed for the courtyard of the Armamentarium in Delft (Fig. 8c), and an algorithm is developed to tessellate the double-curved surface into triangular components, and to assign the interface types and angles for each component. 1250 pieces are designed, varying in mass from 5.4 to 38.5kg, and with an average mass of 24.6kg. The node pieces are identical and require one mould only. The ability of the mould to adjust to the generated designs was further tested by constructing distinct models of voussoirs in wax. These wax models were thereafter used to produced investment moulds for kiln-casting the voussoirs in glass (Fig. 8b).

Concept for achieving free-form interlocking glass shell structures: (a) adjustable mould system in triangular, quadrangular and hexagonal configuration, (b) kiln-cast voussoirs using investment moulds produced with the lost-wax technique; the wax models were produced from adjustable moulds, (c) case study of a free-form shell out of interlocking cast glass components, designed to cover the courtyard of the Armamentarium in Delft.

2.7. The Glass dome

The Glass dome aviary project studies the construction of a dry-assembled cast glass dome using one omnidirectional interlocking component [17] (Fig. 9a). The component is designed by blending three spheres of different size (Fig. 9d), ensuring an interlock in both ring (horizontal, Fig. 9c) and arch (vertical, Fig. 9b) direction. The component has a 2.5kg mass, facilitating the annealing process during casting, and the assembly process. Thermoplastic polyurethane (TPU) interlayers, produced by compression molding, are placed between the glass components both in arch and ring direction. The interlayers in arch direction are identical, while those in ring direction differ in each row due to the changing curvature. A wooden substructure is suggested for assembling the dome, after which a customized compressive steel ring is fixed at the top, while a tension ring is applied at the bottom. To validate the castability and validity of the design, five components were kiln-cast in 1:2 scale (Fig. 9e). Challenges with air-entrapment were identified due to the enclosed mould design, and the introduction of mould vents is suggested to prevent the encountered problem.

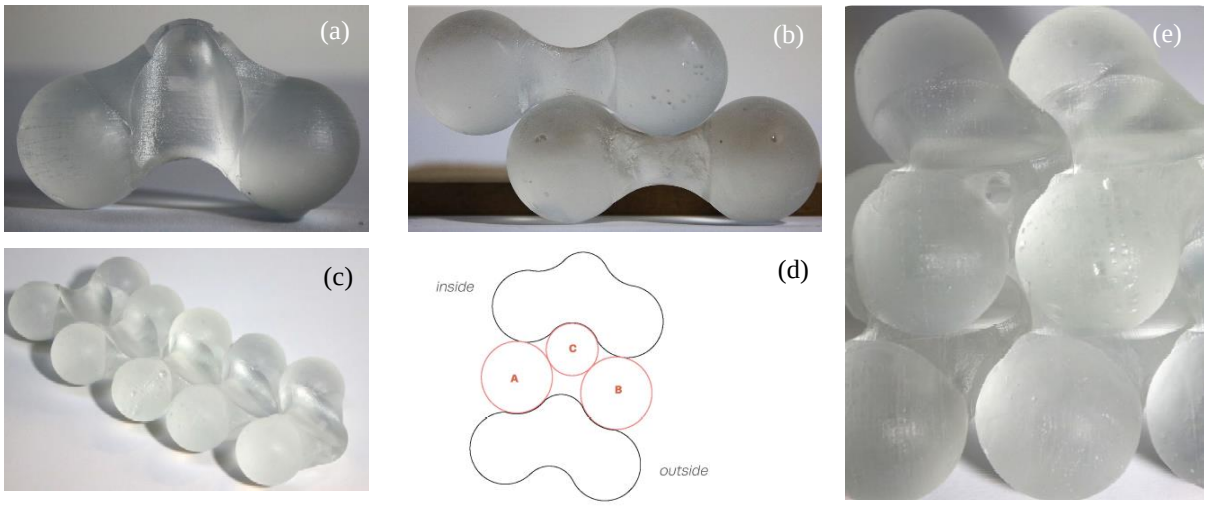

Figure 9. Omnidirectional interlocking cast glass component for a dome structure: (a) top view of the component, (b) array of the components along the arch direction, (c) array of the components along the ring direction, (d) design of the component based on 3 spheres of distinct dimensions to ensure interlock in both horizontal and vertical direction, (e) assembly of the components in both ring and arch direction.

3. Design guidelines

The presented case studies show the design choices made regarding the shape, mass and number of different components, the type of bonding (permanent, interlocking), and the method of assembly, in order to realize the desired curved cast glass structures. Based on this experience, and in combination with basic principles applied to the casting process [18], design guidelines can be developed for future applications. The main design choices are discussed below and presented in Figure 10:

Regarding the general shape of the structure, this should be principally working in compression, to benefit from the high compressive strength of glass. Double-curved, asymmetric geometries increase by definition the number of different components, and normalization of the shape is advised to prevent a plethora of distinct pieces that strain the production process and delay the assembly. Nonetheless, in case of complex geometries, two options are worth considering regarding the design of the component:

(i) using one global geometry and solving the tolerances in the interface. This interface can be an adhesive of high gap-filling capacity (e.g. an epoxy patty) or a stiff, customized dry interlayer (e.g. 3D printed plastic pieces)
(ii) using distinct components produced by adjustable moulds, to reduce the production costs.

In parallel, the bonding strategy between the components needs to be determined. Adhesively bonded structures can be very stiff –based on the adhesive type and bond thickness, but lead to permanent, non-dismountable solutions. Dry-interlocking systems, although less stiff, promote circularity, but also increase the casting complexity; high-precision of the interlocking interfaces is required to achieve homogeneous transfer of the load and thus avoid peak stresses, which increases the production costs. In both cases, the redundancy of the system should be evaluated, ensuring a safe structure even in the event of breakage of a few components. As structural norms and guidelines on the design and calculation of such cast glass structures do not exist, mechanical testing of characteristic mock-ups of the system is necessary, to validate the dimensioning of the structure and the choice of interface material.

Regardless of the solution path selected, several guidelines should be followed for the design of the cast glass components. The mass of each component desirably should not exceed a maximum of 10kg, to reduce the annealing time during the casting process, but also to facilitate the handling of the piece during assembly. To further facilitate the annealing process, abrupt changes in thickness along the piece should be avoided, while sharp edges are also not favourable in terms of casting and construction. Organic, spherical geometries are favourable in terms of annealing, but require closed or press-moulds; careful introduction of vents in those moulds should prevent air-entrapment defects at the surface of the glass components.

Some form of scaffolding is –in most cases- unavoidable, yet, the use of robotic arms is a proven solution for avoiding scaffolding in adhesively bonded double-curved systems. For achieving configurations of high-precision, the preassembling of segments of the structure (again adhesively bonded system) with the use of frames and guides should be considered. Lastly, for minimizing the scaffolding requirements, the brick-by-brick laying per row and the (almost) horizontal application of a fast curing adhesive should be opted for.

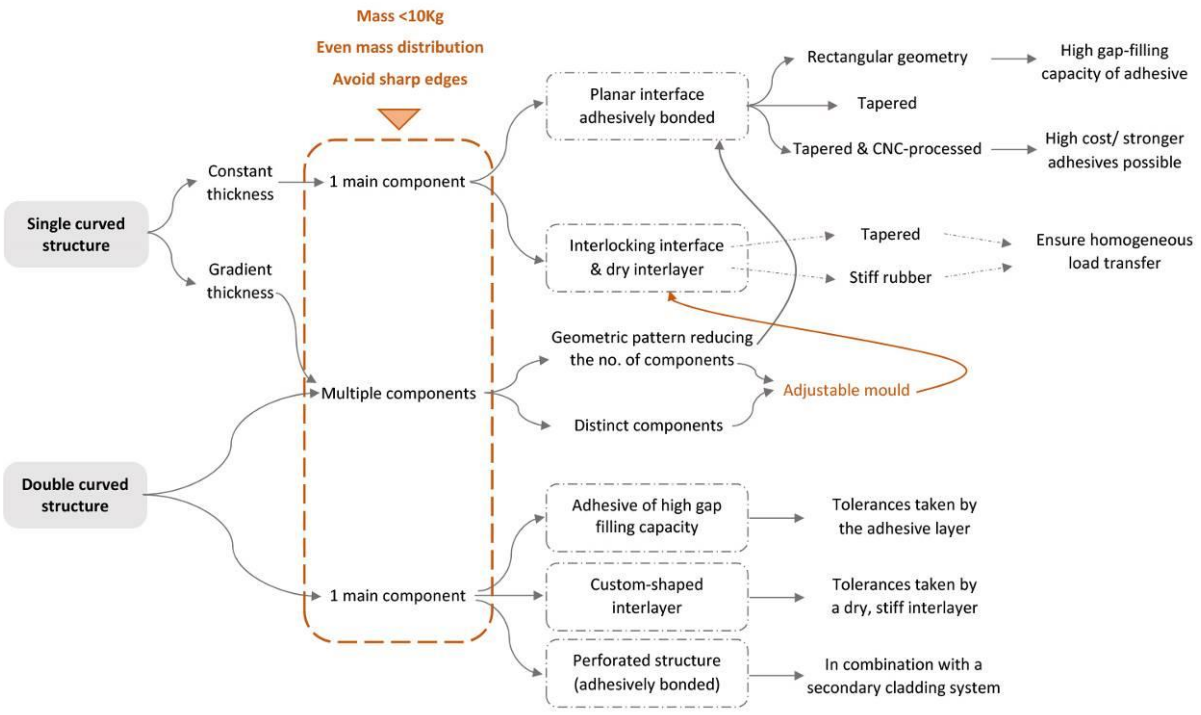

Figure 10. Design selections for achieving single and double curved cast glass structures.

4. Conclusions

Although cast glass is an excellent candidate for materializing strong and transparent arch, vault and dome structures, realized structures using cast glass components are rarely seen. Discouraging factors responsible for this include the lack of engineering data, coupled with the complexities imposed on the casting process due to the (double) curved geometries and the associated high costs. From the studying of a few realized case studies and theoretical projects, guidelines arise concerning the choices to be made on the design of the component, the connection method and the assembly process. These evolve around the decision of absorbing the tolerances at a component level –resulting to multiple different shapes- or at the interface –leading to either thick adhesive layers or custom-shaped dry interlayers. The choice of an adhesive medium versus a dry rubber interlayer has further consequences on the stiffness, demountability, and allowable tolerances of the system. The casting parameters play the most crucial role, as the reduction of the number of different moulds, the reduction of the mass, and the avoidance of post-processing, all work towards the reduction of the production costs and time, making the structure more feasible. Experimental validation of a mock-up of the chosen system is always required for ensuring a safe structure.

Abstract

This research explores the use of holographic building techniques to facilitate the construction of compression-based stacking structures with extreme cantilevers and arched spans inspired by the block stacking problem. Geometric operations including mirroring, scaling, and shifting are used to transfer the loads of each cantilever structure component to one another without the use of glue or fasteners, allowing the structure to stand without support. Three studies are introduced. In the first, the mathematical problem is parameterized using computational tools with a series of tests of an arced cantilever of X-shaped components. In the second study, we focused on arched structures as the scale of to more directly approach the stacking problem. In the third study, we explored the limits of height using limited materials available, including diminishing part lengths and nonuniform scaling of the archetype "arch" structure. Utilizing computational tools and the integration of holographic projection of geometry during the assembly process added precision and constructability. Using these tools, we were able to easily test and iterate on different design options in a virtual environment before physically constructing them. Additionally, holographic projection eliminated the need for physical measurements, support or alignment materials.

Keywords: computational modeling, structural design, holographic assembly, holographic building techniques, virtual reality, augmented reality, arched spans, extreme cantilevers, glue-less assembly, holographic projection

1. Introduction

Compression-based stacking structures, such as arches and cantilevers, have been fundamental to architecture and engineering for centuries. However, the construction of such structures presents several challenges, especially when dealing with extreme cantilevers or arched spans. Traditional building techniques often rely on glue or fasteners to keep components together, which can be impractical or impossible to use when constructing certain types of compression-based structures. So, constructing these structures without support can be a significant challenge due to the need for precise alignment and careful weight distribution.

Holographic building techniques have been gaining popularity in recent years and offer a promising alternative to traditional building methods[1]. By projecting virtual geometry during the assembly process, these techniques allow for more precise alignment and weight distribution, leading to greater stability and structural integrity. In this paper, we present a novel approach to constructing compression-based structures using holographic building techniques.

The block stacking problem, also known as the Leaning Tower of Lire[2], is a classic paradox in statics that has been studied extensively over the years. Researchers have developed a variety of solutions to this problem, making it a useful starting point for exploring the construction of complex compression-based structures. Our approach involves using computational tools to parameterize the mathematical problem of the block stacking paradox and simulate the structures in a virtual environment. This allows

us to easily test and iterate on different design options before physically constructing them, saving time and resources in the construction phase.

Our research aims to contribute to the field of architecture and engineering by exploring a novel approach to constructing compression-based structures using holographic building techniques and computational tools. The goal is to overcome the limitations of traditional building techniques and expand the possibilities for complex and innovative architectural designs. By using holographic projection during the assembly process, we can achieve greater precision in alignment and weight distribution, leading to greater stability and structural integrity. Additionally, by simulating the structures in a virtual environment using computational tools, we can test and iterate on different design options before physically constructing them, saving time and resources in the construction phase.

Through our research, we hope to provide insights into the benefits and limitations of holographic building techniques and computational tools in constructing complex compression-based structures. We aim to address the challenges posed by extreme cantilevers and arched spans, and explore the possibilities for new and innovative architectural designs. Ultimately, our research has the potential to revolutionize the way that compression-based structures are constructed and contribute to the advancement of the field of architecture and engineering. In the following sections, we will present our methodology and results in detail, and discuss the implications of our findings for the broader field.

2. Background

The construction of compression-based stacking structures has been an essential part of architecture and engineering for centuries, with arches and cantilevers being some of the most iconic examples of these structures. However, building these types of structures without support or glue can be challenging, and traditional building techniques often rely on these materials to keep components together. Recent advancements in technology, such as computational tools and holographic building techniques, have opened up new avenues for the construction of complex compression-based structures. In this chapter, we will provide a background on compression-based structures, the challenges involved in their construction, and the technologies that have been developed to overcome these challenges.

2.1. Traditional Building Techniques for Compression-Based Structures

Compression-based structures such as arches and cantilevers have been used in architecture and engineering for centuries. These structures rely on the principle of compression to support loads, which means that the weight of the structure is distributed along its length, rather than being concentrated at specific points[3]. However, building these structures can be challenging, particularly when dealing with extreme cantilevers or arched spans.

Traditional building techniques for compression-based structures often involve using glue or fasteners to hold the components together[4]. For example, in the construction of arches, the stones or bricks are laid in a specific pattern, with the weight of each stone or brick distributed to the adjacent ones. Mortar is then used to fill the gaps between the stones, providing additional stability and preventing the stones from moving.

In the case of cantilevers, traditional building techniques often involve using braces or supports to hold the structure in place while it is being constructed. This is necessary to ensure that the weight of the cantilever is distributed evenly and that it does not collapse under its own weight. Once the structure is complete, the braces or supports are removed, and the cantilever is able to support itself[5].

While these traditional building techniques have been used successfully for many years, they have limitations when it comes to constructing complex compression-based structures. Constructing these structures without support can be a significant challenge due to the need for precise alignment and careful weight distribution.

As a result, new building techniques have emerged in recent years that offer alternative approaches to constructing compression-based structures. One such approach is the use of holographic building techniques, which we will explore in more detail in the following sections.

2.2. Limitations of Traditional Building Techniques for Compression-Based Structures

Despite the long history of compression-based structures, traditional building techniques have several limitations that can make construction difficult, particularly for structures with extreme cantilevers or arched spans. One significant challenge is the need for precise alignment of each component. Even slight deviations from the intended position can lead to structural instability and collapse. This need for precise alignment can be particularly challenging for structures with complex geometries, which can be difficult to measure and align accurately.

Another limitation of traditional techniques is the need for additional support materials, such as scaffolding or bracing. These materials can be costly and time-consuming to install, particularly for large or complex structures. Additionally, the use of these materials can limit the design possibilities, as they can obstruct access to certain areas or limit the range of possible component configurations.

Glue or fasteners are commonly used in traditional building techniques to keep components together. However, the use of these materials can be impractical or impossible for certain types of compression-based structures[6]. Also, traditional building techniques can be limited in their ability to accommodate complex geometries. Structures with complex geometries, such as those with curved or irregular shapes, can be difficult to construct using traditional techniques, particularly when dealing with extreme cantilevers or arched spans. This limitation can limit the range of possible designs and limit the creativity of architects and engineers.

These limitations have led to the development of new and innovative building techniques, such as holographic building techniques, that offer potential solutions to these challenges. Holographic building techniques offer a promising solution to the challenges and limitations of traditional building techniques for compression-based structures. By projecting virtual geometry during the assembly process, holographic techniques allow for more precise alignment and weight distribution, leading to greater stability and structural integrity. This approach also eliminates the need for physical measurements, support, or alignment materials[7].

Overall, holographic building techniques offer a promising solution to the challenges and limitations of traditional building techniques for compression-based structures. By allowing for more precise alignment and weight distribution, holographic techniques can lead to greater stability and structural integrity, making it possible to construct more complex and innovative architectural designs. In the next section, we will present our approach to using holographic building techniques in the construction of compression-based structures with extreme cantilevers and arched spans.

2.3. Holographic Building Techniques as a Solution

Holographic building techniques have emerged as a promising solution to the challenges and limitations of traditional building techniques for compression-based structures. These techniques utilize virtual reality and augmented reality to project holographic images of the structure's geometry during the assembly process[11]. This enables builders to visualize the final structure before its construction, to identify any potential issues, and to test different design options virtually, reducing errors and saving time and resources in the construction phase.

One of the primary advantages of holographic building techniques is the ability to achieve greater precision in alignment and weight distribution, which is crucial for compression-based structures. With traditional building techniques, precise alignment and weight distribution can be difficult to achieve, leading to instability and potential collapse of the structure. Holographic building techniques eliminate

the need for manual measurements and alignment, allowing builders to achieve greater accuracy in the assembly process[8].

Furthermore, holographic building techniques can also reduce the use of materials and resources in the construction phase. With traditional building techniques, builders may need to use additional support or alignment materials, adding to the overall cost and complexity of the construction process. Holographic building techniques eliminate the need for additional materials, resulting in more cost-effective and efficient construction.

2.4. Current State of Field

Over the past few years, construction techniques that use holographic technology to project a virtual model of a structure onto the construction site have emerged, providing new opportunities for building compression-based structures. This approach eliminates the need for physical measurement, support, or alignment materials, resulting in a significant reduction in construction time and cost. An instance of such an approach is found in the Hyphae House and the Paperless Worksite[9], where researchers employed augmented reality on smartphones to construct complex structures without using CNC technology. Despite some placement issues with the blocks, the technology exhibited potential as a construction and visualization method.

Another example of this holographic building technique is the Allbrick Feature Wall[10], where researchers worked with All Brick and the University of Tasmania to create a small feature wall using an interactive mixed reality model that displayed the precise location of each brick. By eliminating the need for templates, drawings, or physical measurements, the estimated 2-week build time was significantly reduced to only 6.5 hours of bricklaying. Holographic instructions were developed by sorting bricks by height and showing one course at a time, with further improvement by showing only an outline of the top face of each brick as a virtual boundary during placement. The HoloLens's precision was well within the tolerances of general construction, as confirmed by a lidar scan of the project.

Despite these advances, there are still challenges in the compression-based structures field. Understanding and researching the structures' behavior under different loads and conditions, particularly those with cantilevers or arched spans, is critical.

3. Methodology

In this chapter, we will detail the methodology used to approach the block stacking problem. We begin by describing the parameterization of the mathematical problem using computational tools, which involves the creation of a dynamic parametric model and subsequent physical model to test its accuracy. We will then move on to discuss three specific studies undertaken within this framework, including the arced cantilever of X-shaped components, arched structures, and limits of height using limited materials. Finally, we will examine the utilization of holographic projection of geometry during the assembly process, providing insights into the advantages and limitations of this approach.

3.1. Parameterization of the mathematical problem using computational tools

The block stacking problem is a well-known paradox in statics that has been extensively studied over the years. The objective of this problem is to stack blocks along the edge of a table in a way that keeps the center of gravity of the assembly on or within the non-overhang side of the table.(Figure 1.). In order to use this problem as a design input, we have created a parametric model of the problem using linear elements.

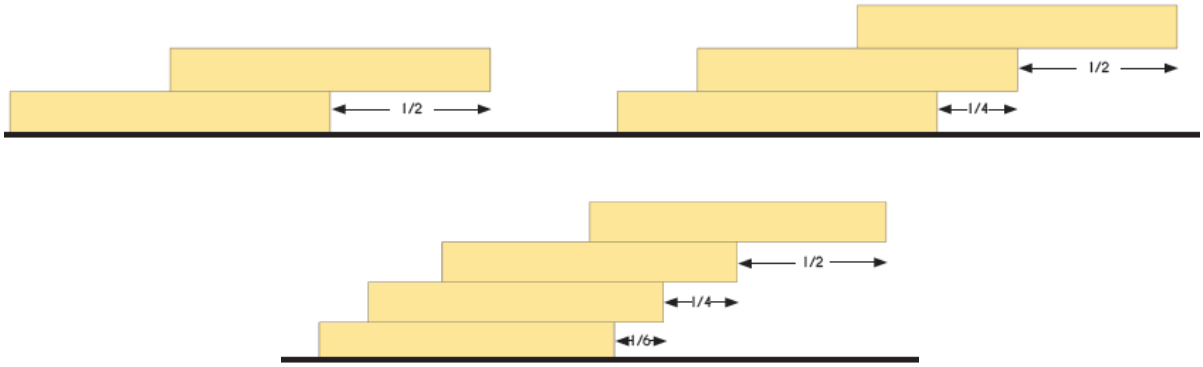

Figure 1. Block Stacking Problem Diagram

This parametric model allows us to explore the relationship between the number of elements and the cantilever distance in a dynamic and interactive way. We have color-coded the model to indicate the cantilever distance, with red indicating the maximum distance and green indicating the minimum distance. This dynamic model has provided us with valuable insights into the behavior of the system and has helped us to identify potential design improvements.

With the information gleaned from the dynamic model, we proceeded to build a physical model of the block stacking problem (Figure 2.). The physical model consists of 4.5-inch long wooden pieces stacked in a manner similar to the parametric model. However, the vertical distance between the wooden pieces in the physical model is greater than 4.5 inches to accommodate supporting pieces.

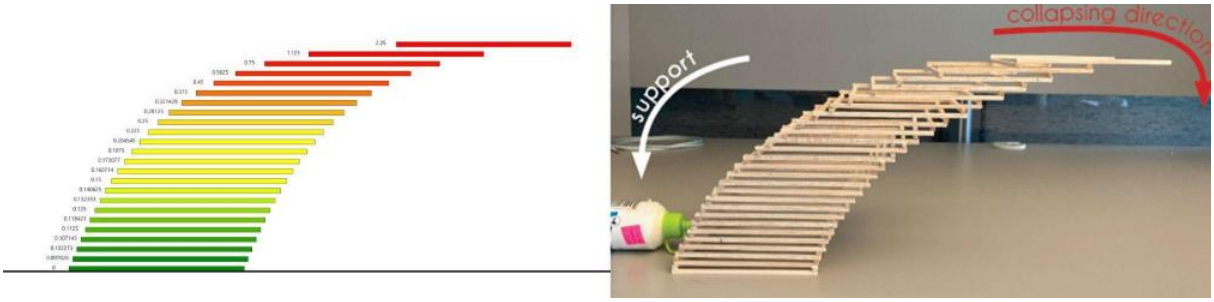

Figure 2. First Iteration Parametric Model & Physical Model

In our initial attempt to build the physical model, we found that it collapsed without any support. This led us to come up with a new iteration of the design. We decided to reduce the length of the wooden pieces as we stacked them higher, as this would provide us with a stronger chance of achieving a self-supporting structure. Thanks to the parametric nature of our model, it was relatively easy to come up with these types of variations and explore their impact on the system.

Since the parametric model is created with parameters, it was easy to come up with variations to improve the physical model. For instance, by reducing the length of the material from 4.5 inches to 2.7 inches, we were able to create a physical model that stands on its own, step by step (Figure 3.). This process allowed us to fine-tune the physical model until we achieved the desired outcome. In contrast to the physical model, the digital model required the addition of supporting lateral wood pieces in every space, due to the lack of lateral stability in the stacking direction. This was necessary to prevent the pieces from falling over immediately, as the digital model only tested the stacking direction from bottom to top. Thus, this modification added an extra level of complexity to the models, and the entire process of creating both the physical models took approximately 1.5 working days, due to the precision required

in the small shifting distances.

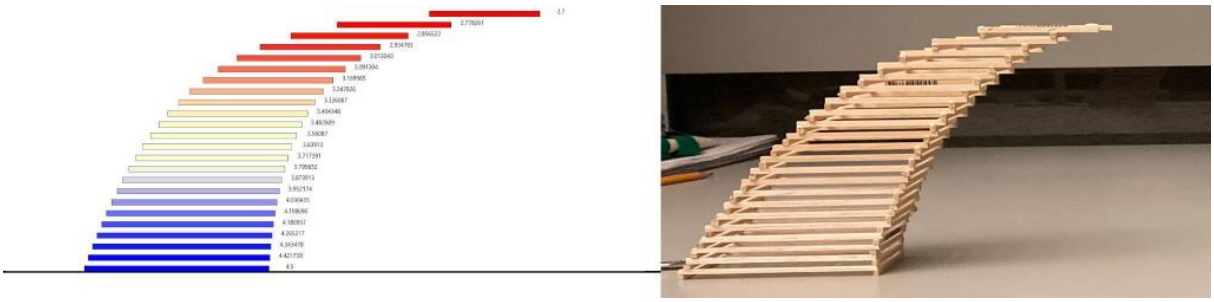

Figure 3. First Iteration Parametric Model & Physical Model

In summary, we utilized a parametric model to analyze the block stacking problem, which enabled us to visualize the problem dynamically and generate insights that helped us create a self-supporting physical model. Through this process, we were able to gain a deeper understanding of the block stacking problem and develop an effective solution.

3.2. Three studies: arced cantilever of X-shaped components, arched structures, and limits of height using limited materials

After conducting experiments with physical models, we decided to prototype different variations of the stacking strategy. Our first prototype aimed to construct an arched cantilever surface with X-shaped stacking components for a portion of the entire structure (Figure 4.). The X shape allowed us to change the stacking angle to construct the portion of the surface more precisely. However, the prototype resulted in a collapsed structure. The angled components created a shear force that shifted the center of gravity, causing the structure to collapse. From this experiment, we learned two important things. First, X-shaped components with different angles can lead to a shift in the center of gravity, resulting in structural collapse. Second, there was no support for the cantilever as it grew with less and less support underneath. These outcomes helped us improve the structural capabilities of our next prototypes.

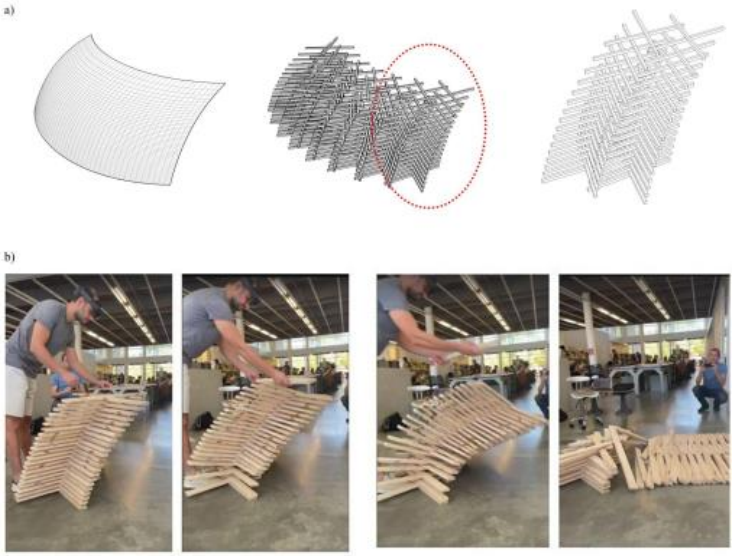

Figure 4. (a) Cantilever Surface and its portion with X shaped Components, (b) Collapsed prototype

Learning from the first prototype, our second prototype utilized 90 degree rotating stacking components from our physical models. We started by decreasing the total height of the prototype, allowing us to use

more wood pieces in opposite directions to support the initial cantilevering piece. We started with a stool-scale stacking, creating a stool by stacking pieces on top of each other. To enhance the stool's structural capacity, we had two units that were similar to each other except for one being mirrored and shrunken down in its width to create an interlocking connection with the initial unit. Following the same idea, we created a bench using a similar procedure, designed to have its initial unit interlocked with the supporting unit of the bench. This enabled us to create both pieces in a way that they support each other (stool to bench). When weight is applied to these furniture pieces, the stacking system locks itself in place, similar to a compression-based structure (Figure 5.).

Figure 5. Stool and bench formation

The success of this prototype encouraged us to proceed with a larger installation. However, we had two important constraints to consider: the number of wood pieces and the length of wood pieces. While we had a parametric model that generated new lengths, we decided to use the wood pieces that were available in our inventory. We sorted the wood pieces from long to short, from the ground up, using a parametric model that took into account the available wood pieces. By doing so, we aimed to use different lengths to create structural stability where the installation touched the ground (Figure 6.).

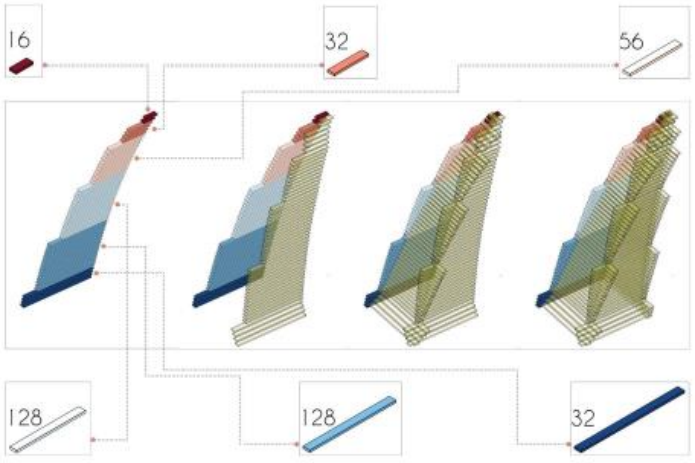

Figure 6. Material Inventory and Distribution

Unlike the second prototype, both units supported the initial unit, created as the same and then shifted to create an interlocking connection. In the end, we successfully built the installation with the available material we had (Figure 7.). The installation demonstrated the potential of the stacking strategy to create a stable structure, even with limited materials. It also highlighted the importance of considering the availability and characteristics of the materials when designing a structure, as well as the need for careful planning and execution to ensure the structural stability of the final product.

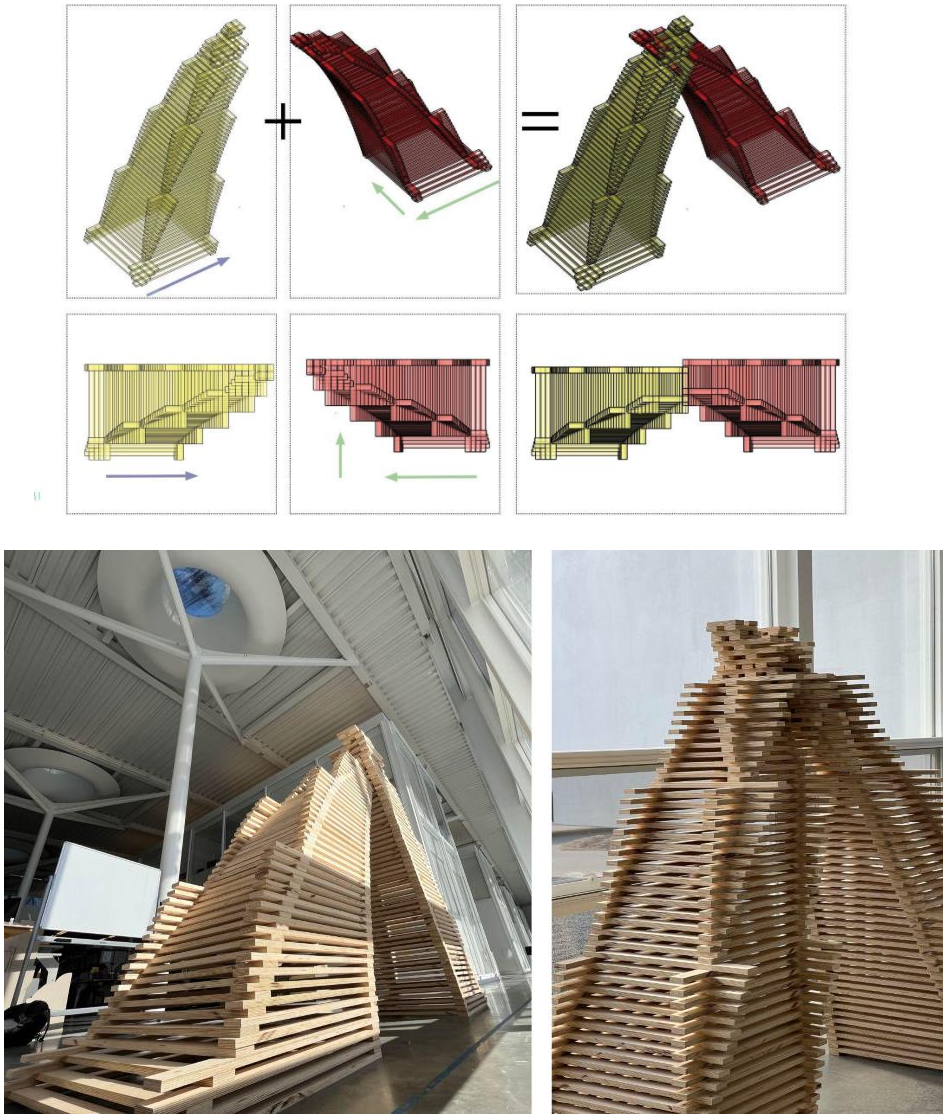

Figure 7. Installation Formation & Finished Prototype

3.3. Utilization of holographic projection of geometry during the assembly process

For all three prototypes that the researchers attempted to build, holographic projection techniques were used to project the computational model onto the site location. This allowed the researchers to perform construction without relying on physical measurements or 2D drawings, which was particularly important for wood stacking due to the small distance on each stacking layer. A straightforward construction technique was followed. First, the model was prepared as a parametric model and visualized with an Augmented Reality headset. This preparation required time to set up the most efficient adjustments. The researchers started by color-coding each wood piece based on its height, but this

created too many colors to follow. They decided to go with only two colors for the stacking, with level 0 in orange and level 1 in blue. This alternating color rule was followed to put the wood pieces. The parameters were set up in a way that this sequence could be controlled by an external phone that had 'Fologram' and/or HoloLens. All this setup was done in grasshopper.

Secondly, a QR code was generated to align the digital model to the physical construction site. The researchers taped the printed QR code on the area where they wanted to build so that they could restart the device and start again where they left off if they encountered technical issues such as running out of battery, losing the model, or HoloLens stopped working, etc. This setup was fundamental for each of the three prototypes, although there were some differences and additions in different phases.

For instance, while prototyping the arced surface geometry with X-shaped components, the researchers used a gravity simulation to detect where the structure would collapse before building the whole portion of it. Kangaroo was used in grasshopper to perform the simulation, which had promising results (Figure 8.).

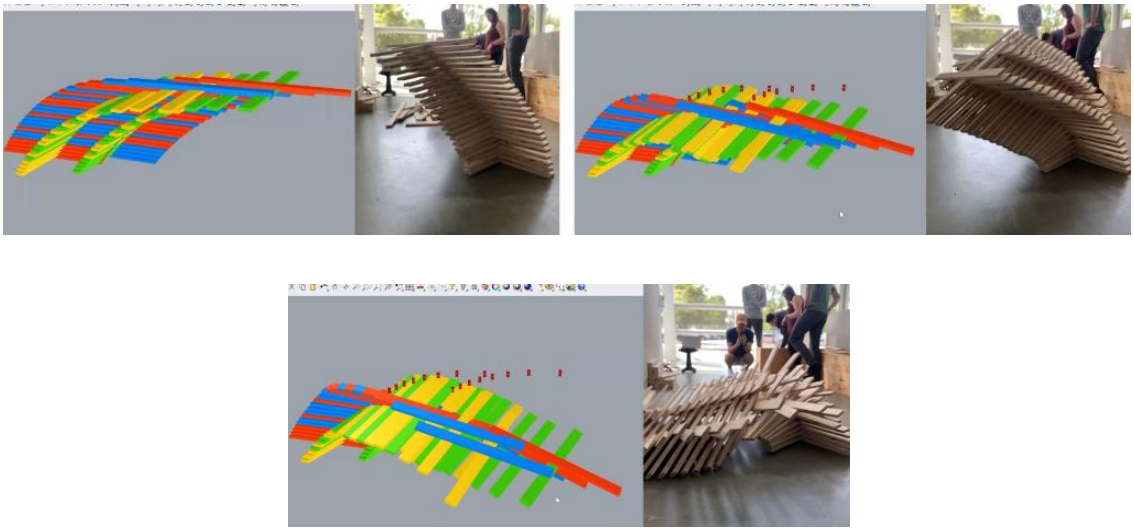

Figure 8. Gravity Simulation that shows the collapse digitally

However, the inefficiency in terms of the time it took to run (over an hour) made the researchers decide not to stick to the simulation. In this prototype, holographic projection was used in a shaded view (Figure 9.).

Figure 9. Shaded holographic projection

But the shaded view created problems in that the researchers could not track the real wood piece when they had HoloLens due to the projection type. Therefore, they switched the projection method from shading to wireframe, which worked better because they could easily align the edges of the wood pieces on the wireframe view. It also avoided any freezing due to heavier geometries that were generated by shaded views. So for the second "Arched structures and their performance" and third "Height limitations of limited materials in block stacking" prototypes, wireframe projection was used (Figure 10.)

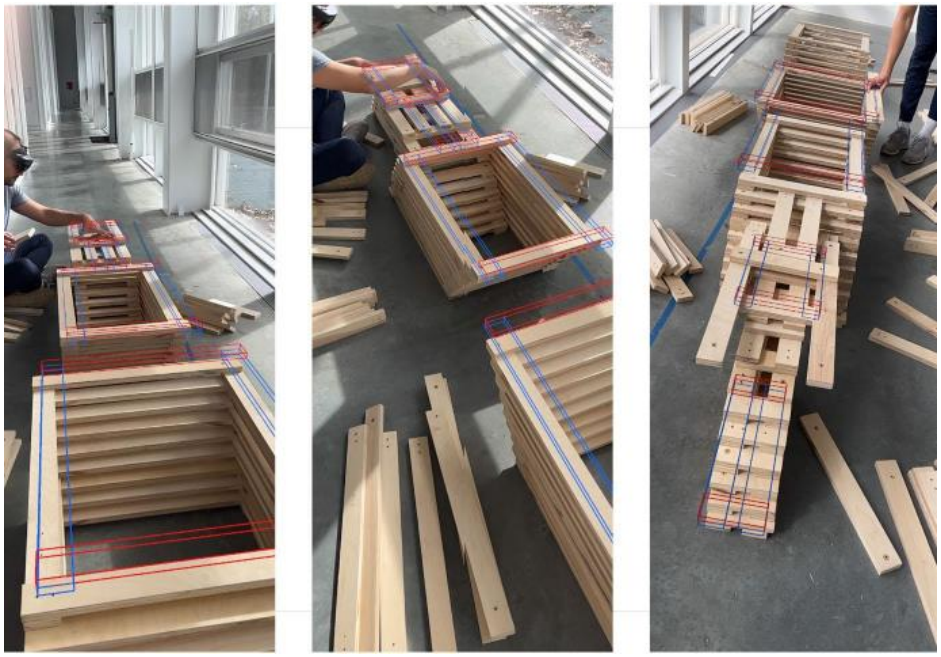

Figure 10. Shaded holographic projection

Holographic projection was used for the construction of all these experiments due to the dynamics of the project that the researchers were working on. It helped them locate the wood pieces in exact locations, even though they shifted slightly on each layer. This was crucial because this notion of movement on each stacking layer enabled the researchers to create these self-standing structures by controlling the center of gravity. Any error while placing them might cause unexpected collapses during the construction phase, but none were encountered. By using holographic projection, the structural design performed in a way that the researchers reached their goal without using glue, fasteners, or any other connection detail.

4. Results

The implementation of computational tools and holographic projection has resulted in a number of significant benefits for the design and construction process. Perhaps most notably, these techniques have enabled the creation of precise and highly constructable design options. By using these tools, we are able to create highly accurate digital models that can be easily translated into physical structures. This has allowed for an unprecedented level of precision in the design and construction process, greatly reducing the likelihood of errors or inefficiencies.

Also, the use of computational tools and holographic projection has also eliminated the need for physical measurements, support, or alignment materials. This has resulted in significant cost savings and reduced waste, as well as a more streamlined and efficient construction process. With these techniques, designers and builders can create complex structures with ease, without the need for extensive support or alignment structures.

Overall, the implementation of computational tools and holographic projection has greatly improved the efficiency, accuracy, and sustainability of the design and construction process. With these tools, designers and builders can create highly precise and constructable designs, while also reducing costs and waste. As the technology continues to develop, it is likely that we will see even more innovative and impactful uses of these techniques in the future.

5.Discussion

The field of architecture has been revolutionized by the use of computational design tools that allow architects to explore complex forms that were once impossible to create, thereby expanding the design solution space. However, traditional design annotation methods can be inefficient, especially in construction environments with limited fabrication means and skilled laborers. To address these challenges, the recent use of holographic projection technology in experimental architectural projects has shown promising results. By projecting computationally generated geometries onto the field of vision using wearable devices or smartphones, architects can create an immersive environment for implementers. Interactive holography provides architects with the ability to translate design intentions into intelligent instructions instead of static drawings, offering a significant opportunity to reduce construction complexity and potentially increase precision[11].

Nonetheless, there may be limitations to the size and complexity of structures that can be constructed using holographic projection-based techniques. While the method has shown promise in constructing small-scale prototypes, it may not be feasible for larger or more complex structures such as bridges or skyscrapers. The construction of these types of structures would require more advanced and robust holographic projection systems, as well as extensive testing and validation to ensure that they are safe and reliable. Another limitation is that the current technology may not be accessible or affordable for all builders and architects. The cost of developing and implementing holographic projection-based systems may be prohibitive for smaller firms or individual builders, limiting the potential impact of this technology on the broader construction industry.

Our work was conducted only on interiors, meaning the structures were not exposed to environmental conditions such as wind, rain, snow, and others. It is crucial to address this limitation in future research by reconsidering the connection details between wood stacks and other materials used in construction. Additionally, the usability of this methodology for real-life structures such as bridges needs to be tested and verified in real-world applications. While holographic-assisted assembly is a promising technology, it requires further development and testing to ensure its effectiveness and reliability in real-world applications.

6.Conclusion

Holographic projection technology has the potential to revolutionize the construction industry by providing a new way of visualizing and planning construction projects. The ability to create 3D holographic models of building designs allows architects, engineers, and builders to better understand the structure of a building before it is constructed, making the construction process more efficient and cost-effective.

Our project aimed to explore the potential of holographic projection technology in the construction industry through the development of a prototype holographic projection system. We used a combination of hardware and software components to create a system capable of projecting 3D holographic models onto a physical space. Our methodology involved testing and refining various components of the system, such as the projector and the software used to create the 3D models. We also conducted user testing with architects and engineers to gather feedback and improve the usability of the system.

While our project was successful in creating a functional holographic projection system, there are still limitations and challenges that need to be addressed. One limitation is that our work was conducted only

on interiors, meaning the structures weren't exposed to environmental conditions such as wind, rain, and snow. Future research could consider the connection details between wood stacks in outdoor settings to ensure the reliability of this methodology in different environmental conditions. Another limitation is the usability of this methodology for real-life structures such as a bridge. Despite the strength and reliability of the methodology, this technique of building should be tested and verified outside with real use, which could create new challenges and improvements in the existing technique. Additionally, the current cost of holographic projection technology is relatively high, which may limit its adoption in the construction industry. Further research is needed to explore cost-effective solutions and how to integrate holographic projection technology into existing construction workflows.

Looking forward, there are several possible research directions that could help to address these limitations and improve the potential of holographic projection technology in the construction industry. For example, research could focus on developing more affordable holographic projection systems, improving the accuracy and resolution of holographic models, and exploring how holographic projection technology can be integrated into existing construction workflows to enhance collaboration and efficiency.

Abstract

Recent research at TU Delft has highlighted the potential of using structural Topology Optimization (TO) for designing large monolithic cast glass structures of maximized stiffness with minimal mass. The mass efficiency of these structures results in considerably shorter annealing times and, consequently in improved manufacturability in terms of time, energy and cost efficiency. Nonetheless, the geometrical complexity and customization of the resulting forms renders them challenging in terms of fabrication. Exploring the manufacturability of such intricate glass structures, in this paper we discuss the different possible fabrication methods for three-dimensional glass structures of complex and customized geometries, via a review of existing literature, experimental work and prototyping. Specifically, with the aim of addressing all possible manufacturing solutions, we look into the following fabrication methods: (i) casting in disposable moulds; (ii) waterjet cutting and lamination of float glass panes and; (iii) additive manufacturing of glass. We assess these methods based on a set of criteria linked to the structural performance, visual quality, fabrication limitations and sustainability. Accordingly, we discuss the potential, challenges and practical limitations of each fabrication method for real-world applications of TO glass structures. Subsequently, we propose the integration of alternative constraints into the TO formulation, so that customized TO tools that better reflect each fabrication method can be created.

Keywords: topology optimization, glass fabrication methods, construction techniques, customized geometry, cast glass, glass structures, shape complexity, disposable moulds

1. Introduction

Ongoing research at TU Delft [1-3] has highlighted the potential of using structural topology optimization (TO) for the design of monolithic, three-dimensional cast glass structures of complex and customized geometries for architectural and structural applications. By maximizing the stiffness while maintaining minimal mass, the design of monolithic, load-bearing glass structures of substantial dimensions can be achieved with considerably shorter annealing times; the castings of the glass mirror blanks of the giant telescopes are a characteristic such example (fig.1, left) [4]. Promising topology optimized structural glass applications include free-form glass shells and nodes [3], glass slabs, bridges [2] and columns (fig.1). So far, the research has focused on the development of a TO formulation for cast glass structural components that allows for an asymmetric stress behaviour and incorporates constraints to ensure feasible annealing times [1] and, in turn, improved manufacturability in terms of time, energy and cost efficiency. Still, there has been little exploration on the fabrication methods of the resulting complex and customized shapes. Thus, this paper reviews the different possible fabrication

methods for three-dimensional glass structures of customized, complex geometries generated by TO. In specific, with the aim of addressing all possible manufacturing solutions we intentionally depart from cast glass as the only possible expression of such geometrically complex forms, and we look as well into alternative fabrication methods (fig. 2). Hence, we explore: (i) casting in disposable moulds; (ii) waterjet cutting and lamination of float glass panes and; (iii) additive manufacturing of glass.

Impressions of TO cast glass bridges (image credits: A.M. Koniari and M. Ioannidis) and floor (image credits: I. M. Stefanaki), and prototype of a TO cast glass node (image credits: W. Damen).

2. Methodology

To assess the aforementioned methods, we first establish a set of criteria linked to the structural performance, visual quality and fabrication limitations; towards sustainability, the waste generation and recyclability of the glass components are also addressed. Accordingly, we discuss the potential, challenges and limitations of each method based on literature review and on our main observations from experimental and prototyping work. Towards the creation of customized TO tools that better reflect each fabrication method, we propose the integration of alternative constraints into the TO formulation.

3. Assessment criteria

With the aim of generating customized, complex geometries in glass, the three different fabrication methods are assessed on aspects related to the (i) structural performance, (ii) optical performance, (iii) fabrication limitations and (iv) sustainability. In specific:

(i) structural performance is evaluated in terms of the inherent strength and the integrated redundancy of the resulting glass components/structure;

(ii) optical performance concerns both the resulting transparency, as well as the finishing surface quality of the components (fig.3);

(iii) fabrication limitations are particularly linked to shape and size limitations of the chosen manufacturing methods, need for post processing and ease of fabrication;

(iv) sustainability regards the waste generation during fabrication and the recyclability of the resulting components.

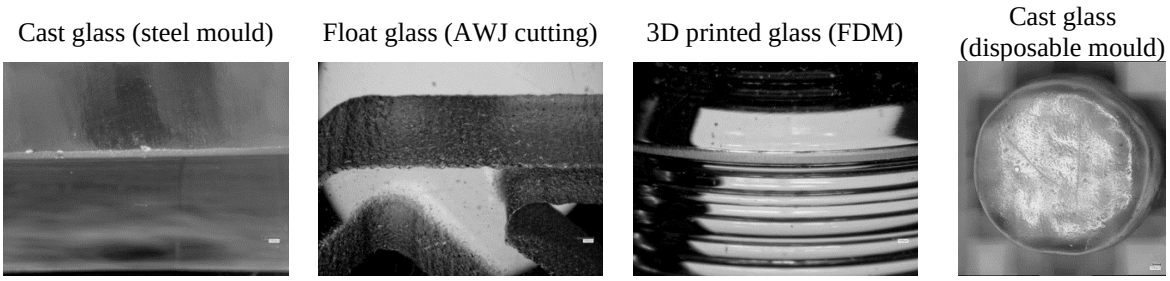

Figure 3: Microscope photos of the finishing surface quality of the different fabrication methods.

As the different assessment criteria are interconnected, they can directly impact each other. For example, the surface finish quality can influence the strength of the glass component, as well as the need for post-processing. Given the novel application of these fabrication methods for structural applications, there are limited if any comparable quantitative data in the forenamed aspects, which can lead to misleading observations. Thus, a qualitative assessment is made as more representative.

4. Fabrication methods

4.1. Casting in disposable moulds

Casting enables the creation of virtually any shape and size in glass. Nonetheless, currently in architecture, structural cast glass components are typically limited to solid blocks, similar in size to standard terracotta bricks [5]. This limited size is mainly due to the excessively lengthy annealing time required in massive glass pieces, which can span up to multiple months [4], and can subsequently result in prohibitive energy and manufacturing costs. The component's geometry and selected glass composition are the most influential factors of the annealing time. Essentially, the higher the thermal expansion coefficient of glass and/or the larger the cross-sectional thickness of the component, the exponentially longer the annealing time required. The optimization of the stiffness-to-weight ratio of cast glass components, e.g. via structural TO, and the use of glass compositions of lower thermal expansion coefficient (e.g. borosilicate glass) can greatly reduce the annealing time and subsequently, allow for larger overall dimensions.

For customized and geometrically complex components such as the one resulting using TO, disposable moulds and kiln-casting are preferred over permanent metal moulds and hot-pouring, as they are considerably cheaper and allow for a significantly higher freedom in shape[1]. Prototyping work at TU Delft has pointed towards two alternative disposable mould fabrication methods for kiln-casting: (i) silica-plaster (e.g. Crystal Cast) investment moulds using a was positive model[2] of the desired geometry that is steamed out (lost wax-technique), as shown in fig.4, and (ii) 3D-printed sand moulds (fig.6). The former, typically used in intricate-shaped glass art castings, are in principle laborious and yield

[1] Considerably more expensive multi-component steel moulds can be used for the casting of complex geometries in glass; nonetheless, such moulds cannot incorporate undercuts.
[2] For highly intricate shapes, the wax positive model can be produced using 3D-printing or sintering of wax. Research in both methods at TU Delft suggests that sintering produces more refined, smooth textures.

compromised dimensional accuracy. An alternative offering higher accuracy, yet also resulting in considerably higher manufacturing costs, is milled alumina-silica fibre ceramic moulds, such as the ones employed in the castings of the giant mirror blanks (see fig.5) [6]. For architectural applications, 3D-printed sand moulds are considered more suitable, due to their low cost, quick production, scalability and high accuracy (up to ± 0.1 mm, defined by the grain size of the sand) [6]. Previous and current experimental work at TU Delft, has shown that 3D-printed sand moulds using inorganic binders are the most promising option for kiln-cast glass components [6]. 3D-printed sand moulds can currently be produced up to 4m x 2m x 1m in dimensions by *Voxeljet printer* VX4000; nonetheless, larger, multi-piece moulds that interlock together can exceed these dimensions.

4.1.1. Structural performance

Similarly to float glass panes, cast glass displays isotropic material properties. Glass's brittle failure is typically triggered by inherent flaws. Massive cast glass pieces are prone to the inverse scale effect: the larger the component, the higher the probability of critical flaws within it, thus the lowest its probabilistic strength [7]. In addition, the lack of a large-scale, automated and controlled production and of quality control standards for cast glass, contribute to an increased occurrence of defects compared to the fully-automated and strictly controlled float glass production [5, 8, 9]. The lack of sufficient strength data and of inherent redundancy in the structure, result to a decreased overall strength of cast glass compared to float and enforce the use of increased safety factors. Thermal tempering that can increase glass's tensile strength, is not advised for volumetric glass components, particularly of ones of intricate geometry, due to their bulky and uneven cross-section[3]. All the above, mandate a significant increase in material use when designing with cast glass compared to float.

[3] In thermal tempering of (float) glass, the material is first heat up and then rapidly cooled down, resulting in the outer surfaces being into compression and the inner surfaces being into tension. In volumetric glass components and/or in perplex cross-sections, tempering in a controlled manner would be extremely challenging, due to the considerably larger temperature deviations between the centre and the surfaces of the glass.

A monolithic glass structure lacks redundancy in case of failure. Possible engineering solutions that allow for redundancy, are the lamination of a float glass layer (if possible in terms of shape), or the segmentation of the structure to enable enhanced redundancy against crack propagation. In this direction, cast glass structures made of interlocking units are a promising solution with inherent redundancy [10]. Finally, initial prototype and experimental work at TU Delft suggests that glass beams with embedded metal reinforcement during casting can have increased ductility, exhibit a warning mechanism prior to ultimate fracture and secure a post-failure load-bearing capacity [11].

4.1.2. Optical performance

The monolithic nature of cast glass allows, in principle, for increased transparency. Nonetheless, the transparency of kiln-cast glass elements is affected by several factors, including the type of glass, firing temperature and annealing schedule, type of mould (fig.3) and coatings applied on it, and post processing. Transparency can be increased if a low-iron glass recipe is used that omits any colouring (e.g. of green tint). Transparency is mainly compromised in the finishing surface quality: grains of the disposable moulds tend to adhere to the glass, resulting in an opaque and rough surface, mandating post-processing, which in turn results in compromised dimensional accuracy and higher manufacturing costs. To achieve a fully transparent and smooth finishing quality of glass cast in disposable moulds, the application of mould coatings is necessary. Previous research at ETH focusing on foundry casting in 3D-printed sand moulds fabricated with inorganic binders and coated with a combination of *Zirkofluid* and graphite-water dispersion yielded promising results [12]. Current experimental work at TU Delft focuses on the further investigation of coatings that can yield a completely smooth and transparent surface quality in kiln-casting[4]. So far, series of kiln-cast prototyping experiments in several annealing schedules using two types of 3D-printed sand moulds (quartz or ceramic sand printed with inorganic binder), sponsored by *ExOne*, and a combination of coatings, sponsored by *Hüttenes-Albertus*, indicate that the combinations with the best finishing quality are (i) molds printed with quartz sand coated with *Arkopal B5* and (ii) molds printed with synthetic (ceramic) sand coated with *Crystal Cast* and *Zirkofluid*® 6672 or 1219 (see fig.7). In specific, kiln-casting experiments at 870˚C at the *TU Delft lab* facilities suggest that direct application of *Zirkofluid* coatings on the mold surface lead to partial adhesion of the sand and coating to the glass (fig.7b). When a substrate layer of *Crystal Cast* is added under the coatings it leads to a better surface quality and no sand consolidation (fig.7d-f). Given the above, 3D-printed molds of a material similar to Crystal Cast could as well be a promising solution.

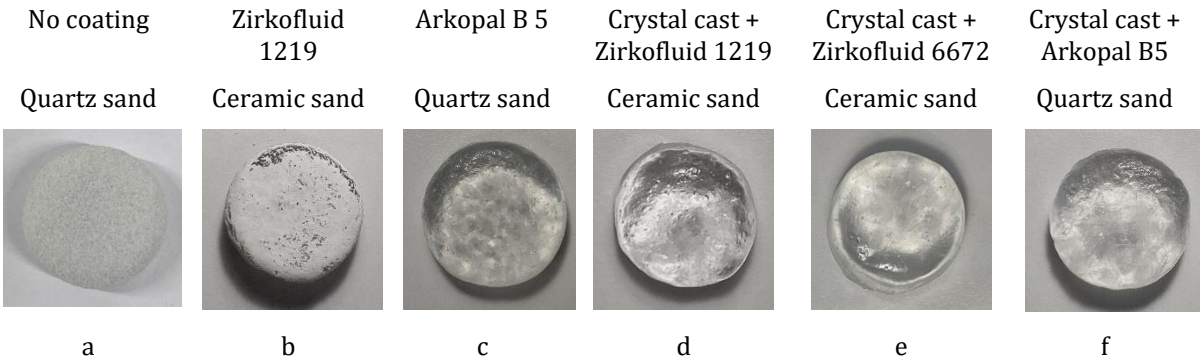

Figure 7: Glass surface of glass specimens kiln-cast at 870˚C in coated 3D printed sand moulds.

4.1.3. Fabrication limitations

The use of disposable moulds allows for great freedom in the shape and size of the cast glass components, as exhibited in existing cast glass art pieces of massive dimensions and/or of highly

[4] Compared to foundry casting, kiln-casting requires a considerably more prolonged heating cycle of the moulds.

intricate shapes [4]. The use of interlocking 3D-printed sand moulds can enable considerably large castings; the potential size of a structure utilizing such moulds has been exhibited in concrete castings, such as the *SMART SLAB* by ETH, where 3D-printed sand moulds were used for the underlying formwork [13]. In essence, the size of the glass casting is confined to the size of the kiln. Even so, custom-made kilns can be built to accommodate large castings, as proved by the castings of the *Giant Magellan Telescope* and of multi-ton glass sculptures by *Roni Horn* [4]. The component's annealing time can be considered the governing factor in limiting the glass component's overall size. Castings of massive cast glass blanks requiring up to 1 year of annealing have been recorded [4], yet such prolonged times would be prohibitive for applications in the built environment. Nonetheless, with the aid of TO, the generation of massive pieces of optimized stiffness-to-mass ratio can be achieved, which in turn can yield feasible annealing times and associated energy costs.

There are limitations in relation to shape though. Shape limitations are greatly linked to the proper annealing of the glass component and to the mould's geometry and strength. For example, abrupt changes in the component's thickness should be avoided as they would result in uneven cooling of the glass. The size and geometry of overhangs, and of very thin voids, should be as well associated with the mould's strength. Furthermore, the use of a mould hinders completely enclosed cavities.

Post-processing, in particular polishing, may be necessary to obtain the desired smooth, glossy finishing surface and to omit dimensional deviations due to the natural shrinkage of glass occurring during cooling [14]. The effect of natural shrinkage can be reduced in some cases by employing spin-casting [4]. Polishing can be challenging in cavities that are not easily accessible by the relevant equipment.

4.1.4. Sustainability

Being monolithic, cast glass can be recycled in a closed-loop. Its recyclability can be compromised, if a sacrificial layer is laminated for safety/redundancy, due to contamination by the lamination foil. The ability to cast directly the desired shape prevents the generation of glass waste. Finally, in the case of 3D-printed sand moulds, their water dissolvable composition enables the remaining sand to be reused.

4.2. Waterjet cutting and bonding of float glass panes

By abrasive waterjet (AWJ) cutting and bonding together multiple float glass layers, freeform, layered 3D glass structures can be made. In this process, three distinct fabrication steps are involved: The float glass production, the waterjet-cutting of the individual glass panes to the desired shape, and finally their bonding or lamination. In specific, AWJ cutting is a subtractive manufacturing method, used for a broad range of materials, including metals, stone and glass; it employs high-pressure waterjets with fine abrasive grains to cut the workpiece material. A computer-controlled head and nozzle with up to 5-axis allow for precise cutting under varying angles and the flow rate and abrasive size can be adjusted for optimal cutting and surface quality of the edge [15]. AWJ cutting of glass panes can lead to rough or non-perpendicular edges (kerf angle, see fig.3), necessitating the post-processing (polishing) of the edge in order to avoid undesirable stress concentrations. Once the individual sheets are AWJ-cut, they should be bonded together. Extensive literature research suggests that industrially fabricated examples using lamination are typically confined to 5-6 layers; one of the largest known multi-layer laminations is the 11-layered *Glass Wippe* by EOC Engineers. Multi-layered structures, such as the horizontally-layered glass sheet sculptures of the 6 m high *Glass Sphinx* (NL) and the 3 m high *Glass Angel* (NL), and the vertically-layered *Laminata House* (NL) opted out of lamination, but also of a conventional adhesive application, as structural glass adhesives are yet to be developed for bonding large surfaces of glass in stacked configurations [16]. Instead adhesive tapes were used for assembling the Glass Angel [17] and

the Glass Sphinx [18]; in *Laminata House*, the individual sheets were cut and pre-adhered on site in sets of 10 using a 2-component silicon compound, then installed in place using a silicone-based sealant.

4.2.1. Structural performance

The structural properties of float glass are well-documented with engineering values provided by several standards (e.g. DIN 18008, EN 16612:2019, NEN 2608:2014, ASTM E1300-00). Owing to the highly automated process and strict quality control in float glass production, float glass presents the highest engineering strength values (for soda-lime glass) among the three discussed fabrication methods. The tensile strength of float glass can be further increased via tempering. The inherent redundancy due to the bonding/lamination of multiple layers and the well-documented, predictable strength of float glass lead to the use of reduced safety factors in this case. The strength can, however, be compromised due to edge flaws introduced by AWJ-cutting; although these can be minimized by post-processing/polishing the edges. It should be noted that layered glass structures are in essence, anisotropic: they present considerably higher strength in parallel to the glass panes than in (long-term) loads perpendicular to the laminate, where, an effective thickness of the laminated or bonded glass should be considered [19].

4.2.2. Optical performance

In principle, float glass panes are of high optical quality. Yet, the transparency of a freeform, layered glass component made of float panes depends on the number and orientation of the glass layers, the overall shape and the viewing angle. In specific, a structure can be perceived as fully transparent when viewed perpendicular to the laminates, and completely opaque when seen parallel to the laminates. Polishing of the cut edges (fig.3) is essential for obtaining a smooth finish surface.

4.2.3. Fabrication limitations

A variety of machinery and materials are used in this method, resulting overall in a complex and costly process. Although individual glass panes can size up to 24m x 3.21m, further size limitations are imposed by the subsequent processing steps. Although AWJ typically has a cutting table of 4m x 2m, it can be customized to accommodate larger sizes. For example, the *yc waterjet* company has produced customized AWJ cutting tables up to 4m x 12m in size for 3-axis AWJ and 3m x 8m for 5-axis AWJ. The total thickness of the layered glass structure is subject to the type of bonding: lamination can be easily achieved for 5-6 layers of glass (each of a max. 25 mm thickness), and has been recorded for up to 11 layers. Beyond this number of layers, a customized adhesive solution should be followed, further adding to the costs and possibly affecting the overall strength.

In terms of shape freedom, a major limitation is that the desired geometry should be made by the bonding of virtually flat elements. In addition, the lamination or bonding process can render challenging the creation of undercuts and voids, as uneven pressure loads can occur during the lamination, which can lead to the eventual failure of the glass. Overall, lamination of multiple layers is challenging and can increase considerably the overall fabrication cost. If the glass sheets are bonded together with an adhesive, its uncontrollable overflow in non-accessible areas can compromise the final visual result. If an adhesive tape is used instead, the tape lines can be visible. Lastly, considerable accumulated dimensional offsets can occur, even with the high accuracy level of float glass thickness and the use of thin tape, as in the example of the *Glass Sphinx* where an accumulated height offset of 4 cm was recorded [20]. Finally, as the AWJ cutting results in a rough surface, subject as well to edge flaws, post-processing of the edge is necessary, which can be challenging in hard-to-access areas of the cut glass piece.

4.2.4. Sustainability

The subtractive nature of AWJ results in considerable glass waste. The discarded cut-out glass pieces, can be recycled by remelting; although this is an energy-intensive process. Once assembled, laminated/ bonded glass components are in principle hard to recycle, due to the difficult separation method and the inevitable contamination of the glass by the interlayers/adhesives.

4.3. Additive manufacturing (AM) of glass

Additive manufacturing (AM) of glass is still in an early stage of development, yet it displays great potential for the fabrication of freeform glass structures. Several AM methods have been explored, but most concern smaller elements [21]. The prevailing AM method for bigger glass elements is *Fused Deposition Modelling* (FDM). FDM involves a continuous filament feeding through a computer-controlled heated nozzle; it is the only method so far with available, yet limited, structural data on glass [22]. Such an AM method for printing silica glass, G3DP, was first developed by *Micron3DP* and *MIT*. G3DP is based on a dual heated chamber concept. The upper part, essentially a kiln cartridge, operates at ~1040°C and pours the molten glass through a nozzle to the desired shape. The object is built within the lower annealing chamber which keeps the glass hot enough so that the next layer of structure adheres to it while the glass can cool down controllably. A second version, G3DP2, allowed for more accurate prints and improvements in speed and printable volume. It includes a digitally integrated thermal control system to accompany the various stages of glass forming and a 4-axis motion control system for flow control, spatial accuracy and precision and faster production rates with continuous deposition of up to 30 kg of molten glass [23]. Up to now, AM of glass has been confined to small-scale objects. The largest in scale project is the *Glass II* [24], which concerns the fabrication of 3m-tall free-standing, pre-stressed hollow glass columns of intricate geometry, each consisting of 15 segments [25].

4.3.1. Structural Performance

AM glass components present anisotropic structural performance. [26] states a 40% difference between the major and minor axis. Loading perpendicular to the plane of the layer (major axis) displays the best performance. More extensive, yet still limited, testing has been performed by [22] in annealed and chemically tempered samples under 3-point bending, suggesting a tensile strength of 51 MPa in the major axis and 41 MPa in minor axis for annealed glass; whereas chemically-strengthened glass samples presented high deviation in the strength, leading to inconclusive results. Due to the small size of the tested samples, the high variation in the resulting values and the use of 3-point instead of 4-point bending tests (which would result in less favourable flexural strength values), in the work of [22] a safety factor of 10 is used. Moreover, the interface between two consecutive layers can display poorer mechanical properties than the rest of the volume. Improper adhesion of the layers can lead to delamination and failure of the sample, as shown by preliminary 3-point bending tests parallel to the layers conducted by [26]. However, the layered structure may be able to stop slow-crack growth. Still, to derive engineering strength values for 3D printed glass components extensive experimental validation remains necessary.

4.3.2. Optical Performance

Similarly to laminated glass components, due to its visible layering, 3D-printed glass using FDM displays directional transparency (see fig.2 and fig.3). In order to achieve the desired, glossy result, the finishing surfaces (top and bottom sides) should be polished using cerium oxide [26].

4.3.3. Fabrication Limitations

3D-printing of glass has a high potential in creating components with complex inner features. Yet, it can only occur within a highly controlled annealing chamber; hence, similarly to cast glass, the glass object is confined to the size of the annealing chamber. Contrary to kiln-casting, two kilns are required in this method, one for the printing cartridge and one for the annealing of the printed object. Currently, the maximum printable area is 320 mm x 320 mm x 350 mm with a flow rate of 5.2 kg/h [22] and a max. capacity of 30 kg of glass [23]. For an element of 10kg in weight, 1 hour is needed for the printing and 8 hours for annealing [25]. Further shape limitations linked to FDM, include overhang limitations which may necessitate supports, and the generation of shapes that can be produced by a continuous thread.

4.3.4. Sustainability

3D-printed glass can be considered a 100% recyclable and waste-free production method.

5. Conclusions

Table 1 provides a qualitative comparison of the different fabrication methods for complex, customized structural cast glass components, such as the ones derived using TO.

Table 1: Qualitative comparison of the different fabrication methods

Criteria		Cast	Waterjet cutting and bonding of float glass	Additive manufacturing
Structural	strength	+ medium	++ high	- low
	redundancy	- no	++ high	- no
Optical	resulting transparency	++ high	+ medium - low	- low
	finishing quality	- medium-low	++ high	+ medium
Fabrication limitations	size freedom	++ high	+ medium	- low
	shape freedom	++ high	+ medium	+ medium
	post-processing	- high	+ medium	++ medium-low
	fabrication cost	- high	+ medium	- high
Sustainability	waste generation	++ low	- high	++ low
	recyclability	++ high	- low	++ high

Waterjet cutting and bonding of float glass presents the best structural performance overall, mainly due to the well-documented and highly controlled properties of float glass, and the inherent redundancy of a multi-layered solution. Adding to the above the possibility of increasing the tensile strength of the components by tempering and the use of reduced safety factors compared to the other two methods, this fabrication method probably yields the most lightweight structure. On the downside, transparency in this case is subject to the directionality of the layers. Moreover, there are considerable limitations in both the size and the shape of the resulting piece. It is also considered the least sustainable solution, as it produces substantial glass waste and the final component cannot be easily recycled back to glass.

Cast glass is the preferred solution in terms of resulting transparency, sustainability, shape and size freedom. The governing restriction size-wise is the annealing time, which, however, can be considerably reduced by an optimized geometry and by choosing a glass composition of low thermal expansion coefficient. An inherent disadvantage is that post-processing of the finishing glass surface is essential, due to the use of disposable moulds for the fabrication of customized components; although, research at both ETH and TU Delft on mould coatings already yields promising results towards obtaining a good surface quality directly in demoulding. In terms of structural performance, cast glass components present lower strength values compared to float. This is attributed to the less controlled casting process and the lack of relevant quality standards, as well as to the inverse scale effect in large glass components. All the above result in the use of increased safety factors, which in turn yield a heavier structure compared to float glass. A monolithic glass structure lacks redundancy, but different engineering approaches, such as segmentation or lamination of a sacrificial layer, could improve the safety of the structure.

Lastly, AM of glass, although still at experimental stage, is perhaps the most sustainable solution as it results in virtually zero waste; it can potentially require the least post-processing as well. Yet, this method results in visible layering of the deposited glass, compromising the overall transparency, presents the lowest structural performance and is subject to multiple fabrication limitations; although some of them, such as limitations in size, can be linked to its infant stage of development.

6. Discussion

Based on the prioritized performance criteria, the most suitable fabrication method can already be pre-selected, as shown in fig.8. Accordingly, to create practical tools that better reflect the needs of the chosen manufacturing method, different adjustments can be incorporated to the TO formulation (fig.8).

Regarding structural performance, the isotropic or anisotropic nature, the risk of defects during the fabrication, as well as compromises in the surface quality can reduce the structural integrity of the final component. Therefore, they largely influence the applied limits for tensile and compressive strength through relevant increased or decreased safety factors, while they also affect the selection of the appropriate material failure criterion in the TO formulation [27, 28].

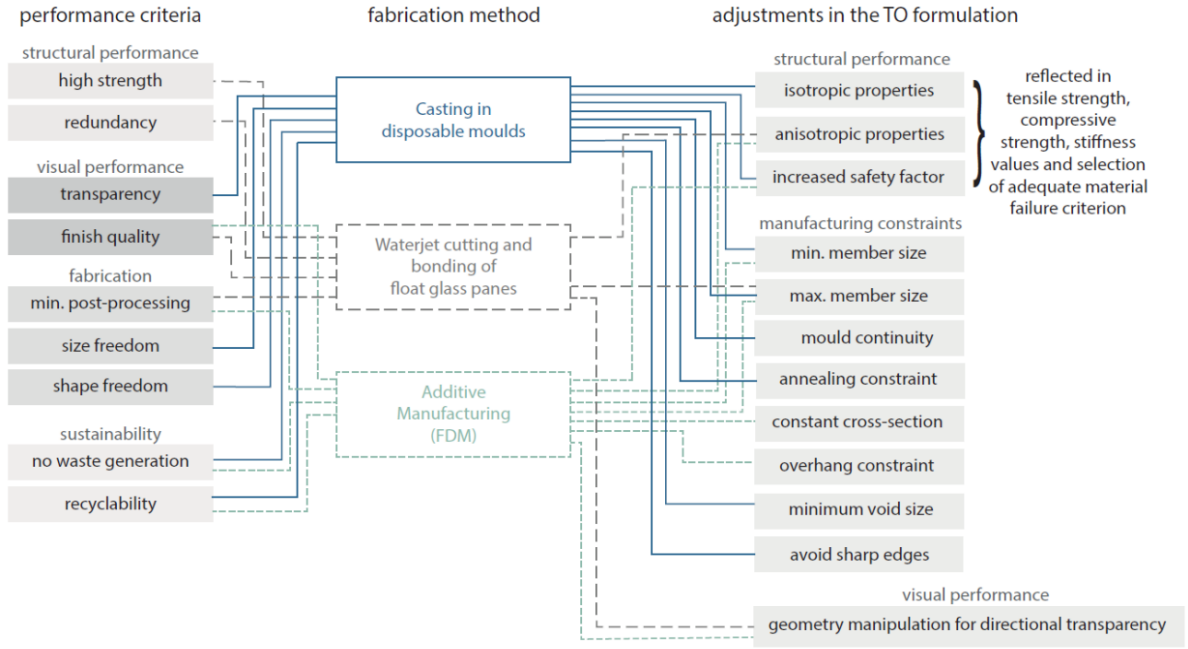

Figure 8: Flowchart showing how the prioritized performance criteria impacts the selection of the most suitable fabrication method, which in turn is reflected in the integration of different constraints in the TO formulation.

Additionally, different practical fabrication-related aspects need to be addressed according to each method. These are related primarily to the size of each member that composes the total complex geometry. Particularly, in the case of 3D printing, the cross section should have a constant dimension that can be created with the available nozzle size, while in waterjet cutting, a minimum member size should be ensured to avoid breakage during the cutting process. In the case of casting, both minimum and maximum member size constraints should be applied. In the latter case, the maximum cross section size should consider both the annealing time limit and the need for an even and smooth gradient of thickness in the geometry [1]. The need for homogeneous mass is also related to the need for elimination of sharp edges in the shape, since these cool down faster than the overall geometry leading to cracks directly in the cooling process. Moreover, a minimum void size should be applied to ensure a sufficient mold thickness to resist the hydrostatic pressure thar arises through casting. Both minimum member and minimum void size can be incorporated with multiple phase projection [29], while the maximum dimension can be applied through the maximum length scale constraint[1, 30]. Lastly, it is also important to eliminate closed cavities in order to ensure mold continuity and allow for effective demolding after casting. This can be applied through the Virtual Temperature Method [31].

In the case of 3D printing, additional aspects that should be considered in the TO formulation are the need to ensure a continuous thread, as well as restrictions in critical overhang angle, which is already studied in similar applications with AM techniques. Lastly, in all cases, the TO formulation can be adapted to comply with design criteria that can ensure directional transparency in the geometry.

Inflatable flexible factory formwork construction: most recent construction techniques and details

Alex Morgan BELL[a,*], Tyler ROBINS[a]

[a,*] Automatic Construction Inc

alex@automatic-construction.com

Abstract

Inflatable flexible factory formwork construction presented here, replaces the onsite labor of cast in place concrete construction with inexpensive-to-transport-and-manufacture flexible formwork which is erected using pumps. This flexible formwork is erected using pumps that supply a) air for shoring, and b) a cementitious material, such as concrete, for the building's structure. The buildings constructed with inflatable flexible formwork are identical in constituent parts, placement, size, architecture, safety and building code compliance to cast-in place concrete buildings. Constructed using drop stitch fabrics, the formwork contains traditional steel reinforcement to create conventional flat walls, floors and roofs. The form is held in position (shored) by pressurized air while cementitious material is injected. In this paper, updates on buildings constructed, cost and experience are detailed.

Keywords: concrete structures, construction methods, inflatable structures, fabric formwork, practice-based research

Figure 1. Buildings under construction: (a) inflatable shoring, (b) flat walls, (c) cast buildings.

1. Introduction

In the United States, the construction sector's productivity has fallen over the last 70 years [1]. The pace of urbanization continues and the UN projects that the rate of global urbanization will grow from 55% to 68% in the next 30 years with 2.5 billion more people living in cities [2].

In conventional concrete construction the building of the formwork, reinforcement and waterproofing is the most expensive construction step and should be the focus of any productivity improvement effort, "[F]ormwork is the single largest cost component of a concrete building's structural frame [3]."

To increase productivity at a global scale, society needs a building system to create conventional concrete construction with reinforcement conforming to current building codes that will be faster to

erect, cheaper to purchase and transport, present relatively few restrictions on building design and require fewer work-hours per building. The inflatable flexible factory formwork (IFFF) construction system meets all these requirements.

2. Inflatable Flexible Factory Formwork (IFFF (I3F)): construction process

2.1. Design

Inflatable flexible factory formwork (IFFF) construction starts with the architecture and engineering designs. The average cast in place (CIP) buildings structural designs remain unchained with IFFF. The plans will be augmented to include construction drawings for the inflation of the shoring and the schedule for the building's construction. During the design phase, architects and engineers will be able to iterate on the design for manufacturability, balancing customization and cost by consulting with the IFFF factories' published capabilities. CAD tooling will include IFFF software plugins to allow for instantaneous quotes of build time and cost, permitting contemporaneous iteration by engineers and architects comparable to procedures followed in electronics manufacturing. Once a design has been finalized and approved by the relevant parties, including the local building departments, the designs will be sent to the IFFF factories for manufacture.

2.2. Factory

Depending on the size of the structure, the IFFF factories will deliver a single form, series of forms or sub components of forms for extremely large buildings. The connections between the forms will be as specified in the plans; normally spliced rebar. The IFFF factories will connect sections of rebar together with flexible joints or include openings for inserting rebar onsite and join fabric together to assemble the formwork. The IFFF factories will build into the form the inflatable shoring according to the construction plans. Once complete, tested and certified, the forms will be folded to a compact size and shipped to the job site.

2.3. Job Site

At the job site, workers will follow the factory construction assembly plan specifying the order in which forms are removed from transport and assembled. Depending on the size of the structure, smaller construction equipment such as skid steers may be all that is required to unroll and stack the forms. For larger buildings, truck cranes will help position the forms in place. The base form will require precise placement on the jobsite via laser line while subsequent uninflated forms will be stacked and connected to the first form. QR codes, hand held computers, and sensors would likely be included on larger buildings to assist with and provide oversight.

Figure 2. Images show progress erecting building.

Common concrete line pumps, air compressors, and ready mix trucks already common on the job site will be used. Using standard fittings the inflatable shoring and concrete pumps will be connected to the forms, starting with the first floor and the inflation of the series of shoring chambers. Sensors will monitor pressure in each chamber for any issues and will control air flow.

Concrete ready mix trucks will deliver self-consolidating concrete, as specified in the construction plans, to the concrete pumps which will fill the first floor forms while shoring remains in place for the full term of the plan. After the length of time specified in the construction plan, usually 1 day minimum, the next floor shoring will be inflated and concrete pumps will fill the second floor. After the concrete strength has reached the required level per floor and shoring is removed, the subsequent trades will begin finishing each floor.

2.4. Formwork details

Fabric formwork is currently used to construct inexpensive domed buildings but remained limited because of the domed shape [4]. Drop-stitch fabric technology, used in IFFF, creates the necessary flat surfaces. Drop stitch fabric is made of two sheets of woven material which are connected via robotic looms with periodic connections between the two layers.

Figure 3. Drop stitch fabric.

The process, patented by the Goodyear Company and called 'air mat' was used in inflatable airplane prototypes in the 1960s. At the time, the material's price was prohibitively expensive and it never found widespread use. In the early 2000's material science and electronic loom technology advanced to the stage that the material became sufficiently inexpensive that it could be used in inflatable water sports for rigid surf boards and gymnastic mats. Drop stitch can not be purchased for less than $10 per square meter and the prices continue to fall.

The woven exterior of the drop stitch can be covered in an additional airtight layer of plastic. In most applications this layer is pvc plastic which is bonded to the fabric to make the forms air tight. However, forms can be specified as both sides air permeable or air permeable only in one side for instance the interior or exterior of a building.

2.5. Pressure

The current assembled structures maintain a pressure up to 200 kPa. The current point of failure at higher pressures is the rupture of the drop stitch thread. For hydrostatic pressure durring concrete pours the highest pressure at the fastest rates of pour for 4.5 meter high walls is 140 kPa which is well within current technology. Material and construction advancements may increase pressure tolerances; for example, current heavy lift bags (designed to elevate thousands of tons with small inflated mats) used in shipping and rescue operations sustain pressures of over 700 kPa.

2.6. Tolerances

The formwork is created on automatic looms with stated tolerances of +/- 1 mm over a 100 meter length of material, well within the convention construction requirements. Whether manually or automatically assembled in the IFFF factories, meeting the conventional tolerance requirements is well within current tolerances for manually created drop stitch surf boards and air mats with current technologies.

2.7. Resistance to puncture & self plugging

The formwork does not need to be airtight because concrete consolidates and plugs holes in formwork. In tests, the authors have determined that holes up to 2 times the average size of the aggregate plug with minimal leakage. The self plugging character of concrete permits stabilization around rebar protrusion, industrial zippers and fabric lashing methods used to attach forms. This is consistent with traditional formwork which also contains many holes which plug.

2.8. Constructing forms

Drop stitch fabric can be formed with either plastic welding, glueing with a solvent, sewing or lashing. Welding lends itself more easily to automation and there currently exist a number of plastic welding companies that specialize in automated pvc tarpaulin welding solutions. Glueing with special pvc cement provides a less expensive, but potentially more labor intensive option.

2.9. Environmental

The formwork can be stripped off or left in place. Ideally the formwork will stay in place as it can provide a vapor barrier and increase tensile strength. When left in place the formwork can be covered as in a conventional wall with traditional facade and insulation on the outside and drywall or plaster on the inside walls.

Drop stitch fabric can be made with almost any plastic, most commonly woven polyester with a pvc coating. Both plastics are inert and extremely long lasting as long as they remain unexposed to ultraviolet light. The plastic not embedded in the concrete can be covered by a traditional facade, painted, or doped for uv resistance.

When left in place, the formwork will be governed by residential code R608.4 and must meet R302.9 flame spread and smoke development index. Both woven polyester and pvc have a flame spread index of less than 25, and a smoke developed index of less than 50 well within IBC building code.

Both pvc and polyester are widely used throughout modern homes from plumbing to furniture, clothes and more. IFFF factories will certify that their fabrics are low-VOC.

2.10. Compressive and tensile testing

A section of formwork was core drilled after 28 days and the compressive strength of the core was compared to a control test cylinder. Across three test cylinders the compressive strength remained a consistent average of 30 mPa with no statistically significant variation between test cylinder and formwork cylinder.

A beam form was created that was 10 cm by 10 cm by 1 meter and a plain concrete beam was cast as well as a drop stitch beam. The beams were supported on each end and force was applied in the middle of the beam until failure. Over three sets of tests, the drop stitch beam's failure point was on average 19% higher than the plain beam suggesting increased tensile strength. Additional tests are ongoing.

2.11. Reinforcement

Reinforcement is used in concrete construction to provide tensile strength (concrete being significantly stronger in compression than tension.) Steel reinforcement in the form of rebar is the most popular form of reinforcement although other methods are available including GFRP, post tensioning cables, and fibers.

While woven material adds to the tensile strength, IFFF will accommodate traditional rebar use and placement. There are two options for IFFF and reinforcement: rebar inserted in the factory or on the jobsite. For jobsite insertion, premade holes in the forms are prepared with rebarwheels so that construction teams, after inflating the shoring, can push rebar into the holes. The rebar inserted is kept in place in the form by the dropstitch and rebar wheels. Traditional tying of the rebar is not required. Conventional rebar placement uses plastic and metal chairs, spacers and wire ties to secure the rebar against movement during the concrete pour.

Figure 4. Rebar in form example.

In conventional construction two sections of rebar are spliced together either by overlapping and tying or by using a mechanical rebar coupler. Similarly, rebar will be overlapped or mechanically coupled. The second option is for IFFF factories to place the rebar throughout the forms and keep the rebar in place by tying between the fabric forms and using standard plastic wheel spacers.

Figure 5. Render rebar and spacers.

In order to allow the forms to fold for transport the rebar will be linked with eyelets or hinged rebar couplers at periodic intervals which allows the rebar to hinge while retaining tensile strengths (see building code section for coupler approvals).

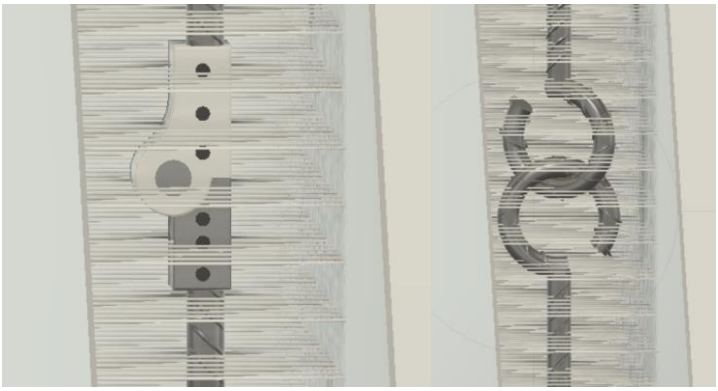

Figure 6. Hinged class b coupler and hook rebar.

IFFF will connect into foundations as in conventional construction by tying the forms into the exposed reinforcement of the foundations. For slab on grade, IFFF can be used without any foundation by specifying in the plans for a thicker slab.

Because the permanent formwork prevents corrosion, the distance the rebar is embedded below the surface of the concrete 'cover' will be less onerous in IFFF construction. However, initially, in order to speed penetration in the market, the rebar will be placed with spacers to meet current cover requirements.

In the future fiber reinforced concrete whether glass, fiber or metal could be used to decrease the amount of rebar required. Further iterations could increase the pressure of the shoring to give the ceilings a slight curvature during casting, forming a slight arch and decreasing the tensile forces.

2.12. Architecture

IFFF will maintain the current flexibility architects have in designing cast in place buildings. As in conventional construction there will be cost savings to using common sizes and shapes for IFFF factories.

The stripped walls are a similar texture to current forms with some variances. In the future surface finish and geometric design could provide aesthetic benefits to architects such as curved or patterned walls.

Figure 7. Stripped walls.

As discussed in the formwork section, the forms can be a vapor barrier or not depending on requirements. In the case of a vapor barrier the resulting building would be tighter than traditional construction with CMU block and wood framing. In further iterations of IFFF, the walls could be formed of two separate forms with an air gap between. This air gap could be then pumped full of insulative materials to create a seamless and insulated concrete wall.

Initial IFFF buildings will provide openings for windows, stairs and some mechanical connections. As IFFF gains adoption it will serve as the foundation for further advancements across the trades. Because the building will be constructed according to the digital plan; conduit, plumbing, hvac and other connections can be provided in the superstructure. The walls would come with mechanical threaded inserts already cast in the outer and inner walls so that the installation of the facade would require only bolting into the set inserts. Similarly, future iterations of IFFF could include interior walls cast separately of light weight concrete, aerated plaster, foams, or other materials to rapidly construct interior walls. These further advancements in automation would build upon IFFF and provide further productivity gains across construction.

2.13. Compression material options: concrete and more

A variety of materials can be pumped into the forms to make up the structure and provide the compressive strength of the building. For most applications the material will be concrete but any pumpable and hardening material can be used.

The use of self consolidating or self compacting (scc) concrete will allow the concrete to flow easily through the forms without required vibration. Non scc concrete can be used with vibration. A special item to consider is the aggregate size and the spacing of the drop stitch material. In general drop stitch spacing should be twice the size of the aggregate used. If larger aggregate sizes are used they can prevent flow in the forms. IFFF factories will allow drop stitch spacing to be specified in the ordering process.

IFFF has been prototyped with aircrete to form lightweight cement structures and polyurethane expanding foam, both providing lightweight and insulative structures. Other materials such as Hempcrete, soil crete, compacted earth, Alker are all lower cost and environmentally friendly options that could be created at the job site and pumped into the forms. The concrete industry's efforts to replace cement with lower C02 emitting binders would complement the IFFF building system.

2.13. Shoring

In conventional cast in place concrete construction, the shoring is used to temporarily support formwork until the concrete has strengthened sufficiently. The erection of the shoring takes place with the creation of the formwork and adds to the cost in labor and time of conventional concrete construction. To support

IFFF either conventional shoring or inflatable shoring can be used. The benefit to inflatable shoring is the IFFF factories will deliver the forms with the shoring pre-attached or in some cases separate from the forms.

Depending on the geometry of the forms the inflatable shoring can be reused or returned to the IFFF factory for recycling into further forms. When using inflatable shoring the IFFF factory will provide an air manifold which connects to each form. The plans will specify a series of compressors to be used on the jobsite. The manifolds include a pressure regulator which will maintain pressure in the shorings.

Sabotage is a problem for all construction and with flexible formwork it is potentially easier for a saboteur to destroy formwork, requiring enhanced in person security on site or remote monitoring in order to prevent unauthorized entry into the construction site.

2.14. Building department approval

IFFF was developed to meet current international building codes and rely on currently approved materials. The NYC 2014 Building Code was chosen as it is one of the most restrictive in the United States. IFFF will meet the entirety of the NYC building code; areas of particular interest are highlighted below.

NYC Building Code 2014 - Chapter 17 Structural Tests and Special Inspections- 1704.4 Concrete Construction

IFFF factories will allow for periodic inspection and reports from concrete construction special inspectors on the formwork and reinforcement. The forms will also include inspection flaps and view ports so that inspectors in the field can inspect the forms and reinforcement.

NYC Building Code 2014 - Chapter 19 - Concrete

ACI 6.3.1 - The embedded polyester fibers are not harmful to concrete. See reinforcement for discussion of added strength but for 6.3.1 assumption is no additional strength.

ACI 7 - The reinforcements used will meet the requirements of ACI section 7. Specifically minimum bend radius as defined in table 7.2.

ACI 12.14.3 Mechanical and Welded splice - The hinged rebar couplers used will exceed the 1.25fy of the bar as specified and couplers used will be ICC-ES certified and meet ASTM A1034.

ACI 13.3.8.5 - Two Way Slab - IFFF couplers will be class b tension lap splice where designated.

NYC Building Code 2014 - Chapter 33 - 3305.3 Concrete Formwork

ACI 3305.3.2 Design of Concrete Formwork - Shoring and formwork designs will come prepared by the factory with the formwork.

ACI 3305.3.3 Formwork Inspection and Observation - As detailed for Chapter 17, inspection ports and certification will be provided. IFFF is currently undergoing testing for ASTM E84 testing for Flame Spread and Smoke Development Index.

2.15. Sustainability

Concrete, a mixture of aggregate and cement, is the most widely used material on earth and its overall carbon footprint reflects this. Portland cement, the most common cement type, has a high embodied emission and is the focus of replacement efforts to develop a more environmentally sustainable product.

Recent efforts have shown that carbonation of cement in concrete can also be used for carbon sequestration. There are multiple companies and research papers that have shown that introducing carbon dioxide into the concrete allows the cement to absorb the carbon dioxide creating a stronger concrete and sequestering the carbon [5]. In most papers the focus for sequestration during curing is

focused on precast plants where the concrete could be placed in a carbon rich atmosphere. Cast in place has been largely ignored due to the impossibility of placing conventional cast in place concrete in a carbon rich atmosphere. However, with the introduction of IFFF which are sealed forms, cast in place concrete can potentially serve as an even greater carbon sequestration point with onsite pumps pumping air into the forms during the 30 day cure period to have the concrete filter and store the carbon.

Automatic Construction has been prototyping a combination of IFFF and accelerated carbonation. The paper [6] details experiments in which the process has been able to sequester all the CO2 released in the calcification of the limestone. And further, the latest results show that the rate of sequestration continues and the building material appears to continue to sequester CO2. This opens up the possibility of IFFF construction + carbonation being a net sink of CO2.

Overall, there are compelling reasons to believe IFFF will improve the sustainability of construction: a) as discussed in the section on compressive materials, IFFF construction can use any pumpable material such as recent formulations of green concrete, mass timber, or hempcrete b) IFFF buildings promise to be more efficient to heat and cool due to the vapor barrier provided by the air tight forms c) IFFF buildings will use less concrete than conventional cast in place structures due to precision manufacturing d) IFFF construction could allow for carbon sequestration on a massive scale.

2.16. Estimates of cost and time reduction

Current prototype IFFF buildings are being made at $215.00 USD per square meter. These prices for single prototypes suggest that the price will fall with scale. In order to compare costs, a 10 floor building, 315 Linwood in Brooklyn NY, was considered from detailed plans and construction accounting. The conventional cast in place superstructure cost $6M vs an estimated $1.2M for IFFF construction. As IFFF buildings are built at greater scale, a more detailed accounting of the cost difference across regions and building types will drive IFFF adoption. Initial estimates suggest that at prototype prices IFFF is already $\frac{1}{5}^{th}$ the cost of conventional construction and will certainly improve in price at scale.

It is difficult to estimate the time savings from IFFF at this stage of technological maturity. Best in class conventional cast in place construction operates on a 2 day cycle adding a floor every two days. The majority of the delay in IFFF will be waiting for the concrete to strengthen while in conventional construction the additional day is required for formwork construction. In buildings shorter than 20 stories the cycle is more commonly 10 days. It is estimated that IFFF construction could decrease times to 1 day cycles achieving a 2x speedup over the current best in class.

The biggest savings in cost and time come from the replacement of onsite labor. Activities from screeding, tying rebar, placing rebar, and the hand building of forms for each floor are all replaced by the onsite pump and single pump operator.

2.17. Beyond buildings

This paper has focused on IFFF for conventional building construction however applications also exist for other concrete structures.

IFFF can be used to create tunnels in which nested flexible tubes are laid in the ground or in water and then filled creating concrete reinforced tunnels. Potentially lowering the cost of under river tunnels.

Inground pools manufactured with conventional forms could be replaced with IFFF allowing for quicker and less expensive setup.

In exotically hard to reach locations, such as future construction on other planets, IFFF's low cost of transport in combination with local materials would be one of the only options to construction. There already exists literature on combining binders with mars or moon dust to create a cementitious product perfect for filling inflatable flexible factory forms.

3. Construction to date

Automatic Construction Inc has built single storey structures in NY, USA using the IFFF method detailed here. All construction to date has been small structures in the 10-30 square meter range. Structures have had flat roofs and pitched roofs. Structures have either used 10 cm or 20 cm walls.

4. Replication of results

IFFF and drop stitch are impressive technologies that should be used more. Below are suggestions for drop stitch/ IFFF projects.

4.1. Drop stitch material

- Drop stitch material is available on Alibaba from a variety of producers. A smaller roll of fabric can be purchased as a sample. The options are primarily 5cm, 10cm, and 20cm for thickness with either PVC or TPU coating. Some larger manufacturers such as Duletai also provide manufacturing of both materials and end products.
- Ecommerce sellers such as Amazon and AliExpress sell square dropstitch inflatable sections as gym mats. These are often excellent ways to get started experimenting, pumping and working with the material. Search "Air Mat Gymnastics" to purchase.
- Drop stitch can be cut with scissors and is easy to cut into panels for fabrication.
- For the edges of the drop stitch the best solution is to glue or weld vinyl coated tarpualine.
- There are a few options for fabricating the drop stitch into structures
    - HH-66 vinyl cement is the best glue to use.
    - Sewing drop stitch is possible with a heavy duty or leather sewing machine
    - Hot air welding requires more skill than gluing and the fumes are potentially more hazardous. However its less expensive and can be faster. Handheld plastic welders are available for low cost.
    - Radio and ultrasonic welders are a more expensive option.
    - The company Weldmaster, as well as others, provided automated solutions for fabric assembly.
- Inflatable contractors are also available who will fabricate and ship drop stitch structure. The contractors will require a design document. Example contractors are AirBox ltd or search " Drop Stitch Inflatable Manufacturer."
- In general, custom drop stitch configurations such as larger spacing for larger aggregate or other permutations are possible but require minimum orders of 1000 square meters.

4.2. Couplers

- HR valves are the standard for air inflation. The air valve will be easily clogged with concrete and should be positioned at the highest point in the forms.
- Concrete couplers should be custom made for the concrete pump connection. The two primary types are HD couplers and Camlock. To attach to the drop stitch requires a backplate which is inserted into a hole in the drop stitch. Then the flange of the coupler is bolted or riveted to the backing plate. Couplers can be manufactured out of steel, aluminum or plastic.
- The amount of concrete vibration required depends on the concrete mix design, the drop stitch spacing vs aggregate size and the distance the concrete has to flow. External vibrators can be

bolted to either the coupler or to similar couplers connected across the forms. Internal vibrators can be inserted into small holes in the forms to increase the movement of the concrete.

Figure 8. Concrete HD coupler in IFFF.

4.3. Pumps

- Air pumps for inflatables will work especially with HR valves. For inner shoring its helpful to have the ability to set the pressure. You can either use a HR valve air gauge or air pump with a pressure regulator.
- Depending on the concrete mix and desired flow rate there are a few options for concrete pumps.
    - Concrete line pumps are available for rental and come with an operator. The line pumps in the United States use HD couplers. Most concrete pumping companies will have reducers to a smaller diameter hose which is easier to handle and connect to the forms. Concrete line pumps can be extremely powerful. Start with a smaller form to gain experience. Set the volume control knob on the pump at its lowest setting and pump slowly to start.
    - Large construction diaphragm pumps for instance the Wacker Neuson PDI series connects with a camlock connection and can pump air crete and most flowable mortars. For small scale prototypes, you can also use diaphragm pumps (either hand operated or 12 volt electric) which are manufactured for bilge pumping.
    - Mortar pumps are available as either electric or gasoline/diesel powered. They usually have a maximum aggregate size but are smaller and easier to use.

4.4. Concrete mixes

- The main variables are aggregate size and concrete flow when choosing a mix. Maximum aggregate size should be less than drop stitch spacing. The concrete should be self consolidating or at least have a high flow/spread. A spread of 50 cm in a inverted cone test is best. Additions of super plasticizer are common in most ready mix locations. For aggregate size, the smallest options are usually a “block fill” variety.
- Another option for prototyping is to use air crete which can be mixed onsite and foamed. The air crete pumps much easier than traditional concrete.
- Expanding polyurethane foam is an option; however, for larger structures the expense is considerably higher than cement options.

5. Conclusion

Inflatable flexible factory formwork (IFFF) construction has the potential to improve global construction productivity without requiring compromises in architecture, new building materials, or untested building designs. Globally the construction industries lack of productivity is creating skyrocketing housing costs

and inadequate housing for the hundreds of millions of people moving to cities each year. IFFF relies on factories to produce formwork with lower onsite labor requirements in a compact and shippable form.

IFFF relies on inexpensive and readily available pumps to supply the unloading, placing and erecting of the structure. IFFF creates robotically precise buildings whose digital foundation will unlock further productivity gains across all building trades.

Abstract

Due to the continuous iteration of digital design and construction technologies, innovation of design paradigm liberates social productivity significantly while it also creates a new possibility of mass customization for architectural individualization and diversity. This thinking of architecture allows architects to accomplish profound design concepts and intentions, such as structural optimization, construction efficiency, and material usage. At the same time, digital design tools and algorithms also powerfully awaken the relevance of tradition and local culture, which is also an essential meaning of technological innovation for social development. The timber reciprocal frame structure is a building structure form with a long history, which has played an important role in history with its concise and practical characteristics. In the field of architecture and engineering, the current trend of combining traditional material and craft with digital technology is promoting the development of timber structure buildings, creating more elegant, environmentally friendly, and low-carbon buildings for humanity. This paper introduces the integrated design and optimisation process, with robotic construction method of large-scale timber reciprocal frame structure, taking the Chengdu Agricultural Expo Exhibition Hall as an example.

Keywords: reciprocal frame structure, shell structure, structural optimisation, digital fabrication

1. Introduction

With the popularization and application of computational design tools and architecture robotics, the intelligent construction platform not only provides a highly flexible system for architectural prefabrication but will also promote the integration of different architecture production processes [1]. In recent years, the rapid development of tools, including computers and robotics, has driven the digital transformation of construction industry [2]. Digital parametric design tool, represented by Rhino and Grasshopper, is a notably developing advanced manufacturing technology in the last 30 years. with the advantage of free manufacturing of three-dimensional structures and material saving, which has been widely used in innovative product exploitation and small-scale manufacturing. However, with the emerging architectural robotics technology, mass customization has become another popular direction for architects to explore. The development in this research field can serve both academia and industry in terms of promoting robotic algorithms, hardware, and applications in construction industry [3]. With the widespread use of architectural robotics technology, the manufacturing industry may no longer depend on traditional factories, which centralize production factors such as labour, capital, and equipment on a large scale, but rather shift to a more flexible production method based on industrial robotics that requires less investment. Combined with the digital construction method of human-

machine collaboration, digital design tools and robotic production has significant potential for practical large-scale manufacturing scenarios [4].

With challenges such as the unreliability of the naturally grown timber overcome during the last decades with novel digital technologies, prefabricated engineering timber has been one of the most digitally advanced sector within the construction industry [5]. It can reduce material waste, onsite labor, and erection time which can lead to improved safety and overall quality while reducing costs [6]. Additionally, by substituting wood, bamboo, and other plant fibers for energy-intensive materials such as concrete and steel in building construction, greenhouse gas emissions from material manufacturing can be greatly reduced [7]. The timber reciprocal frame structure is a building structure form with a long history, which has played an important role in history with its concise and practical characteristics. In recent years, with the development of digital and intelligent design in architecture, the timber reciprocal frame structure has been widely applied and developed. In the field of building structures, the combination of traditional timber material and digital technology is promoting the development of timber structure buildings, creating more beautiful, environmentally friendly, and safe buildings for humanity. This paper aims to explore the application of timber reciprocal frame structure in buildings and the future direction of its digital development. Firstly, this paper will introduce the basic shell geometry selection, pattern generation, and design concept. Secondly, the constructability is optimised based on genetic algorithm in the perspective of timber elements' dimension and joint angles. Furthermore, the robotic fabrication process has been illustrated to prove that the constructability optimisation can significantly reduce the manufacturing cost. Finally, structural performance calculation of reciprocal frame structure unit has been shown for the timber beam categorising. In summary, this paper discusses digital design and optimisation workflow for large-scale reciprocal frame structure based on mass customization scenario, taking the large-scale shell structure of Chengdu Agricultural Expo Center as an example (Figure 1).

2. Methodology

2.1. Reciprocal frame structure pattern generation

The optimized and rationalized shell surface is generated through particle-spring shape-finding algorithm, which serves as the foundation for the subsequent stage of designing a coherent structural system supporting the extension of the shell space. In the design phase, the primary aim is to create a large-span, column-free space within the shell while maintaining its structural integrity. The initial proposal used a dense ribbed timberen beam to achieve this goal. However, after exploration and modelling test, a modified frame structure was determined, and it replaced the dense ribbed timber beams with a reciprocal frame structure (Figure 2). It supports the extension of the shell space and provide a column-free interior. In the phase of designing this reciprocal frame structure, 11 Archimedean paving of orthogonal polygons are selected as the basic pattern for the reciprocal geometry library (Figure 3). This selection was made according to their compatibility with the continuous shell space and their ability to provide stable structural support. This use of reciprocal frame structure allowed for a more coherent and efficient structural system, resulting in a large-span, column-free space within the shell, which was essential for achieving the desired spatial morphology.

Figure 2. Dense-ribbed timber beams and reciprocal frame structures

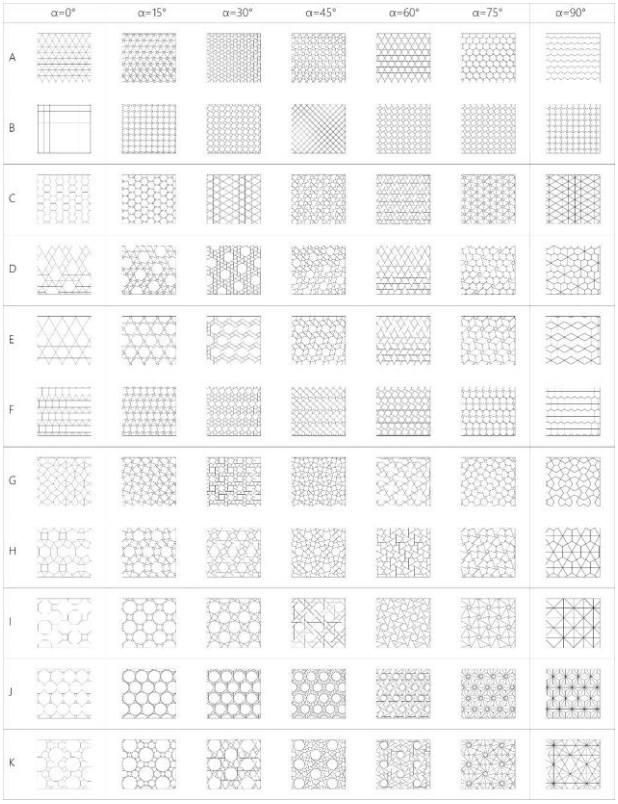

Figure 3. Reciprocal Geometry Gallery

After obtaining a prototype library of rationalized shell surfaces and planar reciprocal geometry, this project started to explore the three-dimensional transformation of reciprocal geometry using rod shape-finding mechanics and projection methods. The primary objective was to achieve an angle-preserving mapping from the plane rod to the shell surface parent, which could ensure that the reciprocal geometry remained undisturbed in both x and y directions. To achieve this, the reciprocal frame structure grid in-plane is adjusted to cover the entire shell surface. This approach resulted in a plane curve that could be fully fitted to the shell surface, which was critical for achieving optimal structural performance (Figure 4).

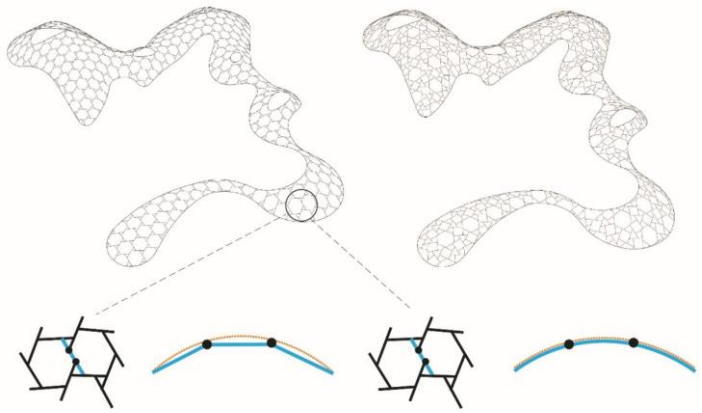

Figure 4. Left: the unit rod generated by the particle-spring method Right: the unit rod generated by the projection method

Two levels of comprehensive screening determine the construction feasibility and structural functional suitability of the hexagonal reciprocal grid. After consideration, a C-grid modified pattern is selected to reduce the impact of right angles in space while reflecting the spatial ductility of the shell structure in the design concept. Figure 5 illustrated that when the C-grid modified pattern is rotated to 16.1°, it achieves a unique reciprocal state where the intersection point is located at the third equilibrium point. This state optimizes the overall structural performance and stability of the grid C modified pattern. In addition, the smallest triangular cells in the reciprocal grid meet basic construction requirements, while the other functions including light positioning and arrangement can be completed in the later process. Figure 6 shows the final result of this refinement process. In summary, this project successfully achieved an angle-preserving mapping from the plane rod to the shell surface parent by using a hexagonal reciprocal grid with a C-grid modified pattern. This approach resulted in improved structural performance and spatial ductility, which is critical for the design of shell structure in the perspective of architecture.

2.2. Constructability optimization of the reciprocal frame structure

In the processing of mapping 3D reciprocal frame structure line model to the shell surface, several types of structural issues referring to the constructability are addressed in this project. These issues are addressed in the optimization of the overall reciprocal timber structure that intersected with the curve boundary in three dimensions (Figure 7)."

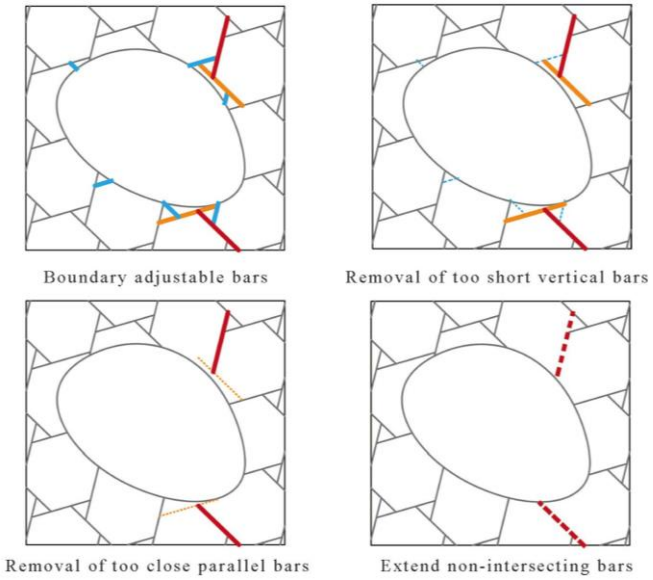

Figure 7. Boundary optimization based on constructability

In order to optimize the reciprocal frame structure, our team implemented a three-step process. Firstly, all timber rod elements with lengths less than 580mm are screened and removed. These short members are typically caused by cutting the triangular units of the reciprocal frame structure with the outer boundary. This crucial step aimed to eliminate unnecessary structural elements and improve the overall stability of the structure. Secondly, all near-parallel members with lengths less than 300mm from the edge line are screened and removed. These members can cause redundancy in mechanical properties and difficulties in positioning during on-site construction. After that, the construction processes are streamlined, and the overall efficiency of the structure is improved. Thirdly, the endpoints of all line segments intersected with other bars are checked and are extended until it intersected with another line segment (Figure 8). This intended to ensure that all structural elements were properly connected and supported, resulting in a more stable and robust structure. Overall, this boundary optimization approach ensures the final structural stability and aesthetical appearance of this reciprocal frame structure.

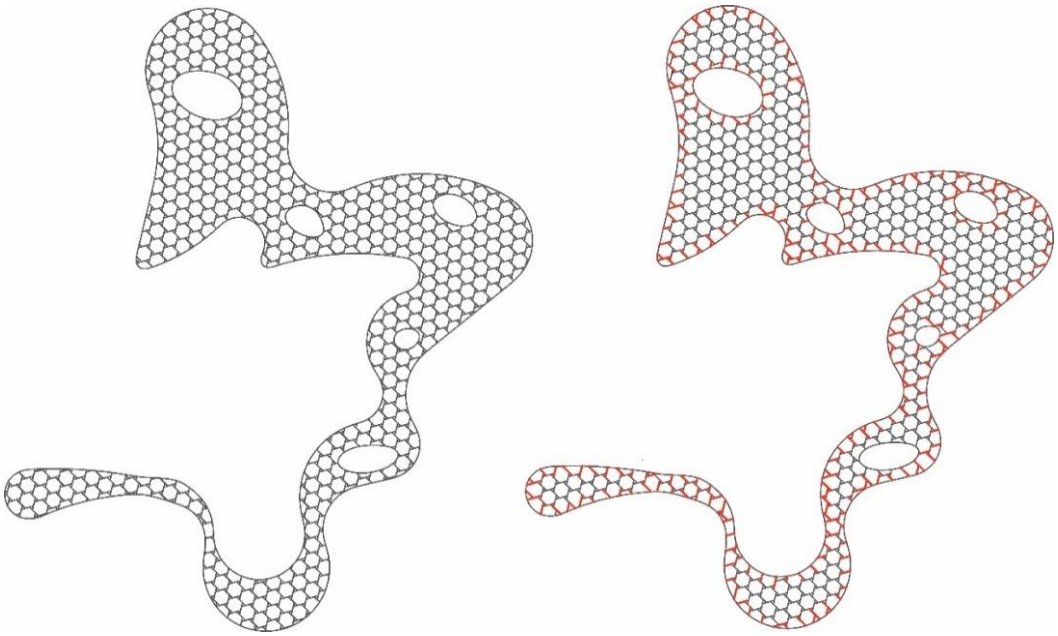

Figure 8. Left: Before boundary optimization Right: After boundary optimization

After completing the boundary-adaptive structure optimization above, it is imperative to geometrically rationalize the unit bars within each reciprocal frame structure. The positioning line of the reciprocal frame structure, derived through projection, manifests as a planar Non-Uniform Rational B-Splines (NURBS) curve with multiple control points. This curve facilitates construction-oriented optimization by controlling the error range and constructing circular arc lines through the extraction of the curve's geometric feature points. To achieve this, the endpoints and midpoints of each rod and curve are extracted independently, enabling the construction of circular arcs conforming to the original NURBS curve. Consequently, the rod positioning line could have promising geometric performance and possibility of reconstruction. In addition, it is crucial to consider the numerical difference in the radius value of the fitted arc from a prefabrication standpoint in a timber processing factory. The timberen rod exhibits various arc radius, which significantly increases the capital and time costs associated with the fabrication process. Hence, the arc radius is optimized, generalized, and integrated, building upon the initial fitting results (Figure 9). This approach ensures a more efficient fabrication process, reducing both the time and resources required for the construction of reciprocal frame structures.

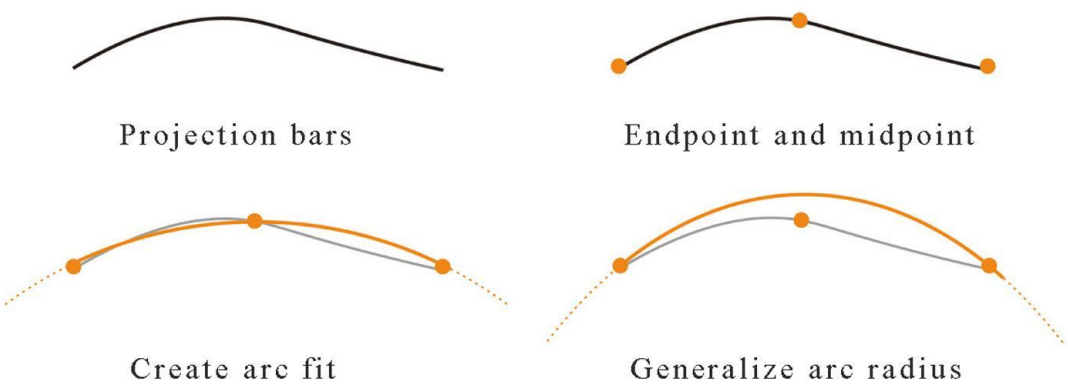

Figure 9. Preliminary fit of rods

This project conducted a comprehensive analysis of arc radius to develop a methodology for generating secondary generalized arcs. Specifically, the first step is to sort arc radius from large to small and assign sequential numbers to each arc. Then, the identified intervals of arcs with similar radius and determined median radius of each interval can serve as the unified radius for the elements. Next, this project used the generalized radius and two control endpoints to iteratively construct a secondary generalized arc. However, it is necessary to control the structural error value generated between the obtained secondary induction arc and the initially mapped rod during this process. To address this issue, the design team extracted four key data: maximum error, minimum error, average error, and median error between the rods. The error indicator was then set as the mean value of these four data. Finally, the feasible radius induction schemes were filtered out by controlling the defined error indicator threshold below 6cm. Figure 10 provides a visual representation of this process. Overall, this radius optimization methodology for fabrication and construction provides a systematic and effective approach for generating secondary generalized arcs with high precision and accuracy. Predictably, this approach has the potential to be applied in a wide range of discipline, including engineering, architecture, and manufacturing, improving the efficiency and quality of complex geometrical constructions significantly.

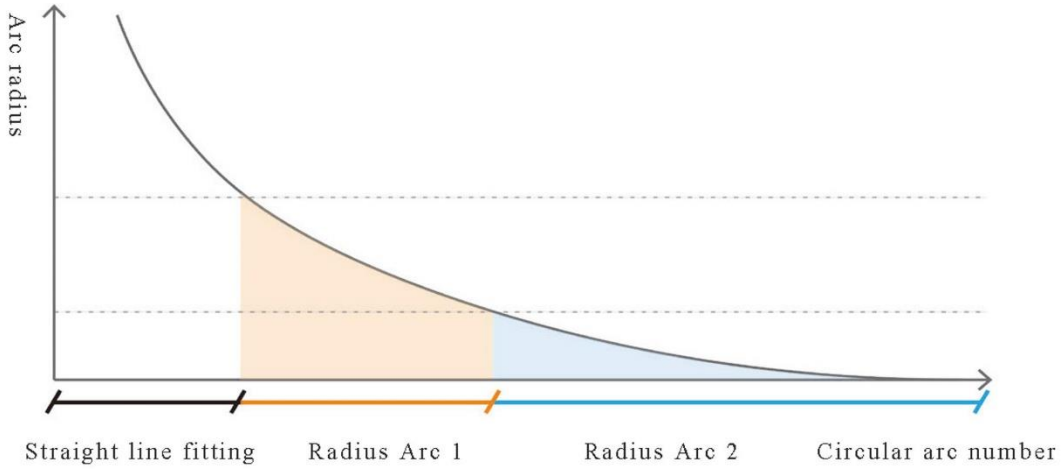

Figure 10. The radius of the induction arc

The digital optimization tool utilized in this project is genetic algorithm carrying out different attempts to divide the induction intervals and test the induction radius. By repetitively calculating and optimizing the steps of the induction radius of the circular arc, it can optimize the radius for improved efficiency. From the initial manual induction of 5 intervals and 5 types of radius optimizations, this project finally obtains only 2 intervals and 2 types of radius circular arc. For rods with oversized arc radius, which are infinitely closed to a straight-line arc, are replaced with straight rods. After that, an optimal inductive solution with an error index of less than 6cm was obtained. To streamline the fabrication process, the rods type of reciprocal frame structure finally can be concluded into three types: straight rods, 3.9m radius circular arc rods, and 9.0m radius circular arc rods. This optimization remarkably reduced the processing and construction costs of factory prefabricated rods through a geometric calculation within a reasonable error range (Figure 11). To include this step, it is rational to state that through the optimization by genetic algorithms, the constructability of the overall shell structure was crucially modified.

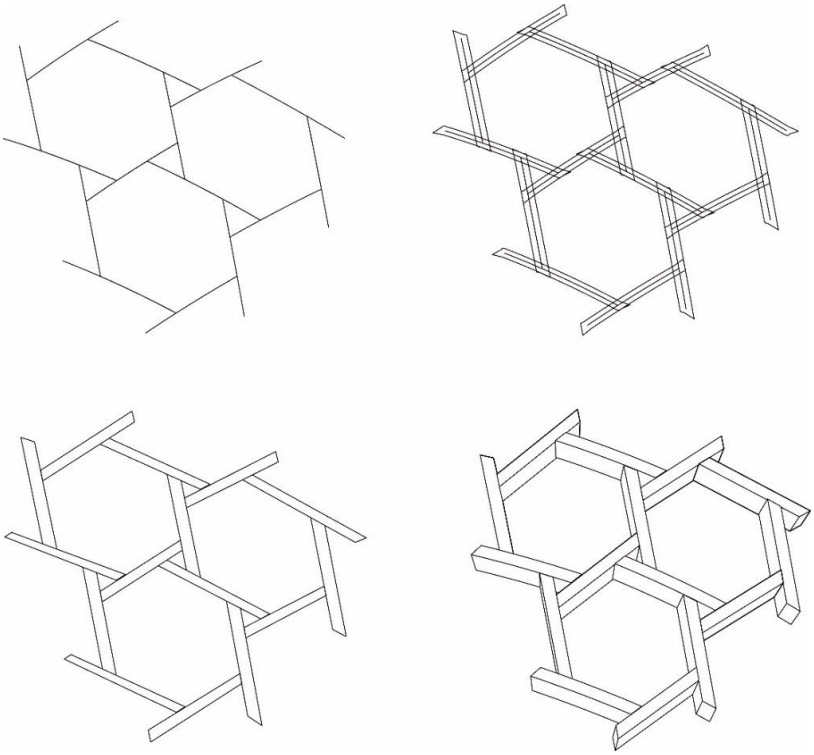

Figure 11. Structural bar conversion of reciprocal frame line mold

2.3. Robotic fabrication of timber reciprocal frame structure

The optimized structural form of the single-curved timber beam in the design process asked for high demands of accuracy and efficiency in the processing of these elements. The laminated timber form, size, hole position, and slot position required for the entire project are all different, while the machining accuracy of each node must be controlled within ±2 mm to meet the requirements of prefabricated assembly. The timber fabrication robotics based on an industrial six-axis robot arm can fully utilize its precise and efficient processing capabilities, making mass customized production of complex timber elements possible (Figure 12). The robotics is equipped with an 18000 rmp spindle motors and can complete all the milling and drilling process of the rods by converting the tool head (milling cutter). The Grasshopper plugin FURobot can convert the architectural model into a path for robotics. Through simulation, it can ensure the smooth fabrication progress and directly generate offline programs. For the same node, the robotics needs a series of processing information. Firstly, the path for rough processing of the timber needs to be formulated, milling out the required overall form from a complete timber material. Then, additional processing paths are required for details such as bolt holes and slots. In addition to architectural geometric information, no other information is required for this process. The mass customization processing method of the robot effectively guarantees the rational completion of mass-produced components, not only improving processing accuracy but also effectively reducing processing time and cost.

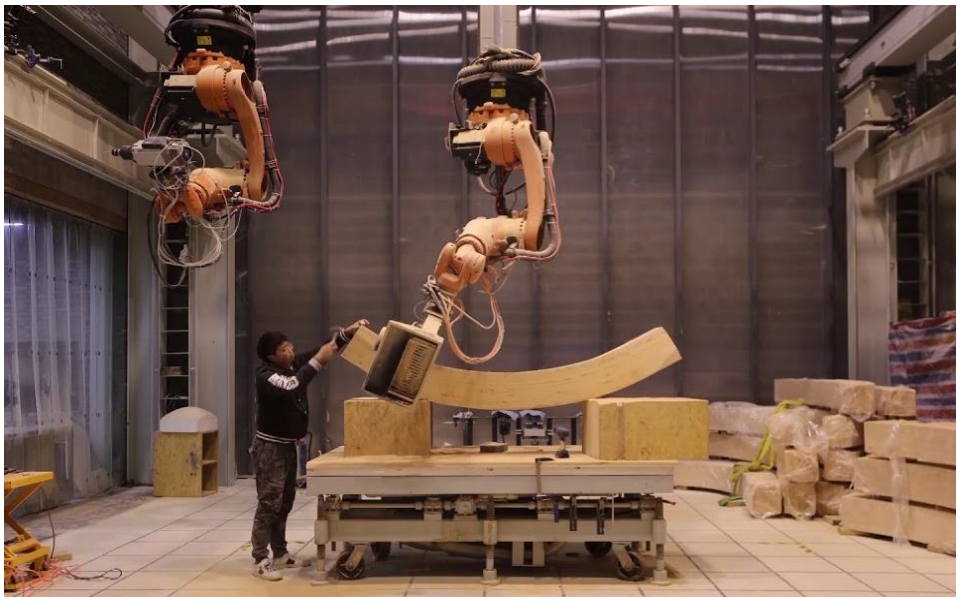

Figure 12. Robotic timber fabrication technology

3. Result: structural performance calculation of reciprocal frame structure unit

In the structural analysis result, the preliminary structural mechanics calculation of the existing structure showed that the overall bending moment and stress of the project could be maintained within a more controllable range while the variation range of the axial force was slightly larger than expected (Figure 13). The rods were grouped together. In additional, the size, material and node design were considered in different axial force areas.

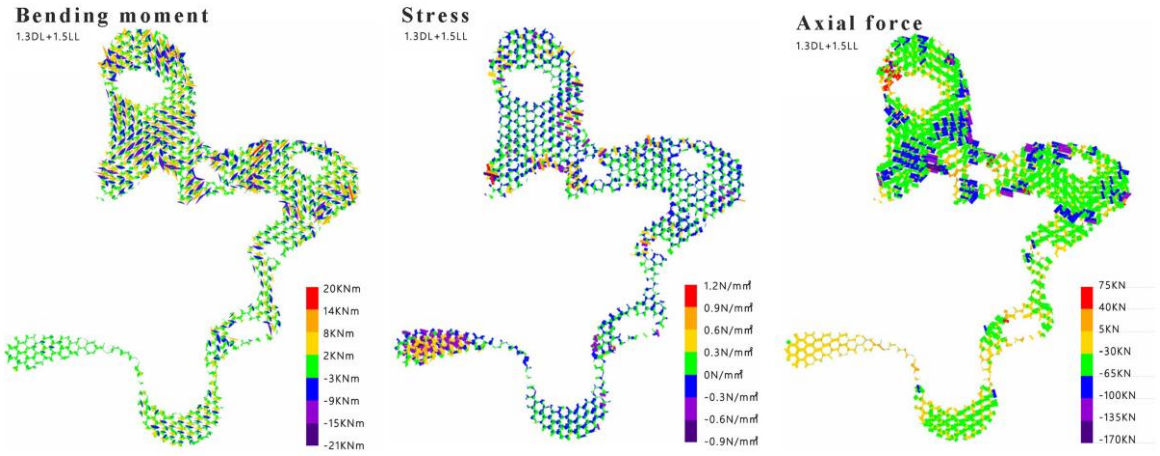

Figure 13. Structural performance calculation

The detailed fabrication strategy our team developed is categorizing timber beams into several parts. To be specific, four types of timber structure unit beams are determined based on mechanical performance calculations. The B1 and B2 beams, which are subject to less axial force, use glued laminated timber

beams with a cross-section of 450*180mm. The B3 beams, which are subject to the greatest axial force, are replaced with more stable timber veneer square steel beams due to their own tensile and compressive requirements and a smaller overall quantity. Since the outermost structural ring beams at the boundary of the rationalized curve and the five skylight openings require better structural stability and better fabrication precision, our team defined them as B4 type beams, using Φ355*16mm round steel beams as the main material (Figure 14). The team also designed different types of nodes based on steel fork plates, bolts, steel nails and other structural members for various types of unit beam members. In this way, a complete theoretical study and construction-oriented digital geometric design of the reciprocal timber structure from the geometric characteristics to the structural performance level has been developed. At the same time, the implementation and effectiveness of its basic form is evident.

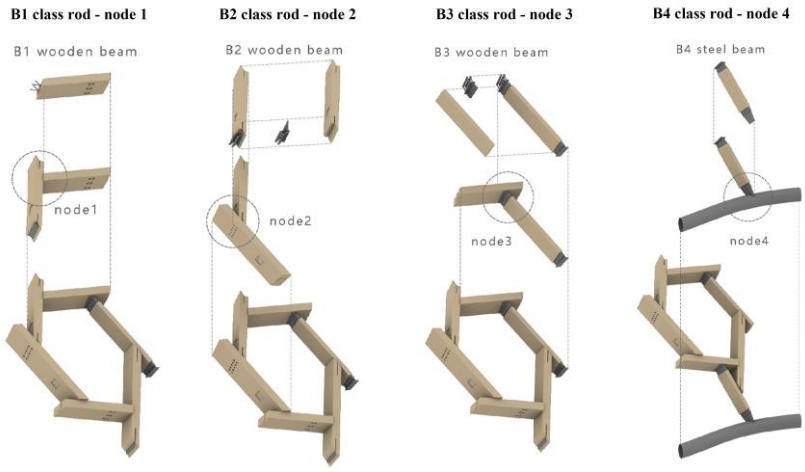

Figure 14. Form and node construction of each type of structural unit

4. Summary

This article presents a project that explores the digital design and fabrication process of a long-span shell roof with a reciprocal frame structure. Overall, this project utilizes digital design tools and genetic algorithms to efficiently prefabricate irregular timber components, from the generation of structural patterns based on an Archimedean paving of orthogonal polygons to the development of reciprocal frame structure geometries with structural performance. During the process of 3D form-finding and structural optimization, the basic planar reciprocal geometry is mapped onto complex hyperbolic shell surfaces, and further optimized using the particle-spring method to enhance the overall spatial structure and interlocking angles. Ultimately, this load-bearing structural system of hexagonal unit timber beams forms a reciprocating force system in the complex hyperbolic space, achieving optimal structural efficiency and material utilization.

In conclusion, the integrated design and optimisation process promotes a paradigm shift in architectural practice. This continuous development of digital technologies integrates performance principles with geometric principles related to shape, structure, and materials to motivate customized material processing in performance-based fabrication. Research and practice in performance-based construction using geometric principles is undoubtedly driving the advancement of digital design, construction research, and industry transformation.

Abstract

Building deconstruction combats the negative environmental effects of traditional demolition by reducing the amount of waste materials and be embraced more than demolition. In order to promote the application of building deconstruction for prestressed structures, the dismantling methods of cable-strut tension structures were investigated in this study. Four possible dismantling methods were proposed based on the idea of releasing inside prestress by relaxing cables, and their mechanical state of the structure during dismantling, dismantling efficiency and cost of the four methods were compared using the numerical simulation method based on VFIFE. Results indicated that the method of relaxing radial cables and method of dropping inner rings has more advantages, while the method of relaxing inner ring cables and method of relaxing radial cables in batches increase the risk of dismantling works. Then, a dismantling experiment was carried out that confirmed the dismantling method of dropping inner rings is feasible and the numerical simulation method is accurate.

Keywords: building deconstruction, wheel-spoke cable-strut tension structures, dismantling method, numerical study, experimental study

1. Introduction

Traditional demolition produces numerous waste products, causing harmful impacts on the environment and society, such as land occupation, groundwater pollution and air contamination [1]. As a result, scholars have proposed the concept of building deconstruction to reduce the negative economic and environmental impacts of demolition. Building deconstruction refers to the systematic dismantling of buildings to recover the maximum amount of reusable and recyclable materials in a safe environmentally responsible, cost-effective manner [2]. Therefore, it has economic and environmental benefits over traditional demolition and tends to become the main strategy [3]. Dismantling refers to the systematic removal of as-built buildings while maintaining the integrity of the building materials and plays an important role in building deconstruction [4]. Several studies have been conducted on dismantling of high-rise buildings [5-7].

The cable-strut tension structure is a self-balanced system composed of continuous cables and discontinuous compression struts [8]. The most interesting features of the cable-strut tension structural system is light weight and high efficiency of force transmission, which have attracted attention from engineers for decades [9]. Therefore, it has been widely used in numerous large-span spatial structures recently such as the Maracana Stadium in Brazil, the Busan Stadium in South Korea [10] and the Shenzhen Bao'an Stadium in China [11]. And lots of studies focused on its erection process. Guo et al. [12] gave four erection methods and designed a tensioning experiment of a scale model that adopted cable-strut tension structural system to verify the feasibility. Yuan and Dong [13] proposed a construction simulation inverse method of prestressed structures based on the inverse process of erection.

However, the dismantling of cable-strut tension structures has received little attentions. As time goes on, a large number of cable-strut tension structures will be demolished due to the degraded performance and inadequate use as time goes on, while there are some challenges resulting from complex structural

Copyright © 2023 by Jiaqi YANG, Yue WU and Guangyao XIN. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

system need to be addressed, such as complex force transferring path, adverse effects of internal force release. Therefore, this study conducted experiment and numerical analysis on the dismantling method of the typical cable-strut tension structure, wheel-spoke structural system, giving a reference for the dismantling project of the same type of prestressed structures.

2. The dismantling methods

The cable-strut tension structures usually be erected by dragging radial cables using winches and tension devices. Studies have demonstrated that demolishing these structures by directly cutting off cables results in prestress release, producing a vibration that affects surrounding people and buildings [14]. Therefore, the dismantling of cable-strut tension structures is achieved through the relaxation of cables, and the relaxed cable is defined as the active cable. Taking the wheel-spoke prestressed structures which is the typical cable-strut tension structure for instance, four dismantling methods were proposed in reference to the erection of the wheel-spoke cable-strut tension structures.

The first dismantling method is achieved by relaxing radial cables, and the main steps are as follows: (1) arrange some relaxation devices on lower radial cables; (2) relax lower radial cables gradually to make the structure slack, and meanwhile, remove all struts and lower cables; (3) relax upper radial cables until the upper inner ring reach the ground; (4) remove the remaining components, and the dismantling is completed.

The second dismantling method is achieved by relaxing inner ring cables, and the main steps are as follows: (1) arrange some relaxation devices on upper or lower inner ring cables; (2) relax inner ring cables gradually to the desired length; (3) arrange some relaxation devices on lower radial cables and relax them, and meanwhile, remove all struts and lower cables; (4) arrange some relaxation devices on upper radial cables and relax them until the upper inner ring reach the ground; (5) remove the remaining components, and the dismantling is completed.

The third dismantling method is achieved by relaxing radial cables in batches, and the main steps are as follows: (1) arrange some relaxation devices on lower radial cables; (2) relax odd-numbered and even-numbered lower radial cables alternately, and meanwhile, remove some struts and lower cables gradually; (3) arrange some relaxation devices on upper radial cables and relax them until the upper inner ring reach the ground; (5) remove the remaining components, and the dismantling is completed.

The fourth dismantling method is achieved by relaxing radial cables and dropping inner rings, and the main steps are as follows: (1) arrange some hoisting points at the inner ring in the centre of the structure; (2) arrange some relaxation devices on lower radial cables, and relax them gradually to make the structure slack, and meanwhile, remove some struts and cables; (3) drop the inner rings by relaxing hoisting ropes until the upper radial cables become slack, and the remove all upper radial cables; (4) drop the inner rings continuously until they reach the ground; (5) remove the remaining components, and the dismantling is completed.

3. Numerical study

3.1. Numerical simulation method based on VFIFE

Due to the nonlinear finite element method has several challenges caused by the singularity of the stiffness matrix of assembly with geometrical instability. Therefore, the vector form intrinsic finite element (VFIFE) was proposed to solve strong nonlinear problems such as large deformation, fracture, and collision. Therefore, this study adopted the VFIFE method to simulate the dismantling process of the wheel-spoke cable-strut tension structures. The main principles of the simulation method are as follows.

The strut is simulated using the 3D bar element which can only bear the axial force. Assuming that a bar element moves in a path element ($t_a \sim t$), the internal force at time t can be calculated as follows:

$$F_t^{int} = F_{ta}^{int} + \Delta F_t^{int} = F_{ta}^{int} + EA\Delta\varepsilon \tag{1}$$

where F_{ta}^{int} is the internal force at time t_a, ΔF_t^{int} is the internal force increment from time t_a to t, E is the Young's Modulus, A is the cross-section area, $\Delta\varepsilon$ is the strain increment.

The cable element is simulated using a straight-line model. The solving process of internal force is the same as the 3D bar element. The difference is that the cable element cannot be compressed. Therefore, the internal force is set to zero when the cable element is slack under compression and expressed as follows:

$$F_t^{int} = \begin{cases} F_{ta}^{int} + \Delta F_t^{int} & \text{tension} \\ 0 & \text{compression} \end{cases} \tag{2}$$

The relaxation of cables is achieved by applying temperature loads, and the internal force increment of the cable element can be calculated as follows:

$$\Delta F_t^{int} = EA\left[\Delta\varepsilon - \alpha\left(T_t - T_a\right)\right] \tag{3}$$

In addition, the outer ring beam of the structure can be defined as the 3D beam element in the numerical model that can bear axial force, shear force, bending moment and torque simultaneously, and each node of the 3D beam element having six degrees of freedom. Assuming that the 3D beam element moves in a path element ($t_a \sim t$), the internal force increment vectors are written as follows:

$$\Delta\hat{\mathbf{F}}_t^{int} = \begin{bmatrix} \Delta\hat{f}_1^1 \\ \Delta\hat{f}_1^2 \\ \Delta\hat{f}_1^3 \\ \Delta\hat{f}_2^1 \\ \Delta\hat{f}_2^2 \\ \Delta\hat{f}_2^3 \end{bmatrix} = \begin{bmatrix} -\dfrac{EA}{l_a}\hat{\Delta}_e \\ \dfrac{6EI_3}{l_a^2}\left(\hat{\varphi}_1^3 - \hat{\varphi}_2^3\right) \\ \dfrac{6EI_2}{l_a^2}\left(\hat{\varphi}_1^2 - \hat{\varphi}_2^2\right) \\ \dfrac{EA}{l_a}\hat{\Delta}_e \\ -\dfrac{6EI_3}{l_a^2}\left(\hat{\varphi}_1^3 - \hat{\varphi}_2^3\right) \\ -\dfrac{6EI_2}{l_a^2}\left(\hat{\varphi}_1^2 - \hat{\varphi}_2^2\right) \end{bmatrix}, \quad \Delta\hat{\mathbf{M}}_t^{int} = \begin{bmatrix} \Delta\hat{m}_1^1 \\ \Delta\hat{m}_1^2 \\ \Delta\hat{m}_1^3 \\ \Delta\hat{m}_2^1 \\ \Delta\hat{m}_2^2 \\ \Delta\hat{m}_2^3 \end{bmatrix} = \begin{bmatrix} -\dfrac{GI_1}{l_a}\hat{\varphi}_1^1 \\ \dfrac{EI_2}{l_a}\left(4\hat{\varphi}_1^2 + 2\hat{\varphi}_2^2\right) \\ \dfrac{EI_3}{l_a}\left(4\hat{\varphi}_1^3 + 2\hat{\varphi}_2^3\right) \\ -\dfrac{GI_1}{l_a}\hat{\varphi}_1^1 \\ \dfrac{EI_2}{l_a}\left(2\hat{\varphi}_1^2 + 4\hat{\varphi}_2^2\right) \\ \dfrac{EI_3}{l_a}\left(4\hat{\varphi}_1^3 + 2\hat{\varphi}_2^3\right) \end{bmatrix} \tag{4}$$

Based on the above theory, the numerical simulation procedure of dismantling process for the prestressed structures is proposed in this study shown in Figure 1.

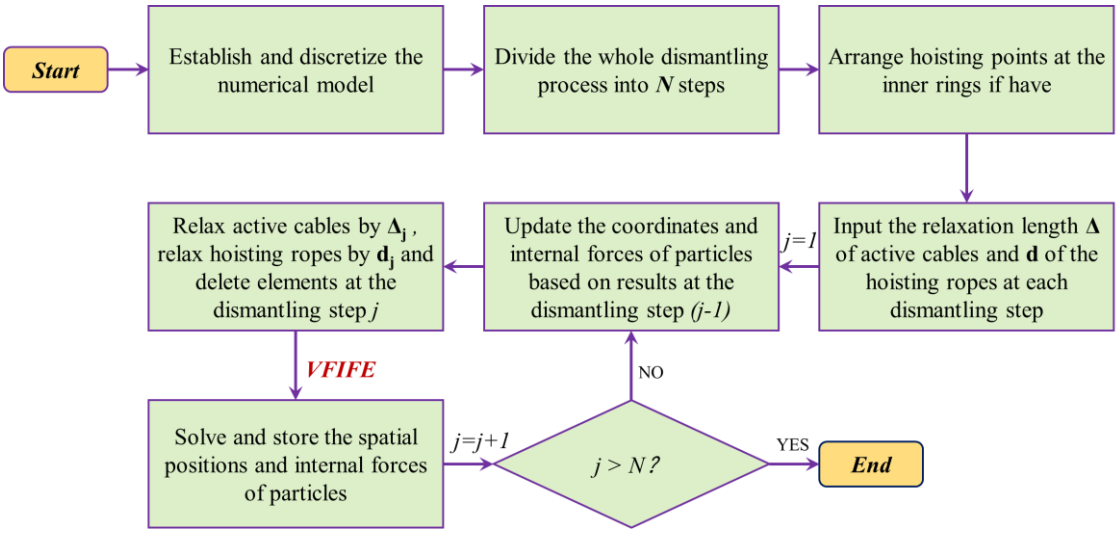

Figure 1. The numerical simulation procedure of the dismantling process

3.2. Comparative analysis of dismantling methods

This section compared the four dismantling methods in terms of mechanical state, dismantling efficiency and cost of relaxation devices. The model for comparative analysis is shown in Figure 2 that is a traditional wheel-spoke cable-strut tension structure. The main components of the model including upper radial cables, lower radial cables, inner ring cables (upper and lower ring), crossed cables between inner rings, four circle struts, outer ring beams and columns. The horizontal projection of the outer ring and inner ring in the model is the circle with the span of 160 m and 80m, respectively. The height of inner rings is 20m.

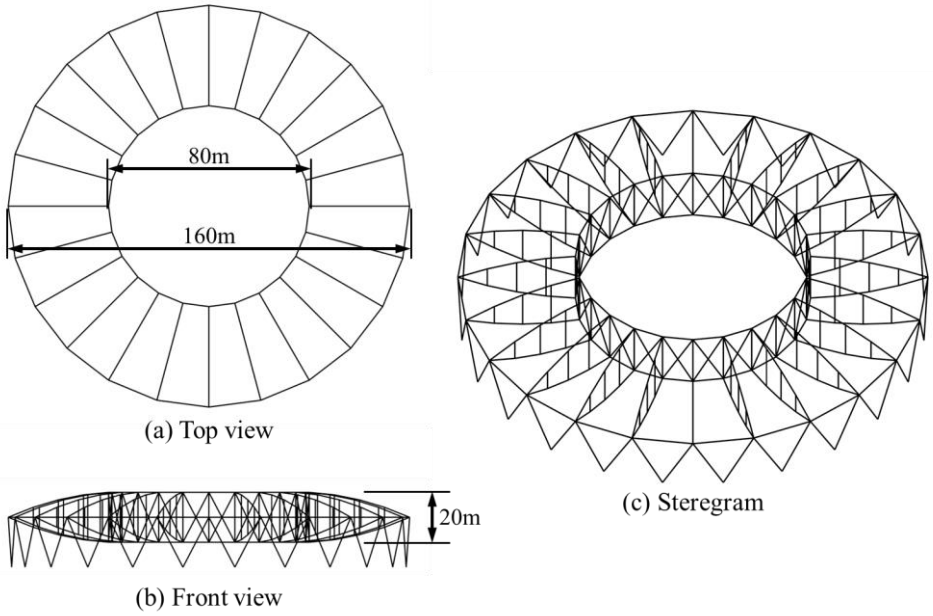

Figure 2. The model for comparative analysis

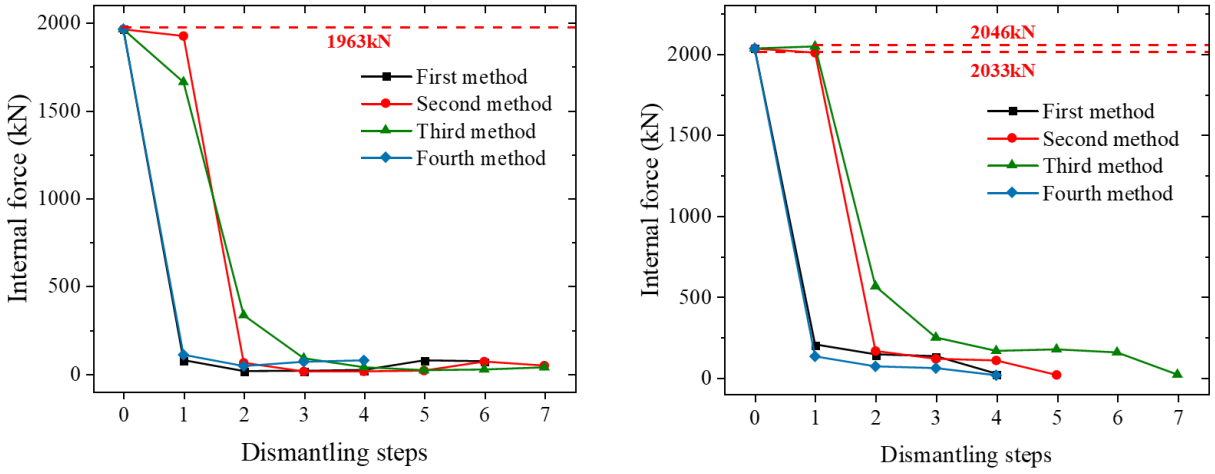


The dismantling efficiency when removing struts at outer circles can be measured by the average relaxation length of the active cables. Table 1 lists the average relaxation lengths of active cables for four dismantling methods. We can know that the relaxation length of the fourth method is the smallest,

which indicates that the fourth method has higher efficiency when relaxing active cables to remove struts.

Table 1. The average relaxation lengths of active cables for four dismantling methods

	First circle struts	Second circle struts	Third circle struts
First method	291	100	496
Second method	260	86	413
Third method	397	100	255
Fourth method	205	120	0

The internal forces of cables during dismantling of four methods are shown in Figure 3. The model is very sensitive to the relaxation of cables and was slack gradually during dismantling. This means it is effective to dismantle wheel-spoke cable-strut tension structures according to the idea of releasing prestress by relaxing cables. In addition, the load-bearing capacity of the relaxation device is determined by the internal force of the active cable during dismantling. The higher the load-bearing capacity requirement, the higher the design cost. As shown in Figure 3, the load-bearing capacity of the relaxation device for lower radial cables should be greater than 2033 kN, 2033 kN, 2046 kN and 2033 kN for the first, second, third and fourth methods, respectively. And the relaxation devices for upper radial cables should be greater than 1963kN for four methods. Therefore, the third dismantling method has least economic advantage due to the high requirement of relaxation device. This study also found that the crossed cables adjacent to the relaxed inner ring cables increased by more than ten times in the second dismantling method, which will greatly increase the risk of dismantling work.

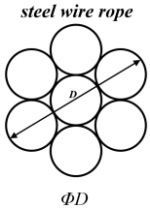
(a) Upper radial cables (b) Lower radial cables

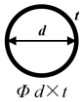
Figure 3. The internal forces of cables during dismantling

According to the above analysis, relaxing inner ring cables in second method and relaxing lower radial cables in batches in third method are adverse for dismantling wheel-spoke cable-strut tension structures. Therefore, the first method of relaxing radial cables and the fourth method of dropping inner rings are advised in this study. The fourth method has higher dismantling efficiency than first method.

4. Experimental study

4.1. Experimental model





The experimental model is shown in Figure 4 that adopted the wheel-spoke cable-strut tension structural system. It comprises upper cables, lower cables, upper ring cables, lower ring cables, crossed cables between upper and lower inner rings, struts and an outer ring beam. The upper cables are crossed with each other, and the lower cables are orthogonal with the inner ring cables. The columns and braces are arranged between the outer ring beam and the steel support platform.

The horizontal projection of the experimental model is an ellipse, whose major and minor axis lengths are 12.675 m and 11.750 m, respectively. The maximum cantilever length is 3.010 m. The elevation of the upper ring cable, lower ring cable and the outer ring beam is 2.904 m, 1.932 m, and 2.340 m, respectively. The properties of components in the experimental model is listed in Table 2. As shown in Figure 5, There are 56 upper cables (UCs) and 56 lower cables (LCs) in the experimental model. The connections between cables and steel components are shown in Figure 6.

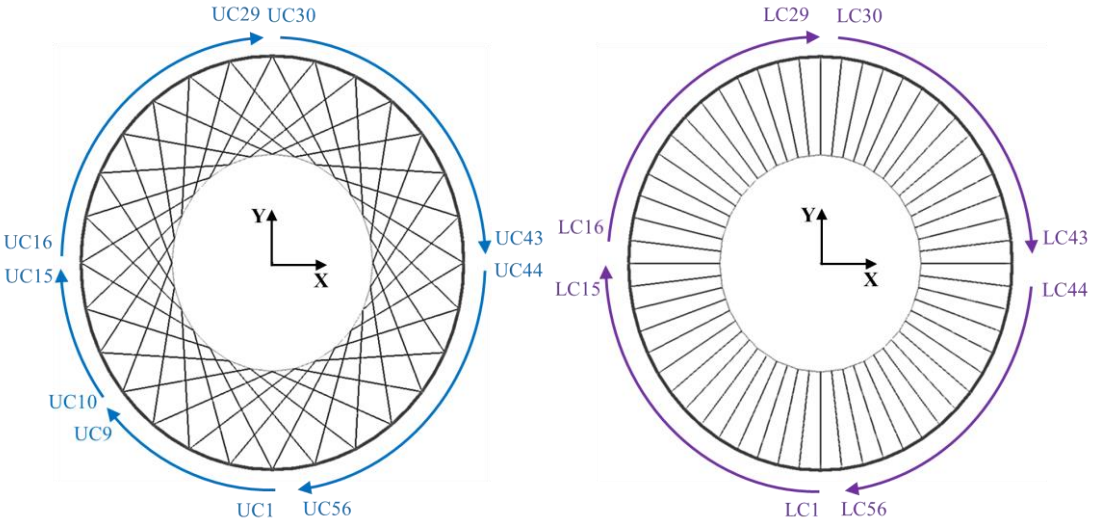


Figure 4. Experimental model

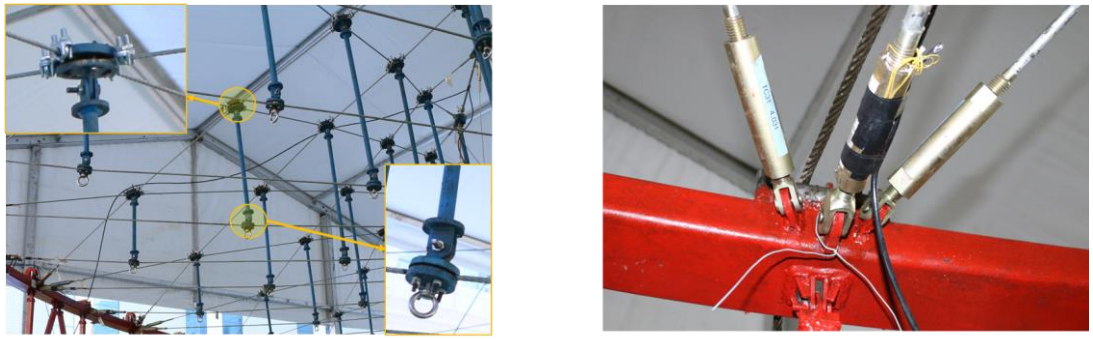
Table 2. The properties of components in experimental model



Component name	Type	Cross section (mm)	Young's modulus (N/mm^2)	Density (kg/mm^3)
Upper ring cable	steel wire rope  ΦD	Φ11	1.60×10^5	6.5×10^3
Lower ring cable		2Φ14	1.60×10^5	6.5×10^3
Upper cable		Φ6	1.60×10^5	6.5×10^3
Lower cable		Φ7	1.60×10^5	6.5×10^3

Figure 6. The connections between cables and steel components

4.2. Dismantling scheme

The dismantling scheme of the experimental model was made according to the fourth method described in Section 2. The lower cable was regarded as the active cable and relaxed using the relaxation device. The dismantling process is described in detail as follows:

Stage 1: The first stage is to arrange seven hoisting points at structural center using the masts and chain hoists, as shown in Figure 7. Afterward, the hooks of the chain hoist are connected to upper ring cable nodes. The length of the iron chain with the hook can be adjusted manually.

Stage 2: In this stage, the odd-numbered lower cables (LC1, LC3, …, LC53, LC55) are considered active. They are relaxed in three steps (steps 1 - 3). The outer struts at the fifth circle are removed after step one, and the outer struts at the third circle are removed after step two. The active cables are relaxed at step three until they became slack. After undergoing all three steps, the odd-numbered lower cables are removed.

Stage 3: The even-numbered lower cables (LC2, LC4, …, LC54, LC56) are considered active in this stage. They are relaxed in four steps (steps 4 - 7). The outer struts at the sixth, fourth and second circles are removed after steps four, five and six, respectively. The active cables are relaxed at step seven until they are slack, and the even-numbered lower cables are removed at this step.

Stage 4: In this stage, the iron chains with the hook of the hoist chain are relaxed, dropping the residual model until the upper cables are slack at step eight. Subsequently, the slack upper cables are removed.

Stage 5: This stage is to relax the iron chains with the hook of the hoist chain until the lower ring cables reach the ground. Afterward, the crossed cables, inner struts and lower ring cables are removed.

Stage 6: This stage involves dropping the inner rings to the ground, removing the remaining components, and sorting them for storage.

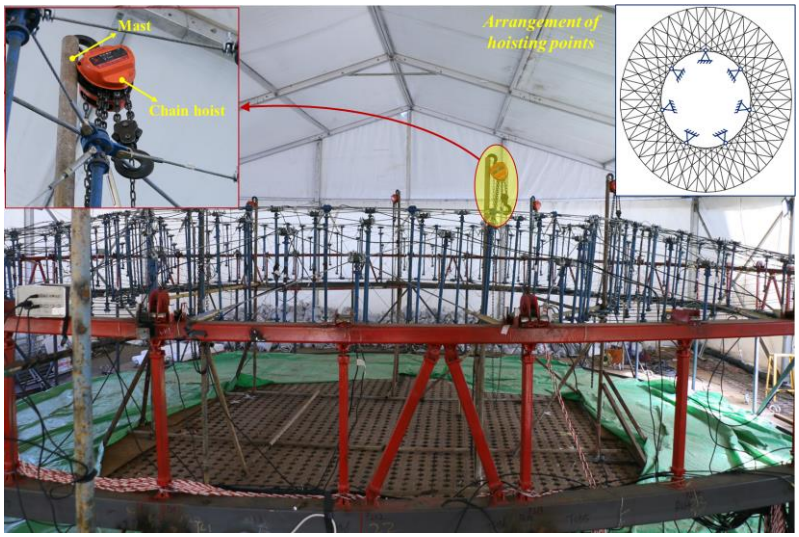

Figure 7. Arrangement of hoisting points

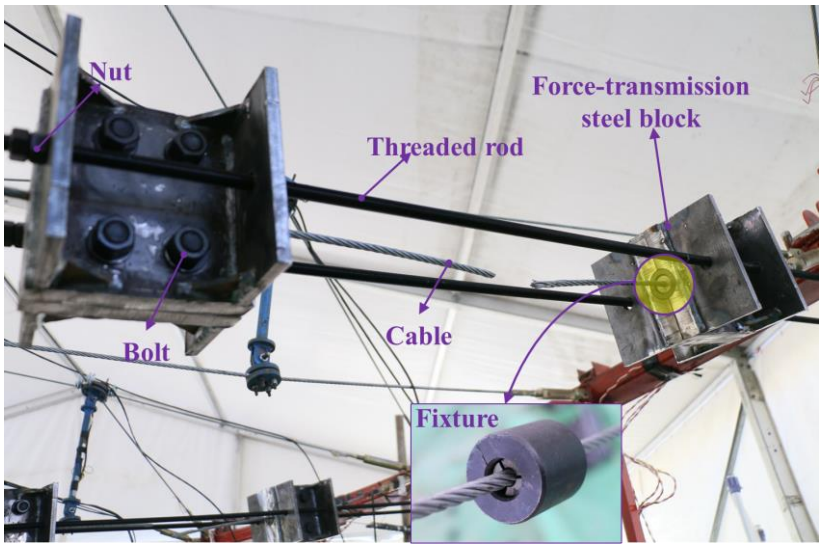
The designed relaxation device is shown in Figure 8. It consists of two force-transmission steel blocks, two threaded rods and two fixtures. The force-transmission steel block can be divided into two pieces connected by four bolts to facilitate installation. A single cable can be tensioned and relaxed by the mean of screwing nuts at the end of threaded rod to make two force-transmission steel blocks close to or away from each other.



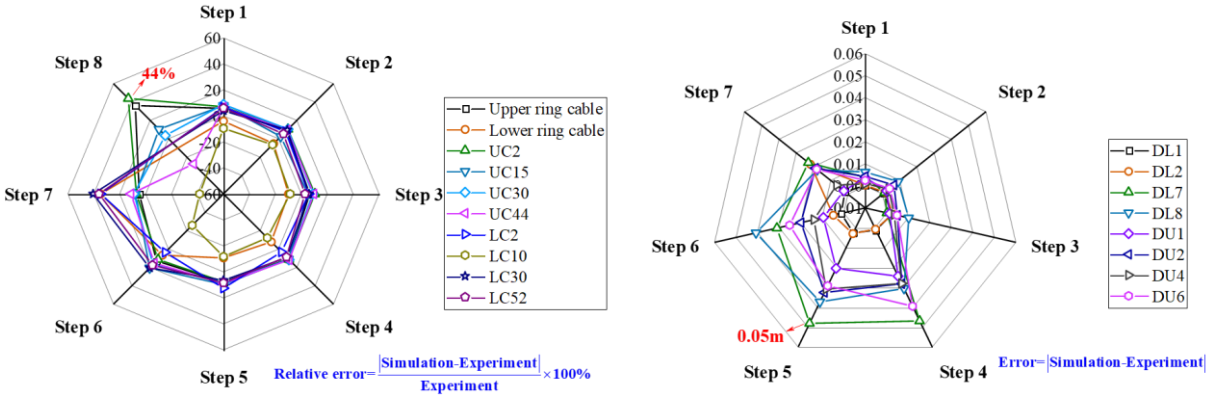


Figure 8. The relaxation device of a single cable

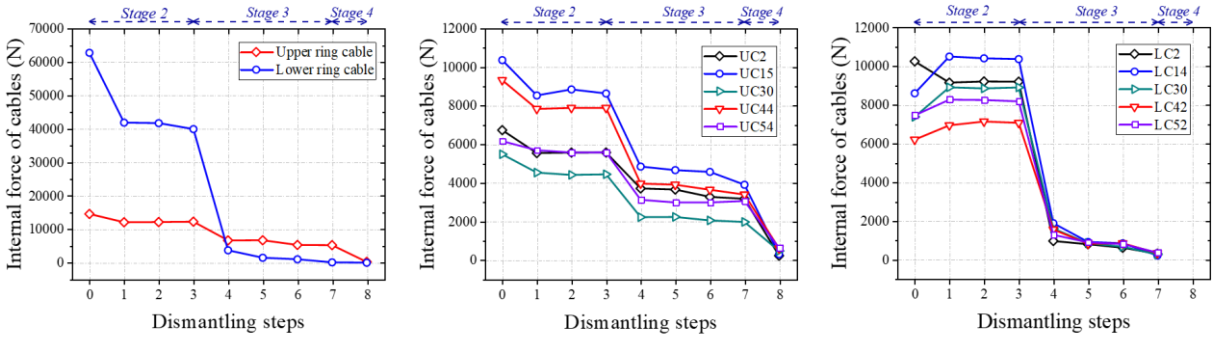
4.3. Results and discussion

The dismantling process of the experimental model was simulated successfully through the proposed numerical simulation method. The damping coefficient was 100, and the time step was 0.0001 s. The calculation stopped when the unbalanced force at each particle was less than 0.1 N.

The errors between experimental and numerical results during dismantling are shown in Figure 9. As we can see, the maximum relative error of the internal force is 44%, which is large and occurs in UC2 at step eight, but the absolute error is only 72 N obtained by the absolute value of the difference between the experimental and the simulated results, which is not large. And the maximum deviation of the nodal vertical displacement is 0.05 m that is 1/255 of the structural span, which occurs in DL7 at step five. The measured errors, accumulative errors and control errors are main reasons that large errors occur during dismantling. In summary, the numerical simulation method proposed in this paper can assist practitioners to formulate the dismantling process with high accuracy.



(a) The relative errors of the internal force (unit: %)

(b) The errors of the nodal vertical displacement (unit: m)

Figure 9. Errors between experimental and numerical results during dismantling

Moreover, the internal forces of cables during dismantling are shown in Figure 10. We can see that the prestress of the experimental model is almost completely released as the relaxation of the active cable and the drop of the inner ring, which reduces the adverse effects of the removal of components. This

indicates the dismantling scheme of the experiment model is feasible. Therefore, the wheel-spoke cable-strut tension structure can be dismantled successfully using the method of dropping inner rings.

Figure 10. The internal forces of different cables during dismantling

5. Conclusions

The dismantling methods of cable-strut tension structures are studied, and the main conclusions are as follows:

(1) It is effective to dismantling the cable-strut tension structures based on the principle of releasing inside prestress by relaxing cables.

(2) The method of relaxing inner ring cables and relaxing lower radial cables in batches are adverse for dismantling wheel-spoke cable-strut tension structures. And the method of relaxing radial cables and the method of dropping inner rings has more advantages on efficiency, safety and economy. This can be used as the reference for practical dismantling projects.

(3) The numerical simulation method based on VFIFE is accurate in tracking the dismantling process of cables-strut tension structures, which provides an effective tool for the numerical analysis and validation of dismantling process.

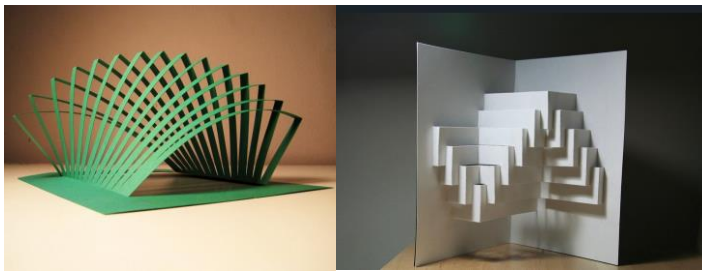
Abstract

Kirigami originates from origami where cutting and folding are combined. The idea of kirigami has been employed in kinematic structure where movement of stretching and folding are made possible. Foldable modular structure unit inspired by kirigami is explored in this study. It is aimed at achieving a foldable structure which has the benefits of minimum space storage requirement and ease in transportation. Kirigami inspired foldable structures have seen application in furniture design. This study focuses on application of idea of kirigami in structures such as bus stops, exhibition booths and structures of temporary nature. In order to achieve a structural concept of kirigami inspired modular foldable structure unit, this study has experimented with three different planar geometrical shapes upon which kirigami patterns are cut: hexagonal, square and triangle shapes. The cut kirigami patterns on different planar geometrical shape are chosen such that the corresponding 3D structure is formed after folding of the planar shape. After considering the ease of arranging modular units in different patterns(such as back-to-back, side-by-side) to form structures with different outlook, the one with triangular geometrical planar shape has been chosen. The study has also experimented with the construction of a full scale kirigami inspired triangular foldable modular unit made of wooden panel to test the feasibility of the proposed idea.

Keywords: kirigami, deployable structure, modular structure

1. Introduction



The concept of kirigami originates from origami where cutting and folding are combined. It is used in kinematic structure where stretching and folding are possible. The use of kirigami to form different architecture objects was pioneered by Chatani[1]. Taking advantage of properties of kirigami, method to design kirigami pattern[2] and computational tool for design of kirigami-inspired lightweight metamaterial[3] have been proposed. A review of recent advances in kirigami design has been compiled by Tao et al[4]. Figure 1 shows examples of objects achievable using kirigami. An example of application of idea of kirigami in furniture design is shown in Figure 2.

This study explores the possibility of applying the characteristics of kirigami to the design of foldable modular structure units. The idea is to use the units to form different structure through different arrangement pattern as shown in Figure 3 which has the benefits of minimum space storage requirement and ease in transportation. This study focuses on application to structures such as bus stops, exhibition booths, and any other types of structure for temporary usage.

The layout of the paper is as follows: i. the experimental study on basic plan geometry, kirigami pattern and folding process of foldable modular unit is first described; ii. detailed study on possible layouts of

arrangement to form different final structures are next presented; iii. the construction of a full scale foldable modular unit is described.

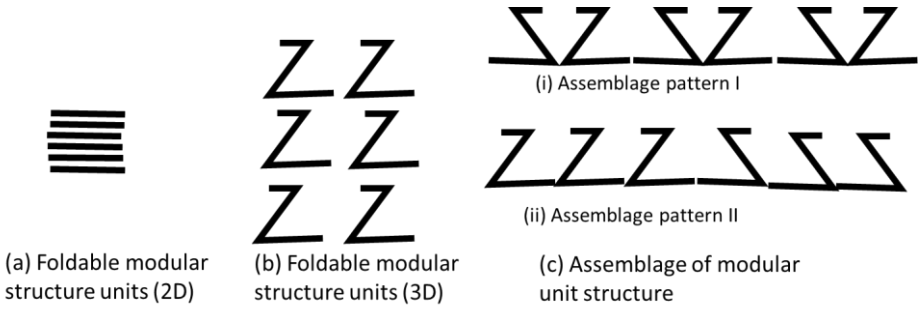

Figure 3. Assemblage of foldable modular structure units.

2. Experimental study on foldable modular structure units

The process of design of a suitable foldable modular structure unit involves: i. investigation of possible shape of plan geometry and choice of kirigami pattern, ii. checking of unfolding shape and iii. selection of the suitable design. Choices of the plan geometry and size of the modular unit are to be decided by the designer. It is important to take note that the plan geometry affects the posible arrangement pattern of modular units while kirigami pattern affects the unfolding process and the final unfolded shape of the modular unit. The type of kirigami structure adopted is the so-called 90° angle type[5] where the single

sheet of paper is folded into two via bending and cutting. Three types of plan geometry were considered: triangle, square and hexagon. The plan geometry was first drawn using AUTOCAD and then mirrored. Kirigami pattern was then added. The pattern was chosen in such a way that a final wall-roof modular structure unit could be formed in the unfolded state. Figures 4 to 6 show the process of design of modular structure unit with plan geometry of triangle, square and hexagon, respectively.

Paper models where then formed based on AUTOCAD drawing with proper cut lines. Figures 7 to 8 show the unfolded shape of the modular structure unit based on plan geometry of triangle, square and hexagon.

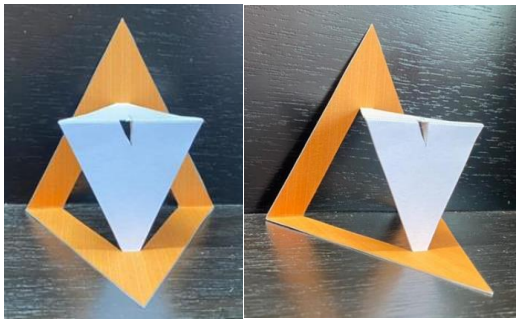

Figure 7. Unfolded shape of triangular modular structure unit.

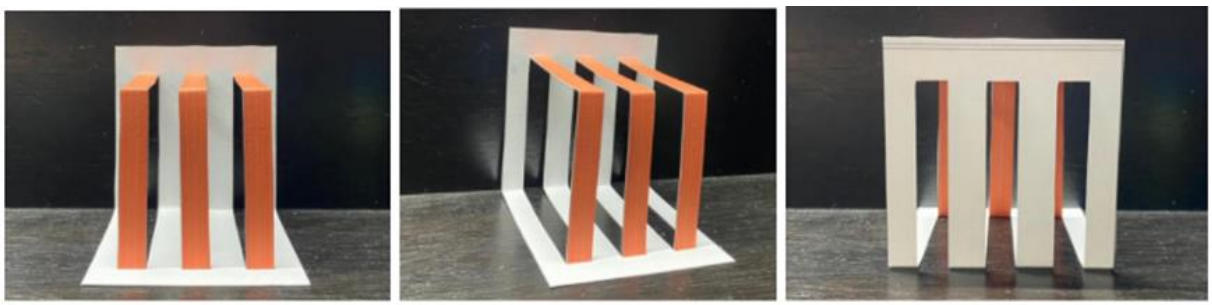

Figure 8. Unfolded shape of square modular structure unit.

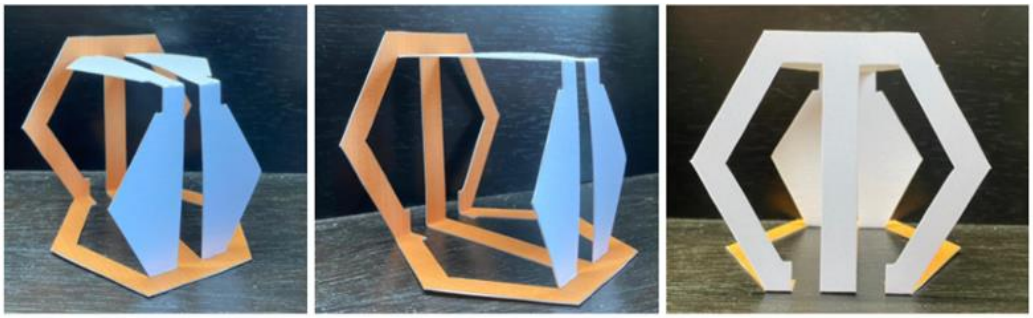

Figure 9. Unfolded shape of hexagonal modular structure unit.

Triangular foldable modular structure unit as shown in Figure 4 and 9 was chosen for further investigation into different possible structure through different arrangement or assemblage patterns of the units. Figure 10 shows the planar drawing of the foldable triangular modular structure unit used for further investigation while Figure 11 shows the paper model of the unfolded triangular modular structure unit. Outcomes of arrangement patterns with units being placed side-by-side and back-to-back were studied. Figures 12 and 13 show the structures formed by placing the unit back-to-back and side-by-side, respectively. By combining of groups of structure formed by side-by-side placement of the triangular modular units, a larger closed loop structure can be formed as shown in Figure 14. The

possibility of forming double layer structure using the triangular modular structure unit was also explored as shown in Figures 15 and 16.

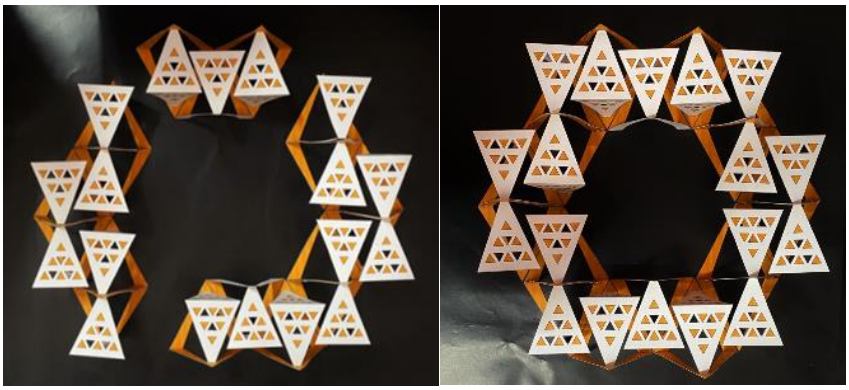

Figure 14. A close-loop structure is formed by combining groups of modular units placed side-by-side.

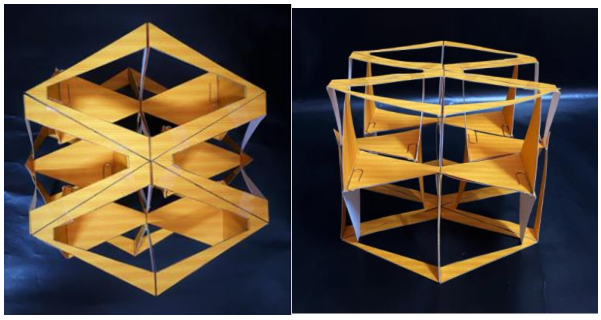

Figure 15. A basic double-layer structure formed using the triangular modular units.

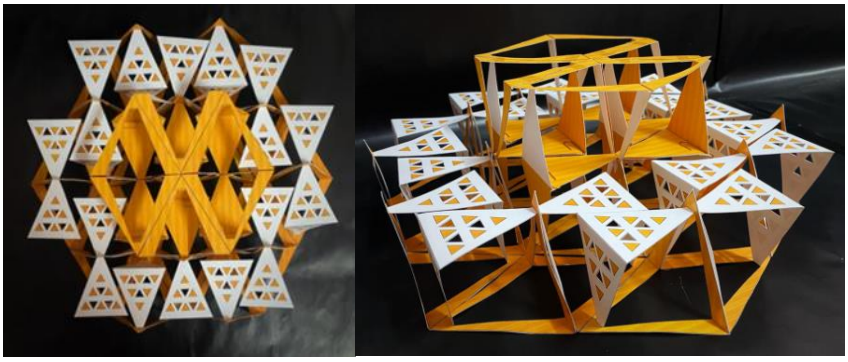

Figure 16. Combination of single-layer and double-layer units formed by the triangular modular units.

3. Physical model of the foldable triangular modular unit

A physical model measuring 2.8 m × 2.425 m (size of base triangle) and 2.425 m (height) was constructed. Plywood with thickness of 12 mm was used. Modular units which were cut based on dimension given in Figure 10 was first made (see Figure 17). Then, hinges were installed in location

of fold lines as shown in Figure 18. The unfolded shape of the physical model of the foldable triangular modular unit is shown in Figure 19.

Figure 17. Parts of the triangular modular unit.

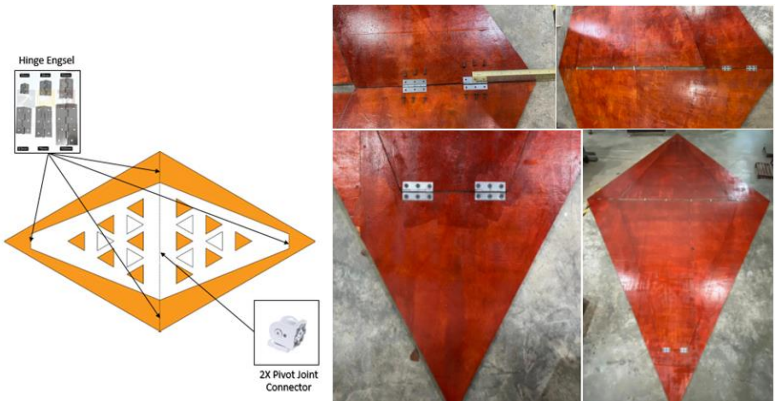

Figure 18. Locations of hinges.

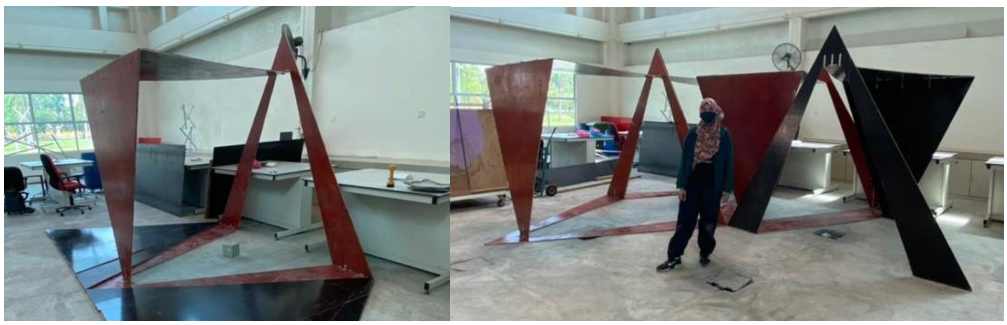

Figure 19. The completed physical model of foldable triangular modular unit.

4. Conclusion

Foldable modular structure unit inspired by kirigami which can be arranged in different pattern to form different structure was proposed. A physical model of the chosen foldable triangular modular structure unit was construction to investigate the practicality of the proposed modular unit. Future study to improve hinge design and to study the structural behaviour of the proposed unit should be carried out in order to bring the proposed idea towards reality.

Comparison of biologically inspired functionally graded deployable geosystems with experimental measurements

Abstract

Deployable structures provide novel methods for resisting tensile forces for underground geosystems. A rotationally deploying geosystem has been developed and can be improved upon through the design of the material construction of the awns. A rigidity-based graded design is biologically inspired and is matched with the expected function of the geosystem. This paper presents an experimental methodology to design and test the optimization of the existing geosystem through the use of functionally graded materials (FGMs). The paper also presents awn grading patterns using FGMs and their experimental results using the developed methodology. By concentrating stiffer material at the bottom of the awn, the awn will deploy out of plane. This is expected to lead to a higher resistance capacity for the system as increases the projected surface area of the awn. A parametric design script will translate planar patterns onto the curved awns and they will be manufactured by a multi-material 3D-printer. This paper determines whether the presented experimental methodology is appropriate for testing material optimization of the awns. It also utilizes this process to design functionally graded materials that improve geosystem performance. The design and experimental methodologies successfully allow for the understanding of how FGMs can be applied to the geosystem. Improving the performance of the geosystem through functionally graded materials would allow for more sustainable construction.

Keywords: deployable, compliant, geosystem, parametric design, experimental validation, functionally graded materials

1. Introduction

1.1 Deployable structures

Deployable structures are structures that move from a compact state to an expanded state, changing shape as they change size [1]. Tuneable flexibility is possible depending on the type of joints and materials used in the structure [2]. Rigid deployable structures, like scissor structures [3] are comprised of materials with high stiffness and need joints in order to deploy. These structures may require locking connections [4]. Single-use deployable structures, used in solar sails and other space applications [5] often feature flexible materials. Despite their decreased stiffness in comparison to rigid materials, flexibility allows for more optimal material use. A hybrid between these two extremes, rigid-flexible deployable structures—examples of which include deployable masts with flexible cables [6]—contain a combination of rigid and flexible elements. This combination of materials can also be seen in applications where flexible, compliant joints connect rigid elements [2]. Deployable structures have been constructed aboveground and in space applications but have not yet been extended to underground uses.

1.2 Compliant structures

Compliant structures utilize plastic or elastic deformations to change shape. These shape changes are generally concentrated in a particular element, whereas deployable structures usually change shape on a system-level scale. Requiring a balance between stiffness and flexibility, these structures are least compliant when they maximize stiffness and are most compliant when they minimize stiffness [7]. Compliant structures are also advantageous because they are lightweight, decreasing transportation requirements [8], [9]. These advantages have made compliant structures popular for a wide range of applications including endoscopic cameras [10], aviation parts [10], and—within the building sector—façade components [11]. Despite their utility, compliant structures have not yet been widely used in structural applications.

1.3 Geotechnical structures

Pile anchors are a type of underground foundation system that must resist compression from gravity and tension from friction. Driven pile anchors are advantageous due to their versatility in withstanding a wide variety of load and soil conditions [12]. However, they can have environmental effects during installation [13]. While there are some downsides to using anchor piles, they are advantageous as foundation elements due to their versatility.

Existing research has been done regarding geosystems involving static or shape-changing protrusions. Static radial fins installed on the perimeter of an anchor pile installed in sand were found to better resist uplift loads [15]. Deployable anchor piles have also been explored. For this system, once the pile is installed in sand, wings hinge outward to provide resistance to uplift loads [17]. As of now, geotechnical research has involved static or rigid body motion. The advantages of compliant systems have not yet been explored in geotechnical engineering applications.

1.4 Bio-inspired design

Deployable and compliant structures are found in nature [1], [11]. Leaves unravelling and flowers blooming are two examples of biological deployable compliant mechanisms [18]. Bio-inspired systems have also been developed within the field of civil engineering. Large-scale origami structures inspired by the folding mechanisms of leaves, petals, and insect wings have been developed using joints in place of folds [19]. These origami structures use a deployable compliant system as a precedent, but the compliant features are not preserved in the final design.

1.5 Functionally graded materials

A material is considered functionally graded when changes in the properties of the material are closely matched with the function of the part in which it is used [20]. Functionally graded materials (FGMs) can have advantages as they can match material properties to function [21]. These materials have been used in a wide variety of applications at both small and large scales. At a small scale, artificial ligaments [22] and microfluidic valves [23] have been developed using FGMs. Large scale architectural work has also leveraged these materials. Agricultural shading devices have been created from 3D-printed biopolymers, using different materials to control insect attraction, structural integrity, and solar protection [24]. Knitted textiles have also been created using different stitch patterns as materials to control shading patterns [25]. FGMs have been used at larger scales but have not yet been applied to structural or geotechnical systems.

2. Overview

2.1 Structure description

This work considers a geosystem (Figure 1) that is comprised of a cylindrical tension-loaded pile covered in a system of compliant fin-like attachments. These compliant elements, called awns, deploy

into the sand through rotation. Foundational work of this paper focuses on only a few awns rather than the whole surface of the pile. When deployed, the awns undergo bending as they change shape and size. This entraps soil and increases surface friction.

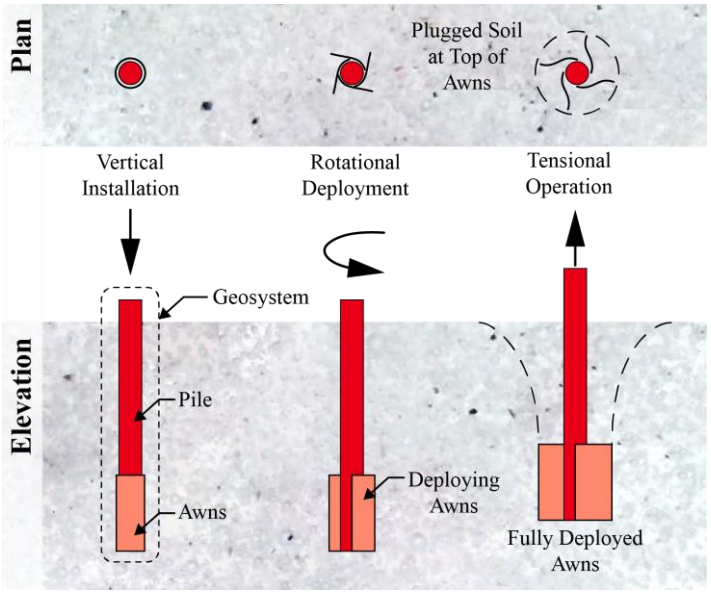

Figure 1. Schematic illustration of the geosystem showing system installation, deployment, and operation.

2.2 Physical fabrication

Additive manufacturing—using a Stratasys Objet500 Connex3 resin 3D printer [26]—was used to fabricate the test members. This machine is capable of printing multi-material parts with a layer thickness of 25 microns over a build volume of 0.5 m x 0.4 m x 0.3 m. GrabCAD Print [27], a software that allows for material selection and model setup, is used to send models to the printer.

Materials with various levels of flexibility are available on the Objet500 Connex3 printer and can be combined with each other to create additional materials with intermediate qualities (Table 1).

Table 1. Polymer materials, their composition, and their properties.

Material Name	**Material Composition**	**Tensile Strength**
VeroMagentaV	100% Acrylic-like resin; Fully rigid	65 MPa [28]
VeroCyan	100% Acrylic-like resin; Fully rigid	65 MPa [28]
Agilus30	100% Rubber-like resin; Fully flexible	3.1 MPa [29]
FLXA-MT-S95-DM-vivid	95% VeroMagentaV, 5% Agilus30; Semi-flexible	62 MPa
FLXA-CT-S95-DM	95% VeroCyan, 5% Agilus30; Semi-flexible	62 MPa

The first three materials noted in Table 1 were used as-is. These included two rigid, acrylic-like materials—VeroMagentaV and VeroCyan—and one flexible, rubber-like material—Agilus30. The following two materials in Table 1 are combinations of the previous materials. The fourth material is a combination of the rigid and flexible materials at a ratio of 95% VeroMagentaV and 5% Agilus30. This produced a semi-flexible magenta polymer called FLXA-MT-S95-DM-vivid. Combining VeroCyan and Agilus30 in the same way produced a similar polymer in cyan called FLXA-CT-S95-DM. This ratio of rigid to flexible material produces a somewhat flexible material and is the most rigid of material

combinations that the Objet500 printer can produce. The tensile strength of FLXA-MT-S95-DM-vivid and FLXA-CT-S95-DM were found by calculating a weighted average of their constituent materials.

3. Methodology

3.1 Awn stiffness variations - global

Initial tests of the geosystem used the semi-flexible polymer, FLXA-MT-S95-DM-vivid [30] as the material was flexible enough to allow the awns to deploy. However, it was important to gain an understanding in how stiffness played a role in the deployability of the system. The variations described here vary the material of the awns to determine whether awns printed in the stiffer VeroMagentaV material would adequately deploy.

An awn with a thin profile was produced in VeroMagentaV and was compared with previously tested awns printed in FLXA-MT-S95-DM-vivid. The VeroMagentaV awn was significantly more rigid than the FLXA-MT-S95-DM-vivid awn.

3.2 Awn stiffness variations - graded

The following set of variations explored awns that program increased stiffness within an awn. These functionally graded awns were inspired by plant structures and concentrated stiffer material at the bottom of the awn to allow for more deformation towards the top of the awn and more stiffness towards the bottom (Figure 2).

Figure 3. Biologically-inspired FGMs applied to a deployable compliant geosystem: (a) geosystem model, (b) leaf, as inspiration and (c) pattern applied onto awn.

Introducing stiffer material at the bottom of the awn would allow the top portion of the awn to deform outwards while keeping the bottom of the awn deploying in the XY plane. This outward deformation would increase the projected surface area of the awn and improve the performance of the awn.

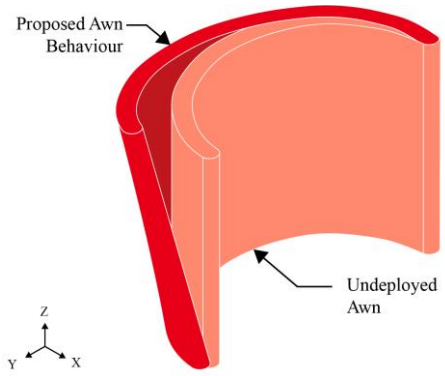

Figure 2. Representation of proposed awn deployment behaviour.

The grading patterns were inspired by the veins in leaves and were drawn flat before being projected onto the curved awns (Figure 4). A baseline awn (Figure 4a) and three patterned awns were compared. The first patterned awn (Figure 4b) had symmetrical linear leaf veins and was positioned so that the

central vein was at the centre of the awn. The second pattern (Figure 4c) featured asymmetric linear leaf veins and was positioned lower on the awn – the centre vein was located at a height of 1/4 times the height of the awn. The last pattern (Figure 4d) was placed at the bottom of the awn and was comprised of two arcs. These two arcs were analogous to the centre vein and the upward-facing vein as seen in the third pattern (pattern c).

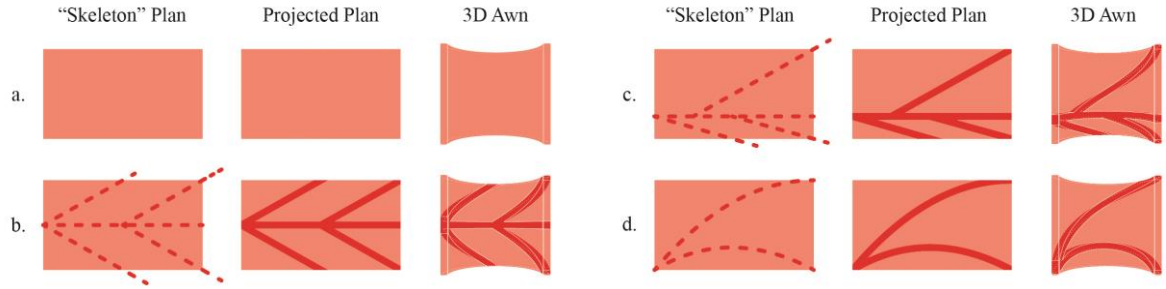

Figure 4. Tested graded patterns and the percentage of rigid material.

In order to transfer the patterns from flat, two-dimensional drawings to a highly-curved three-dimensional awn, Grasshopper—a parametric design tool within Rhinoceros 3D [31]—was utilized. The plugins Parakeet, Pufferfish, Heteroptera, Human, and Telepathy [32]–[36] were also used.

First, an awn footprint was loaded into the definition (Figure 5a). This curve provided the base for the application of the pattern. Each awn was comprised of two connected curves – an inner curve and an outer curve. Once deconstructed (Figure 5b), each curve was discretised into ten linear elements (Figure 5c). The length of these linear curves was defined as l_o for the outer curve and l_i for the inner curve. The linear curves were moved so that they were offset from the original curve (Figure 5d). This ensured that the pattern can be projected in one direction and intersect with the original, non-discretised curve. These offset discretised curves provided the base for the construction of rectangles that were constructed to have the height of the awn (h) (Figure 5e).

The outer pattern canvas was created by generating a rectangle with the length of the ten linear curves (l_o) and the height of the awn (h). The pattern canvas was divided along the horizontal axis so that smaller separator rectangles were created that were the same width as the length of the discretised curves. This process was repeated for the inner curve (Figure 5f). The outer rectangle was baked into the Rhinoceros workspace and a skeleton-like pattern was explicitly drawn in Rhinoceros (Figure 5g). Lines that intersected with the edge of the pattern canvas at an angle were extended so that they would intersect with the edge correctly when thickened. The line-based pattern was loaded into the Grasshopper file and was offset so that each line became 1 mm thick (Figure 5h). This thickened pattern was used throughout the rest of the definition.

The pattern was split into segments corresponding to the separator rectangles. The segments were sorted and reorganized so that ten data branches were created. Each data branch corresponded with and contained the segments located in a single separator rectangle (Figure 5i). The pattern was mapped from the separator rectangles on the larger pattern canvas to the separator rectangles on the smaller one (Figure 5j). These patterns were then mapped from the separator rectangles to the rectangles created from the offset discretised curve (Figure 5k, 5l). The pattern was merged so that unnecessary lines were removed (Figure 5m) and was projected to a surface created by extruding the non-discretised curve (Figure 5n). The solid objects were built from two parts. The first part was created by generating surfaces to fit within the projected curves (Figure 5o) and the second part was formed by connecting the inner and outer curves through the Sweep2 command (Figure 5p, 5q). These two collections of surfaces were joined to create the solid objects (Figure 5r). The final geometry was comprised of a solid awn extruded from the original awn footprint and a collection of solid objects that together create the pattern (Figure 5s).

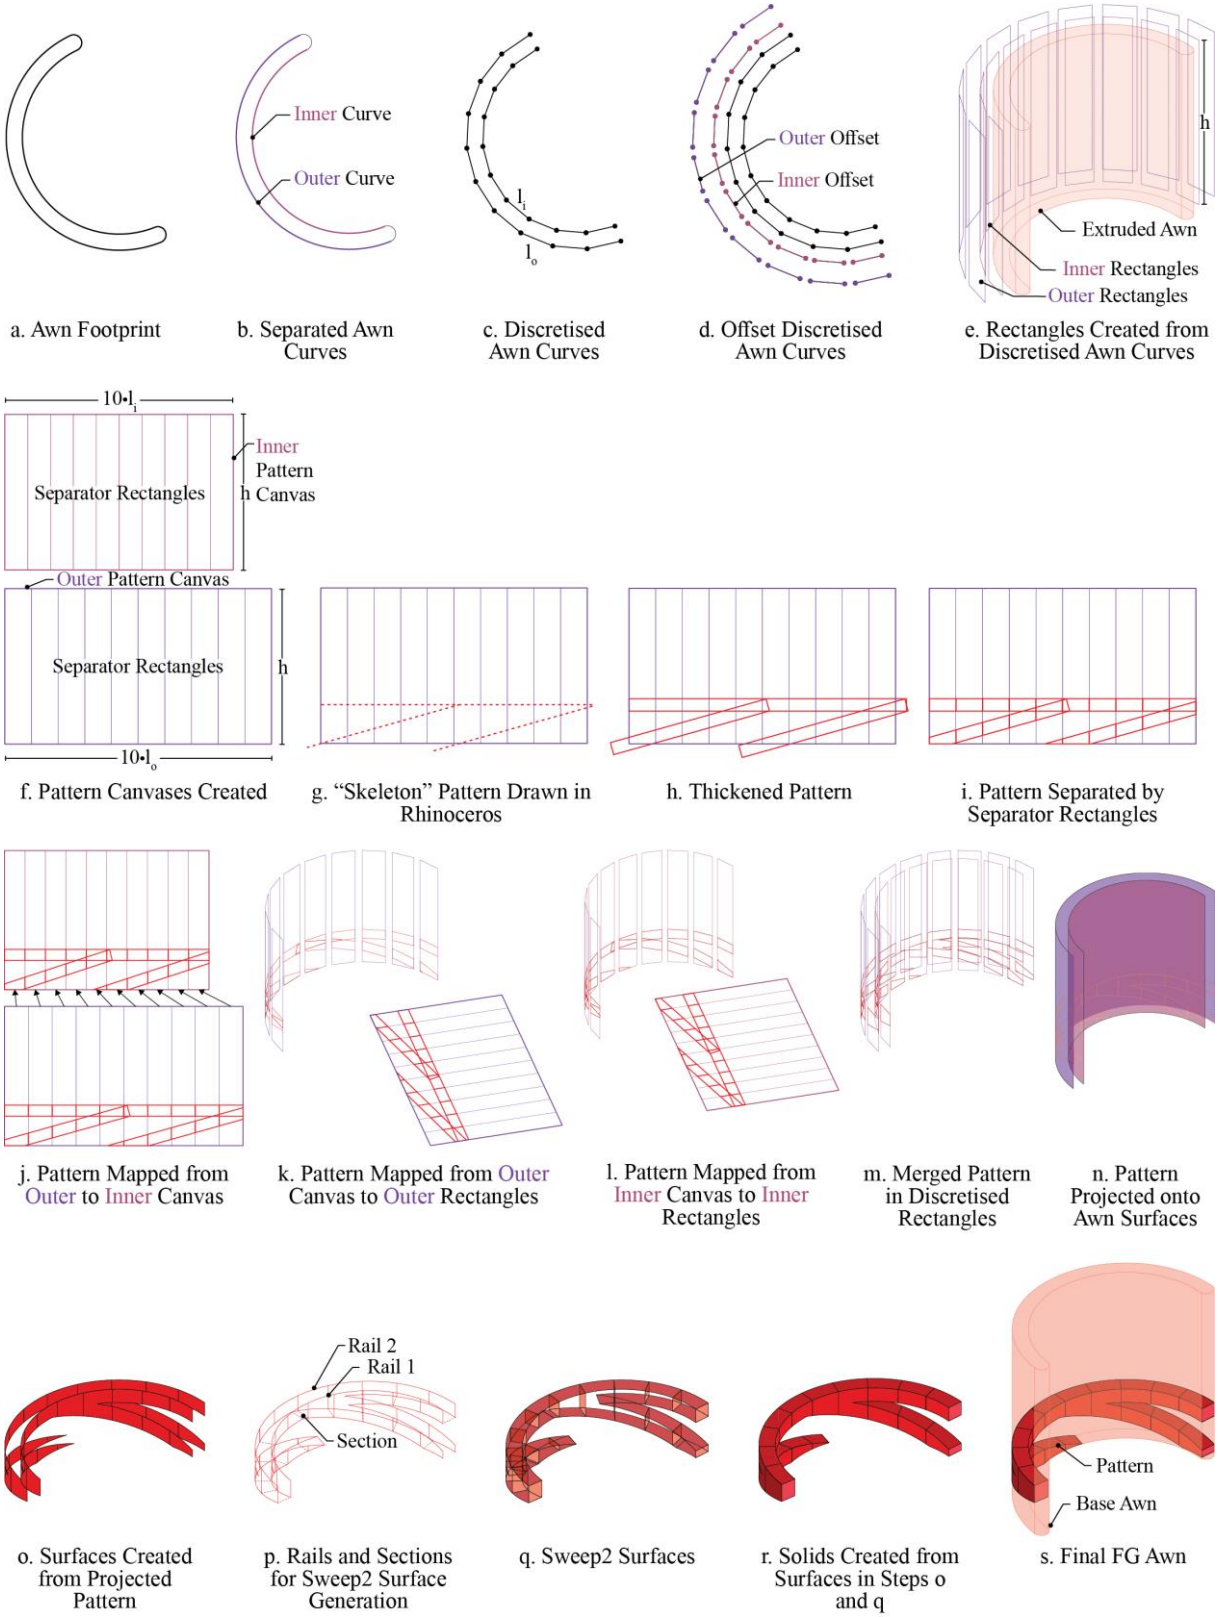

Figure 5. Step-by-step sequence showing generation of a functionally graded patterned awn using the parametric workflow.

A few adjustments were made to the model to facilitate testing. The base awn shape was extended in one direction and a 1 mm wide line was printed in FLXA-CT-S95-DM to ensure that the awn was placed in the same location for each test. Two holes, each with a radius of 1.25 mm, also were created.

Once the three-dimensional model was complete, the awns were printed (Figure 6). The functionally graded awns were loaded into GrabCAD Print to set up the print and used two materials: a semi-flexible background material (FLXA-MT-S95-DM-vivid) and a stiff pattern material (VeroMagentaV). After printing, tracking markers were placed on the awns to show where the start and end of the original awn curve were, excluding the support extension of the awn.

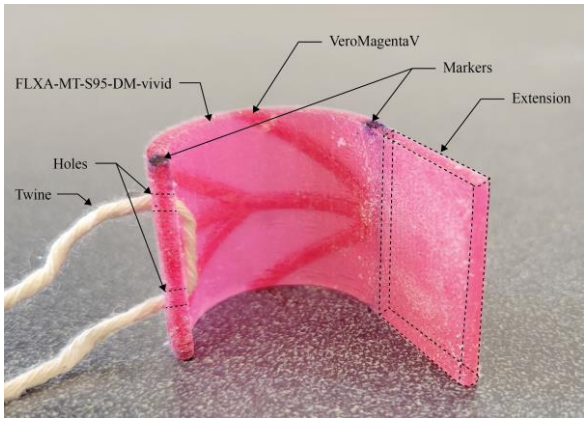

Figure 6. Printed awns for testing, showing materials and parts.

The functionally graded patterns were analysed by performing tension tests on the awns. Cotton kitchen twine was threaded through the two holes on the testing sample so that a knot could be tied on the outside of the awn with 6.4 cm of slack. A PASCO PASPORT High Resolution Force Sensor [37] was placed on the end of the twine. This force sensor has a range of ± 50 N and a resolution of 0.002 N. A piece of 1.905 cm plywood was mounted to a table and the awn was clamped to the edge of the plywood (Figure 7).

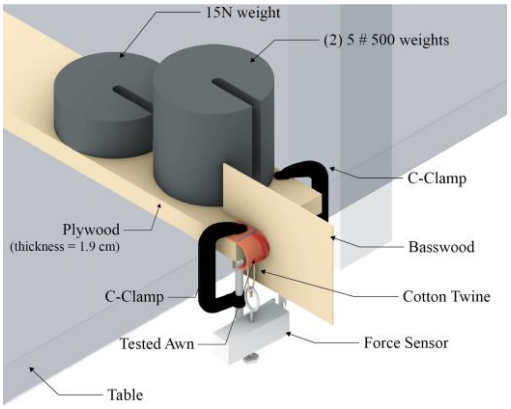

Figure 7. Tension test setup with labels.

An Inswan INS-1 document camera [38] was set up to capture an elevation view of the awn to measure displacement. The PASCO force sensor was recorded on PASCO's Capstone software [39] with a collection rate of 25 Hz. In order to synchronize the force and displacement data, the two outputs were simultaneously recorded with a screen recorder, Open Broadcaster Software (OBS) Studio [40].

The tension tests were performed by loading the awn with 10 N of force, unloading it, and then repeating twice more for a total of three tests. The load was applied instantaneously as plastic deformation and creep are not considered in the scope of this work. The experiment was repeated with the camera facing

the other direction so that both sides of the awn could be analysed (Figure 8). All tests were performed to view the bottom of the awn first and then repeated to view the top.

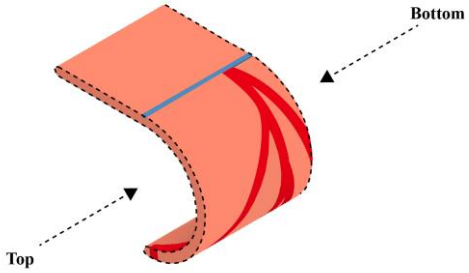

Figure 8. Representation of document camera direction and corresponding awn profiles.

Video frames were extracted from the recordings from the document camera before the test began and at each loading. As the collection rate of the force data was not able to be set to match the frame rate of the displacement data, the still image was extracted for the first frame that recorded a force above 10 N. To process the data, the curves were traced in Rhinoceros 3D. A composite curve was calculated by finding the arithmetic mean of the three loaded curves generated for each pattern. This curve was then compared to the unloaded curve and is discussed in Section 4.2.

4. Results

4.1 Awn stiffness variations - global

When the rigid awns were tested in sand, it was found that the awns did not appreciably deploy (Figure 9).

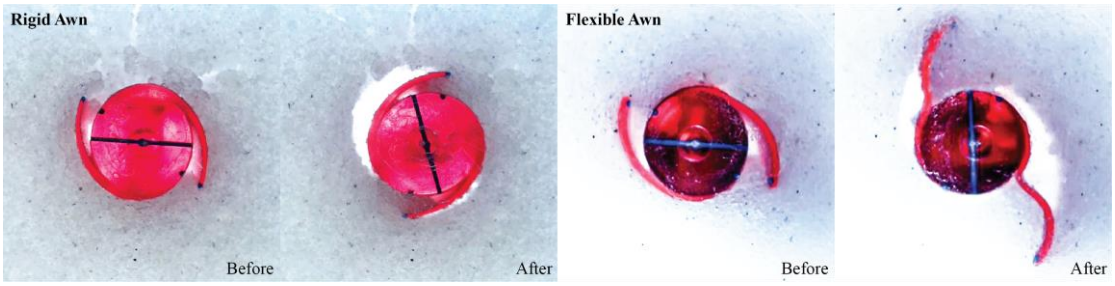

Figure 9. Geosystem with (left) rigid thin awn and (right) flexible awn before and after deployment.

Table 2. Average deployment of rigid and flexible awns.

	Rigid Awns	Flexible Awns
Average Deployment (mm)	0.57	12.41

As shown in Table 2, the rigid awns had deployments under 1 mm. This can be considered negligible, especially in comparison to the 12.41 mm average deployment than can be seen with the flexible awns. Therefore, increasing the stiffness of the awn produced an awn that was incapable of deployment. A more targeted approach is necessary to increase the stiffness of the awns without sacrificing the deployability of the system.

4.2 Awn stiffness variations – graded

The percent elongation of the awns was determined and compared (Figure 10) for both the top and bottom of the awn, as defined in Figure 8.

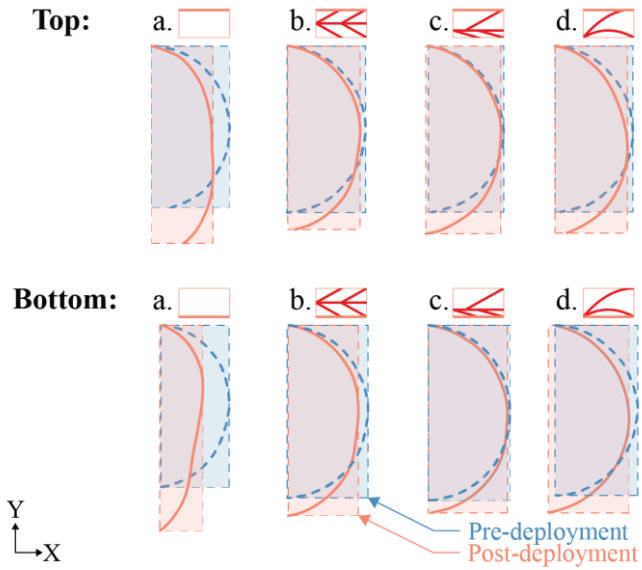

Figure 10. Awn profiles from top and bottom shown before deployment (blue) and after deployment (pink).

Table 3. Percent elongation in the Y direction for the top and bottom of the awn

	a.	b.	c.	d.
Top	22.3%	10.0%	13.0%	12.7%
Bottom	26.9%	10.4%	7.0%	10.3%

Pattern a, a control awn that did not contain a graded pattern, predictably had the most elongation (Table 3). As this awn only contained the semi-flexible FLXA-MT-S95-DM-vivid material, it was the most flexible of the awns tested. Due to the increased stiffness from the pattern in the functionally graded material, the overall stiffness of the awns was greater in patterns b-d compared with a. Pattern b, the symmetrical pattern, showed equal elongation on the top and the bottom of the awn. In contrast, the two asymmetrical patterns—c and d—underwent far more elongation on the top of the awn than the bottom.

These patterns could be helpful in the design of deployable compliant geosystems. A symmetrical pattern like pattern b may help if the geosystem requires slightly stiffer awns than can be achieved with the FLXA-MT-S95-DM-vivid material alone. This type of pattern distributes stiffness evenly throughout the awn. The two asymmetrical patterns—c and d—could be particularly useful because the bottom of the awn elongates less than the top. The bottom of the awn remains flexible enough to deploy but the top of the awn is more flexible. When applied in context on the geosystem, this type of awn can potentially bend out of plane, allowing for a larger projected surface area and more contact with the soil above. Pattern c may be more useful if less flexibility is needed at the bottom of the awn as more material is concentrated there than in pattern d.

6. Conclusions and future work

The parametric design method presented in this paper successfully allows for the design of functionally graded awns. This design method transfers flat patterns to highly curved surfaces for use in deployable compliant geosystems. The work presented here provides a parametric method for the design and an experimental methodology for the assessment and behaviour of the these patterns.

Future work will include more detailed analysis of these and additional patterns. Additionally, these patterns will be applied in context and tested as a full geosystem.

Abstract

This study describes a new shape control method for inspection guide frames that can change according to the shape of obstacles in tunnels. The guide frame is an arch structure that linearly connects VGTs (Variable Geometry Truss) composed of extended actuators and hinges, and its shape can be determined by controlling the length of each actuator. Changing the guide frame by automatic control required confirmation of the position and size of obstacles, and the speed of shape change was slowed in consideration of safety, so it took a lot of time. Against this background, we have developed a feedback control method that allows the guide frame to be freely deformed by placing a pull with a force sensor on a part of the frame and pulling it in the desired direction. Based on the information from the force sensor, the axial force acting on the guide frame was analuzed by using the finite element method, and established a mechanism that can change its shape according to the magnitude of the attractive force. This control method is a simple method of manually deforming the guide frame, and it can be applied to a variety of shapes, and it is effective in terms of safety because the shape can be changed instantly in an emergency.

Keywords: automated inspection system, guide frame, shape adaptation, variable geometry truss, obstacle detection, force control

1. Introduction

Road structures such as bridges and tunnels, which were built in large quantities during the high growth period, have been aging, and in recent years, many structures have increased large -scale repair. Since the tunnel is difficult to modfiy after completion, regular inspections have grasped the progress of deterioration, and maintenance and renewal based on future forecasts are being maintained. In general, regular inspection of the road tunnel regulates the traffic of the car, and the point of the inspection and the auxiliary detectors are performed as close as possible to the inspection site in a high -altitude work vehicle. However, due to the wide inspection range, it takes time to see close visibility and pounding, and long -time traffic regulations are required.

In this study, as shown in Fig. 1, we will construct an inspection system for the outer wall surface that allows movement while avoiding obstacles (disposal equipment, lighting, display boards, etc.) inside the tunnel without the usual traffic control. The stage of practical application has been already reached. In this development, the authors are mainly in charge of development related to variable shape control of inspection guide frames. So far, the three-dimensional laser system that detects obstacles in tunnels have been constructed, and also

Figure 1. View of tunnel inspection system

developed a model device that enables the configuration and shape change of the guide frame, established a method for simulating the shape of the guide frame that avoids obstacles[1].

On the other hand, since the guide frame is operated by an actuator via a motor, it cannot easily change its shape. In addition, considering safety, a mechanism and control to easily move the guide frame in an emergency are also required. Therefore, in order to easily manipulate the shape of the guide frame by human operation, we investigated a deployment method using a force control method. The operator applies a force in the desired direction to move the guide frame, and by transmitting the information of the force sensor to each actuator, the length and speed of its expansion and contraction can be changed. As a result, we aim to develop a force control system that can change the shape of the guide frame.

2. Overview of Tunnel Inner Wall Inspection System

The Tunnel Inspection System aims to replace human close visual inspection and hammering inspection work with robot technology, and is equipped with an inspection unit that automatically detects cracks and floats in the lining concrete. Fig. 2 shows an overview of the tunnel inspection system. Depending on the conditions of the tunnel, a gantry frame type or an aerial work vehicle type equipped with an inspection arm can be used to shorten work time and save labour, while also enabling highly accurate acquisition of the position and shape of floats. In addition, it is possible to efficiently create an inspection report using the acquired inspection data. [2,3,4] The features of this inspection system are shown below.

(1) Flexible Guide Frame: The shape of the guide frame can be freely changed according to the tunnel shape and equipment.

(2) Traveling protection Frame: A frame that runs inside the school and protects third parties from falling concrete pieces during inspections.

(3) Crack Inspection System: Acquire images and unevenness at the same time to identify differences such as cracks and dirt, enabling high-precision detection

(4) Hammering Test Unit: Automatically judge using AI (Artificial Interagency) from the noise of hitting concrete, record the location of the deteriorated part, and display it on the screen

(5) Repair Expert system: Based on the inspection, we propose the optimal repair method that meets the LCC (Life Circle Cost)

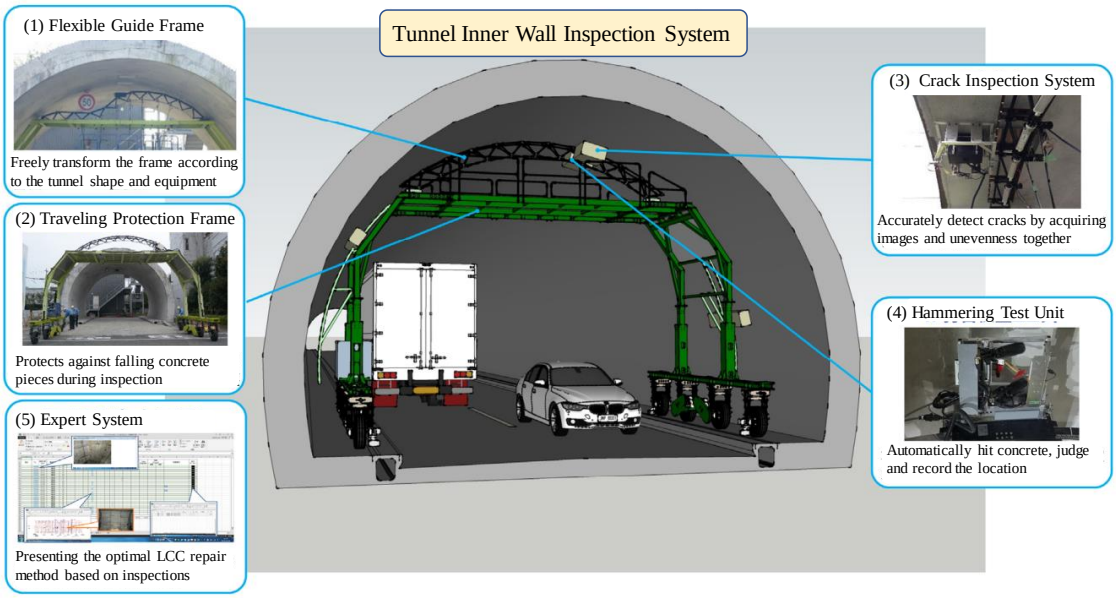

Figure 2. Overview of the tunnel inner wall inspection system and the introduced new technologies

3. Manual deployment experiment of guide frame

3.1. Image of change in shape of guide frame due to manual operation

In this chapter, in order to establish a method that can easily deform the shape of the inspection guide frame, analysis and model experiments using manual operation and force control were performed.Fig.3 shows an image of manual operation of the guide frame. Since the guide frame is composed of multiple VGTs and both ends of the frame are simply supported, part of the shape change affects the entire frame. The operator applies a force F the desired direction to move the end of the guide frame, and by transmitting information from the force sensor to each actuator, changes the extension/retraction length and speed.

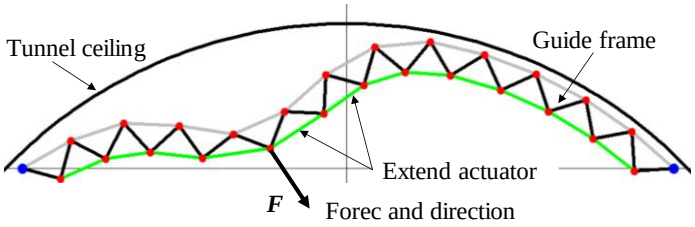

Figure 3. Image of manual operation of the guide fram

3.2. Flow of force control and force sensor

Fig.4 shows the feedback control flow for the shape of the VGT by manual operation and view of force sensor and extended actuator. By operating (pushing or pulling) the manual handle installed on the top of the guide frame, external force is applied to the force sensor. The external force is converted to voltage V, and VGF is activated when $|V|$ is within the control range of VGF ($V_{\text{Min.}}$ and $V_{\text{Max.}}$). Otherwise, stop. In addition, the VGF was extended and shrink according to the direction of the force, and the velocity was proportionally controlled according to the value of $u = k\,|V|$. By continuously running this control flow, the guide frame is gradually changed by manual operation.

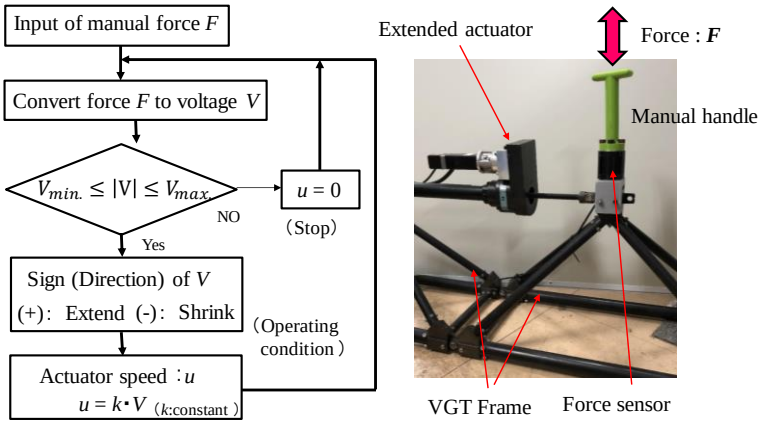

Figure 4. Feedback control flow and VGT actuator and force sensor

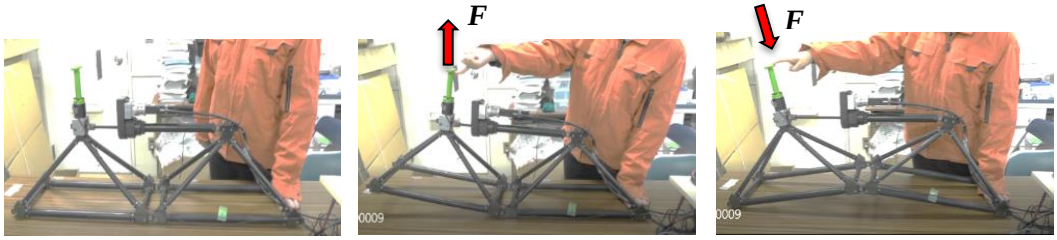


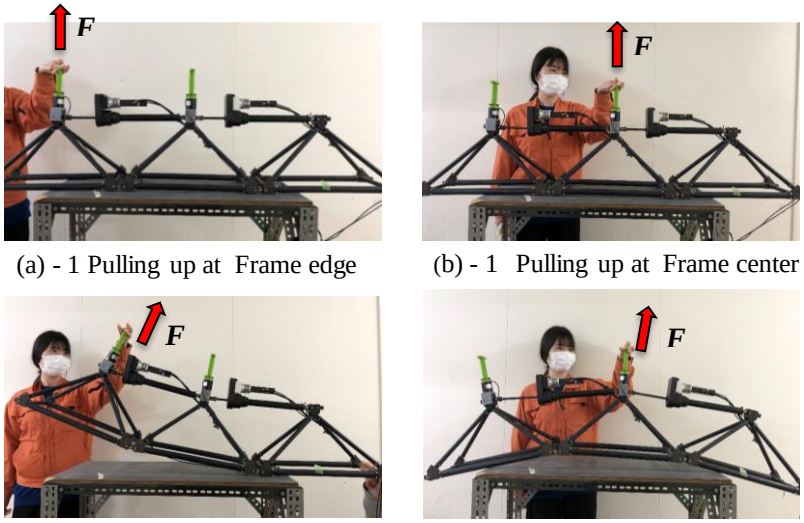
3.3. Force control experiment by manual operation

In order to apply manual force control to the actual guide frame, as a basic experiment, a simple force control experiment combining multiple VGTs was carried out.

3.3.1. Case of one VGT frame

Fig.5 shows the state of the experiment with one VGT. In the initial state where no force is applied (Fig.5-(a)), it remains stationary. As shown in Fig.5-(b), when an upward load (pulling force) is applied,

the frame length becomes shorter and the VGT transforms into a U shape. When the magnitude of the applied force was changed, the frame length velocity changed accordingly. Similarly, as shown in Fig. 5-(c), when an upward load (push force) is given, it can be seen that the shape is greatly transformed into a W shape.



(a) Initial State ($F = 0$) (b) Pulling up ($F > 0$) (c) Pushing down ($F < 0$)

Figure 5. Shape change of one VGT actuator controlled by manual opetation

3.3.2. Case of two VGTs frame

Fig.6 shows the operation test. The shape gradually changes from the initial state (Fig.6 (a)-1: tip of frame, (b)-1: center of frame) when force is applied, and as a result, Fig.6 (a)-2 It became a convex shape change, and in Fig. 6 (b)-2, it became a concave shape change. When the magnitude of the applied force was changed, the frame length velocity changed accordingly. By controlling according to Fig. 4, the actuator that extends differs depending on where the force is applied, so the overall shape also changes. By using this method, the shape of the guide frame can be easily changed by manual operation is possible.

Figure 6. Shape change of two VGT actuators controlled by manual opetation

4. Shape analysis of guide frame imitating force control

4.1. Purpose and method of analysis

The guide frame used in the actual site needs to operate multiple VGT mechanisms, and in order to change the shape of the guide frame composed of multiple trusses, it is necessary to measure the force acting on each truss member. [1]. Here, we applied a downward force to a part of the frame and analyzed the force acting when the shape changed by the finite element method, and investigated the force inside the actuator and the truss displacement. In order to change the shape of a guide frame composed of multiple trusses, it is necessary to measure the force (axial force) acting on each truss member. Here,

we applied a downward force to a part of the frame and analyzed the force adopted for the VGF when the shape was changed.

4.2. Shape analysis of guide frame

4.2.1. Basic Structure of guide frame

The proposed guide frame was constructed on several VGT (Variable Geometry Truss) elements [5],[6],[7]. This VGT was very simple truss structure composed of extendable members, fixed members and hinges, as showing in Fig. 7. By controlling the lengths of the extendable members, it was possible to create various truss shapes. When extendable members are extended simultaneously as indicated in Fig.8, the VGT structure was changed like a spring stretching from (a) to (b). When the extendable members are extended alternately, the structure was changed to a circular shape (c) Moreover, when they are extended optionally and their length were controlled, the structure could be changed into any intended shape (d).

The basic shape of guide frame was assumed to be an arch structure and its two edges were supported on the protection frame. Though the guide frame was changed flexibly by VGTs shape, the shape was limited by upper side of tunnel wall and traffic space area. So, to avoid projecting obstacle in the tunnel space, it was necessary to correspond to the shape of the guide frame close to the section shape of the obstacle as much as possible. Knowing the obstacle location and shape from the drawing map before inspection, the shape of obstacles as speed plate, blower and side lights were able to simulate by motion analysis. In an actual measurement, the shapes of obstacle were detected by the data of LRF continually.

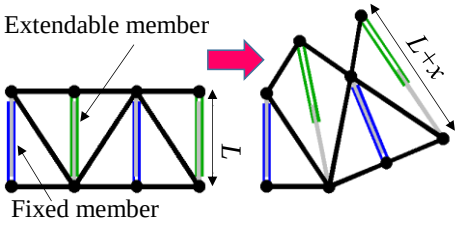

Figure 7. Basic structure of VGT

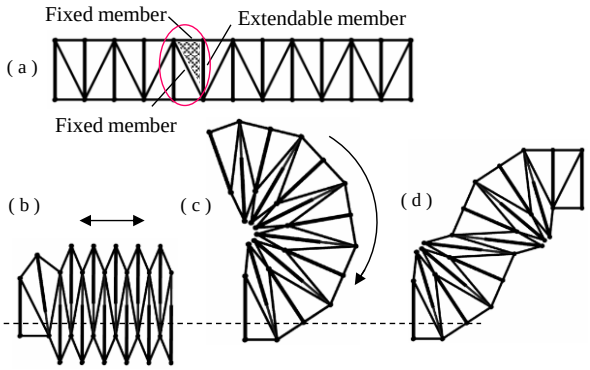

Figure 8. Example of shape change of VGT structure

4.2.2. Basic Equation and Shape of Frame

As analysing the arch structure composed of VGT, the whole of guide frame was assumed to be a cantilever structure as indicated as shown in Fig.9. The frame can replace a robot manipulator combining two fixed-length members in series. When the supported edge of frame was $q(x_0, y_0)$, the top $q(x, y)$ of the x, y co-ordinates of the frame combined with n ($n \geqq 2$) VGT sets was given by Eq. (1) and Eq.(2) using each hinge angle θ_j.(j=1, 2, 3, · ·n),

$$q(x,n) = l_0 \cdot \sum_{k=1}^{n} \cos\left\{\sum_{j=1}^{k} \theta_j\right\} \quad (1) \qquad q(y,n) = l_0 \cdot \sum_{k=1}^{n} \sin\left\{\sum_{j=1}^{k} \theta_j\right\} \quad (2)$$

Where, l_0 was the length of diagonal member of the frame. To transform the shape of arch frame, some hinge positions on the frame only had to change in proportion to target shape. However, for an intended frame shape fixed by equations (1) and (2), it was quite difficult to solve these equations analytically and to decide the angle because the frame was a very highly redundant. In this case, inverse kinematics analysis was applied [8]. Considering a temporal change of the whole of the frame, the top edge

modifying the original point by inverse analysis to all VGT angle velocity $\dot{\theta}_i$, the shape change was absorbed according to the arch.

$$J^{\#} = J^T \cdot (J \cdot J^T)^{-1} \qquad (3)$$

$$\dot{\theta}_n = J^{\#} \cdot \dot{q}_n(x_n, y_n) \qquad (4)$$

Where, J^{-1} indicates inverse Jacobean Matrix (2×n). However J^{-1} isn't necessarily decided because $\boldsymbol{J}$ is not a regular system in n>2. In this case, the suitable matrix such a pseudoinvesre matrix $\boldsymbol{J}^{\#}$ was generally inducedinstead of $\boldsymbol{J}^{-1}$**.** Iterating such modification of shape changes, the shape of original arch was able to carve partially to extent in which the obstacle could be evaded.

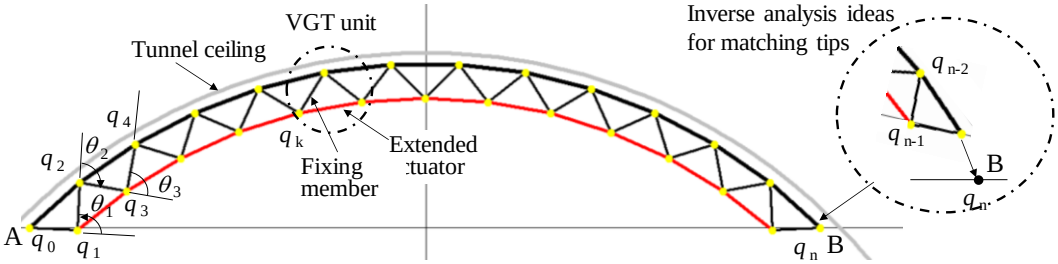

Figure 9. Analysis model of a guide frame composed of VGT

4.3. Structural analysis of guide frame by finite element method

The FEM (Finite Element Method) is an analytical method that divides a continuum such as a member into finite-sized elements and obtains the displacement and stress acting on each element to obtain various values acting on the entire member. Since the force acts on the truss member only in the axial direction, the axial force acting on the frame and actuator of each truss is analysed. Fig.10 shows the analytical drawing of the frame by finite element analysis. Displacements at both ends of each element are ($u_{k,i}$, $v_{k,i}$), ($u_{k,j}$, $v_{k,j}$), axial forces are ($F_{x,i}$, $F_{y,i}$), ($F_{x,j}$, $F_{y,j}$) , the stiffness equation of the truss is given by Equation (5). Here, the component matrix is given by equation (6). By applying this relationship to the entire guide frame and obtaining the displacement of each element, the axial force acting on the actuator is obtained.

$$\begin{bmatrix} F_{x,i} \\ F_{y,i} \\ F_{x,j} \\ F_{y,j} \end{bmatrix} = [K] \begin{bmatrix} u_{k,i} \\ v_{k,i} \\ u_{k,j} \\ v_{k,j} \end{bmatrix} \qquad (5)$$

$$[K] = \frac{AE}{L} \begin{bmatrix} cos^2 a & sina \cdot cosa & -cosa & -sina \cdot cosa \\ cosa \cdot sina & sin^2 a & -cosa \cdot sina & -sin^2 a \\ -cos^2 a & -sina \cdot cosa & cos^2 a & sinac \cdot osa \\ -cosa \cdot sina & -sin^2 a & cosa \cdot sina & sin^2 a \end{bmatrix} \qquad (6)$$

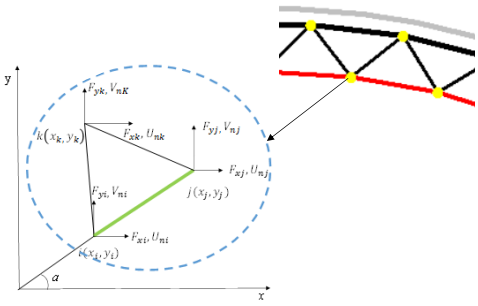

Fig.10 Application of FEM to guide frame

4.4. Shape change of guide frame assuming force control

The force and displacement of the VGT actuator when force (tensile force or compressive force) is applied to a part of the guide frame by manual operation was simulated by the finite element method according to the change of shape. As for the analysis parameters of the guide frame, the values of the

actual model machine (total dead weight: about 140 kg, initial vertical load of each VGF: 7.5 N (outside), 26 N (inside)) were used, and the manual operation The applied load was a relatively small load of F = 10N. In the analysis, the force acting on each member due to its own weight was calculated in advance, and then the analysis including the manual load was performed.

4.4.1. Obstacle avoidance on the side part

By applying a load to the manual operation, if the change in the force acting on each actuator was tensile force, the actuator was extended, and if it was compressive force, control was performed to retract the actuator. A constant proportional to the change in force was found for the extension speed of the actuator, and the speed of each actuator was determined. The step time for analysis was 0.1 second, and up to 200 steps were executed.

Fig. 11 shows the shape of the guide frame that changes according to this load. Fig. 12 shows the changes in the axial force (force excluding the force due to its own weight) acting on the actuator part (bottom chord) of each VGT due to this hand load. The guide frame changes in the manual direction according to the number of steps. A tensile load acts on the VGF near the manual load, and a compressive load acts on the VGF near the end. It can be seen that the guide frame moves downward in the manual direction according to the number of steps. On the other hand, the guide frame on the opposite side has a change that swells like a curve. A tensile load acts on the VGF near the manual load, and a compressive load acts on the VGF near the end. It can be seen that both ends are supported and the forces are balanced according to the uneven shape of the guide frame.

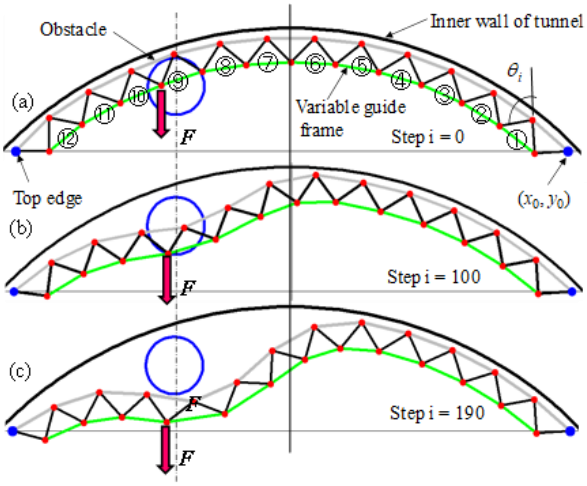

Figure 11. Shape change of guide frame simulated by manual control (Side Obstacle)

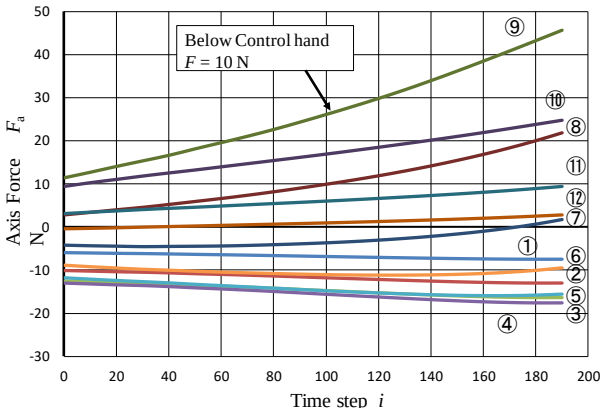

Figure 12. Axis force of actuators of guide frame simulated by manual control (Side Obstacle)

4.4.2. Obstacle avoidance in the central part

Using the same control method as in 4.4.1, the shape of the guide frame was analysed by applying a manual load to the center in order to avoid the obstacle in the center. Fig. 13 shows changes in the shape of the guide frame, and Fig. 14 shows changes in the axial force acting on each VGT actuator. The axial force of each actuator was almost equal on the left and right, and the values were almost symmetrical. Tensile force was observed in the actuator near the manual load, and compressive force was observed in the actuator near the end.

Based on the above, in the actual machine, a force sensor is attached to each actuator, and once the speed of the VGT according to the sign and load is determined, the shape is changed manually. Basically, it can be handled by force control according to the feedback flow shown in Fig. 3. In previous methods,

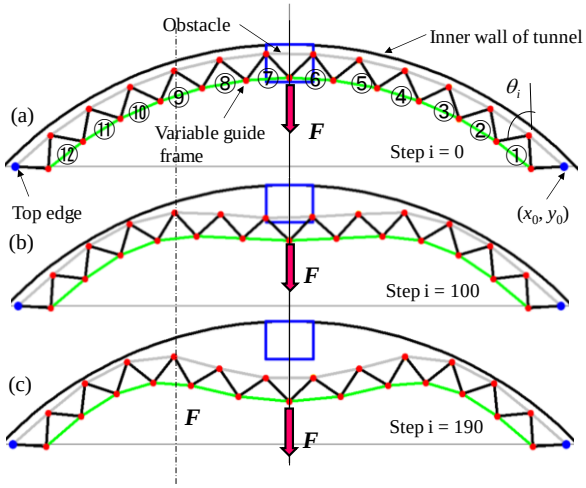

Figure 13. Shape change of guide frame simulated by manual control (Center Obstacle)

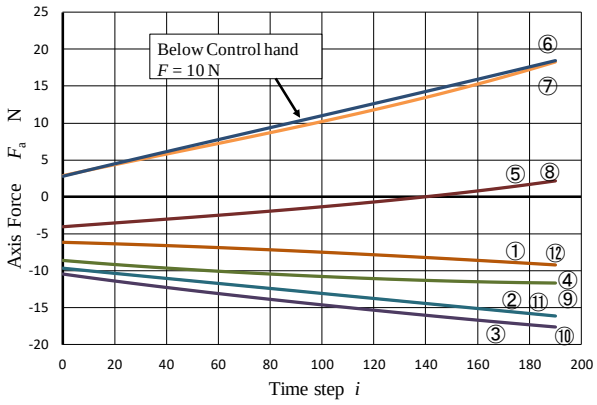

Figure 14. Axis force of actuators of guide frame simulated by manual control (Center Obstacle)

the position of the obstacle was measured by a laser, and the guide frame was automatically opened and closed based on its shape. In this case, the speed of opening and closing is very slow and not necessarily efficient. In the manual operation proposed here, the operator actually sees the shape of the obstacle, so the operation is more efficient, and fine adjustments can be made easily. It is also possible to perform the operation in case of emergency, which will greatly contribute to safety.

5. Conclusion

In this study, by using a deformable frame that can adapt to the tunnel shape, we have developed a tunnel inspection system that can inspect the inner wall surface without the usual traffic control. In order to make it easier to use the guide frame of the developed inspection system, we investigated a force control method that can easily change the shape of the guide frame by manual operation. We conducted manual experiments using multiple VGF mechanisms and confirmed that the shape can be changed according to the feedback flow. For application to the entire guide frame, it is necessary to operate multiple actuators, and the axial force of each actuator due to manual loading was analyzed. From the analysis results, it was confirmed that the sign and magnitude of the axial force changed depending on the part where the manual load was applied.

In the future, we would like to install a force sensor on the actual guide frame and determine the speed of the actuator according to the sign and value of the load generated by manual loading, aiming at practical application.

Abstract

We introduce a novel family of structures that can be inflated from a plane to form a three-dimensional surface using articulated straight pouches with inextensible membranes. Specifically, we propose a modular design using a quadrangle surrounded by four slender pouches, whose inflation causes the surface to form a saddle shape. We show a fabrication method using heated nylon films with heat adhesives separated by paper mask patterns inside. We first show a geometric model to explain and predict the out-of-plane deformation and the bi-stability effect inherited in this structure. Through a geometric analysis and an elastic simulation of a pouch, we show that lowering the width-length ratio of pouches reduces the imperfection of shapes. We further propose a method for controlling the height of saddles using concentric patterns. We then extend structural modules into multiple-grid systems and identify the multi-stable behaviours of the overall structure.

1. Introduction

Air-inflated pneumatic structures, i.e., structures formed by closed membrane sections, have been extensively used for realizing lightweight structures. In recent studies, researchers focus on novel aspects of air-inflated structures as the method to create three-dimensional surfaces and motions from planar states by utilizing inextensible membranes. Niiyama et al. [1] realize a transformable air actuator by inflating tubular pouches patterned on double-layered sheets. Siefert et al. [2] studied the out-of-plane bending of air tubes induced by the incompatibility caused the inflation. Panetta et al. [3] used a similar idea to program a pattern of laid-out flat air tubes that can be inflated to achieve a target three-dimensional (3D) surface. These approaches are characterized by the use of inextensible membranes that are pulled and deformed by air pressure, which is in contrast to conventional air-inflated pneumatics that focus more on the air as the structural element than the membrane. However, when inextensible air pouches are inflated, the induced bending of the tubular pouch caused wrinkles on the surface. These wrinkles may lead to structural failure if the scale of structures becomes larger. To apply the approach of air-induced out-of-plane surface transformation to a large-scale structure, the wrinkling problem has to be solved.

In this study, we propose a novel structural unit with segmented straight air pouches connected by foldable creases. The articulation will allow for a structure with a large amount of out-of-plane surface deformation with fewer effects of wrinkles. Specifically, we propose a modular design using a quadrangle surrounded by four slender pouches, whose inflation causes the surface to form a saddle shape. Unlike existing surface inflatables, the pouches remain straight after inflation and thus are free of wrin-

kling. The proposed module has two stable positions that can be programmed to form different surfaces by tessellating the modules.

We first show the manufacturing and inflation steps of the unit structures in Section 2. We show a geometric model to explain and predict the unit's out-of-plane deformation and the bi-stability effect in Section 3. We study the imperfection of the geometric models to show that lowering the w/l ratio of pouches reduces the imperfection in Section 4. We further propose a method for controlling the out- of-plane deformation for the structural unit using concentric patterns of pouches in Section 5. Finally, we extend structural modules into multiple-grid systems and identify the multi-stable behaviors of the overall structure in Section 6. We introduce a notation that labels the shape of each stable state by '+1's and '-1's. We propose a dynamic-relaxation-based simulation model to predict the stable states for a given assignment of labels.

2. Manufacturing and inflation

The proposed unit structure is manufactured by utilizing the 2D patterning based on CNC-cutting of sheet materials and heat adhesive nylon pouch. The process mainly consists of three stages (Figure 1): Cutting The process of fabrication starts with the preparation of sandwich-like paper and nylon sheets. We finish our design in Rhinoceros, export it to the Silhouette paper plotter, and cut copy paper out of the pattern. Then cut out the nylon pouch and place the pattern inside.

Heating In order to let the two layers of nylon sheets weld, we set the temperature at 180 ◦C and the pressure at 8kg for 45s. The process needed to be done twice to make sure the sheet is well merged. Inflation Finally, we cut through the pre-laid air hole and seal one side with tape. We then attach an air compressor and inflate the planar structure with a pressure around 150 − 180kpa. The interior of the structure is nearly vacuum such that it takes several times to inject and release such that the structure can be fully inflated.

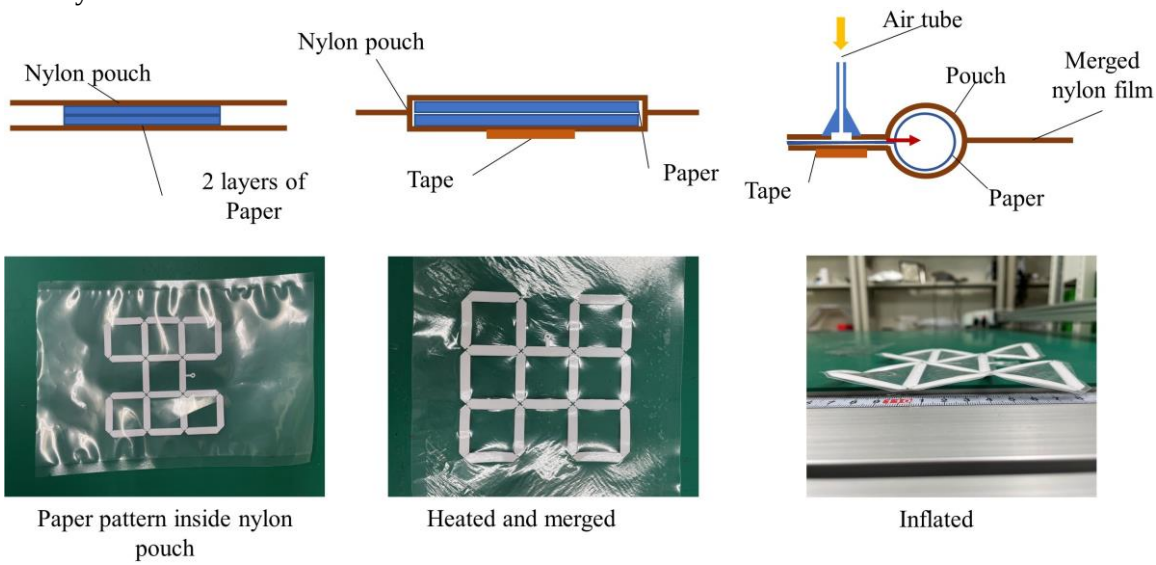

Figure 1: The fabrication process.

3. The structural unit and its geometric model

3.1. Overview of the structural unit

Our basic structural unit is a flat quadrilateral sheet consisting of 4 straight air pouches (Figure 2). The sheet is a composition of two layers of heat-adhesive nylon sheets with paper masks laid in between. When we sandwich these layers and apply heat by ironing, the paper sheets act as the insulator keeping the two layers separate while the remaining sheets get fused. This creates 4 closed straight air pouch sections (with air channels connecting them). When we pump air into the air pouches, each of them inflates into a cylindrical shape and then performs the transformation from a flat sheet to a 3D shape.

Here we call the width of each tube air pouch of the structural unit in its planar state w. Ideally, if the air pouch is entirely inflated, the two layers of paper mask and material form the boundary of a circular cross-section (Figure 2-2). Hence the projected width $w'$of the air tube after inflation is calculated as $2w/\pi$ given the condition that the material is not extensible against air pressure. This width difference provides the effect of in-plane shrinkage and causes the surface to deform into 3D. The width difference is calculated as:

$$\Delta w = w - w' = (1 - 2/\pi)w \approx 0.36w \tag{1}$$

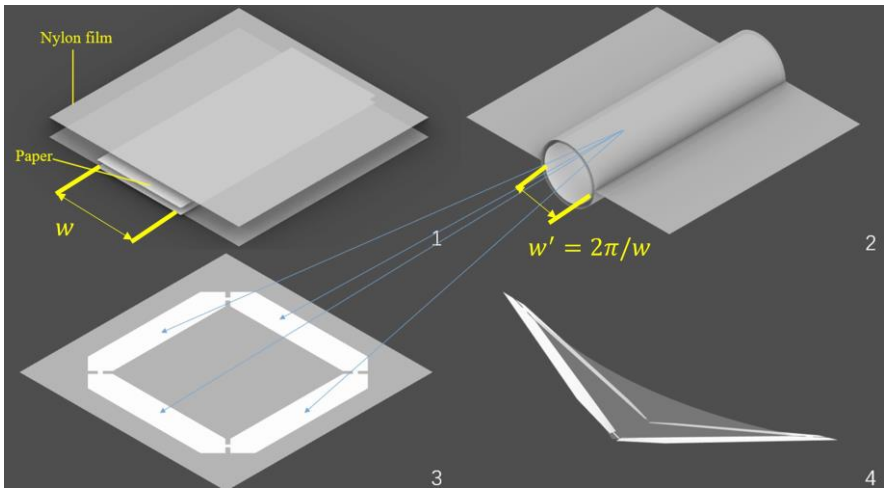

Figure 2: 1. Paper masks are laid in between nylon sheets. 2. Straight air pouches being inflated. 3. Four straight air pouches compose a single structural unit. 4. The deformation of a structural unit.

To understand the out-of-plane deformation of a single structural unit, we consider a quadrilateral MNPQ (Figure 3) and then take a quarter of the quadrilateral MNO, where MN is one side of the structural unit and O is the center. Let H be the midpoint of MN. The structural unit transforms into M 'N 'P 'Q', while keeping the origin O' = O when the projected length OH is reduced by the width difference Δw of an air pouch, i.e., OH on the plane becomes OH' = l/2 - Δw/2. Consequently, vertices M and P move in the z direction by h and N, Q move by -h. In arbitrary quadrangular cases (Figure 3) △MHO ≃ △M 'H'O, we can calculate the distance from the unit center to all edges, OH' as an example:

$$h^2 + \left(\frac{l}{2} - \frac{\Delta w}{2}\right)^2 = \left(\frac{l}{2}\right)^2 \tag{2}$$

Which accordingly tells the actual height h of the structure unit:

$$h = \frac{1}{2}\sqrt{\Delta w(2l - \Delta w)} \tag{3}$$

Equation (3) reveals that the deformation of the structural unit is decided by w/l. In a slender case of the pouch, when $w/l \ll 1$, the relatively high h/l is approximately proportional to $\left(\frac{w}{l}\right)^{\frac{1}{2}}$.

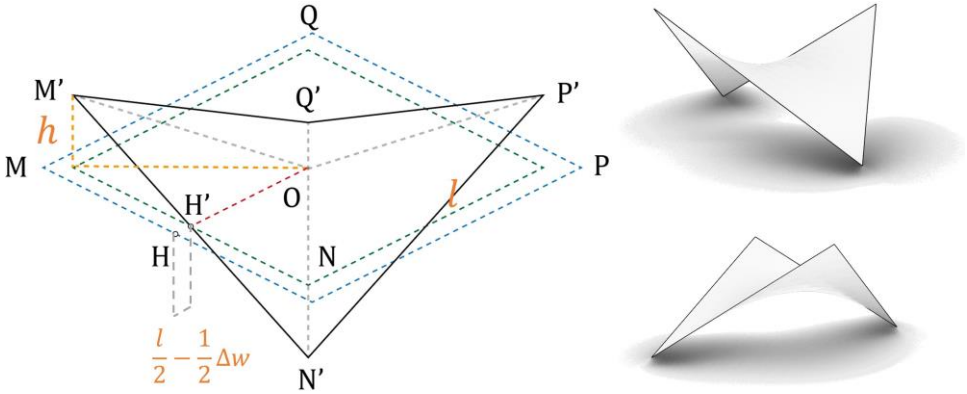

Figure 3: The geometric model and the bi-stable states for a structural unit.

3.2. The bi-stability

All elements of the paper are to be in the font Times New Roman. These guidelines give the basic layout, and the out-of-plane deformation induced by the air inflation breaks the four-fold symmetry of the entire pattern into two-fold symmetry. The structural unit needs to find a new equilibrium position such that the out-of-plane deformation happens. When it deforms, the unit needs to choose two upward vertices and two downward vertices from either the group of vertices (M, P) or (Q, N) (Figure 3 Right). Consequently, there are two possible ways for the vertex pairs to go. This bifurcation causes the structure to have two stable positions and the snapping behavior between the two stable states.

4. Detail discussions on the geometry for the structural unit

In the abovementioned geometric model, we assumed that the pouch deforms into a perfect cylinder. However, the cap part of an air tube will cause shape imperfection because it does not fit the transformation from plane to three-dimensional shape. The imperfection causes (1) length shrinkage (Figure 4 Left) and (2) non-constant shrinkage in width (Figure 4 Right) that is accompanied by wrinkles. The intrinsic mismatch between the planar state and three-dimensional shape is unavoidable, but it can be minimized. In the following sections, we show that these imperfections and wrinkling can be mitigated by making the w/l ratio small enough. Specifically, length shrinkage is an order of w/l ratio. Also, our numerical simulation revealed that non-constant width shrinkage is reduced by a smaller w/l ratio. In other words, the w/l ratio should be kept as small as possible for the least imperfection of pouch shapes. We use $w/l \leq 0.2$ in our design for the physical model for better shape prediction and structural soundness.

4.1. Length shrinkage for a pouch at the cap part

The imperfection causes the change in the height of the cap and thus in the total length. To study the imperfection, we consider that some of the materials between the cone part and the cylindrical part are "removed". Physically, the unnecessary material gets wrinkled. We consider the deployed state of the cone-shaped cap, and the cylindrical body to be a perfect match. We develop them along the suture lines between the cap and the body to obtain the flat state of a cone and cylinder. If we let the angle and the radius of the cap in the flat state be denoted by α *and* r, respectively, the height (the distance from the cap top to the suture line) of the cone r' in the inflated state is given by the equation:

$$r' = r \cdot \sqrt{1 - \left(\frac{\alpha}{\pi}\right)^2} \tag{4}$$

Therefore, the length shrinkage of the whole pouch is:

$$\Delta l = r - r' = r \cdot \left(1 - \sqrt{1 - \left(\frac{\alpha}{\pi}\right)^2}\right) = O(r) = O(w) \tag{5}$$

Here, we conclude that the size of the cap is only proportional to the width of the tube. This suggests that the strain in length direction decreases $\Delta l/l \rightarrow 0$ as the tube gets slender $w/l \rightarrow 0$.

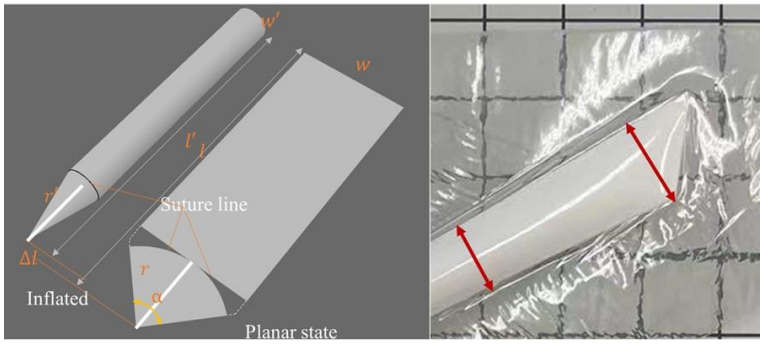

Figure 4: Left: Imperfect match for planar and 3D shape. Right: Non-constant shrinkage in the pouch width.

4.2. Width difference along a pouch and its verification

To check the effect of non-constant width shrinkage, we performed a numerical experiment with triangulated mesh based on the dynamic relaxation method using springs representing inextensibility, angular springs representing bending stiffness of sheets, and the pressures for the inflation process (Figure 5). We implemented this setting using Kangaroo 2 in Grasshopper of Rhinoceros 7.

We simulated two models of (w, l) =(10,mm,50mm),i.e.,w/l = 0.2,and (w, l) = (10mm,100mm),i.e., w/l = 0.1. To analyze the imperfection in width shrinkage, we measured the non-uniform inflated width w'(x') as the function of the position x' ∈ [0, l'] along the length direction of the pouch. Figure 7 shows the plot of w'(x') for the case w/l = 0.2 and 0.1. We set the precision tolerance to 5% of the ideal width $2w/\pi$. The region of precision i.e., the region within w'(x') ∈ [0.95 × (2w/π),1.05 × (2w/π)] is 86.4% of the length of the body for w/l = 0.2. The region of precision for w/l = 0.1 is 97%. We observed that the region of imperfection is local near the cap, and thus its size is expected to be the order of w. Therefore, they can be neglected when w/l ratio is small. We also observed a similar result from the

shape of physical air pouches (Figure 8). For practices, we choose $w/l \leq 0.2$ for a better appearance. These discussions support our geometric model in (Section 3.) if w/l ratio is small enough.

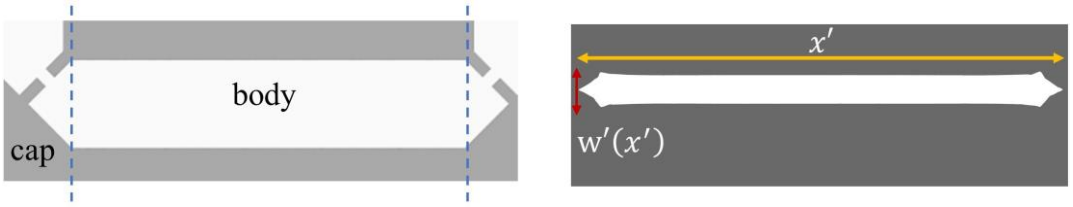

Figure 5: Top: Body part in the layout. Bottom: x' stands for half pouch width, and $w'(x')$ stands for width.

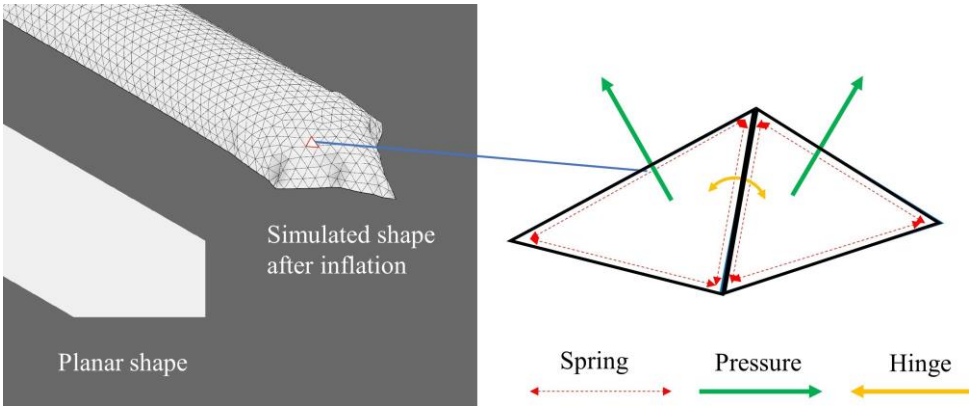

Figure 6: The simulation contains 3 kinds of constraints: The "spring" keeps the length of mesh edges imitating the in-extensible nature of the material. The "pressure" simulates the air pressure. The "hinge" of the edge within the adjacent mesh faces shows the effect of the thickness coming from the nylon sheet.

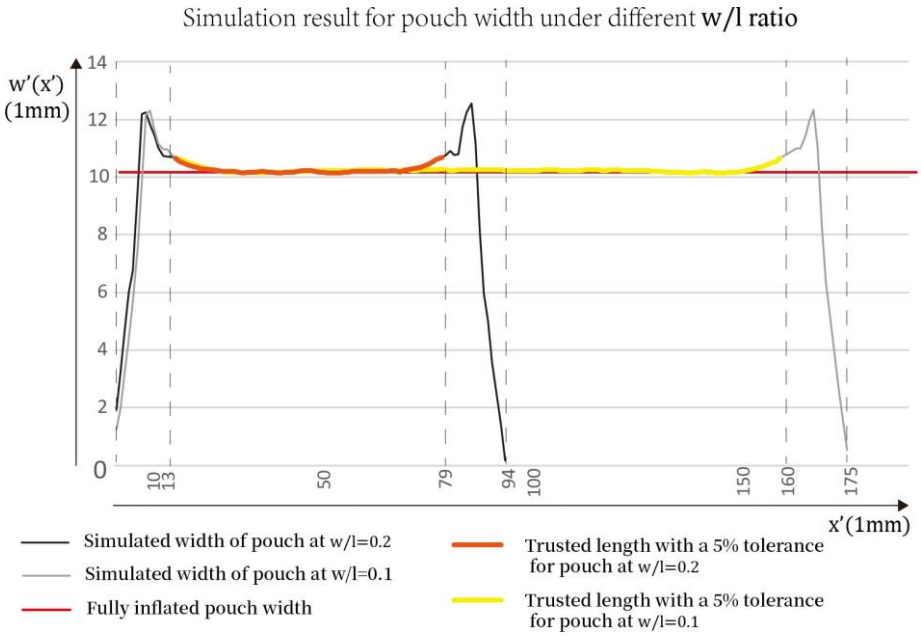

Figure 7: The simulation results for pouches at w/l ratio of 0.2 and 0.1.

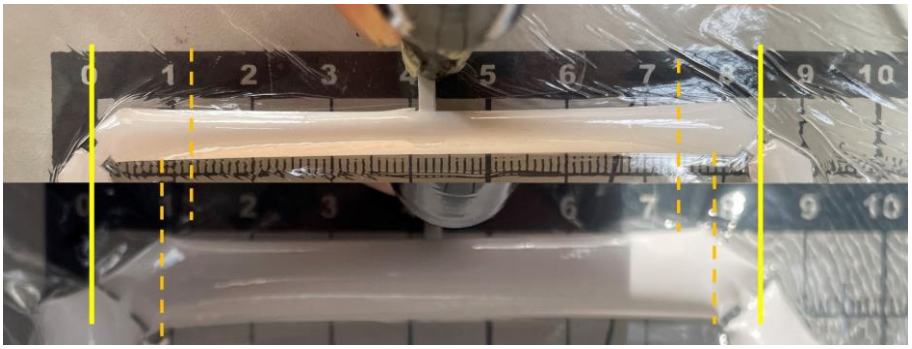

Figure 8: Comparison of the width differences of physical air pouches. Top: a pouch of $w = 8mm$ and $l = 84mm$. Bottom: a pouch of $w = 16mm$ and $l = 84mm$.

5. Actuation control using aligned pouch pattern

5.1. Actuation control

To improve the precision and reduce the effect of wrinkling, it is ideal to reduce w/l. However, the out-of-plane actuation measured as h/l also becomes small when w/l is small. Inspired by the shape study from K.Liu et al.[4], we found it is necessary to adjust Δw effectively while keeping the actual proportion w/l small. To achieve this goal, we show an approach of adding aligned air tube sets in one unit from the boundaries to the center.

To produce effective Δw while keeping the pouch proportion, we align slender pouches in parallel. Specifically, for a ring composed of four pouches, we align a smaller concentric ring composed of four pouches inside the ring. We take a pouch unit with three rings of aligned air tubes (Figure 9) as an instance. For air tubes adjacent to each other one or two small air channels are designed to let the air go through.

The straightforward prediction model for the concentric ring model is to use the summation of all aligned pouches $\sum \Delta w_i$ and replace the single width difference Δw of Equation (3). We evaluate this model in the following subsection, while we conclude that this model requires improvement.

$$h = \frac{1}{2}\sqrt{\sum \Delta w_i (2l - \sum \Delta w_i)} \tag{6}$$

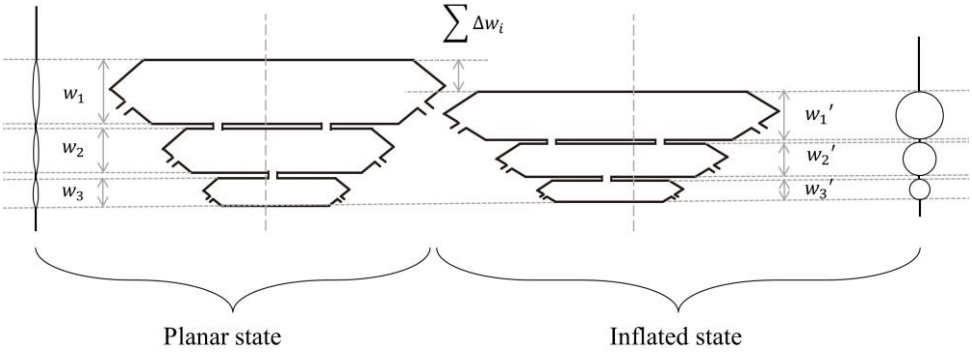

Figure 9: The deformation for the pattern with aligned air pouches before and after inflation.

5.2. Evaluation

We performed experiments to verify our geometric model. We compare three kinds of units: the original unit, the unit with 2 rings of pouches, and the unit with 3 rings of pouches (Figure 10). The length of the unit is $l = 84\,mm$, and the width of the pouches are $w_1 = 14\,mm, w_2 = 10\,mm, and\ w_3 = 7.14\,mm$ from the outer to the inner pouches. We inflate them all at the pressure of 150 kPa and measured their vertical displacement. For each specimen, we measured the height three times and took the average to obtain $H_{average}$ and calculated its half h_{actual} (Table 1). We compare h_{actual} with the corresponding value h according to our geometric model to verify whether our method of adjusting the unit actuation is plausible.

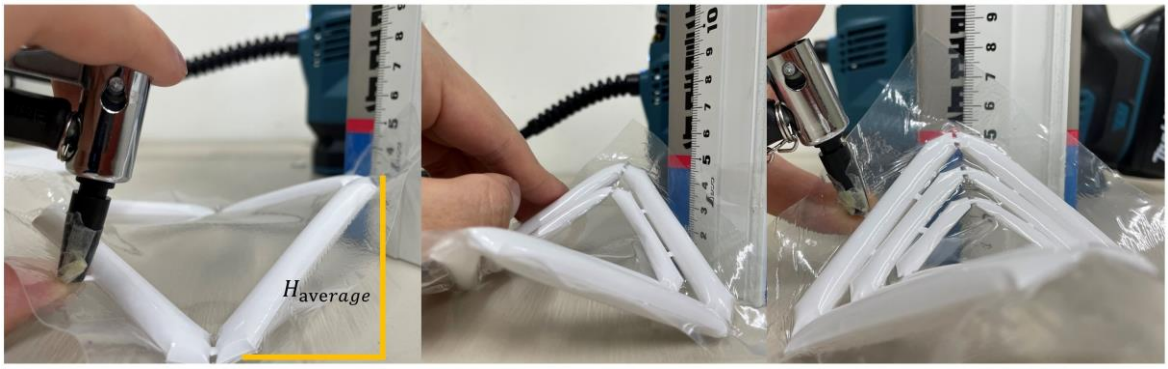

Figure 10: Measuring the vertical displacement of each unit

	$1\ Ring\ (mm)$	$2\ Rings\ (mm)$	$3\ Rings\ (mm)$
$w/l\ ratio$	$1/6$	$1/6$	$1/6$
$Haverage\ (mm)$	27.3	43.4	46
$hactual\ (mm)$	13.7	21.7	23
$h\ (mm)$	14.39	18.64	21.05
$Deviation$	-4.79%	16.42%	9.26%

Table 1: The result for comparison between the normal unit and alignment layout pattern.

The result of the comparison shows that more actuation is indeed generated by adding rings of air pouches. However, the actual height deviates from the height predicted by the geometric model; the deviation defined as $(h_{actual} - h)/h$ is added as the bottom row of Table 1. The deviation shows that the unit with a single ring transforms into a slightly lower value than the expected geometric model. This is justified by the imperfection caused by the bending stiffness and in-plane stretch of the material that makes the section of the pouches non-circular. However, we obtained non-straightforward results for the case with two and three rings, where the actual height is higher than the predicted height. This suggests that the straightforward model of simply adding the width differences in Equation (6) misses some effect that happens in the actual material. An improved model to predict the behavior of multiple

rings needs to be investigated.

6. Multi-stable grid pattern

So far, we have focused on the shape of a single structural unit. To achieve a larger surface, we propose expanding the structural unit into a grid system. By combining multiple units yields a multi-stable structure that can be programmed into many deployed states.

6.1. Different connections and grid pattern layout

Here we evaluate two types of square unit grids based on their orientation: *the aligned grid* that repeats squares along their edges, and *the diagonal grid* that repeats squares along their diagonals (Figure 11 (a)). Also, the connection between units is another detail that affects the final shape of the structure. Here with the illustration of Figure 11 (b), each connection between two adjacent units is either a single hinge or a pouch. We call them *hinge connection* and *pouch connection*, respectively. The pouch units connected by the hinge connection deform more independently because the hinge connection is softer. Also, the bending between neighboring units is concentrated at the hinge line. On the contrary, the pouch connection resists bending by a whole pouch. In an ideal model, a hinge connection is considered a revolution joint, while a pouch connection is considered a rigid connection.

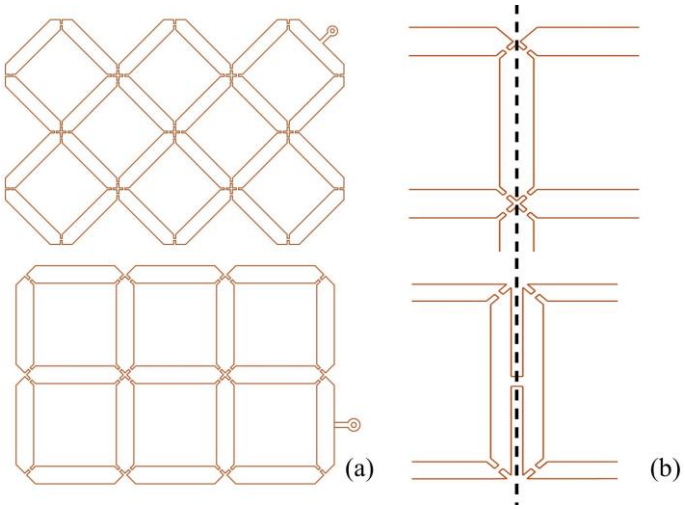

Figure 11 (a): Up: The diagonal grid. Bottom: The aligned grid. (b): Up: The pouch connection. Bottom: The hinge connection.

6.2. Notation method

To state each stable state simultaneously for a structure with multiple units, we mark each unit +1 and −1 based on its bi-stable behavior (Figure 12). Through this approach, we can determine any shape with only a matrix containing a bunch of +1 s and −1s. We name a structure consisting of all +1s or −1s the two ultimate states and the structure alternating +1s and −1s the two neutral states. With the help of +1s and −1s, we can directly tell different stable states (shapes) of one structure. Since each unit has a bi-stability, the n-unit grid system has 2^n possible nominal stable states. In reality, the structure may not

have so many possible combinations for +1s and −1s. We will verify some of them below.

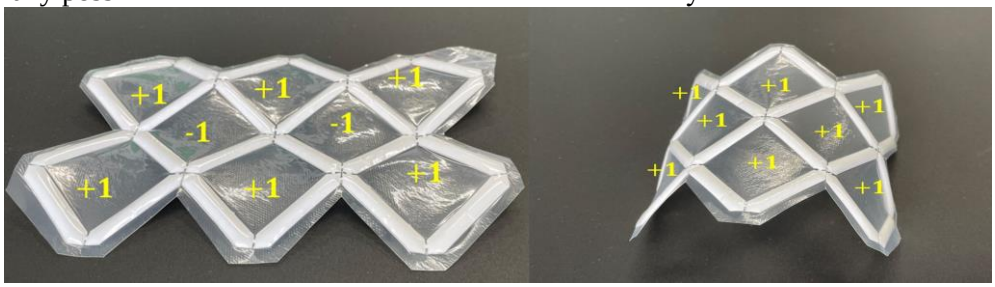

Figure 12: The +1 and −1 notations for two ultimate states. Left: A neutral state. Right: An ultimate state.

6.3. Possible and impossible states

Figure 12 is a model for a diagonal grid constructed with the pouch connection. In the neutral state (Figure 12 Left), the whole system forms a flat but wavy shape. in one of its ultimate states (Figure 12 Right), the shape is similar to a Yoshimura pattern in origami, thus the diagonal grid provides a perfect analog of a vault shape. Figure 13 shows the physical example of an aligned grid constructed with the pouch connection. It is similar to the diagonal grid in its neutral state. But when it turns to an ultimate state, the grid will scroll inwards to a cylinder whose ruling directions are parallel to the polyline created through a combination of adjacent diagonal lines among pouch units (Figure 13 Right). Note that the curvature directions of the ultimate state for both cases align with the diagonal directions of the unit. This is because the unit's principal curvature directions of the hyperbolic paraboloidal shape are aligned with the diagonal direction.

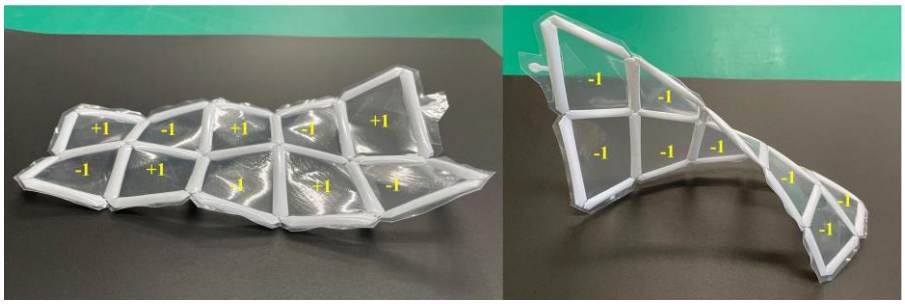

Figure 13: Left: A neutral state. Right: An ultimate state

The ultimate and neutral states exist for every combination of diagonal or aligned grids, and pouch or hinge connections. However, the existence of other states cannot be ensured for some combination of layouts and connections. Here we give an example of non-existing patterns in Figure 14. Here, we compare $2 \times n$ aligned grids with hinge and pouch connections. Some non-ultimate or non-neutral patterns applied to the pouch connection automatically turn back to a neutral state. In hinge connection, the state stayed in a correct assigned pattern for the $2 \times n$ aligned grid. This phenomenon suggests that even n-unit grid has nominally 2^n possible states, some of the states are not always workable in reality. To understand the possible and impossible states, we need to understand the compatibility between units. A model with a hinge connection can be considered as rigid origami with non-planar quadrangular panels, while the pouch connection is considered as the tessellation of rigid bodies connected rigidly. In reality, the hinges allow elastic deformation; thus, it is more allowing than the rigid model. The stability

under the elastic energy makes some modules able to exist or not. To consider the elasticity, we perform a bar-and-hinge-based simulation to check the feasibility of physical models.

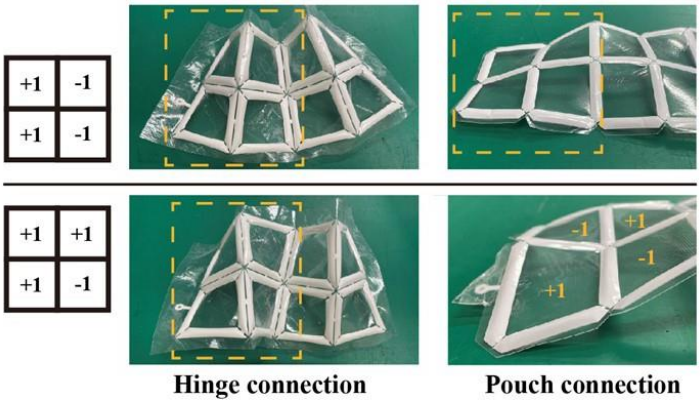

Figure 14: Hinge connections work for both notation but pouch connections fail at a combination of three +1s and one −1s.

6.4. Shape prediction

We model each unit as four triangles using M', N', P', Q', O in the geometric model (Section 3.). The target length of each edge of the triangle is set to the length of the geometric model after the inflation. We realize this length constraint as a linear spring. We also provide angular springs between four triangles. to represent the out-of-plane bending stiffness of the module (Figure 15).The connections between modules are modeled as angular springs, where the spring stiffness of the hinge connection is lower for free rotation at unit boundaries, and the pouch connection is higher to resist bending. We performed a simulation of this spring system on Kangaroo 2. To specify +1 or −1 of the model at the flat state, the target angle of the angular springs between four triangles in the module is initially set to the angle measured from M', N', P', Q', O in the corresponding +1 or −1 state. After the simulation

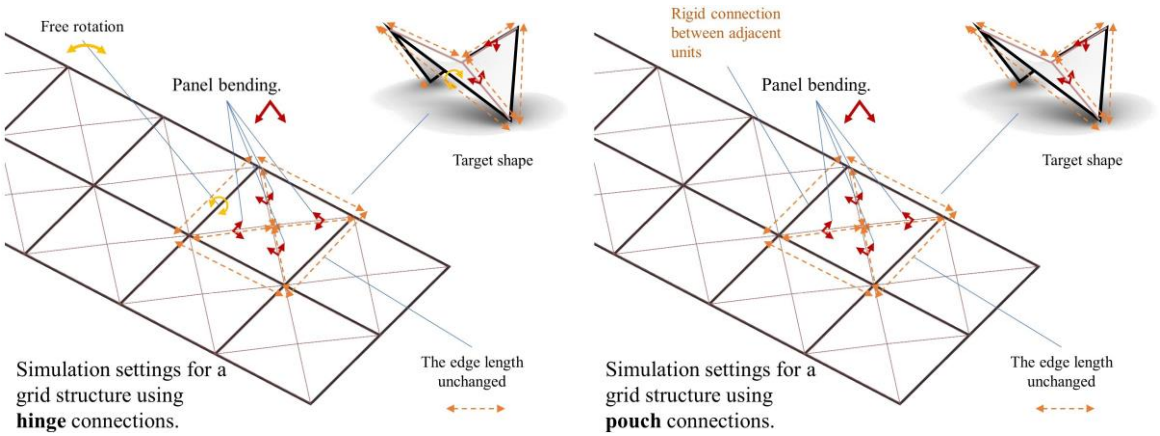

Figure 15: For grids with both connection types, we set all the unit boundaries are rigid and divide a unit into 4 triangular panels then assign each edge between the panels with opposite angles to imitate the bifurcated deformation according to the shape of a single structural unit.

finds a specific +1 or −1 pattern, we set the target angle of the angular springs to 0 to remove the bias.

6.5. Simulation result and conclusion

In the pouch connection model, we obtained the resulting shapes of the neutral and ultimate states as desired. Even after the removal of the bias, the shape stayed in the correct state. We also tested this simulation setting in some other patterns as shown in Figure 16 Left and middle, the resulting 3D shape was able to turn back to a flat piece, which was its initial state when the folding angle is reduced to 0. For the hinge connection model, we similarly obtained the resulting shapes of the neutral state and ultimate state. However, the state is not stable, and the model with hinge connection transforms as a one-DOF mechanism (Figure 16 Right).

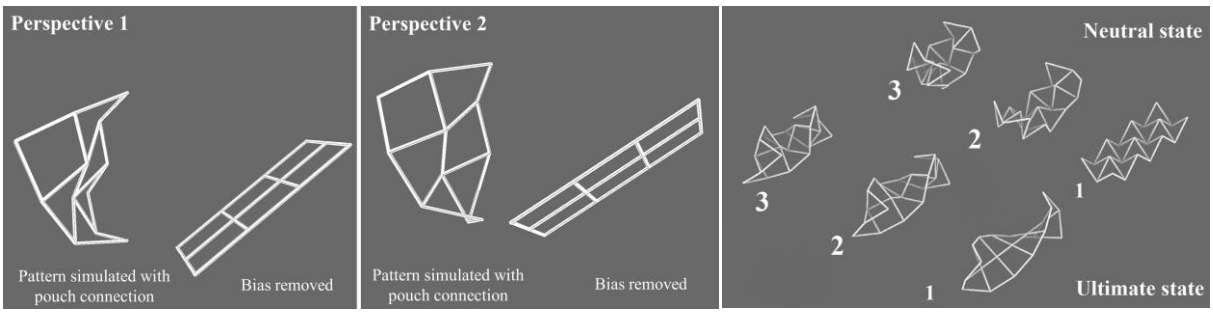

Figure 16 Left and middle: The simulated result for an arbitrary pattern made with pouch connection and the shape returned to a flat piece after the rest angle is reset to 0. Right: The shape sequence of the one DOF motion under the simulation result of hinge-connected patterns.

Abstract

The C-cross section thin-walled deployable boom (C boom) has a high storage ratio and can be used in various deployable structures. In the state of storage, the C boom should have no material failure, and in the working state, it should provide high bending stiffness and natural frequency to make the structure stable. This paper studies the mechanical properties of C booms in folded and deployed states. The change of maximum stress in the folding process of C booms and the boundary effect on the stress are studied in ABAQUS. The C boom with variable cross-section and the perforated C boom are proposed and studied to reduce mass and improve stiffness. The bending stiffness and natural frequency of these two types of booms are studied and compared with C booms with the same mass.

Keywords: deployable boom, C boom, optimization, variable cross-section, perforated

1. Introduction

A deployable boom can be stored in a small volume, and it can deploy by releasing stored strain energy to make the boom in working states. The C boom has a low manufacturing cost and can deploy easily, and it can be used as the support frame of deployable space structures such as antennas, solar sails, and solar panels.

The C boom should meet the requirements in both folded and deployed states. In the state of storage and during the process of storage, the C boom should have no material failure and enough steady-state moments as the power for the deploying process, while in the working state, it should provide high bending stiffness and natural frequency to make the structure stable. The yielding control criterion of C boom during the pure bending state is derived and verified by the FE model[1]. The natural frequency of C booms has been derived from experimental data, a FE model, and a beam model[2]. The length of the ploy region under the folding state of the C boom is derived, according to the classical long-wave solution of deformation of an initially cylindrical shell[3]. The classical solution of the steady-state moment of the C boom in the folding state is modified considering the boundary layer effect in the hinge region[4]. Most researches focused on the mechanical properties of common standard C booms, but there are few studies on C booms with variable cross sections or holes, which is an effective method to reduce the mass of booms.

This paper mainly studies the mechanical properties of the C boom in folded and deployed states, and the C boom with variable cross sections and the perforated C boom are proposed and studied to reduce mass and improve performance. Firstly, the change of maximum stress in the whole folding process of C booms, and the influence of the boundary effect on the maximum stress are studied in ABAQUS. Then, C booms with variable cross sections and the perforated C boom are designed to improve the deployed stiffness, and the bending stiffness and natural frequency of these two kinds of booms are analyzed by parametric studies. Finally, the bending stiffness and natural frequency of these two kinds

of booms and C booms with the same mass are compared to verify their contribution to improving the unfolding stiffness.

2. Performance of C boom at folded state

The key to the performance of C boom at folded state is to control the maximum stress in the folding process and the folded state to not exceed the yield strength so that the boom remains elastic and can fully release the elastic potential energy during the deploying process. This section studies the change of maximum stress during the folding of the C boom. In the process of folding, the boundary will also affect the stress of the C boom, which is related to the length of the ploy region.

2.1. Stress in the process of folding

The folding process is accompanied by the sudden change of bending moment, and the size and position of the maximum stress will also change during the formation and development of the localized fold. In the process of folding, the formation of the hinge is a dynamic process, but the time of this process is very short, and the performance studied in this paper is little affected by the inertia force, so the static solver is adopted to simulate the folding process. This paper creates finite element models using the stabilizing parameter set to default values within the static option from ABAQUS and studies the change of the maximum stress of the whole model $S_{\max,b}$ during the process from the natural state to the 180 ° folding of the C boom. And $S_{\max}$ is the maximum value of $S_{\max,b}$. The model adopts S4R shell elements, and to provide an appropriate balance between accuracy and computational expense, an element is divided every 2 ° along the arc of the section. The semi-structure and plane symmetry conditions are used, and the finite element results in this paper are mirror images. As shown in Figure 1, the sections at both ends of the C boom are coupled and constrained to PC1 and PC2 respectively, and a 90 ° angle is added to PC1 and PC2 respectively so that the C boom can be folded 180 °.

(a) (b) (c)

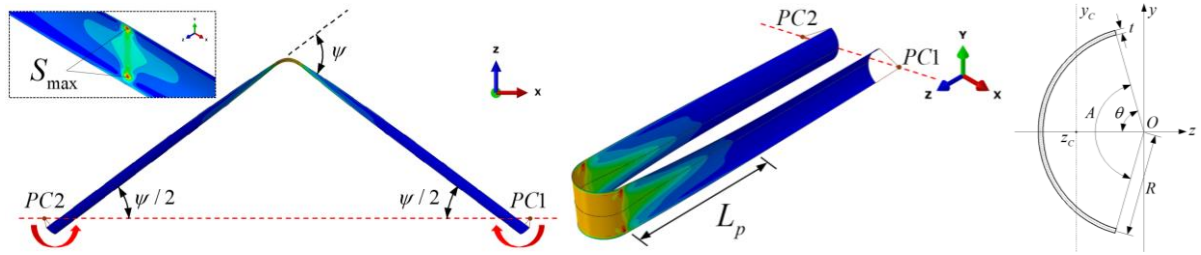

Figure 1. The finite element model: (a) the process of folding, (b) after folding, (c) cross-section geometrical dimension of the C boom

The material of C booms in this paper is 301 stainless steel, and its material properties are shown in Table 1. As shown in Figure 1, the unstressed cross-section of C booms is taken to be a circular arc of thickness t, the subtending angle A at the radius R, and $\theta=(A/2)\cdot(\pi/180)$. In this section, t =0.1mm, and the values of $R=10,15,20,25,30,35,40$mm, and $A=60,70,80,90,100,110,120$ degrees.

To make the stress not affected by the boundary, the length of the C boom L is taken as

$$L=\pi R+4L_p \tag{1}$$

$$L_p=\frac{(R\theta)^2}{\pi}\left[\frac{1-\nu^2}{120}\right]^{\frac{1}{4}}\frac{1}{\sqrt{Rt}} \tag{2}$$

to ensure that there is a section of the area without transverse deformation on both sides of the hinge after the C boom is folded 180 °. The length of the ploy region L_p in formula (2) is derived according to the classical long-wave solution of deformation of an initially cylindrical shell[3]. The simulation results show that formula (2) can well estimate the length of the ploy region, thus avoiding the influence of boundary on stress.

Table 1. Material properties of C booms

Young's modulus of elasticity for material E （Mpa）	200000
Poisson's ratio ν	0.3
Density ρ （kg/m^3）	7850

The variation of $S_{\max,b}$ and section bending moment M with the bend angle of the hinge ψ during folding is shown in Figure 5. It can be found that when M suddenly changes, $S_{\max,b}$ also changes. When the section reaches the steady-state bending moment, the $S_{\max,b}$ also remains steady, and it can be calculated[1] by the formula for the steady-state maximum stress

$$S_{\max,\text{steady}} = \frac{E}{1+\nu} \cdot \frac{t}{R} \tag{3}$$

However, according to the $S_{\max,b}$ curve, the maximum value of $S_{\max,b}$ does not occur in the steady state, but within a short range after a sudden change of M. Therefore, $S_{\max,b}$ in the folding process of C booms is studied.

As shown in Figure 2, when R and A are small, the maximum value of $S_{\max,b}$ occurs after the elastic hinge is formed, and the value is close to $S_{\max,\text{steady}}$. In this case, the maximum value of $S_{\max,b}$ in the folding process can be approximately calculated by the formula (3). When R and A are large, $S_{\max,b}$ will exhibit a "jump" phenomenon during the formation of the hinge, and there is a significant difference between the maximum value of $S_{\max,b}$ and $S_{\max,\text{steady}}$. For example, when R=40mm and A=110 °, the maximum value at which $S_{\max,b}$ "jumps" is approximate twice the value of $S_{\max,\text{steady}}$. The mises stress is shown in Figure 1 and $S_{\max,b}$ occurs in the region where the transverse curvature of the fold changes abruptly. When the $S_{\max,b}$ "jumps" phenomenon occurs, formula (3) cannot be used to estimate the maximum stress during the folding process, but specific numerical simulation is required.

(a) (b) (c) (d)

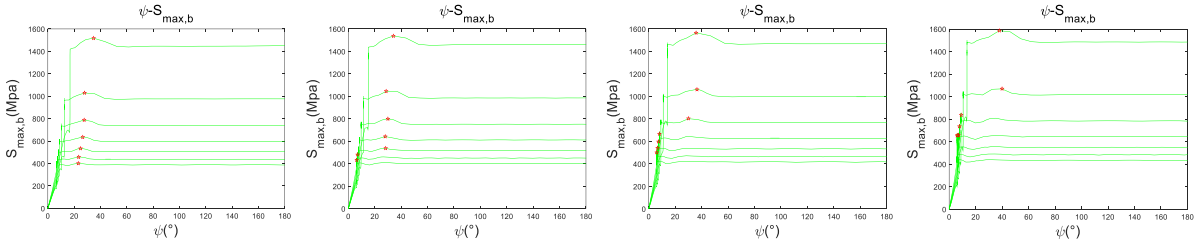

Figure 2. Maximum stress of C booms during the folding process: (a) A=60 °, (b) A=70 °, (c) A=80 °, (d) A=90 ° (curves from top to bottom represent R=10,15,20,25,30,35,40mm, respectively, and pentagrams represent the maximum values of $S_{\max,b}$)

2.2. Folding stress affected by boundary

C booms are typically used as support frames or hinges in deployable structures, with at least one end fully fixed. The hinge cannot infinitely approach the fixed end due to the ploy region. And section 2.1 studies this kind of folded state without boundary effects. However, when there is a design requirement or external force that forces the hinge to approach the fixed end, the stress of the boom will change. And this section studies this boundary effect on $S_{\max,b}$.

Based on the results of the finite element model in Section 2.1, as shown in Figure 3, after the C boom is folded 180 °, PC2 is fixed, and PC1 is pulled towards the opening direction of the hinge for a distance. Define x_{PC2} as the distance between PC2 and the endpoint of the hinge near the PC2. $S_{\max,b}$ during the pulling process is studied.

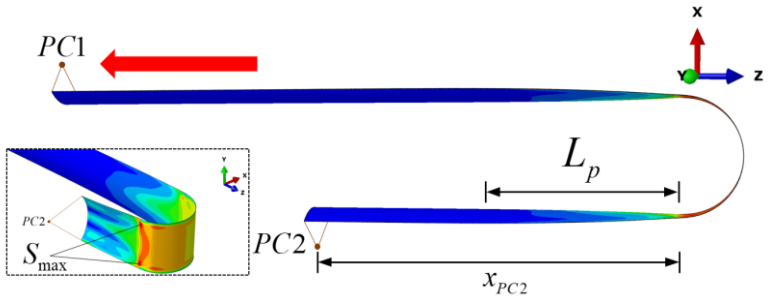

Figure 3. Pulling process of the C boom

As shown in Figure 4, when $x_{PC2}/L_p>1$, $S_{\max,b}$ remains approximately unchanged. When $x_{PC2}/L_p<1$, $S_{\max,b}$ begins to increase sharply, and boundary begins to affect the shape and size of the ploy region. At the same time, the longitudinal radius of curvature of the hinge also decreases. $S_{\max,b}$ occurs at the boundary of the hinge near the PC2, as shown in Figure 3. When $x_{PC2}/L_p=0.5$, $S_{\max,b}$ can be increased to 1.5-2 times the original value. Therefore, in engineering design, it is necessary to consider the impact of the hinge position x_{PC2} on the maximum stress during folding. Generally, x_{PC2} is compared with L_p, and the value of L_p can be calculated by Formula (2). When $x_{PC2}/L_p>1$, the boundary effects on $S_{\max,b}$ can be ignored, and the maximum value of $S_{\max,b}$ can be approximately calculated by the result of folding in Section 2.1. When $x_{PC2}/L_p<1$, a specific numerical simulation is required to determine the maximum value of $S_{\max,b}$, but this kind of design is not recommended unless necessary.

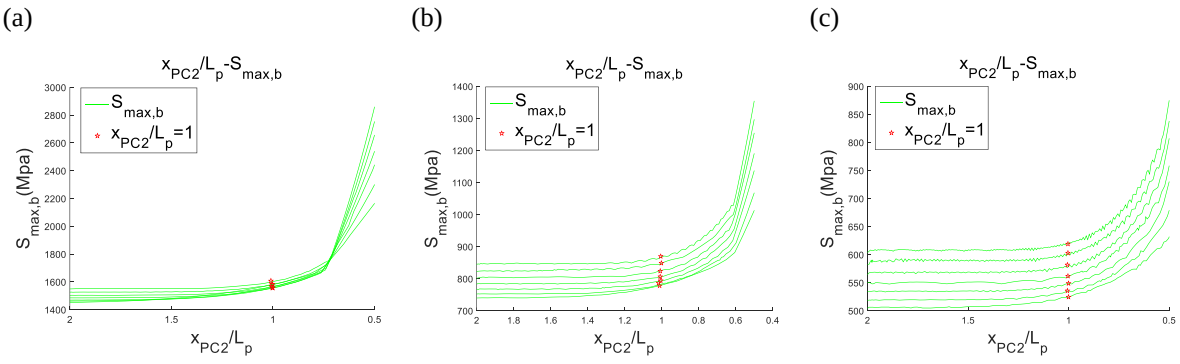

Figure 4. Maximum stress of C booms during the pulling process: (a) R=10mm, (b) R=20mm, (c) R=30mm (curves from top to bottom represent A=120, 110, 100, 90, 80, 70, 60 degrees, respectively)

3. Performance of C boom at deployed state

After the unlocking device is triggered, the C boom will release the stored elastic potential energy and expand to the final working state. The key to the performance of C booms at deployed state is sufficient stiffness. The common indicators for evaluating stiffness are bending stiffness and the natural frequency. Based on these two indicators, this section studies the impact of the size parameters of C booms on the stiffness at deployed state, and proposes two methods to improve the stiffness, namely, variable cross-section C boom and perforated C boom.

3.1. Parametric study on C boom

This section conducts a parametric study on the stiffness of C booms at deployed state. The material properties are shown in Table 1, and in this section, t =0.1mm, R = 10,15,20,...,60,65,70mm, A = 60,70,80,...160,170,180 degrees, L =500,600,700,800,900,1000mm.

3.1.1. Bending stiffness

Considering the small deformation of deployed C boom, its bending stiffness can be calculated according to the mechanics of material. As shown in Figure 1, θ is half of A, S is the area of the section, the y_C-axis is the centroid axis parallel to the y-axis, z_C is the z-coordinate of the y_C-axis, and I_{yO} and I_{yC} are the area moments of inertia relative to the y and y_C axes.

$$\theta = \frac{A}{2} \cdot \frac{\pi}{180} \tag{4}$$

$$S = 2R\theta t \tag{5}$$

$$I_{yO} = 2\int_0^{\theta} Rt\left(R\cos\alpha\right)^2 d\alpha \tag{6}$$

$$z_C = \frac{1}{S}\left(2\int_0^{\theta} Rt\left(-R\cos\alpha\right)d\alpha\right) \tag{7}$$

$$I_{yC} = I_{yO} - Sz_C^2 = \frac{R^3 t}{\theta}\left(\theta\sin\theta\cos\theta + 2\cos^2\theta + \theta^2 - 2\right) \tag{8}$$

The trend of EI_{yC} with R and A is shown in Figure 6, where EI_{yC} is positively correlated with R and A. When R >30mm and A >100 °, EI_{yC} increases significantly.

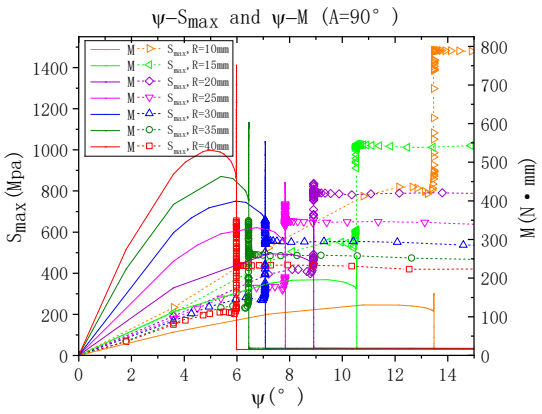

Figure 5. Bending moment and maximum stress with ψ

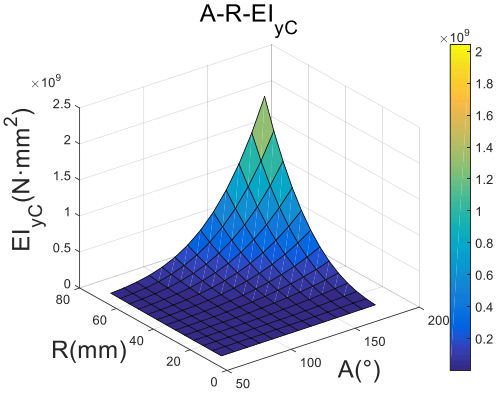

Figure 6. Bending stiffness of the C boom

3.1.2. Natural frequency

The natural frequency reflects the overall stiffness of the component. Generally, C booms are required to have a high natural frequency to ensure a stable working state. This section studies the first-order natural frequency of the cantilevered C boom f_c. Its material properties, elements, and size parameter values are the same as those of the finite element model in 2.1. The simulation results are shown in Figure 7.

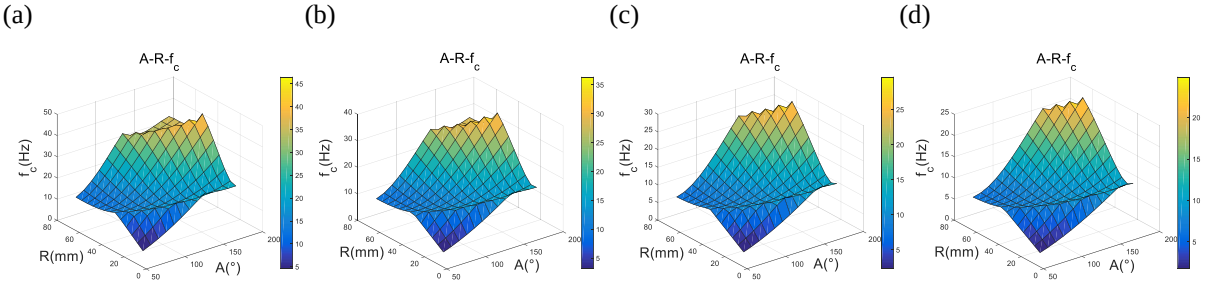

Figure 7. The first-order natural frequency of cantilever C booms: (a) L =500mm, (b) L =600mm, (c) L =700mm, (d) L =800mm

It can be seen that the trend of f_c with R and A is not monotonous, but there will be two peak lines corresponding to smaller and larger cross-sectional dimensions, respectively. When R and A are small, f_c has a significant increase with the increase of the cross-sectional dimension. When R and A cross the first peak line, f_c decreases slightly, and then rises significantly to the second peak line. When R and A cross the second peak line, f_c will have a significant decrease and remain stable within a certain range. Therefore, in engineering design, if a higher f_c is desired, the combination of R and A near the second peak line can be selected.

3.2. C boom with variable cross-section

In deployable structures, C booms are commonly used as support frames and bear uniform linear loads or concentrated loads at the ends. The section near the fixed end usually bears a greater bending moment than the distal end. From the perspective of mass reduction, the cross-section along the longitudinal direction should be variable.

This section suggests a C boom with a variable cross-section, as shown in Figure 8. In this kind of boom, R is uniform, while the subtending angle A_{vc} linearly decreases from A_2 at the fixed end to A_1 at the free end along the longitudinal direction. With the fixed end as the origin of the x-axis, A_{vc} at the coordinate x is

$$A_{vc}(x) = A_2 - \frac{A_2 - A_1}{L} x, \text{ where } A_1 \le A_2,\ x \in [0, L] \tag{9}$$

3.2.1. Bending stiffness

Because the bending stiffness of a C boom with variable cross-section varies along the longitudinal direction, it cannot be used to evaluate the stiffness of the boom. However, it is possible to compare whether the stiffness of a C boom with variable cross-section has improved compared to that of a C boom with the same mass according to specific working conditions. This section focuses on the application of ribs as support members in the wrap-rib deployable antenna. Due to accuracy requirements, when the mesh surface of the antenna is tensioned, the deformation of the ribs should be

controlled within the allowable range. The tension of the mesh facing the ribs is equivalent to a uniformly distributed load along the longitudinal direction, and the displacement of the free end of the ribs also reflects the overall deformation of the ribs. In this section, a cantilevered C boom with variable cross-section is established, and a uniformly distributed load $q = 10^{-3} N/m$ is applied on its middle line, to obtain the displacement z_{vc} of the free end of the boom along the load direction, as shown in Figure 9. The material properties are shown in Table 1. The method for determining a C boom with the same mass is to ensure that the material, t, R and L are the same as those of a C boom with variable cross-section, and determine a C boom with a subtending angle A_{emvc} to make it have the same mass as the C boom with variable cross-section, which gives

$$\rho t R A_{emvc,rad} L = \int_0^L \rho t R A_{vc,rad}(x)\, dx \tag{10}$$

where

$$A_{emvc,rad} = \frac{A_{emvc}}{180} \cdot \pi \,, \quad A_{vc,rad}(x) = \frac{A_{vc}(x)}{180} \cdot \pi \tag{11}$$

(a) (b)

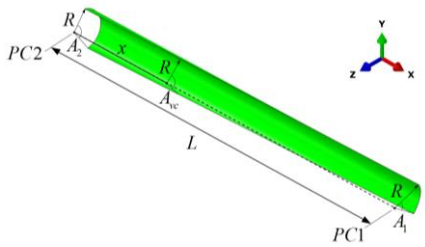

Figure 8. The C boom with the variable cross-section

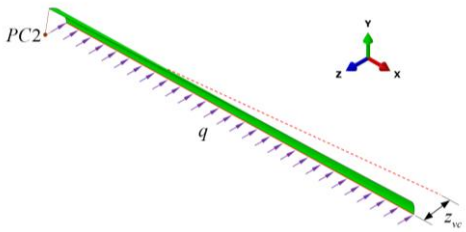

Figure 9. The uniformly distributed load

Apply the same boundary conditions and loads to the C boom with the same mass to obtain the displacement of the free end along the load direction z_c. Here, Rat_z is defined as $Rat_z = z_{vc} / z_c$. A parametric study is carried out, in which t =0.1mm, R =10,20,30,40,50,60,70mm, A_1 =60, 80, 100, 120, 140, 160, 180 degrees, $A_2 = A_1 + 20,...,180$ degrees, and L =500,600,700,800mm. The simulation results are shown in Figure 10.

(a) (b) (c) (d)

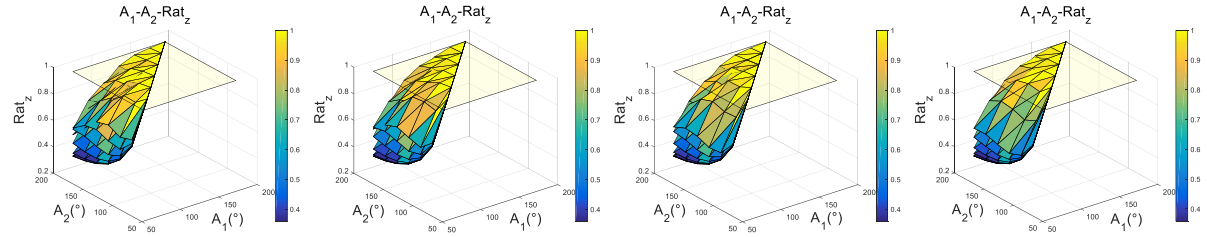

Figure 10. The ratio of displacement $Rat_z = z_{vc} / z_c$: (a) L =500mm, (b) L =600mm, (c) L =700mm, (d) L =800mm (the 7 curved surfaces in each figure correspond to R =10-70mm, and the yellow plane represents $Rat_z = 1$)

It can be seen that all curved surfaces are below the 1 plane, that is, for C booms with variable cross sections, $z_{vc} < z_c$. When A_1 is smaller and A_2 is larger, the displacement decreases more significantly,

and the minimum displacement can be reduced to 0.3-0.4 times the original value. Therefore, under the action of uniformly distributed load, the stiffness of the C boom with variable cross-section is improved compared to the C boom with the same mass, and the smaller A_1 is and the larger A_2 is, the more significant the stiffness improvement will be.

3.2.2. Natural frequency

This section studies the first-order natural frequency of a cantilevered C boom with variable cross-section f_{vc}. The material properties, elements, and parameter values are the same as those of the finite element model in 3.2.1., and the simulation results are shown in Figure 11.

It can be seen that with the decrease of A_1 and the increase of A_2, the first-order natural frequency of C booms with variable cross sections will also increase, indicating higher stiffness. To compare the natural frequency of the C boom with the same mass, the first-order natural frequency of it is calculated using the same model as in Section 3.2.1. Here, $Rat_{f,vc}$ is defined as $Rat_{f,vc} = f_{vc} / f_{c,vc}$, and the simulation results are shown in Figure 12.

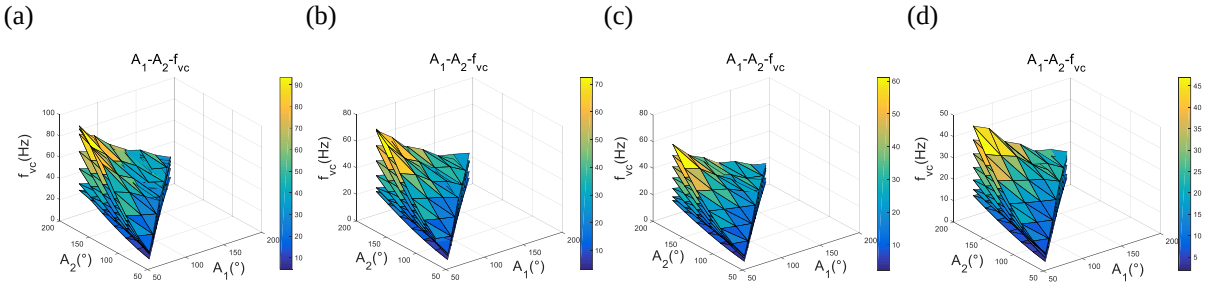

Figure 11. The first-order natural frequency of cantilevered C booms with variable cross sections: (a) L =500mm, (b) L =600mm, (c) L =700mm, (d) L =800mm (the 7 curved surfaces in each figure correspond to R =10-70mm)

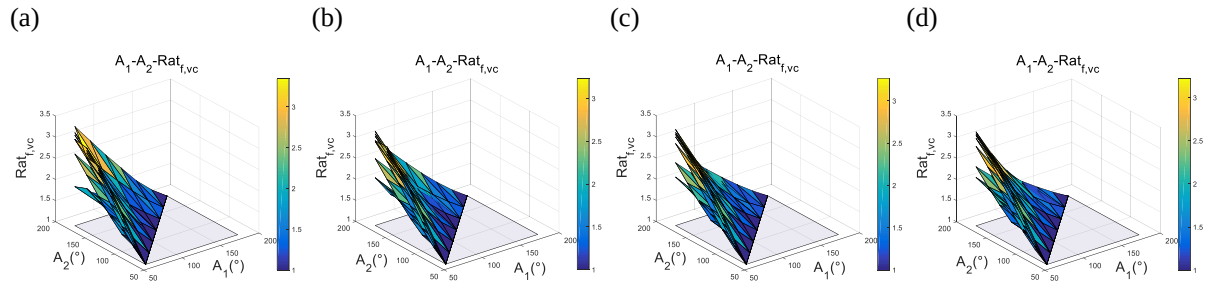

Figure 12. The ratio of first-order natural frequency $Rat_{f,vc} = f_{vc} / f_{c,vc}$: (a) L =500mm, (b) L =600mm, (c) L =700mm, (d) L =800mm (the 7 curved surfaces in each figure correspond to R =10-70mm, and the purple plane represents $Rat_{f,vc} = 1$)

It can be seen that the C boom with variable cross-section has a higher first-order natural frequency, that is, a higher stiffness, compared to the C boom with the same mass. When A_1 is smaller and A_2 is larger, the stiffness increases more obviously, which is consistent with the conclusion in Section 3.2.1.Therefore, in engineering design, C booms with variable cross sections can be used to reduce the mass of components and improve stiffness.

3.3. Perforated C boom

This section suggests a perforated C boom, which is made by drilling some holes in the C boom. The specific method is to divide the projection surface of the opening direction of the C boom into several squares, with the side length d of the square being $1/n$ times the width of the belt spring. In this paper, n is taken as 5. Correct L so that it is equal to an integer multiple of d and is closest to the design length, so that the holes are evenly distributed along the longitudinal direction of the boom. Draw a circle with the center of the square as the center and D as the diameter. Here, H is defined as $H = D/d$, where $H \in [0,1)$. Remove the projection of the circular region on the boom and the drilling is completed, as shown in Figure 13. Here, the hole ratio Rat_{hol} is defined as the ratio of the mass of the perforated C boom m_{hol} to the mass of the original C boom m_c.

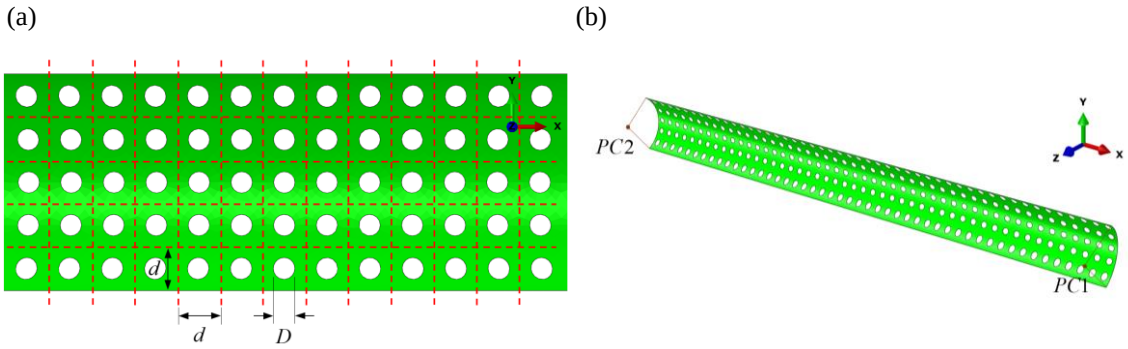

Figure 13. Perforated C boom: (a) distribution of holes on the projection plane, (b) distribution of holes in the boom

3.3.1. Bending stiffness

Due to the uniform distribution of holes along the longitudinal direction, it can be approximately assumed that the bending stiffness of the perforated C boom along the longitudinal direction is the same, and therefore it can be used to evaluate the stiffness of the boom. The bending stiffness can be obtained by numerical simulation of pure bending. As shown in Figure 13, the sections at both ends of the boom are coupled and constrained to PC1 and PC2 respectively, then a 1 ° angle around the y-axis is added to PC1 while PC2 is fixed. The bending moment of the boom section $M_{y,1\deg}$ is extracted and the bending stiffness can be derived as $EI_{hol} = 180 M_{y,1\deg} L/\pi$. The material properties are shown in Table 1. To ensure the accuracy of the simulation results, at least 8 elements are distributed along each hole edge in the finite element model.

By changing H, perforated C booms with different Rat_{hol} can be obtained, and a parametric study on EI_{hol} is carried out, in which t =0.1mm, L =500mm, R =10,20,30,40,50,60,70mm, A =60, 80, 100, 120, 140, 160 degrees, and H =0.1,0.2,0.3,0.4,0.5,0.6,0.7. The simulation results are shown in Figure 14.

As can be seen from Figure 14, the higher the hole ratio, the smaller the bending stiffness. However, drilling also reduces the mass of the boom, so the bending stiffness of the C boom with the same mass was studied. The method for determining a C boom with the same mass is to ensure that the material, t, R and L are the same as those of a perforated C boom, and determine a C boom with a subtending angle A_{emhol} to make it have the same mass as the perforated C boom, which gives

$$\rho t R A_{emhol,rad} L = m_{hol} \tag{22}$$

where $$A_{emhol,rad} = \frac{A_{emhol}}{180} \cdot \pi \tag{33}$$

The bending stiffness of the C boom with the same mass EI_{emc} can be obtained using the same method of loading and bending stiffness calculation as the perforated C boom. Here, Rat_{EI} is defined as $Rat_{EI} = EI_{hol} / EI_{emc}$, and the simulation results are shown in Figure 15.

(a) (b)

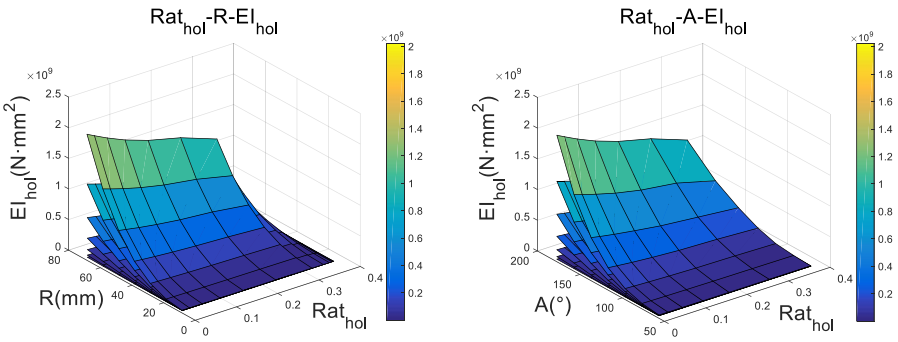

Figure 14. The bending stiffness of the perforated C boom EI_{hol} : (a) trend of EI_{hol} with Rat_{hol} and R (curved surfaces from top to bottom represent A =180, 160, 140, 120, 100, 80, 60 degrees, respectively), (b) trend of EI_{hol} with Rat_{hol} and A (curved surfaces from top to bottom represent R =70,60,50,40,30,20,10mm, respectively)

(a) (b)

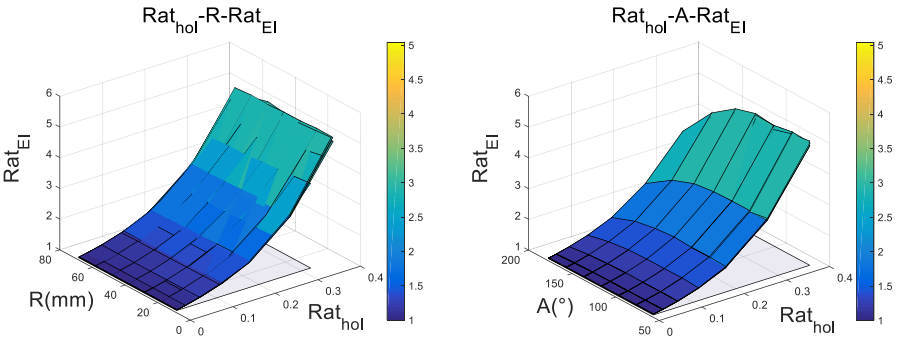

Figure 15. The ratio of bending stiffness Rat_{EI} : (a) trend of Rat_{EI} with Rat_{hol} and R, (b) trend of Rat_{EI} with Rat_{hol} and A (there are 7 surfaces in each figure representing different A and R, but they almost coincide)

It can be seen that compared to C booms with the same mass, perforated C booms have higher bending stiffness. And the higher Rat_{hol}, the more significant the improvement in bending stiffness.

3.3.2. Natural frequency

This section studies the first-order natural frequency of a cantilevered perforated C boom f_{hol}. The material properties, elements, and parameter values are the same as those of the finite element model in 3.3.1., and the simulation results are shown in Figure 16 and Figure 17.

As can be seen, the higher Rat_{hol}, the smaller f_{hol}. However, the trend of f_{hol} with A and R is not monotonic, but there is a peak line, that is, each R corresponds to an A, making f_{hol} reach an extreme point. To compare the natural frequency of the C boom with the same mass, the first-order natural frequency of it is calculated using the same model as in Section 3.3.1. Here, $Rat_{f,hol}$ is defined as $Rat_{f,hol} = f_{hol} / f_{c,hol}$, and the simulation results are shown in Figure 18 and Figure 19.

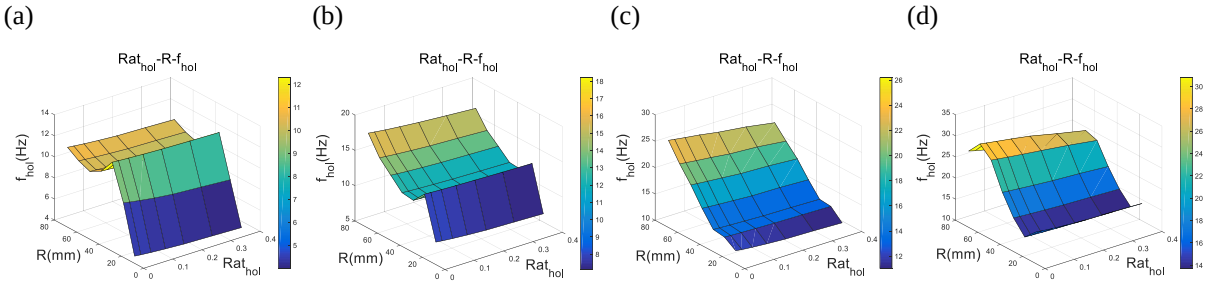

Figure 16. The trend of f_{hol} with Rat_{hol} and R: (a) A=60°, (b) A=80°, (c) A=100°, (d) A=120°

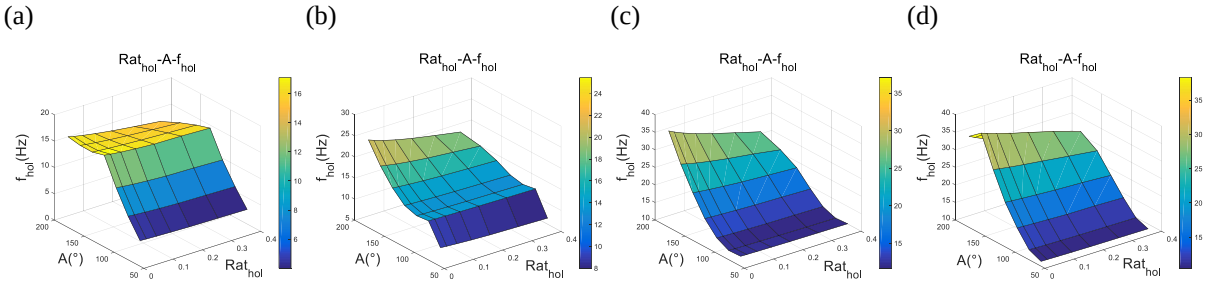

Figure 17. The trend of f_{hol} with Rat_{hol} and A: (a) R=10mm, (b) R=20mm, (c) R=30mm, (d) R=40mm

It can be seen that most perforated C boom has a higher first-order natural frequency, that is, a higher stiffness, compared to the C boom with the same mass. And the higher Rat_{hol}, the more significant the improvement in stiffness, which is consistent with the conclusion in Section 3.3.1. However, there are also some perforated C booms whose f_{hol} is lower than $f_{c,hol}$. For example, when R=70mm, A =160 °, and Rat_{hol} =0.3482, f_{hol} is only 67.11% of $f_{c,hol}$.

Therefore, in engineering design, perforated C booms can be used to reduce the mass of components and improve stiffness. However, in pursuit of higher natural frequencies, it is necessary to distinguish according to Figure 16-19 or conduct specific numerical simulations.

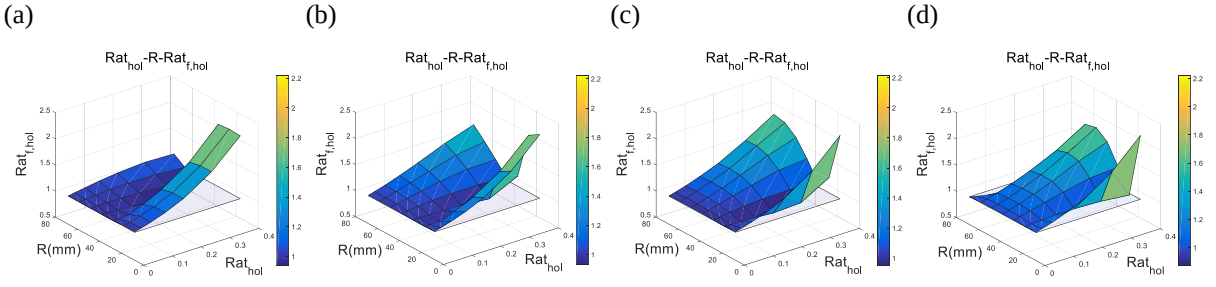

Figure 18. The trend of $Rat_{f,hol}$ with Rat_{hol} and R: (a) A=60°, (b) A=80°, (c) A=100°, (d) A=120°

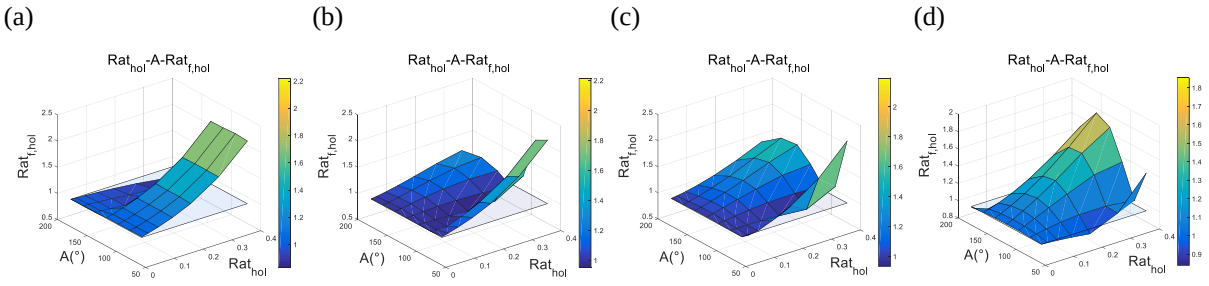

Figure 19. The trend of $Rat_{f,hol}$ with Rat_{hol} and A: (a) R=10mm, (b) R=20mm, (c) R=30mm, (d) R=40mm

4. Conclusions

This paper studies the mechanical properties of the C boom in folded and deployed states. The maximum stress during the folding process of C booms is studied. When the cross-section size is large, the maximum stress will exhibit a "jump" phenomenon. The boundary also affects the stress. When the distance between the hinge and the fixed end is less than the length of the ploy region, the maximum stress will increase sharply. The bending stiffness and first-order natural frequency of deployed C booms are studied. The C boom with variable cross section and the perforated C boom is suggested and studied to reduce the mass and improve the stiffness. The bending stiffness of these two types of booms is improved compared to C booms with the same mass, and the first-order natural frequency is also improved except for a small number of perforated C booms.

Abstract

To meet the demand for deployable antennas with high storage ratio and lightweight， a wrap-rib deployable antenna was developed in this paper. The antenna was less than 0.6 kg in weight, 0.5 meter in aperture and could be stowed in 1.5 U (10 cm× 10 cm× 15 cm). Paraboloidal mesh reflector was designed for X-band operation. The reflector was composed of ribs, metal mesh and side cables. The ribs were not only the driving elements of the reflector but also the fixing boundary of the metal mesh. C-shaped cross section was adopted for the ribs. The wrapping process of C-shaped stainless steel rib was analyzed theoretically and numerically. It was verified that ribs were in elastic state during wrapping process. Based on surface accuracy required by X-band， the number of ribs was determined as 16 and the focal length to aperture ratio of the reflector was 0.45. The reflector surface was found through shape finding analysis in which both the deformation of ribs and the distribution of tension in mesh were considered. The optimal curve of ribs was designed by minimizing the surface error through genetic algorithm. Two prototype antennas were assembled and the shapes of reflector surface were measured before and after shaking table tests. The surface RMS error was 0.8-1.0mm and had little change after multi-deployment.

Keywords: deployable antenna, wrap-rib, shape finding analysis, surface accuracy test, repeat accuracy

1. Introduction

Spaceborne deployable antenna structure can be stowed during transportation and storage, and can be deployed to a stable working state when in orbit. According to the shape of the reflector, deployable antenna can be divided into three types: solid reflector antenna; inflatable reflector antenna and mesh reflector antenna. The mesh reflector antenna has the advantages of light weight and high storage ratio, and it is easy to realize large aperture. According to the different supporting structures, the mesh reflector antenna can be divided into radial-rib antenna, wrap-rib antenna and truss antenna.

The CubeSat is a kind of microsatellites. A standard unit (1 U) of the CubeSat is a cube with an effective size of 10 cm× 10 cm× 10 cm and a mass not exceeding 1 kg. Compared with traditional satellites, the characteristics of microsatellites represented by CubeSat can be summarized as follows: microsatellites are small in size, light in weight, and easy to achieve a rocket to launch more than one satellite; the design life of microsatellites is often short, but the development cycle is also short and the cost is low; multiple microsatellites can form a distributed space system to achieve global coverage, and the single microsatellite has a high degree of integration, which can adopt modular design.

With the large increase in the demand for microsatellite, the modularization and standardization of microsatellite can realize the advantages of low cost, high performance and short development cycle. The research and development of standardized deployable antenna for microsatellites has important engineering application value.

The small size and light weight of microsatellites put forward many harsh requirements for the deployable antenna carried by them, such as: extreme lightweight, minimal storage volume, high surface accuracy, etc. The mesh reflector antenna has good results in surface accuracy, storage efficiency, mass and aperture. It has good comprehensive performance. Compared with radial-rib as given by SERC and JPL, the stiffness of wrap-rib is smaller, so the surface accuracy of wrap-rib antenna is slightly lower. But the wrap-rib antenna structure is simpler. The weight is lighter. And the storage efficiency is higher.

The paraboloidal reflector antenna installed on a microsatellite such as CubeSat can greatly enhance the satellite's communication capability. The Space Engineering Research Center of the University of Southern California (SERC) has developed a radial-rib deployable antenna. The antenna was 0.5 meter in aperture and could be stowed in a load area of 10 cm× 10 cm× 16 cm in Colony I CubeSat. The antenna consists of 30 ribs, each of which has two rotating hinges for deployment [1]. NASA Jet Propulsion Laboratory (JPL) developed a novel Ka-band radial-rib deployable antenna for Rain Cube CubeSat. The antenna consists of 30 ribs, and it could be stowed in 1.5 U (10 cm× 10cm × 15cm) [2-4].

The radial-ribs of the antennas as given by SERC and JPL are each 30 rigid rods with a rotating hinge in the middle. The antenna reflector of the Colony I CubeSat is deployed by using the spring to push out of the storage container. The antenna reflector of the Rain Cube CubeSat is deployed by using the screw to push out of the storage container. The two antenna reflectors have high and stable surface accuracy, but the structure is complicated. So the installation is slightly complicated. The storage efficiency is slightly low. The mass is slightly heavy. And the deployment reliability is slightly low.

In this paper, a wrap-rib deployable antenna was developed. The ribs of the antenna are 16 thin-walled rods with 0.1mm thick C-shaped cross section. The reflector is deployed by the drive of the elastic potential energy stored in the elastic wrapped ribs. The reflector structure is slightly simple. So the installation is slightly simple. The storage efficiency is slightly high. The mass is slightly light. And the deployment reliability is slightly high. Through the key position design and standardized installation technology, the reflector has a good and stable surface accuracy. Moreover, The height adjustment structure of the feed and the design of stowing the reflector through the shells make the installation, testing and stowing of the deployable antenna very convenient.

In this paper, the curve of wrap-rib was optimized. Two prototype antennas were constructed to analyzed and tested the surface accuracy of reflector.

2. Concept and design

A wrap-rib deployable antenna was developed in this paper. The antenna was less than 0.6 kg in weight, 0.5 meter in aperture and could be stowed in 1.5 U (10 cm× 10 cm× 15 cm). Paraboloidal mesh reflector was designed for X-band operation. The antenna includes locking and unlocking device, deployable reflector, deployable shell, and deployable feed, as shown in Figure 1. The deployable reflector, deployable shell and deployable feed are deployed by the drive of some elastic members. Locking and unlocking device includes rope for storage, endotherm knife and other components.

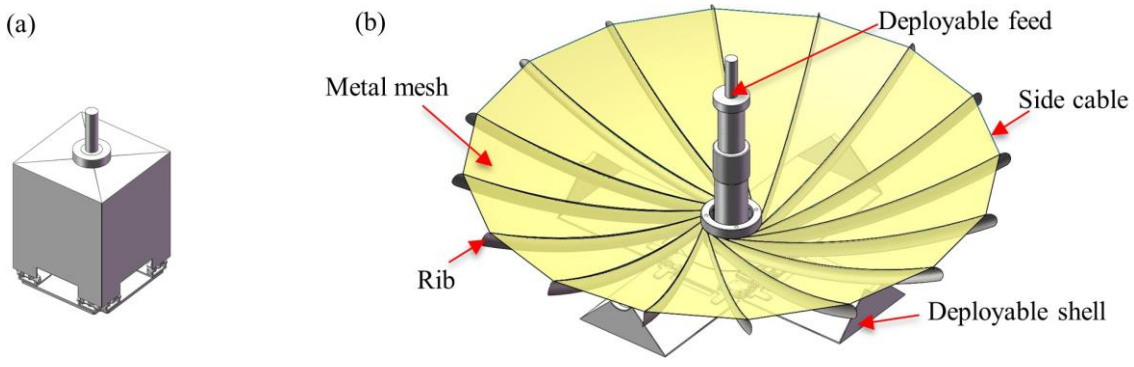

Figure 1. Configuration of wrap-rib deployable antenna: (a) stowed state, (b) deployed state.

The deployable reflector is composed of ribs, metal mesh and side cables. The root of every rib is fixed on the central hub of the antenna. The edge of the metal mesh is tensioned by the side cables. High strength and high elasticity materials such as stainless steel can be selected for the ribs, which can meet the requirements of space environment and ensure that ribs remain elastic in the wrapping process. The cross section of the ribs can adopt lenticular shape, C shape or double C shape, which have high flexural rigidity. C-shaped cross section is easy to process, so the ribs of prototype adopt C-shaped cross section in this paper. The deployable shell includes shells, pin shafts, torsional springs and locking device. The deployable feed includes telescopic sleeve, sleeve spring, feed, feeder and height adjustment structure.

The sequence of the stowing process is: reflector → shell → feed → locking device. The reflector is stowed by wrapping the ribs around the central hub, and the mesh should be located above the ribs to avoid being squeezed. Then the four shells are rotated around the pin shafts and locked. The stowed shells prevents the reflector from deploying. The deployable feed is stowed by compressing sleeve spring, and the claw at the top of the deployable feed in the stowed state prevents the four shells from deploying. Finally, the deployable feed is locked in the stowed state by a pre-tightened rope and the spiral-shaped feeder is secured in the sleeve. The section of stowed state antenna is shown in Figure 2

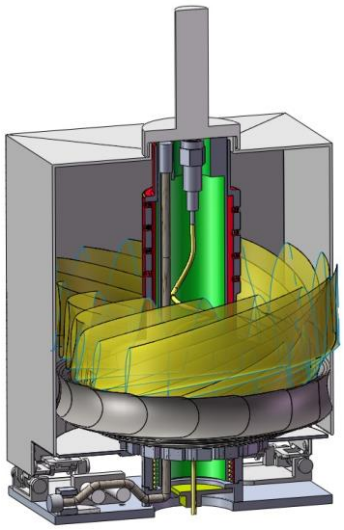

Figure 2. The section of stowed state antenna

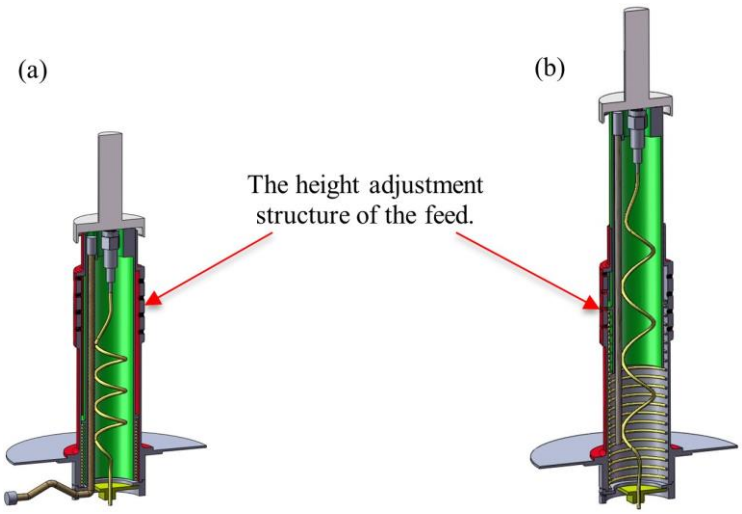

Figure 3. The section of deployable feed: (a) stowed state, (b) deployed state.

The sequence of the deploying process is: unlocking device → feed → shell → reflector. The antenna can be deployed by applying electricity to the endotherm knife. Firstly, by using the endotherm knife to cut the pre-tightened rope, the deployable feed is deployed under the push of the sleeve spring, and the feeder is elongated. Then, the claw at the top of the deployable feed do not restrain the four shells, which are deployed and locked in the deployed state by the drive of torsion springs at the pin shafts. Finally, the reflector is deployed by the drive of the elastic potential energy of the wrapped ribs, and the mesh of reflector is tensioned by ribs. The stowed state and deployed state of deployable feed is shown in Figure 3, and the outer sleeve contains the height adjustment structure of the feed.

The reflector surface is paraboloid when it is deployed. Four shells are simultaneously rotated outward 90°, then locked on the back of the reflector. The deployable feed is pushed near the focus of the reflector. The deploying process is shown in Figure 4. In the deployed state, the position of the shells and the feed are locked, and the mesh of reflector is tensioned by ribs.

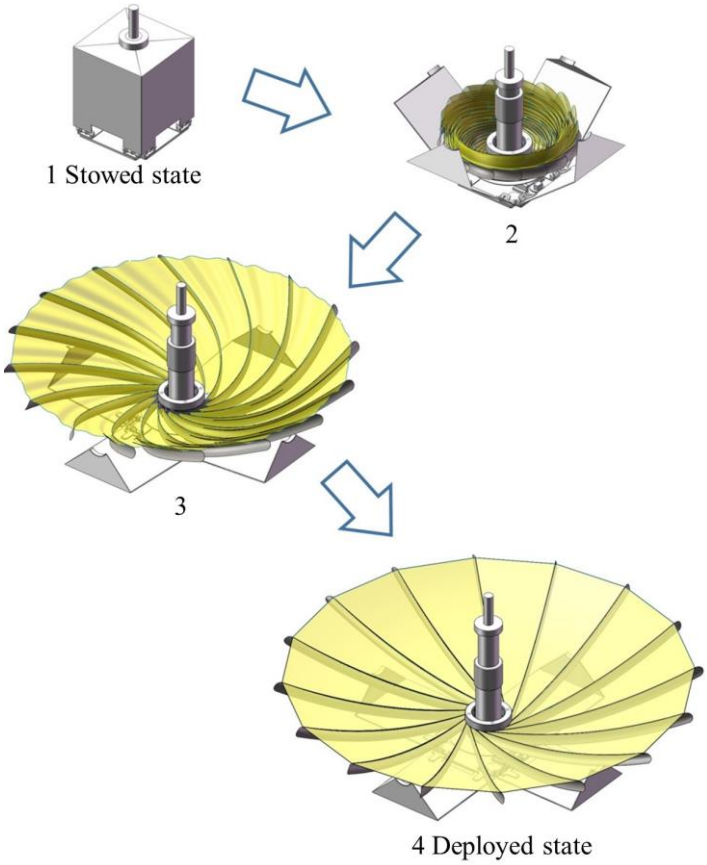

Figure 4. Deploying process

3. Rib and its wrapping analysis

3.1. Cross section of rib

Metal mesh should be tensioned and ribs support the mesh, so the cross section of rib should make the rib have enough flexural rigidity. Also, the rib should be in an elastic state under stowed state. In this paper, C-shaped cross section stainless steel rib is adopted. The cross section is flattened and wrapped for storage. In the deployed state, the cross section is restored to C-shape to provide better flexural rigidity. The geometric parameters of C-shaped cross section include radius of curvature R, thickness t and central angle θ, as shown in Figure. 5. After the cross section is flattened, it is wrapped around the

central hub of the antenna. In the stowed state, the wrapping radius r of wrapped rib is half of the outside diameter of central hub.

Based on the flexural rigidity and stress in the stowed state of rib, the following design parameters were selected in this paper: R = 15 mm, θ = 56°, t = 0.1 mm, r = 25 mm.

The ribs should be made of high strength and high elastic modulus materials to meet the requirements of space environment. In this paper, high strength stainless steel is used to make the ribs of the test prototype. The elastic modulus of the material is 206 GPa and the tensile strength is 1300 MPa.

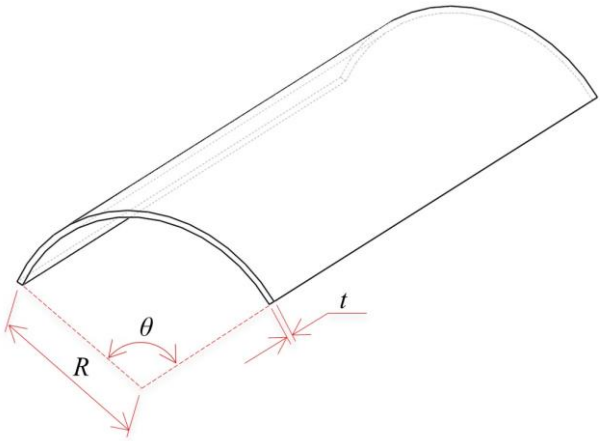

Figure 5. The cross section of wrap-rib

3.2. Approximate theoretical analysis of wrapping process

The approximate theoretical analysis of the wrapping process of rib was carried out. Ignoring the curve shape along the length of the rib, the wrapping process of the C-shaped cross section straight rib around the 2r diameter cylinder was analyzed. The theoretical analysis model is shown in Figure 6. The x direction refers to the direction along the rib length, and the y direction refers to the direction along the cross section. the convex surface of the rib is wrapped tightly to the central hub.

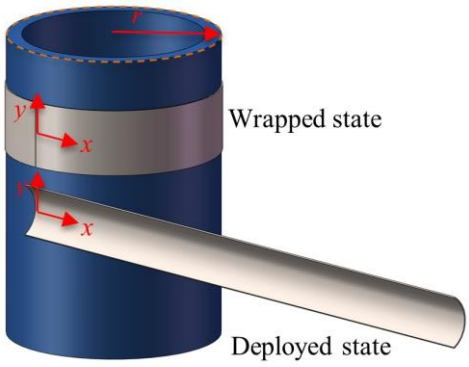

Figure 6. Analytical model of wrapping process

The wrapping process of C-shaped cross section rib includes two processes: section flattening and wrapping. According to the thin shell theory [6], equations (1) ~ (3) represent the stress-strain relationship at the position where the distance from the central surface is z.

$$\sigma_x = \frac{E}{1-\mu^2} z(\Delta k_x + \mu \Delta k_y) \tag{1}$$

$$\sigma_y = \frac{E}{1-\mu^2} z(\Delta k_y + \mu \Delta k_x) \tag{2}$$

$$\tau_{xy} = 0 \tag{3}$$

$\triangle k_x$ and $\triangle k_y$ are the curvature changes in the x and y directions, respectively. Ignoring the slight differences of curvature changes along the thickness direction, and considering the two processes of flattening and wrapping, the curvature changes can be obtained as shown in equation (4):

$$\Delta k_x = \frac{1}{r}, \Delta k_y = \frac{1}{R} \tag{4}$$

The magnitudes of two principal stresses on the convex surface of wrapped rib are shown in equations (5) and (6):

$$\sigma_1 = \frac{Et}{2(1-\mu^2)}(\frac{1}{R} + \mu \frac{1}{r}) \tag{5}$$

$$\sigma_2 = \frac{Et}{2(1-\mu^2)}(\frac{1}{r} + \mu \frac{1}{R}) \tag{6}$$

The cross section parameters (t = 0.1mm, R = 15mm) and the wrapping radius (r = 25mm) were substituted, and the elastic modulus and Poisson's ratio of stainless steel were considered, then the Mises stress was calculated as equation (7) :

$$\sigma_M = \sqrt{\sigma_1^2 + \sigma_2^2 - \sigma_1 \sigma_2} = 821.5\text{MPa} \tag{7}$$

3.3. Numerical analysis of wrapping process

The antenna reflector in this paper is a paraboloid. The curve of rib which is the boundary of the mesh is temporarily considered as a parabola. And the actual design curve of rib was slightly adjusted after subsequent optimization design in the Section 4 of the paper. Finite element software ABAQUS was used to analyze the wrapping process of parabolic single rib. The curve equation along the length of the rib is temporarily taken as $z = x^2 / 900$ (0 mm$\leqslant$ x $\leqslant$ 250 mm). In order to realize the tight wrapping of rib around the central hub, two additional 50 mm diameter cylinders were added to the numerical analysis model, both of which were set as rigid bodies. The reference points of the two cylinders were controlled for displacement loading. First, the C-shaped cross section rib was flattened, then turn one cylinder forward and reverse the other cylinder, and the rib was tightly wrapped around the cylinder. Limited sliding contact is arranged between the two sides of the rib and the surface of the cylinder, and the friction coefficient is set at 0.2. The finite element analysis model is shown in Figure 7. The Mises stress nephogram of the concave side and convex side after wrapping is shown in Figure 8.

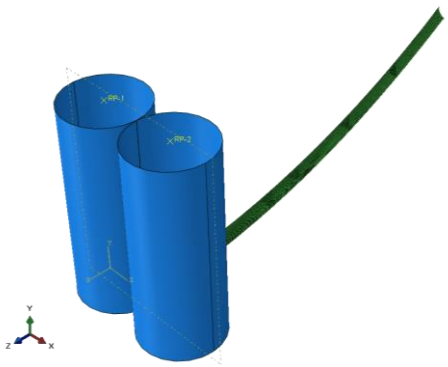

Figure 7. FEM model of wrapping process

As shown in Figure 8, the maximum Mises stress under wrapped state was 942.9 MPa on concave side and 946.9 MPa on convex side. The maximum Mises stress calculated by the finite element method was slightly larger than the approximate theoretical value, that is because the finite element model considered the curve shape along the length of rib and the contact friction.

In this paper, stainless steel ribs (material tensile strength: 1300 MPa) were fabricated. Through the wrapping test, the rib maintained a good elastic state, and no obvious plastic deformation was observed.

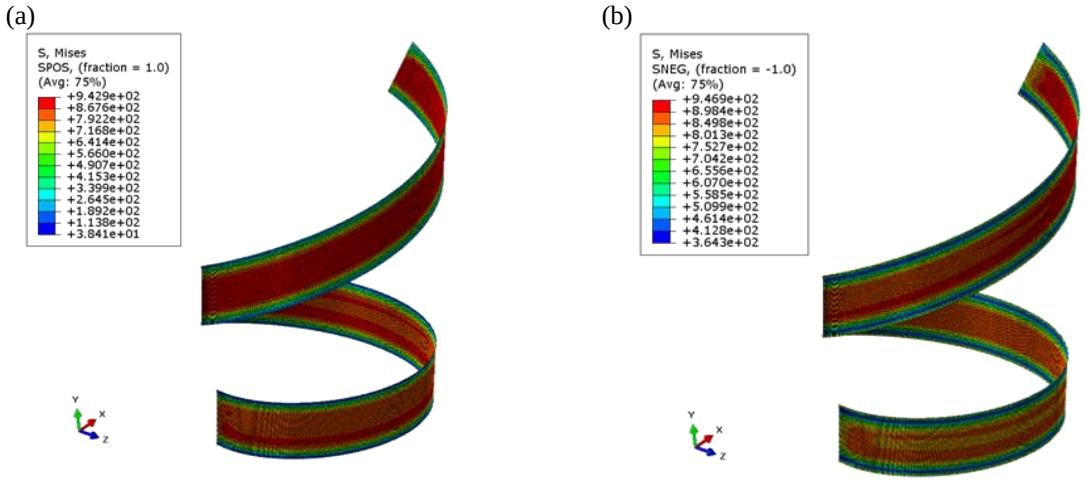

Figure 8. Mises stress of wrapped rib: (a) concave side, (b) convex side.

4. Surface accuracy analysis of reflector

4.1. Number of ribs

The number of ribs is mainly determined by the surface accuracy requirement of the reflector. The more the number of ribs, the higher the surface accuracy of reflector can be achieved, but the more complex the structure is. Without considering the machining error and installation error of the actual model, the back-pillow effect of the reflector and the rib deformation, the surface accuracy of reflector with different number of ribs and different focal length to aperture ratio of the reflector is roughly estimated, and the estimated RMS are defined as RMS-E. Three focal length to aperture ratio f/D (D = 500 mm) were set: 0.3, 0.45 and 0.5. Ribs were arranged in the tangent direction of the central hub. The mesh between ribs was assumed to be the flat plane. The calculated RMS-E values of reflector are shown in Figure 9.

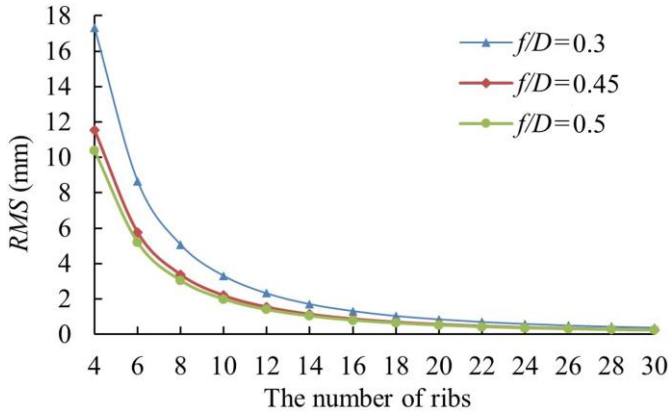

Figure 9. Relationship between number of ribs, f/D and RMS-E

The deployable antenna is considered to be used in X-band operation. Surface accuracy RMS less than 1 mm can meet the requirements of X-band antenna. In this paper, the focal length to aperture ratio of reflector is 0.45, the number of ribs is 16, and the RMS-E value is 0.88 mm.

4.2. Surface accuracy considering rib deformation and back-pillow effect

Compared with radial-rib as given by SERC and JPL, the stiffness of wrap-rib is smaller. Under the tension of the mesh and the side cable, the rib will have elastic deformation at deployed state. Also, there will be back-pillow effect on the mesh surface. To evaluate the surface accuracy of the reflector, it is important to determine the shape of the reflector through reasonable shape finding analysis. For this reason, the ribs are taken as elastic boundary of mesh, and the deformation of ribs is considered in the process of shape finding. The shape of the reflector with uniform tension is obtained by iterative calculation.

The finite element model of reflector was established by ANSYS software for shape finding analysis. In the shape finding analysis, the pre-tension of the mesh surface was set at 2 g/cm (The thickness of the mesh is 0.08 mm, so the prestress is 0.025 MPa), and the force of the side cable was set according to the vertical span ratio which is 1/10. The shape finding analysis process is as follows:

(1) Establish the finite element model of the deployed reflector, including the ribs, mesh and cables. Virtual small elastic moduli are used for the mesh and cables.

(2) Set the predetermined prestresses for the mesh and cables and then carry out FE calculations.

(3) Update the structure shape with the deformed shape.

(4) Repeat steps (2) and (3) for several iterations, until the stresses in the mesh and cables are close to the predetermined prestresses.

The Mises stress distribution of the mesh was obtained after 50 iterations, as shown in Figure 10. The maximum node displacement increment with the number of iterations is shown in Figure 11.

It can be seen from Figure 10 that the tension of the mesh after 50 iterations is close to the pre-set 0.025MPa, and the stress distribution is relatively uniform. In Figure 11, after 12 iterations, the maximum node displacement increment of each iteration is less than 0.1mm. From the uniformity of stress distribution and maximum node displacement increment, we can know that the reflector has reached the equilibrium position after 50 iterations, and the shape finding analysis has been completed.

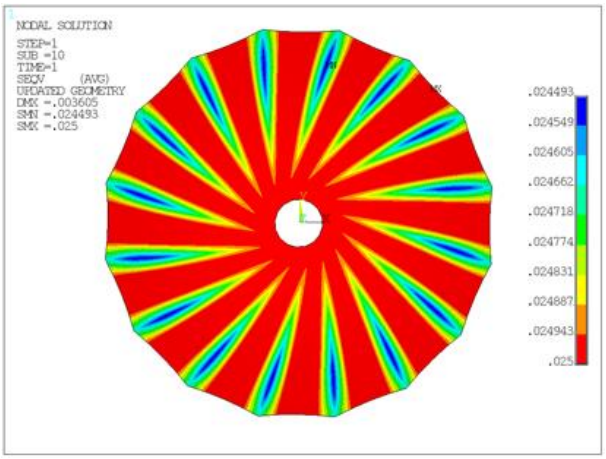

Figure 10. Mises stress distribution of mesh after 50 iterations

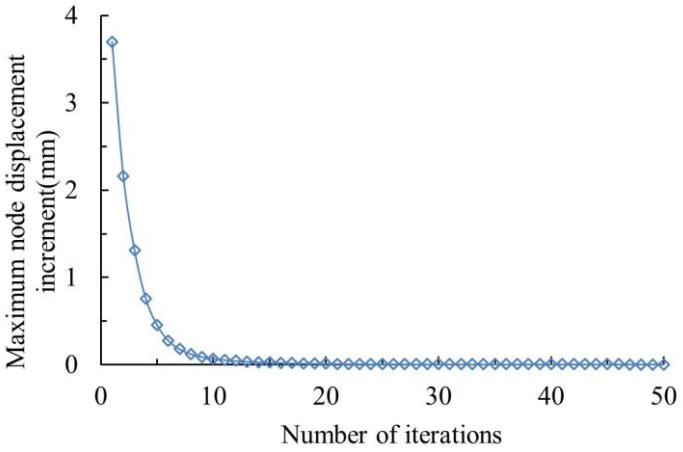

Figure 11. Maximum displacement increment in iterations

The ribs after the shape finding analysis have a rotation deformation about the central axis of reflector. The coordinates of the reflector after shape finding were extracted, and the RMS value of the reflector is 1.22 mm, which is larger than the RMS value of 0.88mm in the non-tension state before shape finding analysis.

4.3. Optimization for the curve of rib

Due to rib deformation and back-pillow effect, the surface accuracy of reflector is obviously reduced. The surface accuracy of reflector can be improved by optimizing the rib shape.

In this paper, the curve equation along the length of rib is set as a parabolic equation $z = ax^2+bx+c$ (0 mm$\leqslant x \leqslant$ 250 mm). Coefficient c could be set as 0 in describing the shape of rib. Aiming at the minimum RMS value of the reflector, coefficients a and b of the equation were optimized by genetic algorithm [7]. According to the initial values of coefficients which were a_0 = 1/900 and b_0 = 0 as given in Section 3.3, the value ranges of optimization variables were set as 1/1000 $\leqslant a \leqslant$ 1/800 and -0.01 $\leqslant b \leqslant$ 0.01. There were 100 individuals in each generation. The variation rate was set as 5%, and the termination criterion was that the propagation generation reached 40. The evolution process is shown in Figure 12. After the 29th generation, the change of the optimal RMS value between the two adjacent generations was less than 0.001 mm. Taking the optimization results of the 40th generation, the curve equation of rib is z = 0.001102 x^2 – 0.007368 x (0 mm$\leqslant x \leqslant$ 250 mm), and the RMS value of the reflector is 0.71 mm, which is less than 0.88 mm (see Section 3.3) or 1.22 mm (see Section 4.1). By optimizing the shape of rib, the surface accuracy of reflector is effectively improved.

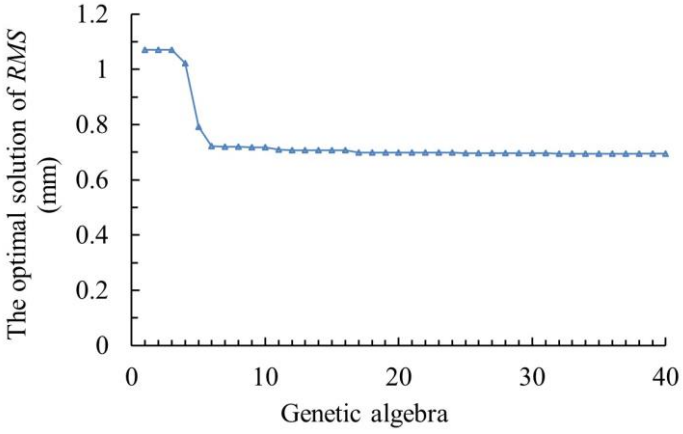

Figure 12. RMS optimization process

5. Measurement of surface accuracy

5.1. Measurement scheme

Two prototypes of 0.5m aperture wrap-rib deployable antenna were assembled.

Non-contact photogrammetry is used to measure the surface accuracy of the reflector of prototype. The measuring system includes camera, light lamp, calibration frame, marking point and supporting post-processing software system.

In this paper, the spacing of target points is 20 mm, and the error of surface accuracy caused by the spacing of target points is about 0.03 mm, which is far less than the RMS value of the reflector. The spacing of target points can meet the measuring accuracy of the reflector.

Take some pictures of the reflector with target points. After the target points are captured, the image processing software is used for post-processing to obtain the target points coordinates, as shown in Figure 13 and Figure 14.

Figure 13. Prototype of deployable antenna with target points on its reflector

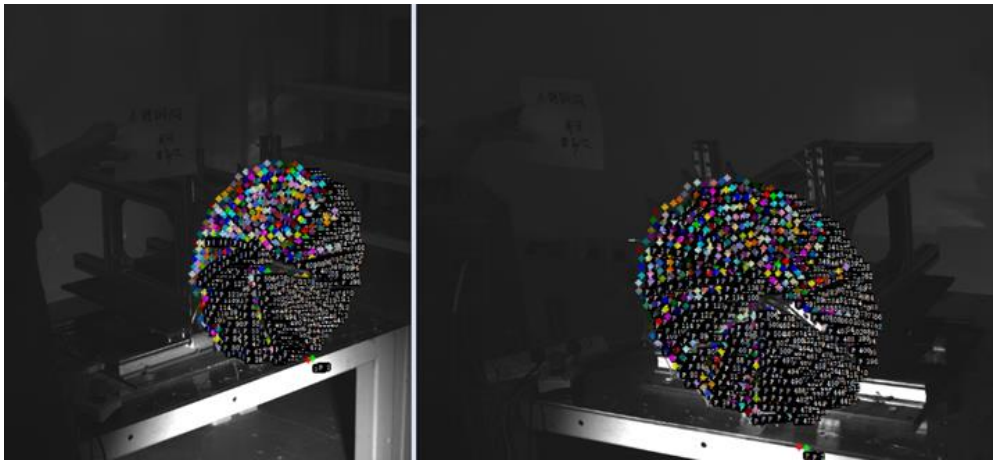

Figure 14. 3D coordinates of target points

After surface fitting of the target points, the fitted parabolic equation was obtained (see Figure 15). By comparing the coordinates of the target points with the fitting paraboloid, the RMS of the reflector was calculated.

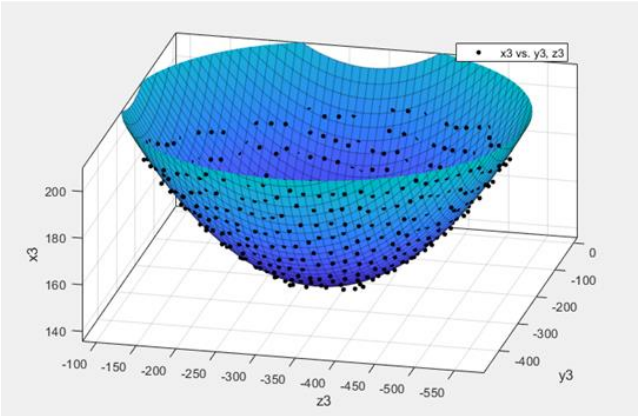

Figure 15. Paraboloid fitting

The surface accuracy of the reflector was tested under five conditions. They are:

(1) The prototype had not been stowed after assembled;

(2) The prototype had been stowed and deployed for the first time;

(3) After shaking table test, the prototype had been stowed and deployed for the second time;

(4) The prototype had been stowed and deployed for the third time;

(5) The prototype had been stowed and deployed for the fourth time.

5.2. Measurement results

1) RMS based on self-fitting paraboloid

The self-fitting paraboloid is taken as the target paraboloid in each condition. The RMS measurement and calculation results are shown in Table 1.

Table 1. RMS based on self-fitting paraboloid

Condition	(1)	(2)	(3)	(4)	(5)
RMS (mm): prototype A	0.98	0.90	0.86	0.86	0.86
RMS (mm): prototype B	0.81	0.79	0.83	0.76	0.79

2) RMS based on the fitting paraboloid of condition (1)

The fitting paraboloid of condition (1) is taken as the target paraboloid in each condition. The RMS measurement and calculation results are shown in Table 2.

Table 2. RMS based on fitted paraboloid of condition (1)

Condition	(1)	(2)	(3)	(4)	(5)
RMS (mm): prototype A	0.98	0.92	0.89	0.88	0.92
RMS (mm): prototype B	0.81	0.85	0.83	1.00	0.82

The RMS of the two prototypes was 0.8-1.0 mm, and the repetition accuracy is good. According to that the surface accuracy RMS of the reflector should be no more than 1/30 wavelength (about 1mm for X-band), the two prototypes can meet the surface accuracy requirement of X band operation.

6. Conclusions

A wrap-rib deployable antenna was developed in this paper. The antenna was 0.5 meter in aperture and could be stowed in 1.5 U. Paraboloidal mesh reflector was designed for X-band operation. The shape of ribs was optimized. Two prototype antennas were assembled to analyze and test the repetition accuracy of the reflector.

The stainless steel ribs adopt C-shaped cross section in this paper. The wrapping process of C-shaped stainless steel rib was analyzed theoretically and numerically. It was verified that ribs were in elastic state during wrapping process. Based on surface accuracy required by X-band， the number of ribs was determined as 16 and the focal length to aperture ratio of the reflector was 0.45.

A shape finding iterative algorithm was suggested which consider both the deformation of ribs and the distribution of tension in mesh. On this basis, The optimal curve of ribs was designed by minimizing the surface error through genetic algorithm. The theoretical RMS of the optimized reflector is 0.71 mm.

Two prototype antennas were assembled and shapes of reflector surface were measured before and after shaking table tests. The RMS of the reflector was calculated based on the self-fitting paraboloid and the condition (1) fitting paraboloid respectively, and the RMS was 0.8-1.0mm. After shaking table test and several times stowage and deployment, the surface accuracy of reflector has no obvious change, and has relatively stable repetition accuracy. The prototype can meet the surface accuracy requirement of X-band.

Abstract

With the aim of contributing to a higher degree of circularity in the building construction sector, and a more efficient use of resources, the here presented research explores the potential of upcycling scrap wood into hypar-shaped modular construction components, to be used as basic units in reusable and reconfigurable construction systems. The work employs empirical methods and pursues a research by design approach. In addition to introducing a new approach toward upcycling scrap wood, we also present a novel method for building hypar components from planar wooden pieces. Furthermore, the paper features a design proposal for a pavilion that is intended as a contribution to the IASS 2023 Design Competition. This pavilion is also expected to serve as a proof of concept for the above-mentioned construction and upcycling method. We conclude with an overview of future research and an indication of potential applications of the presented construction system. On a more general note, the work suggests going beyond the use of shell structures as monolithic and static artefacts. By investigating reusable and reconfigurable shell-based structures, it adds to and expands on existing research on segmented shells.

Keywords: timber and bio-based structures, modular timber structures, circular construction, hyperbolic paraboloids, reconfigurable structures, upcycling scrap wood, conceptual design, methods and construction technologies for sustainable shell structures, digital modelling and fabrication

1. Introduction

Reducing the environmental impact of the building construction sector has emerged as one of the prime challenges for practitioners and researchers in Architecture, Engineering, and Construction (AEC) over the past few years. As stated previously [1], increasing the use of timber can be one way of addressing this challenge. Preconditions for this are short routes of transport and certified sustainable forest management. For a truly sustainable use of timber, it is equally important to extend the service life of wooden components as much as possible, and to unlock alternative material sources such as scrap wood. This research explores the potential of upcycling scrap wood into modular construction components with a hypar geometry, to be used as part of reconfigurable construction systems.

A hypar is a certain type of doubly ruled surface. According to [2], a ruled surface is defined as “a surface generated by a moving straight line with the result that through every point on the surface a line can be drawn lying wholly in the surface.” A similar definition is provided in [3]: “Cylinders, cones, one-sheet hyperboloids, and hyperbolic paraboloids are surfaces that carry families of straight lines. Thus, they could also be generated by moving a straight line.”

The capacity of hypar structures for merging load-bearing and stabilizing functionalities with architectural qualities [4] becomes evident in numerous built examples. Depending on the construction method and the material used, hypar structures can consist of discrete, similar, and sometimes even identical elements. This could contribute to the reusability of their basic elements [5]. As modular

entities or units, timber hypar components could become an alternative solution to conventional prefabricated building components.

In addition to being based on simple straight lines, hypars have yet another compelling geometric property. As pointed out in [6], "[…] flat quads can be created by connecting the corresponding points of intersection of the generatrices in diagonal direction." In [6], this property is highlighted in the context of using glass panels as cladding for hypar steel grid shells. The here presented research investigates the potential of employing this property for segmented timber shell components, as illustrated in *Figure 1*.

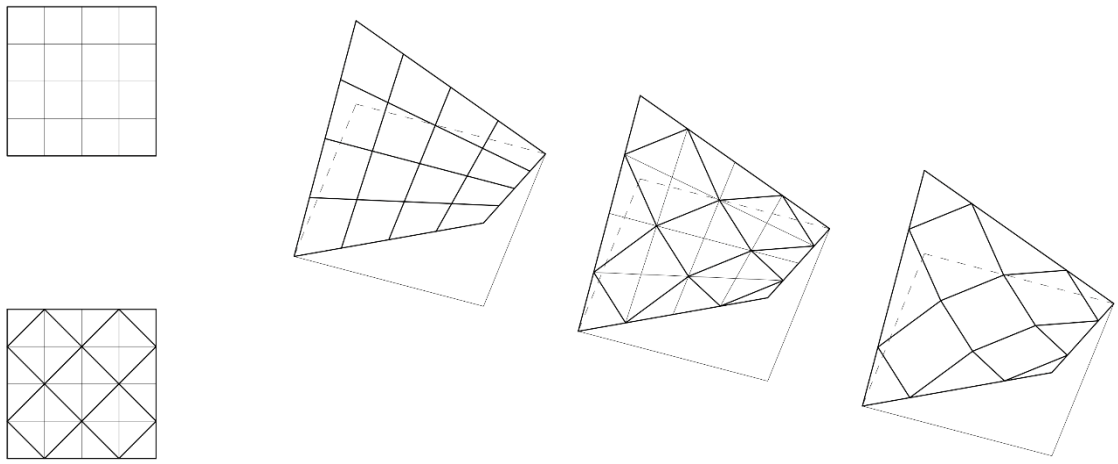

Figure 1. Left: Top view of a hypar with five equally spaced rulings (top) and a quadrilateral mesh based on top of these rulings (bottom). Right: Stepwise generation of a quadrilateral mesh based on the rulings of a hypar with a square base.

2. Design space explorations

This research explores the potential of upcycling scrap wood into modular construction components with a hypar geometry, to be used as part of reusable and reconfigurable construction systems. The design space of multi-hypar structures fundamentally depends on the geometry of the basic hypar unit. So far, two different hypar geometries have been studied as a basic unit for multi-hypar configurations.

The first one approximates a Schwarz P minimal surface when multiplied twelve times, as shown in *Figure 2*. This geometry can also be found in some of Ángel Duarte's mathematics-inspired sculptures, as well as in projects he developed together with Heinz Isler [7]. Duarte's work was identified as a relevant precedent while preparing teaching material for the MSc course "Tectonics in Engineering and Architectural Design" in the fall semester of 2020. The starting point for constructing the geometry of this hypar is a square in which a smaller and 45° rotated square is inscribed, using the midpoints of the larger square's edges as corners of the smaller one. Following this, the edge lines of the smaller square are rotated up by 45° in pairs of two, using the neighboring edges as rotation axes. Then, the now inclined edge lines are extended so that they connect and form a closed tetrahedral polyline. The four spatially articulated edges are then mirrored around their center point. The two intersecting polylines define the outlines of twelve identical, albeit differently oriented hypars.

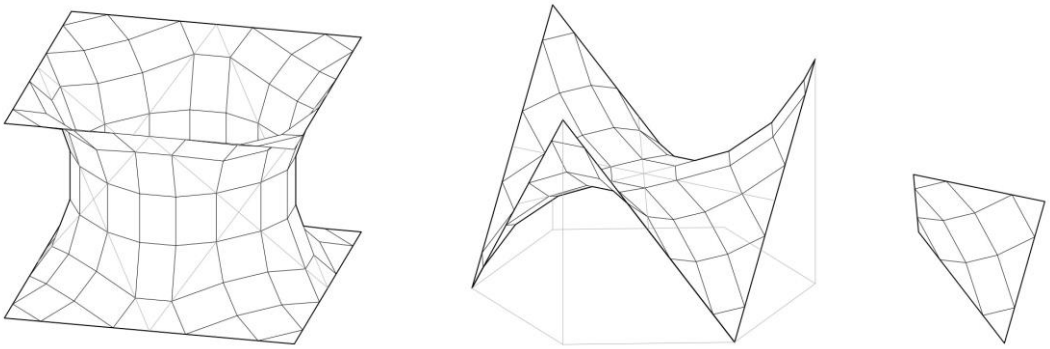

Figure 2. Two options of using patches of an approximated Schwarz P surface: in closed Schwarz P surface condition (left) with twelve patches, and as an open configuration with six patches, to be used for example as a pavilion (right), using planar quad meshing.

The second hypar geometry is based on a cube, meaning that the edges of the hypar surface are identical to the diagonals of a cube's faces. Six of such hypars can be combined into star-shaped higher-order units, as shown in *Figure 3*. The possibility of doing so was observed in the outcome of a combinatorial design workshop that was part of the MSc course "Tectonics in Engineering and Architectural Design" in the fall semester of 2021.

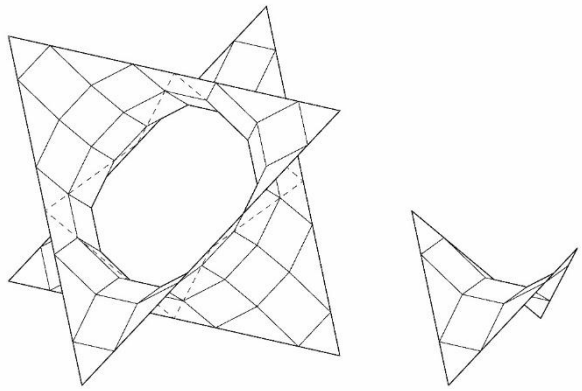

Figure 3. Six identical hypars, with a hypar surface that can be inscribed in a cube, can be combined into a star-shaped higher-order unit. This example also shows how neighboring triangular mesh faces, on the boundary of adjacent hypars, can be merged into quads.

3. Design and fabrication of a pavilion

The here presented pavilion design is the outcome of an ongoing research project that investigates the potential of upcycling scrap wood into modular construction components based on hypar geometry. The construction method used takes advantage of a geometric particularity of hypars, which enables the creation of quad meshes aligned diagonally with the rulings. Thus, it becomes possible to fabricate such double-curved shell components from planar wooden pieces.

In addition to introducing a novel construction method, and a novel approach towards upcycling scrap wood, the pavilion highlights the potential of using hypars as modular construction components. The underlying hypar geometry is based on a cube. As explained above, six of such hypar components can be combined into star-shaped higher order units, six of which are included in the proposed design. As an entity, the pavilion displays properties similar to those of periodic surfaces, see *Figure 6*.

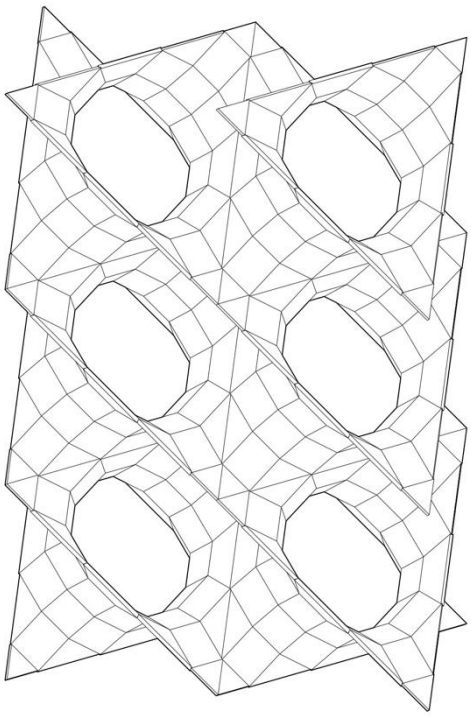

Figure 4. Axonometric view of the pavilion design, which incorporates six higher-order units. The pavilion has an approximate length of 180 cm, a width of 90 cm, and a height of 270 cm.

When moving around it, its appearance smoothly transitions between open and closed. Potential applications of this modular system could be façade elements, loadbearing walls, room dividers, skylights, or other.

For the exhibition at IASS 2023, we aim to build this pavilion, respectively demonstrator, out of scrap wood pieces, connected with wooden dowels or similar, and partially with glue. The joints between the higher order units will be designed to be reversible, allowing for the disassembly and future reuse of the components, potentially in a variety of different configurations.

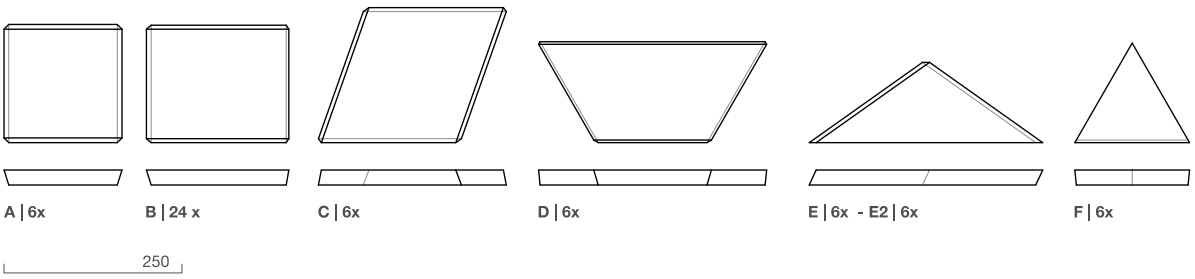

Figure 5. Top and side views of six different panel geometries.

3.1. Geometry and construction

The design space of modular hypar structures is partially determined by the way in which an immaterial hypar geometry is brought into the physical world. A closed volumetric hypar can be generated by equal distance offset, or by one-directional extrusion of the hypar surface.

There are several methods of constructing timber shell components with a hypar geometry. The most common approach is probably that of generating a grid shell, which can be achieved by extruding the rulings of the hypar, or by placing straight elements on these rulings. Another method is to combine mutually rotated layers of timber boards into assemblies similar to Cross Laminated Timber (CLT), and to connect them to an edge beam [8, 9]. Yet another option could be steam bending, which would imply size constraints and a relatively high consumption of energy.

The here proposed method enables the construction of segmented shells with wooden panels, which are geometrically described as convex polyhedrons, defined by the intersecting half-spaces of their six boundary planes.

The planar segments of a hypar are given by the diagonals of the subdivided hypar's quad meshes. The result is a planar quad mesh, which needs to be offset to obtain the geometry of the final segmented shell structure. This would be relatively easy if the hypar-based mesh would be conical. Only conical meshes have the property that their offset results in planar edge and mesh faces in equal distance, as in conical meshes, all quads adjacent to one vertex are tangent to a common cone.

However, similar to other quad-meshes based on doubly curved surfaces, the hypar-based mesh is not conical, which leads to flawed results when applying standard offset procedures. One way of solving this issue is mesh adjustment, for example via the *conicalize* function that is part of the interactive physics/constraint solver Kangaroo, which is included in the current version of Grasshopper. Another option would be to chamfer the corners of the offset quads [10].

As using these options could cause fabrication challenges and increase design complexity, we apply a method where the panels are defined as convex polyhedrons that are generated by the intersecting half-spaces placed on their boundary planes. Two of these are the inner and outer offset planes of the origin plane of the panel, and the four other are the boundary planes placed along the shared edges with the neighbouring panels. These edge boundary planes are laying along common edges, and are aligned with the average of the normal vectors of the two connected faces. It is noteworthy that in the case of synclastic surfaces, the boundary plane of the vertex neighbour faces, located on the respective vertices, should be added to the definition as well.

The resulting panels will share their long edges, provided they have the same thickness and their planar edge surface. Due to the non-conicality of the basic mesh, their offset vertices will not coincide, which is tolerable in this case. This method also enables a straightforward definition of segments made of materials with different thickness.

3.2. Joints, connections, and assembly

The pavilion is comprised of six modules, or higher-order units. Each of these higher-order units consist of six hypars with a low mesh-subdivision resolution. There are four main types of panels within one higher-order unit: triangular, rectangular, rhombic, and trapezoid shapes. The rhombic and trapezoid panels are the result of merging two or three triangular panels adjacent to the individual hypars' edges or corners, as indicated in *Figure 4*.

With a 270 cm high pavilion design, one higher-order unit has an edge length of 120 cm and consists of 60 panels. The edge length of the panels is between 16 and 30 cm, and the panel thickness is approximately 20 mm. The segments of the higher order units are milled out of scrap wood pieces, mainly from plywood or LVL, and optionally from solid wood boards. These pieces are glued and joined by internal dowel-like connections, such as cylindrical dowels, biscuit connectors, or tongue and groove joints with loose tongues. The challenge of assembling elements with various angles is addressed in the joint design, and here with the dowel orientation, which is based on a pre-defined assembly sequence. One possibility is to join the panels into strips, which are then merged into one half of a higher-order unit.

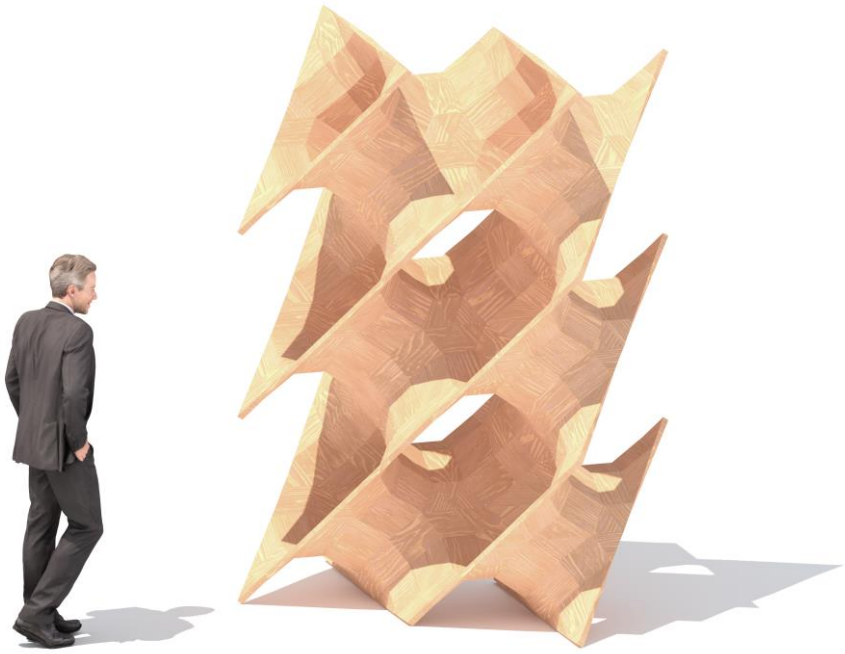

Figure 6. Rendered axonometric view of the pavilion.

Two halves are then glued together to form one whole. A simple formwork and tension belts are envisioned to apply pressure on the glued surfaces during the curing process, a method that could be applied for each edge. The joints between the higher order units will be designed to be reversible, allowing for the disassembly and future reuse of the components, potentially in a variety of different configurations. One option is that the modules are connected with dowel connections, and secured by wooden wedges or screws. An alternative method is the use of mechanisms with easier access, such as hinge- or clamp-like metal fasteners.

The final design and joinery solution also depends on the fabrication method and its constraints. The panels can be fabricated in various ways, most favorably via 5-axis CNC milling, but possibly also with a robotic arm, or with a traditional circular saw. The above-mentioned joinery solution describes the current design stage of the demonstrator. Later on, we plan to develop and compare different joinery on full-scale prototypes, mainly with cylindrical wooden dowels, biscuit connectors and finger joints.

4. Conclusion and future work

In this paper, we propose to upcycle scrap wood into hypar timber components, to be used as basic elements of modular and reconfigurable construction systems. We provide insights on the design space of multi-hypar structures and elaborate on the different factors that have an impact on it. We present the design of a pavilion that implements a novel construction method for hypar shaped segmented timber shell components, using scrap wood as material.

Currently ongoing studies investigate the potential of using hypars with irregularly spaced rulings as a means of incorporating or adapting to material stock with specific geometric properties. We are also preparing a survey that will inquire on the quality and quantity of wood scrap produced in selected areas of Europe, the results of which will allow us to refine the target definition of the optimization process.

Additional studies will be required to obtain deeper insights on the structural properties of the above-described structures, by means of numerical and experimental testing. Here it will be interesting to study the impact of the connection details as well as the overall composition and orientation of different multi-hypar configurations.

Future studies will also explore the potential of double-layer configurations. Building with two layers instead of one could facilitate the inclusion of insulation or other functions. Shifting the paneling patterns of the two layers against each other – similar to the mutually shifted tiles in Catalan vaults [11] – could support water and wind tightness. More importantly, this could also lead to advantages regarding the structural performance.

Acknowledgements

The possibility of combining six cube-based hypars into star-shaped higher-order units was observed in the outcome of an online-workshop on combinatorial design. During the workshop, the students worked with Grasshopper and the plug-in WASP. The workshop was part of the MSc course "Tectonics in Engineering and Architectural Design" in the fall semester of 2021, and carried out by the developer of the WASP plug-in, Andrea Rossi.

Abstract

Free-form surfaces have been increasingly adopted in contemporary architectural designs to create unique and elegant structures. However, fabricating these doubly curved surfaces using panel and frame systems may pose great challenges to building construction, as the three main components—nodes, beams and panels—usually exhibit vastly different shapes. While previous studies attempted to reduce the shape variability for one or two of these components, clustering and optimisation of all three remain underexplored. In this work, we present a mesh-based computational design framework that clusters and optimises nodes, beams and panels together to reduce the shape variety of elements for free-form surfaces. The proposed method uses a vertex-based similarity metric to partition panels into a user-specified number of groups and cluster beams based on the associated edge lengths. Box-constrained optimisation is then employed to obtain congruent faces and matching beam lengths while satisfying gap size, fairness and shape preservation constraints. Finally, connection holes on the spherical surfaces of nodes are clustered and optimised to allow their use at multiple locations. The practicality of the proposed method is demonstrated through the design and fabrication of a full-scale pavilion with doubly curved surfaces, which resulted in a significant reduction in the number of different nodes, beams and panels.

Keywords: clustering, optimisation, free-form surface, space frame structure, mesh, Hangai Prize applicant

1. Introduction

Free-form surfaces are becoming increasingly popular in architecture due to their exceptional aesthetic qualities and unique elegance that distinguish them from the typical uniformity in building designs. However, manufacturing these surfaces with conventional methods could present immense difficulties and high expenses due to their intricate geometries and varying surface curvatures. Such complexities have prompted researchers and practitioners to develop innovative rationalisation strategies to simplify fabrication, improve structural performance and enhance the affordability of free-form surfaces [1–5].

Several rationalisation strategies have been proposed to address the manufacturing challenges of free-form structures [6–8]. One such approach involves the planarisation of mesh faces, which aims to realise complex curved surfaces through a set of discrete planar faces, thereby reducing manufacturing costs. Apart from triangular meshes, whose faces are naturally planar, this concept has been employed in quadrilateral meshes [9] and hexagonal meshes [10]. Another approach focuses on reducing the shape variety of different elements (i.e., nodes, beams and panels) to facilitate the mass production of standardised components and consequently lower the production cost and ease construction. Given these

benefits, this method has been adopted to reduce joint variability [11, 12], reuse nodes and beams for diverse structures [13], cluster beams during truss layout optimisation [14] and tile free-form surfaces using sets of panels [15–18]. This strategy can help reduce the number of moulds for casting-based and vacuum-forming manufacturing, simplify the setup and improve quality control of other fabrication techniques, including computer numerical control (CNC) machining and 3D printing. However, previous studies have primarily focused on clustering and optimising one or two of the three main elements (i.e., nodes, beams or panels). Simultaneous consideration of all three shows promise but remains largely unexplored.

In this paper, we present a novel mesh-based computational design framework that clusters and optimises nodes, beams and panels together to reduce the shape variety of elements in free-form surfaces. The framework uses the vertices, edges and faces of a given triangular mesh to represent the nodes, beams and panels of the target free-form surface. The method employs a vertex-based similarity metric to partition panels into a user-specified number of groups, and beams are clustered based on associated edge lengths. Box-constrained optimisation is used to obtain congruent faces and matching beam lengths while satisfying gap size, fairness and shape preservation constraints. Additionally, connection holes on the spherical surfaces of nodes are clustered and optimised for use in multiple joint positions. To demonstrate the effectiveness of the proposed method, we designed and fabricated a full-scale pavilion with doubly curved surfaces (3.23 m × 3 m × 1.8 m) based on an optimised free-form mesh. As shown in Figure 1, the constructed pavilion structure demonstrates a significant reduction in the number of different nodes, beams and panels.

Figure 1. A full-scale pavilion was constructed to demonstrate the practicality of the proposed method. (a) Optimised free-form mesh, (b) rendered model, where panels in the same group have the same colour and (c) constructed pavilion using 3D-printed nodes, timber beams and laser-cut acrylic panels.

The paper is structured as follows. Section 2 describes the methodology for clustering and optimising nodes, beams and panels of free-form surfaces. Section 3 presents numerical studies for three different doubly curved shapes. Section 4 details the design and construction results of a full-scale pavilion. Finally, Section 5 concludes by highlighting the key features of the proposed method.

2. Methodology

The proposed method is based on a global framework that alternates between clustering and optimisation of elements in a triangular mesh. Beams and panels are grouped into user-specified numbers of clusters using the method described in Section 2.1. Next, a box-constrained optimisation framework, as outlined in Section 2.2, is applied to steer members in the same group towards a congruent shape, with additional constraints to control gap size, fairness and closeness to the input mesh. Finally, nodes are evenly assigned to groups and optimised to allow their use in multiple joint locations, as described in Section 2.3.

2.1. Clustering of beams and panels

2.1.1. Similarity metric

The similarity metric in this work is a numerical measure that quantifies the shape difference d between two different members. In the case of straight beams, the shape difference d_b between member p and q is calculated as the difference between the two associated edge lengths:

$$d_b(p,q) = l_p - l_q \tag{1}$$

where l_p and l_q are the edge lengths for p and q, respectively.

To compute the shape difference d_p between two panels on mesh faces m and n, a three-step process is employed based on previous work [18]. Firstly, the corners of n are arranged in six permutations relative to m's reference corners 'abc', from which six possible correspondences are determined (see Figure 2). Secondly, the corresponding corners are mapped using the principle of least squares rigid motion [19], in which corners ABC are transformed to A'B'C' to minimise the sum of squared distances ($\|aA'\|^2 + \|bB'\|^2 + \|cC'\|^2$). Finally, the lowest summed value of squared distances between transformed corners and reference corners is chosen as d_p, and the edge correspondence (i.e., $\overline{AC}$ to $\overline{ac}$, $\overline{AB}$ to $\overline{ab}$, and $\overline{BC}$ to $\overline{bc}$) is recorded for subsequent optimisation. In Figure 2, the last permutation yields the lowest shape difference d_p of 3.5.

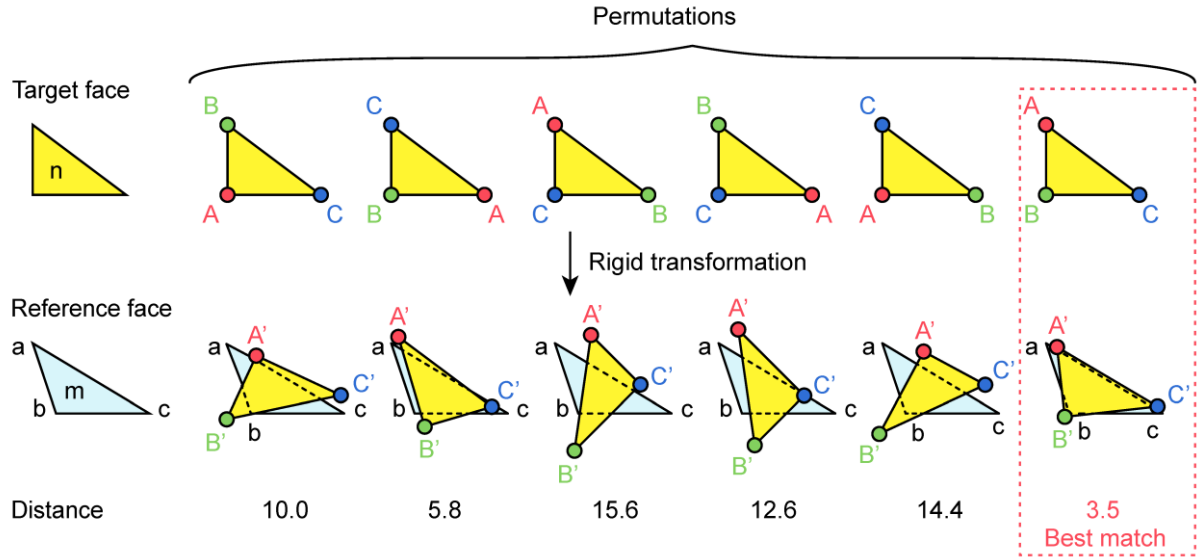

Figure 2. A three-step process is used to calculate the shape difference d_p between two panels.

2.1.2. Clustering method

The clustering approach for beams and panels uses the farthest point sampling strategy [20], gradually increasing the number of clusters until reaching the user-specified limit. First, one member is selected as the initial centroid, and all other elements are affiliated with it. Next, the shape difference of each element with respect to the centroid is computed, and the one with the largest value becomes the new centroid. In the subsequent iteration, each element is evaluated against the new centroid. Elements achieving a smaller shape difference than in the previous iteration are assigned to the new centroid, forming a new clustering configuration. By repeating this process, the final clustering configuration ensures that elements with similar geometry are grouped. In this work, the user-specified numbers of clusters for beams and panels are denoted as N_b and N_p, respectively.

2.2. Optimisation of beams and panels

2.2.1. Geometric formulation of beams and panels

The geometric formulation of beams and panels based on mesh vertices is illustrated in Figure 3. Mesh edges (pink dashed lines) represent beams between adjacent mesh vertices (pink circles). In construction practices, gaps are intentionally left between panels and beams to account for thermal expansion and construction errors. The gap size should adequately accommodate connectors and beams while avoiding the formation of major visual defects, thereby balancing practicality and aesthetics. To meet these requirements, we represent panels as a slightly smaller region (shown in blue) bounded by mesh edges (indicated by pink dashed lines) and determine their corners using a vertex-based relationship, as follows:

$$A^* = A + \overrightarrow{\boldsymbol{AA^*}} = A + \boldsymbol{v_{AB}} + \boldsymbol{v_{AC}} = A + \frac{\overrightarrow{\boldsymbol{AB}}}{|\overrightarrow{\boldsymbol{AB}}|} * \rho_{AB} + \frac{\overrightarrow{\boldsymbol{AC}}}{|\boldsymbol{AC}|} * \rho_{AC} \tag{2}$$

$$\rho_{max} > \rho > \rho_{min} > 0$$

where the panel corner A^* and mesh vertex A are related through scaled vectors $\boldsymbol{v_{AB}}$ and $\boldsymbol{v_{AC}}$ in the directions of $\overrightarrow{\boldsymbol{AB}}$ and $\overrightarrow{\boldsymbol{AC}}$, respectively, with ρ as a design parameter that governs gap size. The bounds for ρ are set by the user-specified upper limit ρ_{max} and lower limit ρ_{min}. By introducing the gap size parameter ρ, the equality constraints for beams and panels are differentiated (e.g., $|\overrightarrow{\boldsymbol{AB}}| \neq |\overrightarrow{\boldsymbol{A^*B^*}}|$), which provides more design freedom in the optimisation process. The proposed method involves two sets of design parameters: the XYZ coordinates for each mesh vertex (represented by pink circles) and two gap size parameters ρ (e.g., ρ_{AB} and ρ_{AC}) for each panel corner (represented by blue circles). For a triangular mesh consisting of A vertices and B faces, there are $3A + 6B$ design parameters to be optimised.

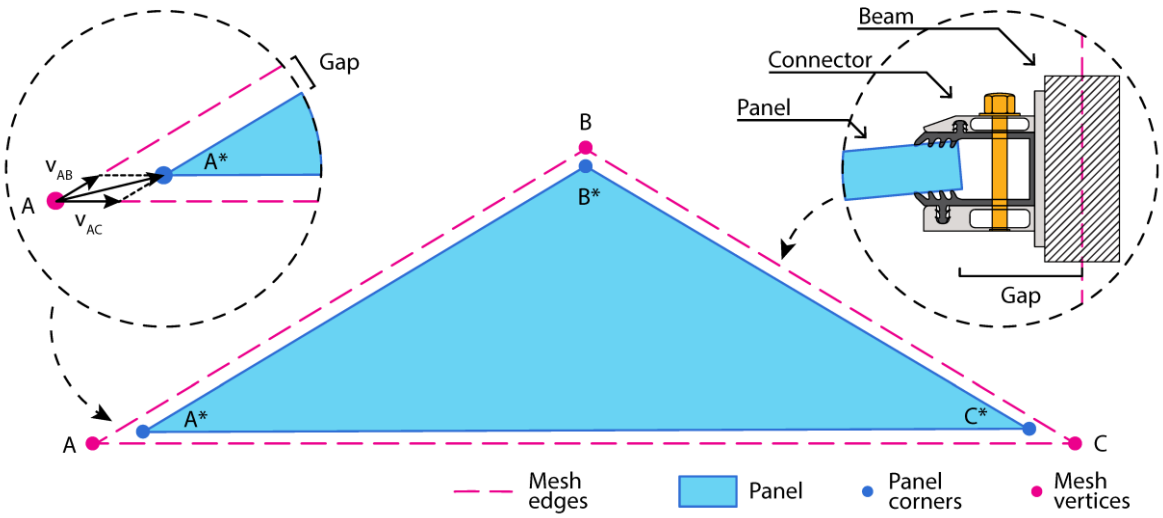

Figure 3. The proposed method represents beams using mesh edges in pink dashed lines and formulates panel corners (A^*, B^*, C^*) based on the gap size parameter ρ and the neighbouring mesh vertices (A, B, C) to ensure sufficient space for connectors.

2.2.2. Gap size constraint

The proposed method uses two approaches to control the gap size. Firstly, the gap size parameter ρ is subject to box constraints within a user-specified range, as described in Equation (2). Secondly, a gap size term F_g is introduced, as follows:

$$F_g = \sum_{i}^{n} (\rho_i - \rho_{ave})^2 \tag{3}$$

$$\rho_{ave} = \frac{\sum_i^n \rho_i}{n}$$

where the individual and average gap size parameters are denoted by ρ_i and ρ_{ave}, respectively. In total, there are n gap size parameters. Optimisation ensures that the gap sizes between panels and beams become more consistent throughout the structure.

2.2.3. Congruent panel constraint

The proposed method equalises the edge lengths of panels clustered in previous steps (Section 2.1) to obtain congruent panels for triangular meshes. To this end, a panel shape term F_p is introduced, as follows:

$$F_p = \sum_j^m \left(e_j - e_{ave}\right)^2$$
$$e_{ave} = \frac{\sum_j^m e_j}{m} \tag{4}$$

where e_j and e_{ave} denote the individual and average edge lengths within a group of m candidates, respectively.

2.2.4. Fairness constraint

Achieving smooth and aesthetically pleasing surfaces is of utmost importance in free-form architectural designs. Therefore, a fairness term F_f based on the principle of Laplacian smoothing [21] is formulated, as follows:

$$F_f = \sum_k \left(v_k - \frac{1}{\langle N(v_k) \rangle} \sum_{p \in N(v_k)} v_p \right) \tag{5}$$

where $N(v_k)$ represents the set of one-ring neighbouring vertices of v_k, and $\langle N(v_k) \rangle$ denotes the number of elements in this set. This term helps avoid sudden curvature changes between adjacent nodes and promotes smooth surfaces on the optimised mesh.

2.2.5. Original shape preservation

The proposed method constrains the displacement of mesh vertices from their initial positions to preserve the geometric features of the input mesh. This is achieved by imposing box constraints on mesh vertices using a user-specified maximum movement distance d_{max}, as follows:

$$v_x^* - d_{max} < v_x < v_x^* + d_{max}$$
$$v_y^* - d_{max} < v_y < v_y^* + d_{max} \tag{6}$$
$$v_z^* - d_{max} < v_z < v_z^* + d_{max}$$

where v^* and v are the initial and optimised vertex positions, respectively.

2.2.6. Beam length constraint

Beam lengths are equalised using the beam length term F_b to ensure congruency within each cluster, as follows:

$$F_b = \sum_h^w (l_h - l_{ave})^2 \tag{7}$$

$$l_{ave} = \frac{\sum_h^w l_h}{w}$$

where l_h and l_{ave} represent the individual and average beam length within a group of w candidates, respectively.

2.2.7. Global objective function

Combining the subgoal terms F_g, F_p, F_f and F_b gives the global objective function F for optimisation:

$$F = \omega_g F_g + \omega_p F_p + \omega_f F_f + \omega_b F_b \tag{8}$$

where ω_g, ω_p, ω_f and ω_b represent the weights assigned to the gap size, congruent panel, fairness and beam length terms. The minimisation of the objective function F is accomplished using nonlinear conjugate gradient optimisation with box constraints [22]. Applying box constraints to the gap size parameters ρ and vertex positions v helps to meet the functional requirements without excessively complicating the optimisation process.

2.2.8. Post-processing

Despite the significant reduction in shape differences achieved through optimisation, members in the same cluster may still have small discrepancies, preventing them from being manufactured using the same mould. As a solution, each beam and panel is replaced by the average shape in their corresponding cluster. After replacement, two parameters are computed and compared against user-specified thresholds: the maximum percentage change in beam length before and after the replacement, which should be lower than the threshold t_b, and the minimum and maximum gap between new corners and adjacent mesh edges, which should fall in the range of $t_{p.min}$ to $t_{p.max}$. If either criterion fails, the number of clusters (N_b for beams and N_p for panels) should be increased to provide more design freedom for optimisation. This process is repeated until the optimised mesh meets all requirements.

2.3. Node clustering and optimisation

After optimising the mesh by achieving congruent panels and matching beam lengths, the next step is to evenly distribute and merge nodes to enable their use in multiple joint locations. Building on previous work [13], the proposed method implements node clustering and optimisation in three steps (see Figure 4). The algorithm randomly selects candidates for each cluster to achieve an even distribution of nodes among clusters (see Figure 4 (a)), where high-valence nodes are prioritised for grouping with low-valence ones to minimise congestion. Once the nodes to be merged in a cluster are identified, we seek the optimum rotation of each node to distribute their connection holes evenly on the spherical surface. Each node is considered a rigid body within a cluster, and connection holes on the node share the same rotation along XYZ axes (see Figure 4 (b)). The global objective function for node optimisation F_n aims to find the optimum rotation angles of nodes in all clusters and is expressed as:

$$F_n = \sum^{C} \sum_{i \in H}^{H} \sum_{j \in H}^{H} \frac{1}{d(R(\gamma_a, \beta_a, \alpha_a)i, R(\gamma_b, \beta_b, \alpha_b)j)} \tag{9}$$

where C and H denote the set of all node clusters and all connection holes centres in the present cluster, respectively; i and j refer to two individual connection holes centres that locate on node a and b, respectively, $d(\ldots)$ calculates the Euclidean distance between two points in 3D, and R is a rotation matrix:

$$R(\gamma, \beta, \alpha) = \begin{bmatrix} \cos\beta\cos\gamma & \sin\alpha\sin\beta\cos\gamma - \cos\alpha\sin\gamma & \cos\alpha\sin\beta\cos\gamma + \sin\alpha\sin\gamma \\ \cos\beta\sin\gamma & \sin\alpha\sin\beta\sin\gamma + \cos\alpha\cos\gamma & \cos\alpha\sin\beta\sin\gamma - \sin\alpha\cos\gamma \\ -\sin\beta & \sin\alpha\cos\beta & \cos\alpha\cos\beta \end{bmatrix} \tag{10}$$

where the rotation angles α, β and γ are along the XYZ axes. During optimisation, connection hole centres in close Euclidean distance contribute significantly to the objective function and are avoided. To prevent overlap between connection holes, the minimum distance between their centres L_{min} can be computed based on hole radius r, hole depth D and node radius R (as shown in Figure 4(c)):

$$L_{min} = 2\sin\left(\tan^{-1}\frac{r}{R-D}\right) * D \tag{11}$$

If the distance between connection hole centres falls below the minimum allowable value L_{min}, the algorithm will attempt a new node clustering scheme as in step one or increase the total number of node clusters N_n.

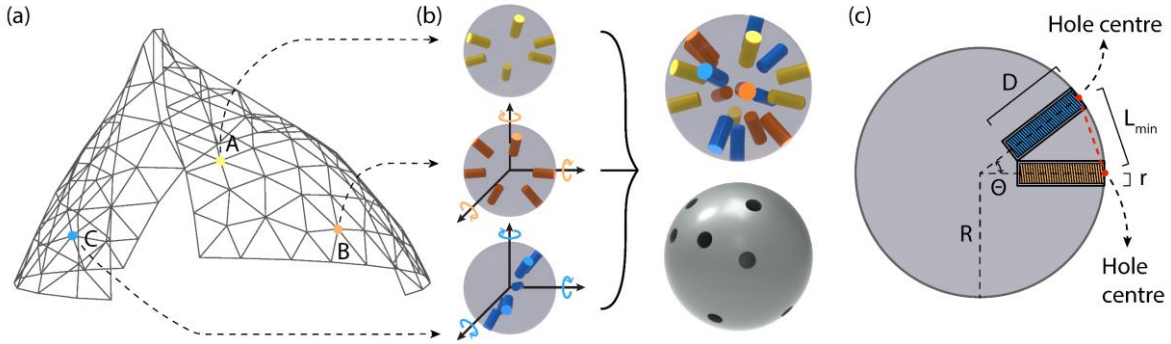

Figure 4. Node clustering and optimisation are achieved in three steps: (a) distribute nodes randomly into clusters based on vertex valence, (b) optimise node orientation to maximise the distance between connection holes' centres on the spherical surface and (c) check against the minimum allowable distance between connection holes' centres to avoid overlaps.

2.4. Workflow

The workflow of the proposed method is illustrated in Figure 5.

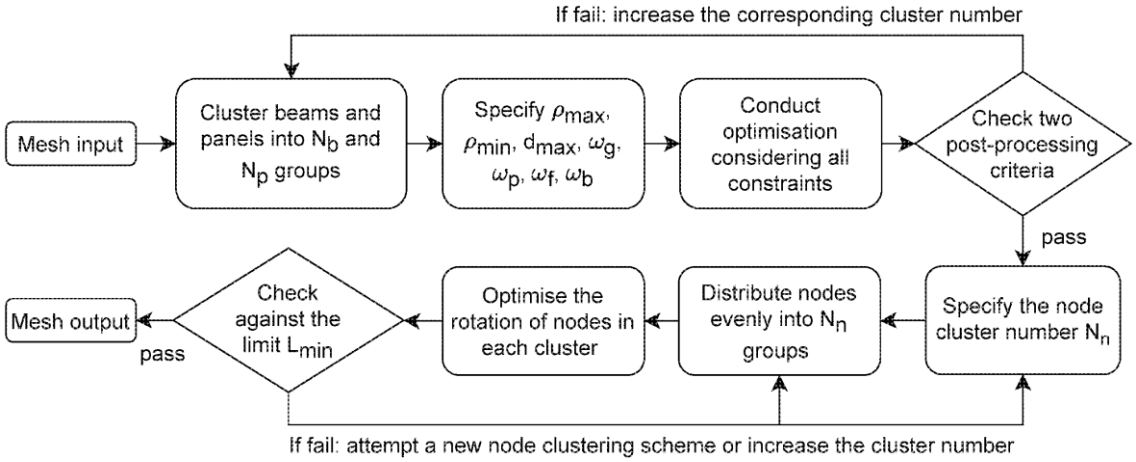

Figure 5. Workflow of the proposed method.

3. Numerical analysis

The effectiveness of the proposed method is tested on three free-form surfaces, as shown in Figure 6. The gap size parameters ρ_{min} and ρ_{max} and the maximum vertex displacement limit d_{max} are set to 2%, 4% and 2% of each mesh's average edge length. The weights assigned to the four subgoal terms ω_g, ω_p, ω_f and ω_b are 1, 1, 3 and 5, respectively. ω_f and ω_b are given larger weights to increase the surface smoothness and reduce the error in beam lengths. Following average shape replacement, the

percentage change in beam length t_b should be lower than 0.01%, while the minimum and maximum gap between new corners and adjacent mesh edges, $t_{p.min}$ and $t_{p.max}$, should be within the range of 2% to 4% of the average edge length. Elements within the same cluster are matched in colour for visualisation. Table 1 summarises the results of clustering and optimisation for the three free-form surfaces. On average, the number of different panels, beams and nodes has been reduced by 87.4%, 88.5% and 79.5%, resulting in a substantial decrease in both fabrication costs and construction difficulties.

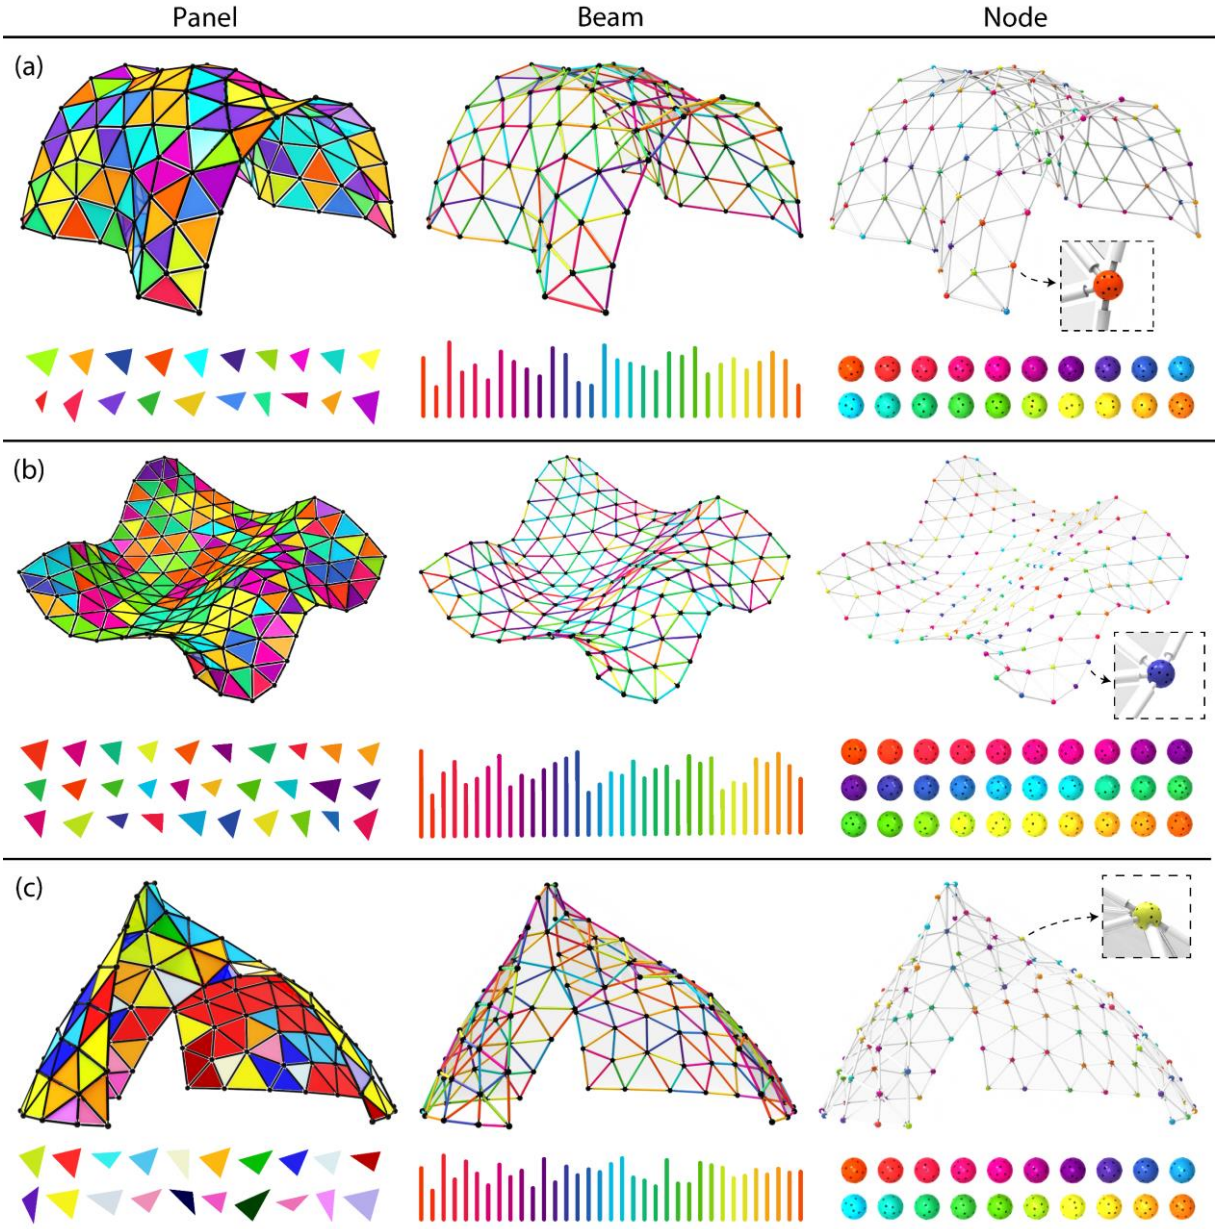

Figure 6. Clustering and optimisation results for three free-form surfaces: (a) tunnel, (b) wave and (c) pavilion. Elements within the same cluster are matched in colour for visualisation.

Table 1. Reduction in the number of panels, beams and nodes after clustering and optimisation.

Cases	**Panel**			**Beam**			**Node**		
	Original	New	Change	Original	New	Change	Original	New	Change
Tunnel	156	20	87.1%	251	30	88%	96	20	79.1%

Pavilion	160	20	87.5%	261	35	86.5%	102	20	80.4%
Average	–	–	*87.4%*	–	–	*88.5%*	–	–	*79.5%*

4. Application to a full-scale pavilion

4.1. Design details

A full-scale pavilion was designed based on the optimised result of the pavilion case in Section 3 to showcase the practical application of the proposed method. The pavilion, as depicted in Figure 7 and Figure 8, has dimensions of 3.23 m × 3 m × 1.8 m and features laser-cut transparent acrylic panels, timber rods as beams and 3D-printed nodes at joints. To fill the gaps between panels and beams, aluminium-strengthened U channels have been used as connectors, which are affixed to timber rods using industrial-grade chemical adhesives. Beams are connected to nodes using M4 hanger bolts and couplers, allowing for easy assembly and disassembly. Nine segments of heavy timber plates are joined together at the base of the pavilion to provide stability for the entire structure.

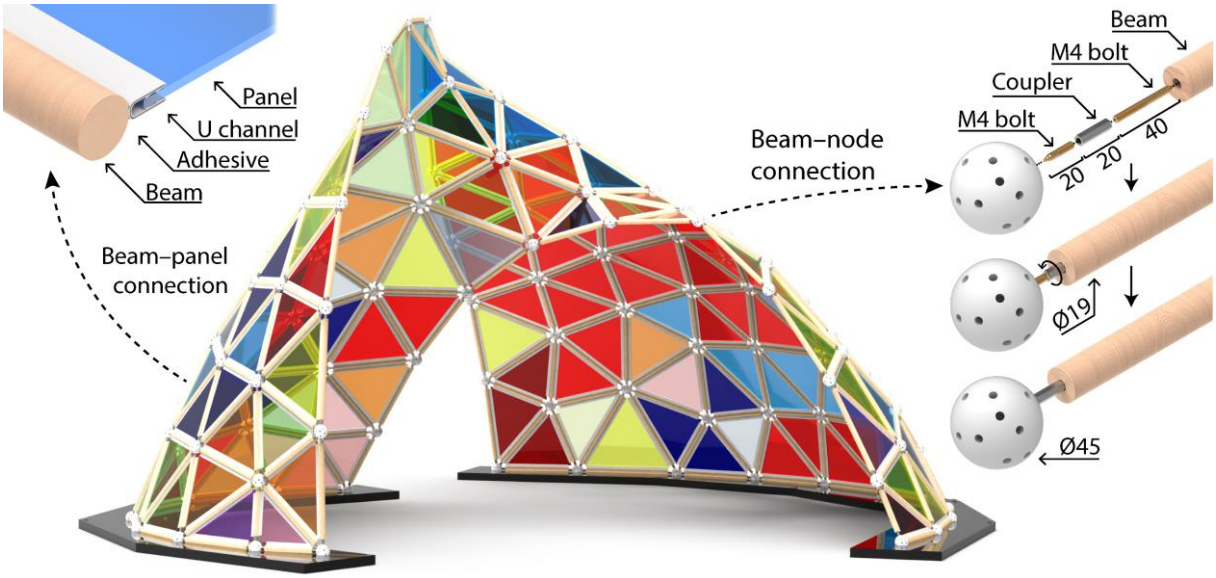

Figure 7. 3D model of a full-scale pavilion designed using the proposed method.

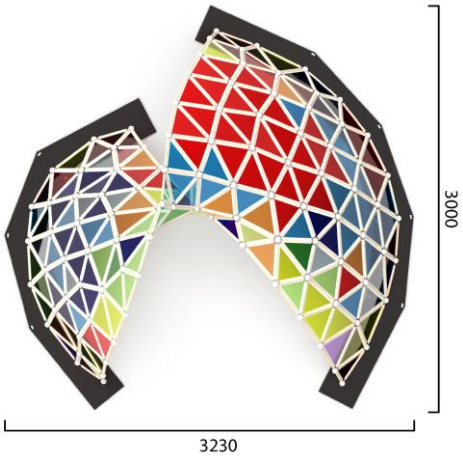

Figure 8. Top view of the pavilion design.

4.2. Construction

The preparation and construction of the full-scale pavilion were conducted in a multistep process. In the laboratory, 261 timber rods and nine bases were mechanically cut, while 102 nodes were 3D printed and 160 panels were laser cut (see Figure 9(a) for the fabricated components). The pavilion frame was then constructed in modules and transported to the construction site. The timber bases were placed on the ground and joined together to establish a stable foundation. Different modules were then combined to form the self-supporting frame of the pavilion, and the panels were assembled using U channels and chemical adhesives. A video showing the pavilion construction is provided in the supplementary file.

The completed pavilion is depicted in Figure 9(b). Although some minor discrepancies were noticed due to fabrication and construction errors, the construction results closely resemble the simulated model presented in Figure 7. Lighting was added to the frame of the structure, as shown in Figure 10, to enhance the pavilion's aesthetic appeal at night. The pavilion's successful construction confirms the feasibility of the proposed method, demonstrating that free-form surfaces can be constructed using clustered components without compromising aesthetics. The efficient use of materials can also reduce manufacturing costs and alleviate fabrication and construction difficulties.

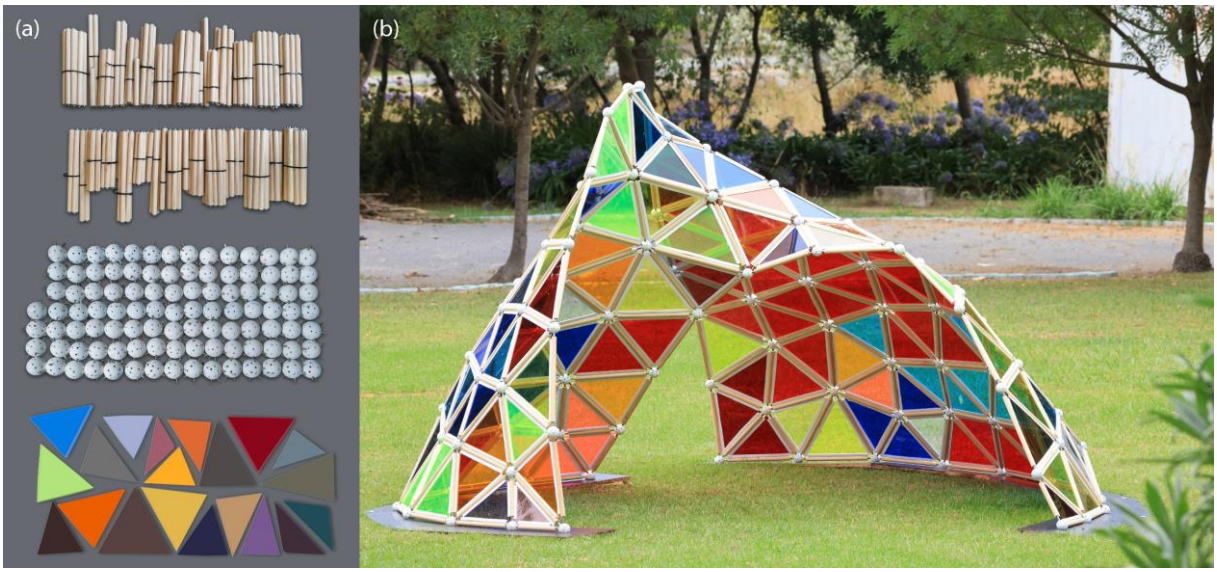

Figure 9. (a) 261 timber rods, 102 nodes and 160 panels were fabricated and grouped in 35, 20 and 20 clusters, respectively; (b) the constructed result closely resembles the simulated model.

Figure 10. Side views of the assembled pavilion during the day and at night.

5. Conclusion

This paper presents a novel design framework that clusters and optimises nodes, beams and panels together to reduce the shape variety of elements in free-form surfaces. Given a mesh as input, the proposed approach clusters beams and panels into user-specified numbers of groups based on geometric shape similarity. Then, a box-constrained optimisation method is applied to obtain congruent panels and matching beam lengths while satisfying gap size, fairness and shape preservation constraints. Finally, nodes are clustered and optimised for use at multiple joint locations. The proposed method is evaluated on three different free-form surfaces, revealing an average reduction of 87.4%, 88.5% and 79.5% in the number of different panels, beams and nodes, respectively.

The effectiveness of the proposed method is further validated by constructing a full-scale pavilion based on one of the case studies. The successful assembly of the pavilion confirms the practicability of the proposed method, as the target free-form surface can be constructed using clustered components without sacrificing aesthetic quality. The cost-effective approach developed from this study offers a potential solution to rationalising large-scale free-form architectural designs. Our future research will extend the proposed method to consider the structural performance of shell and spatial structures.

Acknowledgements

The authors would like to thank Chongjun Bi, Bing Li, Qianyun Sun, Tao Xu, Yunzhen He, Jiaming Ma and Zicheng Zhuang for helping prepare and assemble the pavilion, Huang Meng and Yongbao Liu for providing the construction site, Xiang Gao for helping fabricate the components and Xiangju Meng for assistance in preparing the video.

Abstract

Topology optimisation methods have been implemented on many architectural projects, and their design layouts always are fabricated with additive manufacturing methods due to their complex organic forms. However, there are still some difficulties that limit the application potentials of additive manufacturing in real projects, including size limitations of the fabrication devices, construction cost and transportation probabilities. Therefore, different from the conventional fabricating methods, this research achieves topologically optimized models using a subtractive manufacturing method with timber mortise-and-tenon joints from the Chinese traditional wooden tectonic system. In this paper, an initial shell model with specific plane angles is generated for Bi-directional Evolutionary Structural Optimization (BESO) due to the carpentry assemble requirements. Then, different classical mortise-and-tenon joints are selected to connect timber parts in different force-transferring paths and fabrication limitations, including plugging joints, connecting joints, and steering joints. Finally, with the convenience of on-site augmented reality (AR) assisted techniques, the lightweight timber parts can be easily assembled only by several people in an extremely short time. This project presents an effective and innovative way to achieve material efficiency and lightweight through a combination of innovative advanced tools and traditional woodworking techniques. These timber joints can be also used in architectural design in the context of Chinese traditional tectonics. The prototype pavilion is proof of the concept for the great potential in applications of on-site modular buildings, installations, and artworks.

Keywords: BESO, mortise-and-tenon joint, topology optimization, timber structures

1. Introduction

Topology optimization has gained continuously growing attention in architecture design due to its potential for generating elegant and lightweight structures with high structural performance. During the last two decades, there are several classical topology optimization methods have been developed widely and deeply, e.g., Homogenization method [1, 2], the solid isotropic material with penalization (SIMP) method [3, 4], the evolutionary structural optimization (ESO) [5, 6], Bi-directional evolutionary structural optimization (BESO) [7, 8] and the level-set method (LSM) [9, 10]. And there are two main tendencies of topology optimisation in architectural research fields. On one hand, more and more contemporary architectural projects absorb topology optimisation as their concept design sources, e.g., Akutagawa River Side in Takatsuki City [11], tree-like pavilions [12], Qatar National Convention

Centre & Shanghai Zendai Himalayan Art Centre [13, 14], concrete slab [15], Volu Dining Pavilion [16], and so on. On the other hand, topology optimisation methods can also be introduced for structural form analysis for traditional architectures, e.g., Sagrada Familia [17], Palazzeto Dellospori of Rome [18], Chinese wooden mortise and tension joints [19], Chinese rainbow bridge [20], etc. However, there is seldom research combining the above two directions to perform a new structural-effective architectural design with traditional tectonic form features and constructing probabilities.

Furthermore, although most classical topology optimisation methods are effective in finding the globally optimised solutions around the whole design domain, there are usually some objective constraints or subjective preferences which also play important roles in architectural form-finding. Faced with these non-structural requirements, many researchers have been developing lots of modified topology optimisation methods for specific aims, e.g., introducing detail constraints for concept design [21, 22], eliminating enclosed voids [23], obtaining self-supporting optimized models [24], generating diverse truss structures[25], simulating leaf morphogenesis [26], etc. And in this project, the carpentry manufacture techniques of mortise-and-tenon joints make special demands on the topologically optimised layouts, which requires modified BESO algorithms as well as customised finite element analysis models.

Therefore, an innovative structural design-fabrication working-flow based Multi-volume constraint BESO method [27] and Chinese traditional mortise and tension joint carpentry are introduced with a pavilion project named X-Form 3.0 in this paper. Compared with its two previous versions (X-Form 1.0 & 2.0) [12, 28], X-Form 3.0 consists of timber components connected with mortise and tension joints, which means that the fabrication of this project is subtractive manufacturing rather than additive manufacturing in the past projects. Therefore, this paper proposes a new structural topology optimisation workflow oriented to subtractive manufacturing. And with the Chinese traditional mortise and tension joints, this installation can be transferred easily with several light slender parts and assembled on-site with a few people, which shares the great potential in applications of on-site modular buildings, installations, and artworks.

2. Structural form-finding

2.1. Multi-volume constraint BESO method (MV-BESO)

To form a structural design with slender tree-like components, the multi-volume constraint BESO (MV-BESO) method [27] is introduced. This is because conventional topology optimization methods are aimed at achieving the solution which maximizes the structural performance under a certain global volume fraction constraint and always form continuum solid parts instead of slender rods. However, the Multi-volume BESO aims to achieve the same object with several local volume fraction constraints and share the ability of adjusting local structural designs. The basic problem of MV-BESO is different from the description of conventional topology optimization methods, and it can be written mathematically as below:

$$min\ C(\boldsymbol{X}) = \frac{1}{2}\boldsymbol{U}^T\boldsymbol{K}\boldsymbol{U} = \frac{1}{2}\sum_{i=1}^{N} x_i^p \boldsymbol{u}_i^T \boldsymbol{k}_i \boldsymbol{u}_i \tag{1}$$

$$subject\ to\ SUBV_k(\boldsymbol{X}_k) = \sum_{i=1}^{N_k} x_i v_i \le SUBV_k^* \tag{2}$$

in which C , $\boldsymbol{X}$, $\boldsymbol{U}$, $\boldsymbol{K}$, N are the objective function (compliance), design variable vector, displacement vector, global stiffness matrix and total element number in the global domain, respectively. $SUBV_k^*$, $\boldsymbol{X}_k$ and N_k are the local target volume, local design variable vector and local element number of *k*-th sub-domain. The terms v_i , x_i , k_i and $\boldsymbol{u}_i$ are the volume, design variable, stiffness matrix and nodal

displacement vector for *i*-th element. Particularly, the value of x_i is alternatively x_{min} (a prescribed small positive value, e.g., 0.001) or 1.

For stiffness optimization, the sensitivity α_i for *i*-th element, which is the criterion for design variable x_i, can be calculated as the gradient of compliance with respect to the design variable [29],

$$\frac{\partial C(\boldsymbol{X})}{\partial x_i} = -\frac{1}{2} p x_i^{p-1} \boldsymbol{u}_i^T \boldsymbol{k}_i \boldsymbol{u}_i \tag{3}$$

$$\alpha_i = -\frac{1}{p}\frac{\partial C}{\partial x_i} = \begin{cases} \frac{1}{2}\boldsymbol{u}_i^T \boldsymbol{k}_i \boldsymbol{u}_i & \text{when } x_i = 1 \\ \frac{x_{min}^{p-1}}{2}\boldsymbol{u}_i^T \boldsymbol{k}_i \boldsymbol{u}_i & \text{when } x_i = x_{min} \end{cases} \tag{4}$$

And when the penalty coefficient *p* tends to infinity, the sensitivity number α_i becomes the one in hard-kill BESO method [29],

$$\alpha_i = -\frac{1}{p}\frac{\partial C}{\partial x_i} = \begin{cases} \frac{1}{2}\boldsymbol{u}_i^T \boldsymbol{k}_i \boldsymbol{u}_i & \text{when } x_i = 1 \\ 0 & \text{when } x_i = x_{min} = 0 \end{cases} \tag{5}$$

The above sensitivity is usually modified to solve the mesh-dependent problem [30], using a filtering scheme:

$$\tilde{\alpha}_i = \frac{\sum_{j=1}^{N} w_{ij}\alpha_j}{\sum_{j=1}^{N} w_{ij}} \tag{6}$$

$$w_{ij} = \max(0, R_{min} - d_{ij}) \tag{7}$$

in which d_{ij} is the distance between the center of the *j*-th element and the *i*-th element. R_{min} and α_i are the filter radius and the original sensitivity of the *j*-th element.

To achieve a convergent solution, another historical average of $\bar{\alpha}_i$ in different iterations is introduced [30]:

$$\bar{\alpha}_i = \frac{\tilde{\alpha}_i^{(n)} + \tilde{\alpha}_i^{(n-1)}}{2} \tag{8}$$

In MV-BESO method, for *k*-th sub-domain, the element sensitivities are ranked in each iteration to determine a threshold with local target volumes of next iteration, $SUBV_k^{(n)}$, which is defined based on the current volume $SUBV_k^{(n-1)}$ and the evolutionary ratio δ.

$$SUBV_k^{(n)} = SUBV_k^{(n-1)}(1-\delta) \tag{9}$$

The threshold can be used to evaluate if the element shall be changed in a such way that if one solid element's sensitivity is lower than the threshold, its design variable will be switch from 1 to x_{min}, and the design variable of a void element will be changed from x_{min} to 1 as well if its sensitivity is higher than the threshold.

The cycle of FEA and BESO evolution continues until the following convergence criterion defined in the variation of the objective functions is satisfied [30]:

$$\frac{\left|\sum_{i=1}^{N}\left(C_{k-i+1}-C_{k-N-i+1}\right)\right|}{\sum_{i=1}^{N}C_{k-i+1}} \leq \tau \tag{10}$$

where k is the current iteration number, τ is an allowable convergence error (τ = 0.001 in this paper), which means stable compliance at least in successive 10 iterations.

2.2. Topology optimization with structural predesign

As Fig.1 shows, the pavilion in this project has a centrosymmetric free-form roof with width and length of about 3960mm and 3900mm, respectively. The curved roof is consisted of several quadrilateral or triangular plates (grey parts) and supported by three equal tree-like wooden structures (blue parts). Therefore, in the following structural form-finding process, only one-sixth part is introduced with symmetric condition settings.

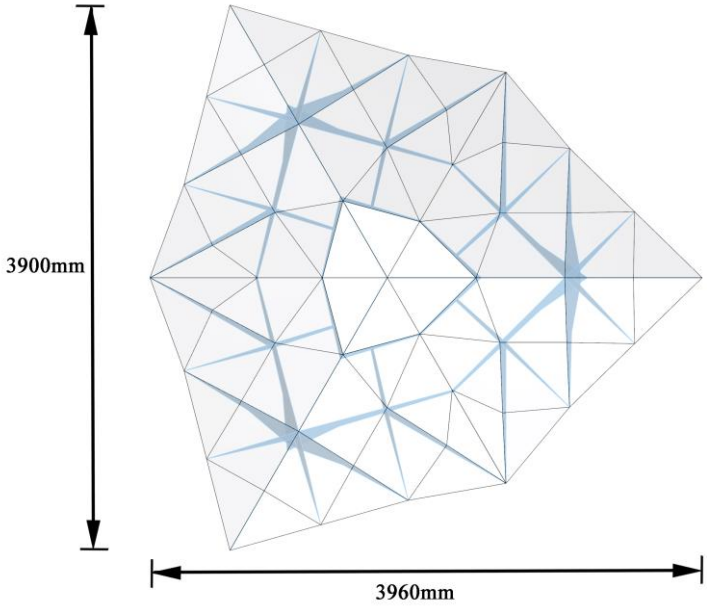

Figure 1. The top view of whole X-Form 3.0 pavilion.

The timber structure components are required to be hexagonal or octagonal columns to leave the spaces for mortise-and-tension joints carpentry works, which means that the timber components need to link each other with the fixed plane angles of 0, 45, 90, 135, or 180 degrees. Therefore, as illustrated in Fig.2, an initial shell model with the specific plane angles is generated as the basic design domain for the topologically optimised form-finding. Moreover, the above initial design domain is divided into 30 sub-domains and 6 non-design domains to get the locally optimised structure design with MV-BESO method effectively.

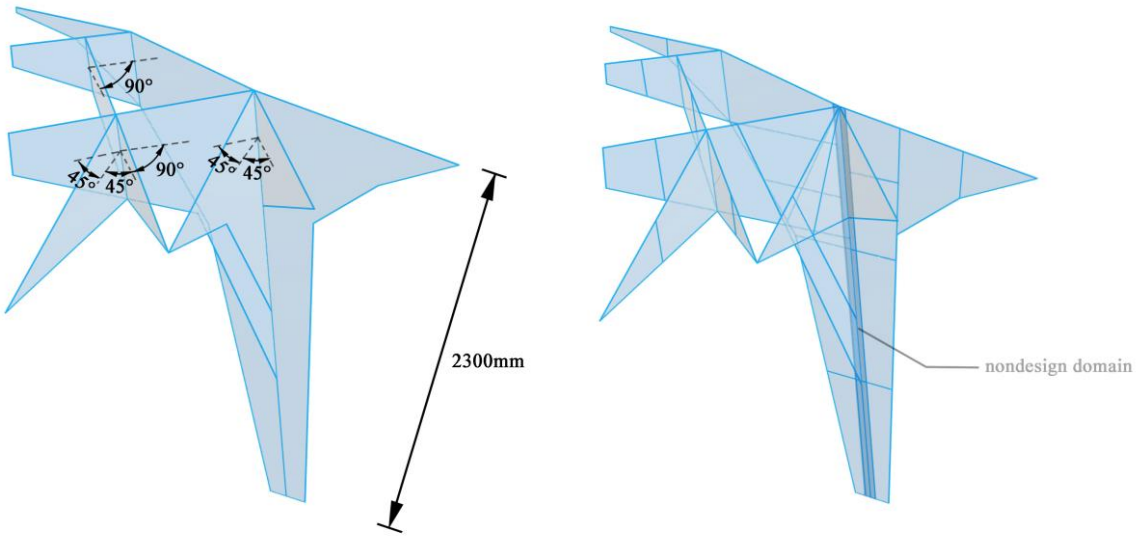

Figure 2. Initial model and sub-domain settings for MV-BESO methods.

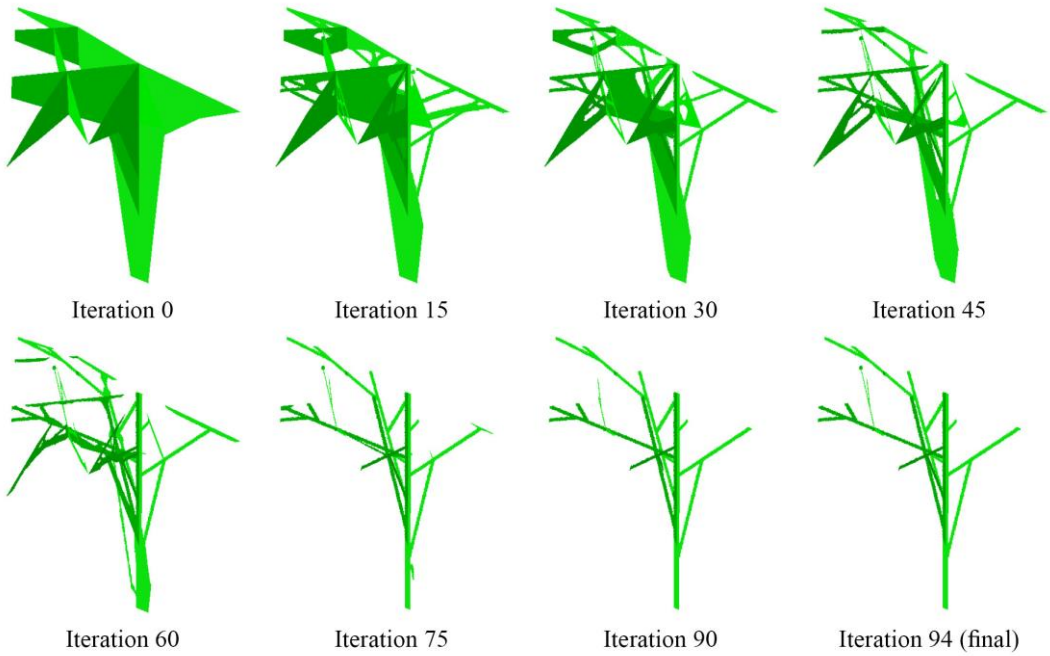
Fig.3 illustrates some typical stages of MV-BESO stiffness optimisation process from iteration 1 to iteration 94. This FEA model is divided into 100,000 shell elements with the thickness of 10 mm. The material assumption is assumed as Young's Modulus of 700 MPa and Poisson ratio of 0.45. The MV-BESO parameters are Rmin of 20 mm and ER of 1%. All the local volume fraction constraints for sub-design domains are 45%. With the boundary conditions and loading cases (Fig.4 a), it is obvious that each sub-design domain removes its materials during the evolutionary loop. After 94 iterations, the final optimised structural layout is generated and reshaped as octagonal rods according to the requirements from carpentry work (Fig.4 b).



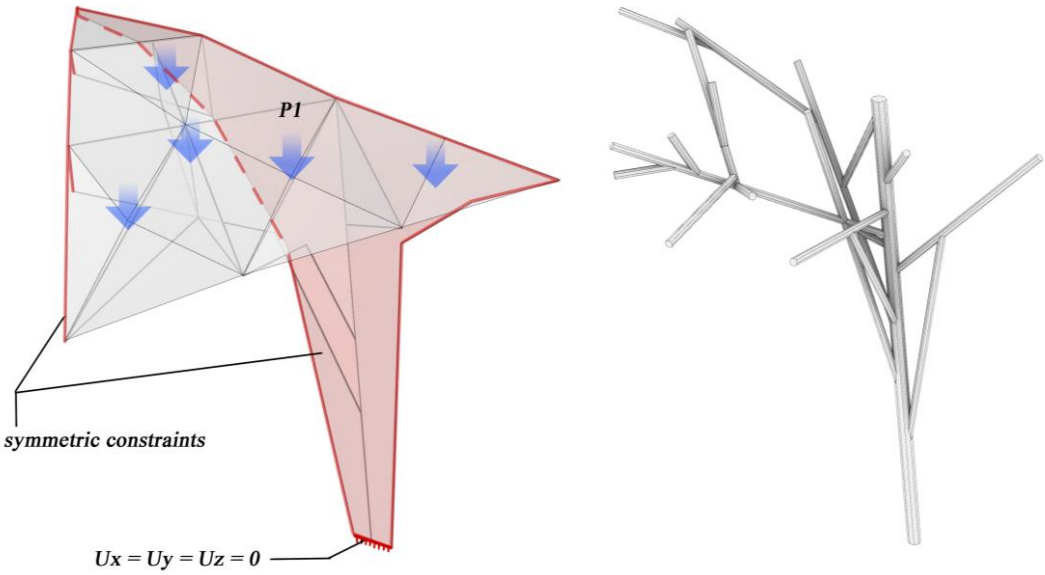


Figure 3. MV-BESO evolutionary history of X-Form 3.0.

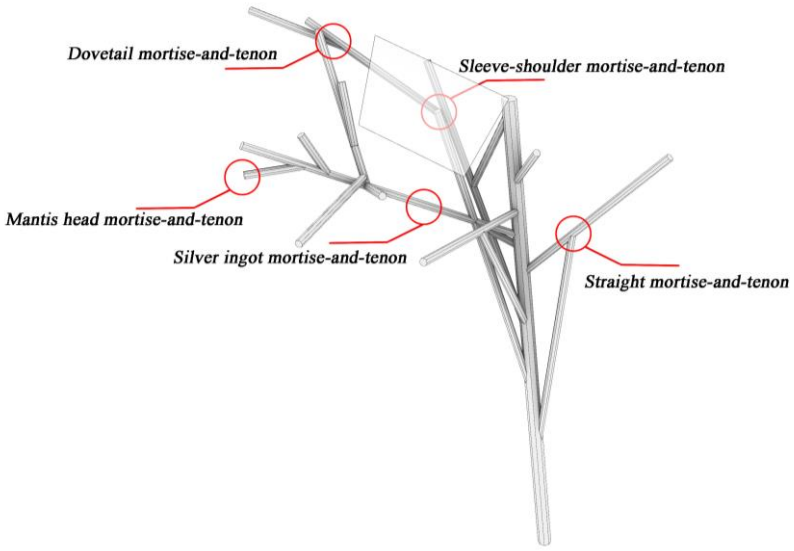
Figure 4. Boundary conditions & load case (a) and modified structural layout(b).

3. Wooden mortise-and-tenon joint and on-site assembles

One of the project's aims is to form an innovative wooden working flow which can be transferred and assembled easily, so the above optimised structure with MV-BESO needs to be divided into several slender timber rods with the maximal length of 1500mm and section diameters from 60mm to 20mm. Then, several different kinds of Chinese traditional mortise-and-tenon joints are introduced to link different structural members without any nails. The selected mortise-and-tenon joints are straight mortise-and-tenon, dovetail mortise-and-tenon, silver ingot mortise-and-tenon, mantis head mortise-and-tenon, and sleeve-shoulder mortise-and-tenon, etc.



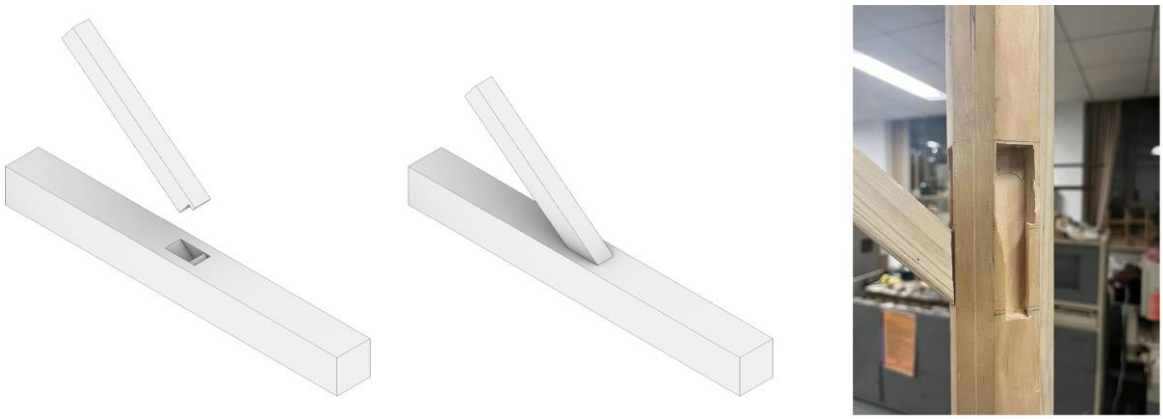


Figure 5. Diagram of different mortise-and-tenon distributions in X-Form 3.0.

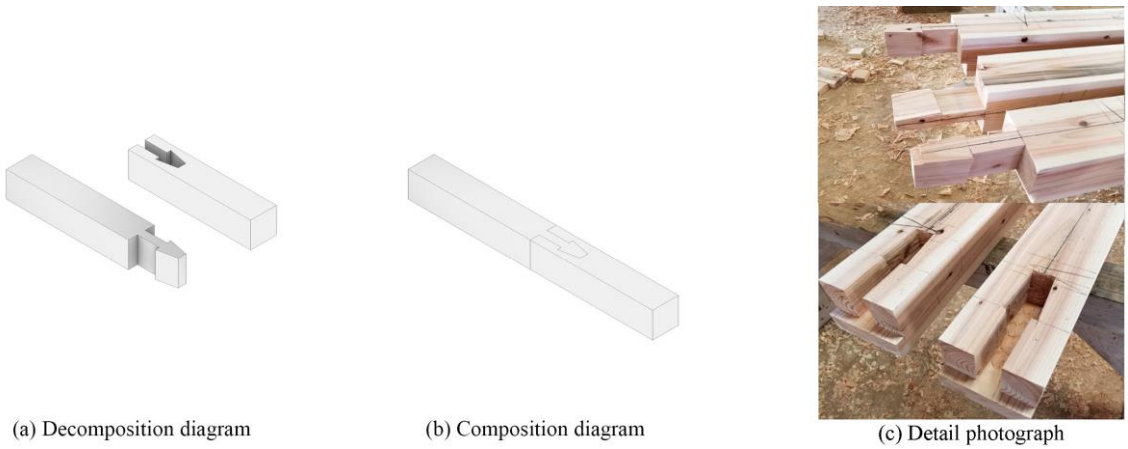
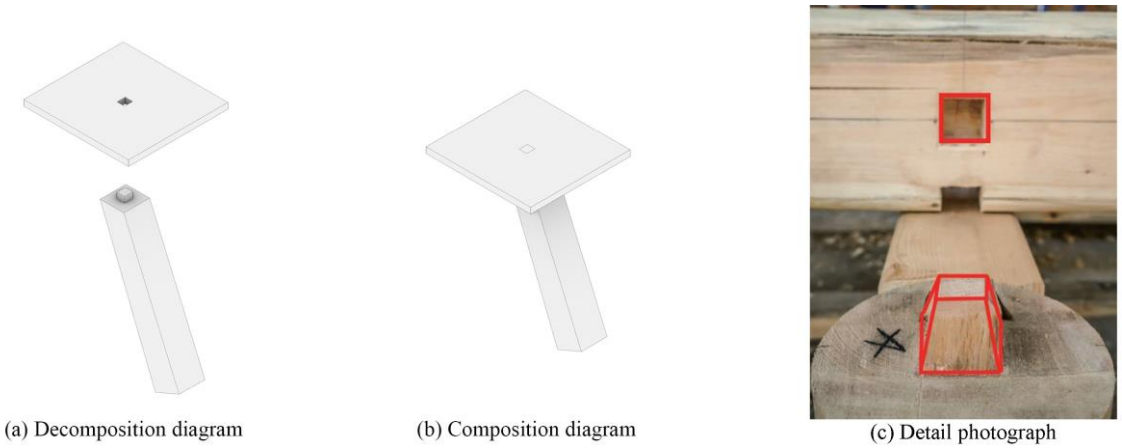
3.1. Plugging joints

In this pavilion fabrication, the most commonly used plugging joint is straight mortise-and-tenon joint, which is usually applied to insert the end of one rod into the middle of another rod (**Fig. 6**). With this joint, it is really convenient to form a structural rod like a "tree branch". Therefore, it is very suitable for generating tree braches.



(a) Decomposition diagram (b) Composition diagram (c) Detail photograph

Figure 6. Diagrams of straight mortise-and-tenon joint.



3.2. Connecting joints

The word "connecting joints" here represents the mortise-and-tenon joints which are implemented for the main purpose to link two structural parts, instead of generating new parts or new directions. And there are two kinds of connecting joints in this pavilion, which are mantis head mortise-and-tenon joint and sleeve-shoulder mortise-and-tenon joint, respectively (**Fig. 7-8**). The former one is used to combine two parallel rods into one. It is really necessary to link the three tree supports together with the mantis head mortise-and-tenon joint. And the function of sleeve-shoulder mortise-and-tenon joint is to fix roof panel to the top of tree branch.

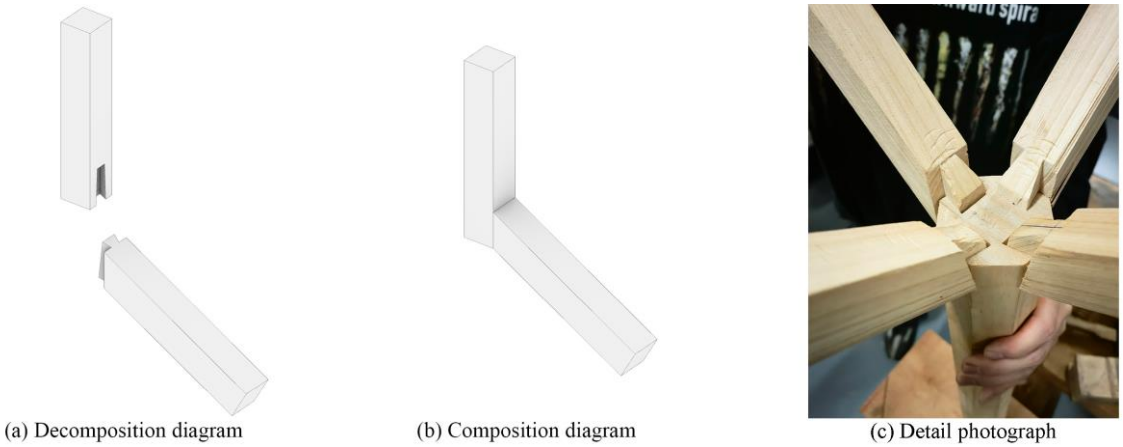
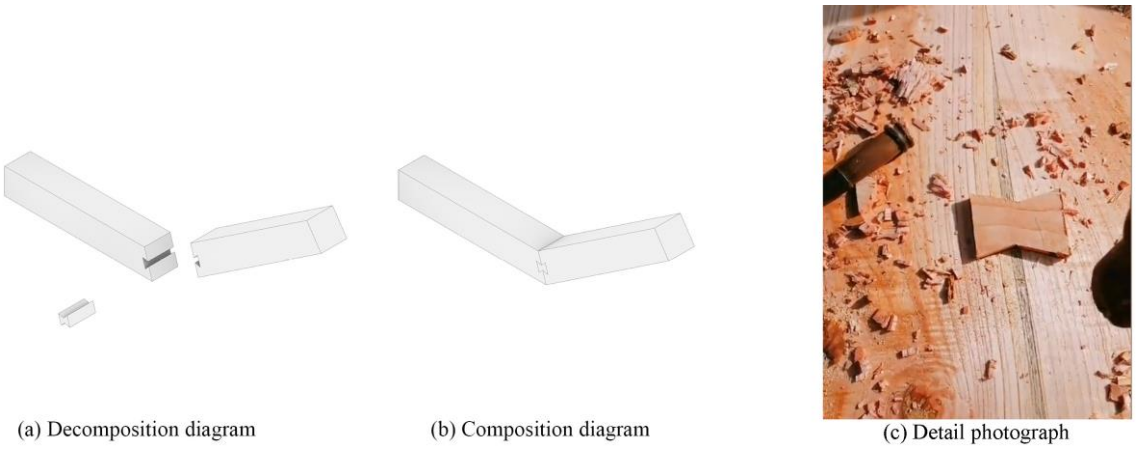
Figure 7. Diagrams of mantis head mortise-and-tenon joint.



(a) Decomposition diagram (b) Composition diagram (c) Detail photograph

Figure 8. Diagrams of sleeve-shoulder mortise-and-tenon joint.



3.3. Steering joints

The last kind of mortise-and-tenon joint in this project is steering joint, and it is the main component to change rod direction. As Fig. 9-10 shows, both dovetail mortise-and-tenon joint and silver ingot mortise-and-tenon joint can undertake this task. One biggest difference between the two joints is that dovetail mortise-and-tenon joint can only link light parts, while silver ingot mortise-and-tenon joint is always used in the main structure components.

Figure 10. Diagrams of silver ingot mortise-and-tenon joint.

Figure 11. Rendering view of X-Form 3.0.

3.4. Augmented reality on-site assembles

Taking the advantages of mortise-and-tenon joints, X-Form 3.0 is carrying-friendly and assembling-friendly. For example, the whole weight of wooden material is only 24kg, and the slender structural rods can be divided into two suitcases easily. Furthermore, the mortise-and-tenon joints also share the

advantages of on-site assembling with Fologram. Fologram is an augmented reality equipment which can transform 3D models into full-size construction guides through augmented reality glasses such as Hololens. This program is dedicated to overlaying digital guidance in the workspace to assist in the construction of complex projects that require a series of measurements, verification and targeted management, enabling step-by-step guidance for masonry work during construction. Thus, using Fologram, anyone can easily and effectively assemble the rods together (Fig. 12).

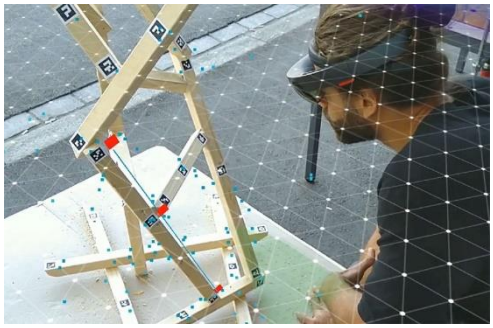

Figure 12. Fologram augmented reality construction technology.

4. Conclusion

This paper introduces the whole working flow of X-Form 3.0 including structural form-finding, joint fabrication and on-site assemble. The most notable contribution of X-Form 3.0 is that it presents a successful example to integrate topology optimisation based form-finding method with Chinese traditional wooden tectonics.

Firstly, a modified BESO method, MV-BESO method, is introduced to form the slender structural rods for timber fabrication. To achieve this, it is necessary to pay more attention to the initial model design according to carpentry requirements. Then, five different mortise-and-tenon joints are implemented to appropriately link different structural members. In this phase, the traditional carpentry also plays a great role in the fabrication because there are always some complex shapes in the mortise-and-tenon joints which can not be fabricated by robots. Finally, taking the advantage of mortise-and-tenon joints, the team can conveniently transfer all the structural components and assemble them on-site with Fologram. Furthermore, it is notable that X-Form 3.0 is only a preliminary attempt to integrate topology optimisation with traditional subtractive manufacturing, and there are still some parts which require more in-depth studies, e.g., an effective BESO method to generate timber rods, a robotic fabrication method to make complex wooden joints, and so on.

This innovative pavilion is a demonstration of the combination of new design and traditional construction techniques, explaining the design and construct process of the pavilion through exploration of emerging technologies in both digital design and subtractive manufacturing, which shares great significance for architects, engineers, and designers.

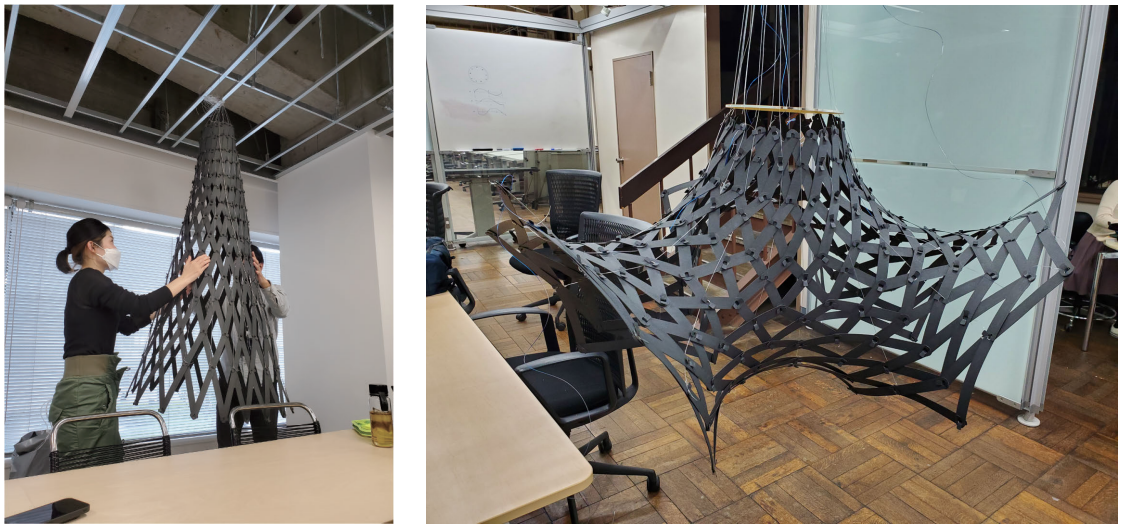
Abstract

Frilly ruffles appearing in natural forms, such as coral and leaves, are induced by in-plane differential growth. Previously, we proposed a mechanism using bending-active scissors that reproduces these self-organized ruffles through the incompatibility of in-plane deformation produced by scissor units; however, the study left unsolved questions. This study analyzes the symmetry-breaking process of deployment and zero-stiffness wave-like motion after deployment through simulation. We propose how to control this wave-like motion by pulling the group of threads. We fabricated a meter-scale structure by assembling bar and pivot parts made of vulcanized fiber, chemically processed cellulose paper. The joint parts are utilized the material's plasticity in a wet state and stiffness in a dried state.

Keywords: bending active scissors, zero-stiffness, negative gaussian curvature, frills and ruffles, buckling

1. Introduction

Frilly ruffles in biological forms such as coral and lettuce leaves are a great inspiration for architectural and product design [1]. Such buckled surfaces induced by in-plane differential growth are ubiquitous in nature [2, 3]. Previously, we proposed a mechanism based on bending-active scissors that effectively reproduces these self-organized ruffles through the incompatibility of in-plane shear deformation produced by bending-active scissor units [4]. Although we obtained the desired ruffled form, the process of symmetry breaking, the form after the buckling, and their behavior were not fully investigated.



In this study, we analyze the process of symmetry breaking through simulation to understand the buckling process better. We show that the number of frills is affected by the balance between the in-plane and out-of-plane stiffness. We identify the families of locally stable configurations with different rotational symmetry, where states within the same family are connected to each other through a wave-like quasi-zero-stiffness motion.

We show how to control this wave-like motion along the perimeter by pulling the group of threads in a coordinated way. We provide a method for obtaining the control motion of threads by inversely computing from our simulated geometric model. Then, we verify the actuation using the simulation model.

We fabricated a meter-scale structure by assembling bar and pivot parts cut out from sheets of vulcanized fiber, which is chemically processed cellulose paper. The fabrication of joint parts utilizes the material's

plasticity in a wet state and elasticity in a dried state. We show the fabrication process and the joint's detailed design.

Figure 1: Our structure in a meter scale.

2. Geometric model

We follow the notation and the principles of the structure from Ono and Tachi [4]. The structure is based on bending-active scissors that can deform between a linearly folded state and a surface of constant negative Gaussian curvature. We use flat members for the scissors so they can only bend in the normal direction of the surface, so it can be considered as a type of geodesic grid shells [5]. Since the straight element is kept straight in the in-plane direction (geodesic), the mechanism has one degree of freedom (DOF) in-plane transformation, allowing for easy control of the deployment. However, this motion produces the angle excess at the vertex and non-zero Gaussian curvature leading to frustration if the mechanism is kept in a plane. The frustration of in-plane scissor deformation effectively reproduces differential growth, which results in the out-of-plane buckling of the surface into a ruffled form.

In our mechanism, m polar scissors [6] units of different sizes are vertically connected to form a mirror-symmetric column, and n columns are connected rotationally symmetrically to form a surface of revolution (Figure 2). The shape of the i-th scissors ($i = 1, \dots m$) from the bottom of a column is defined by the short edge length r_i and the long edge length R_i, and its deployed configuration can be expressed by the lower bottom $x_i \in [0, 2r_i]$ of the isosceles trapezoid that each scissors unit spans. x_i becomes larger as the unit deploys (Figure 4). Also, the length of the upper base X_i is given by $X_i = \frac{R_i}{r_i} x_i$.

Consider one column of the entire mechanism. Then, adjacent units are related as $x_{i+1} = X_i$, so the deployment state of each module is sequentially determined once x_1 of one end of the column is determined. Because of the in-plane rigidity of members, the structure forms a 1 DOF mechanism in an intrinsic sense. The mirror symmetry of the one-column allows the columns to be connected to each other with rotational symmetry, and the entire mechanism also works in a one-DOF manner intrinsically. Since there exists a state where $x_i = X_i = 0$, the entire mechanism can be folded into a compact cylindrical shape, $x_i = 0$ for any r_i, R_i.

The curvature of the surface can be explained by the curvature of the polyline forming the boundary of the one-column (red curves in Figure 4). The Gaussian curvature of the entire surface is zero when the

polyline becomes a straight line (middle of Figure 4), positive when the polyline is convex (left side of Figure 4), and negative when the polyline is concave (right side of Figure 4). Thus, the opening and closing of the scissors deform the polyline and result in changing the intrinsic curvature of the entire surface.

We design such that the deployed state has a constant negative curvature. We compute the shapes of each unit using the constant negative curvature condition gives a relationship between the area A_i and the angle θ_i by the Gauss-Bonnet equation [4]. Here, we constructed a model with $n = 18$ and $m = 8$. In the simulation models (Section 3. and 4.), we set the lengths of the bars to

$$r_1, \ldots, r_8 = 44.1, 40.4, 36.1, 37.5, 44.9, 57.3, 74.6, 97.0 \text{ mm} \quad (1)$$

$$R_1, \ldots, R_8 = 44.1, 52.6, 52.1, 53.6, 62.1, 77.2, 98.6, 127.1 \text{ mm}. \quad (2)$$

In this model, x_1 deploys from 0 to $x_1^{\text{target}} = 28.8$ mm, when it reaches the constant negative curvature state with frills.

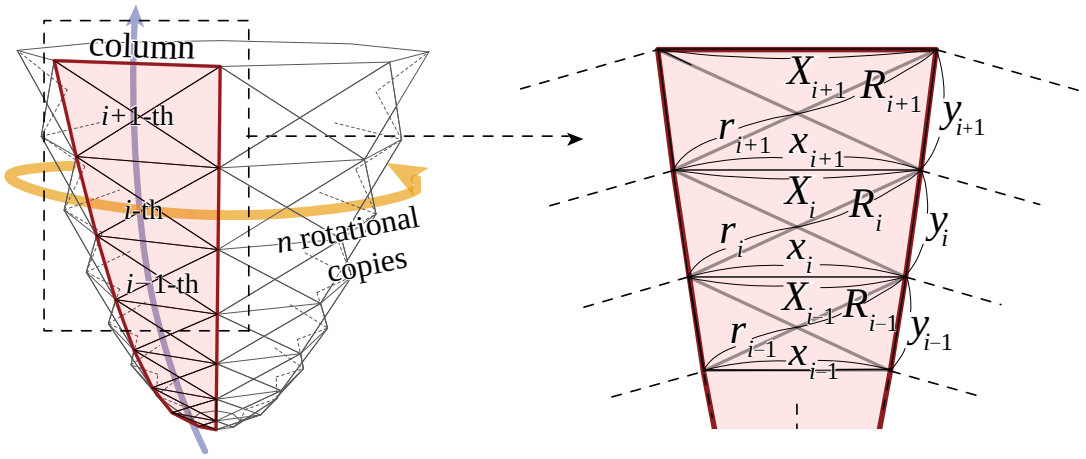

Figure 2: Notations and design parameters for the design. Left: entire structure comprising n rotational copies of one column (colored). Right: close-up view of one column.

3. Analysis of frills

We create a computational bar-and-hinge model to simulate the elastic behavior of our structure. Under this model, we first simulate and analyze the deployment process from the cylindrical state to a target frilled state. From a single simulation instance, we provide a smooth interpolation of the target surface, from which we can create a single parameter family of solutions to the obtained frilled state. We iden-

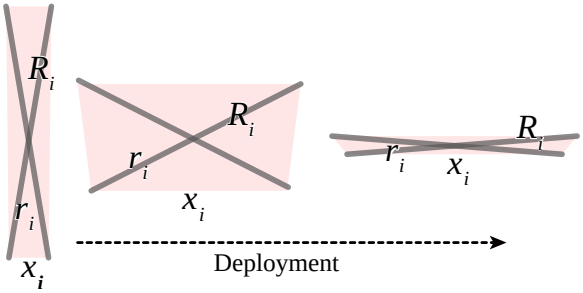

Figure 3: Change in X_i as scissors deploy.

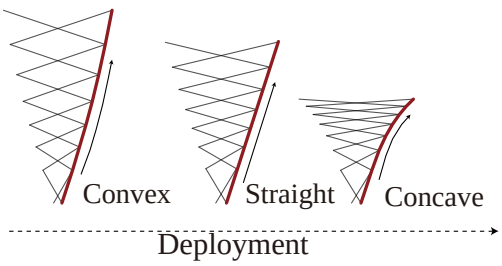

Figure 4: Change in the column's boundary polyline.

tify that these solutions have the same potential energy and that there exists a one-DOF zero-stiffness wave-like motion for a frilled state. Moreover, we show that the number of frills is determined by the proportion between the out-of-plane bending and in-plane stiffnesses.

3.1. Simulation model

Instead of directly modeling a scissor element that can bend and twist and be joined by pivots, we approximate the system as a partially homogenized shell under an equilibrium of in-plane stiffness and out-of-plane bending stiffness. Here, we modify the bar-and-hinge model [7, 8] that model the in-plane stiffness using bars (springs) and out-of-plane stiffness using hinges (angular springs). We solved the equilibrium state using *Kangaroo 2* [9] using provided goals and custom goals.

Figure 5 shows the composition of constraints in the bar-and-hinge model. To represent the in-plane stiffness, we let the unit trapezoid with a single pair of scissors consist of four bars along the diagonal scissor elements and four bars along the bases and the legs of trapezoids. We found that applying the same stiffness to all eight bars resulted in an overconstrained system that led to jaggy and unstable results. To solve this issue, we set the full stiffness to only six bars, namely the four diagonal bars and two bases, while keeping the legs' stiffness very small. Empirically, we chose 0.015 of the full stiffness bars, which makes the legs not the main element to carry the load but act as the regularization term to avoid artifacts due to discretization. For the bar elements, we used *length* in Kangaroo 2, which is a straight spring system.

To represent the out-of-plane stiffness, we use a customized *hinge* component that represents the angular springs between two triangles. The stiffness of each hinge is computed to equate with the beam with a cross-section of $w \times t$.

The following is the list of constraints, potential energy U, and the names of goals used in Kangaroo. Here, E represents Young's modulus.

1. **In-plane** The linear springs that keep each r_i, R_i, and x_i at their original length. $U_{\text{in}} = \frac{1}{2} Ewt \left(\frac{\ell - \ell_0}{\ell_0} \right)^2$, where ℓ is the length of each bar and ℓ_0 is the target length of the bar. We used [Lenght(line)]
2. **Regularization** The linear springs that regulate discretization artifacts. We keep y_i at the ideal length, but with a small value $U_{\text{reg}} = \frac{p}{2} Ewt \left(\frac{\ell - \ell_0}{\ell_0} \right)^2$, where $p = 0.015$. [Length(line)]
3. **Out-of-plane** The angle springs that keep the quadrangles planar to represent the out-of-plane stiffness. $U_{\text{out}} = \frac{1}{2} \frac{Elt^3}{8h} \rho^2$, where ρ is the fold angle between two triangles, l is the length of the hinge, and h is the sum of heights of the triangles sharing the base. [Hinge]
4. **Boundary condition** Constraints that keep the bottom vertices of the mechanism in an ideal position on the same plane. [Anchor]

Note that our model is not accurate enough to predict the exact load and energy from the given dimension. Instead, the model focuses more on how the overall behavior is dimensionally affected by parameters. Our system is governed by the balance between the in-plane and out-of-plane stiffness of the surface, where the former is proportional to the thickness t and the latter is proportional to the cube of the thickness t^3. Therefore, we vary t to calibrate and control the system's behavior. Specifically, our model computed with the thickness of $t = 3\,\text{mm}$ reproduced a similar result to our fabricated physical models with thinner material $t = 1\,\text{mm}$. Therefore, we varied t from $2\,\text{mm}$ to $4\,\text{mm}$ and performed the rest of the simulation.

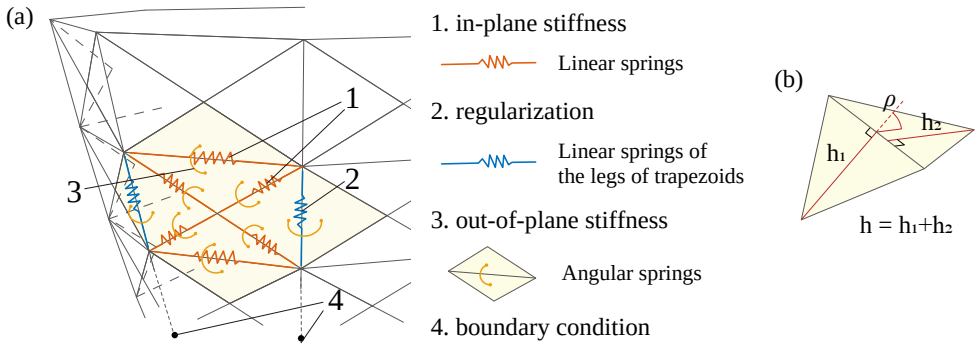

Figure 5: (a) Constraint conditions of the simulation model. (b) The fold angle ρ and heights of the triangles h.

3.2. Deployment results

We simulated the deployment process from the rotationally symmetric state to the desired ruffled form, using the model created as described in Section 3.1.. We changed x_0 from $14.4\,\mathrm{mm}$ (rotationally symmetric state) to $28.8\,\mathrm{mm}$ (fully deployed state) in 1000 steps; for each step, we performed a sufficiently large number of steps (average 35.6 steps) of iterations in Kangaroo 2 solver, to emulate a quasi-static process.

For all parameters $t = 2, 3, 4\,\mathrm{mm}$, the mechanism first deploys while keeping the rotational symmetry; but when it reaches a limit, the mechanism loses its rotational symmetry and forms a ruffled surface. Figure 6 shows the potential energy of the mechanism associated with this symmetry-breaking buckling process. We plot the graphs with the x_1 on the horizontal axis and the potential energy on the vertical axis. First, the mechanism deploys without any in-plane energy introduced. Just after x_1 passes the limit of the geometric model with rotational symmetry [4], the in-plane potential energy increases rapidly, and the structure reaches a highly frustrated state. Then, the symmetry breaks with a reduction of the in-plane potential energy and an increase of out-of-plane potential energy.

Typically, the resulting forms have an N-fold rotational symmetry, i.e., there are N repetitions of ups and downs within one cycle. We call this number N the frill number N. We found that the frill numbers differ for different thicknesses and change during deployment (Figure 6).

Specifically, for (a) $t = 2\mathrm{mm}$ case, the symmetry changed from $N = \infty$ (circular symmetry) to $N = 4$. (b) for $t = 3\mathrm{mm}$, the symmetry first changed from $N = \infty$ to $N = 4$ and took many steps of iteration after the deployment to change into $N = 3$. (c) for $t = 4\mathrm{mm}$, the symmetry moved from $N = \infty$ to $N = 4$, and then $N = 2$. Although the final stable state is affected by the thickness, the results suggest the existence of (near) metastability at different frill numbers.

3.3. Frill number analysis

We examine the metastability of and the transition between the states with 2, 3, and 4 frills, i.e., if they are the global or local minimum energy states for different thicknesses. To compare the energy states of the mechanism with different frill numbers, we run the same simulation with the initial state of frill number values of 2, 3, and 4 computed from different thickness settings. A typical transition process was in Figure 7, where the horizontal axis shows the timestep and the vertical axis shows the potential energy. First, in ~ 200 steps, the energy drops and reaches the plateau state while keeping the shape almost identical. However, later with 5 to 10 times more steps, the form falls into a different local minimum energy state but with the same frill numbers. High hinge fold angles suggest that these states

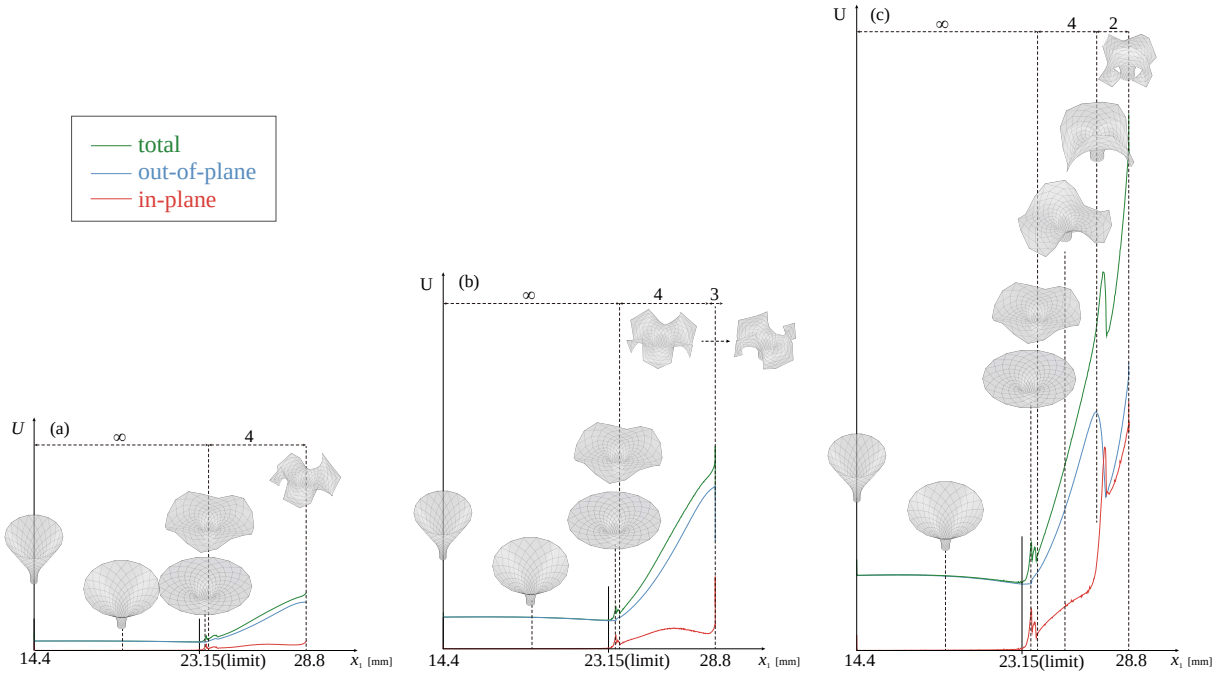

Figure 6: Plot of the potential energy U respect to the shift change x_i. Here we use $\sum U_{\text{in}} + \sum U_{\text{reg}}$ is used as the in-plane energy, and $\sum U_{\text{out}}$ is used as the out-of-plane energy.(a) $t = 2\text{mm}$, $N = \infty \to 4$, (b) $t = 3\text{mm}$, $N = \infty \to 4 \to 3$, (c) $t = 4\text{mm}$, $N = \infty \to 4 \to 2$. The vertical short bar at 23.15 mm is the theoretical limit for the geometric model with rotational symmetry.

after transition may not be a real phenomenon but an artifact of our bar-and-hinge model.

Figure 8 compares the potential energy of these plateau states for different t. This suggests that the chosen state in the forward deployment state is not necessarily the minimum energy state. However, it requires a finer elastic model to fully describe the metastability of the structure.

3.4. Interpolated surface and phase-shifting motion

Macroscopically, the original cylindrical configuration has a circular symmetry, i.e., it can be rotated at an arbitrary angle about an axis $N = \infty$. Also, the in-plane deployment that aims at the constant Gaussian curvature everywhere has the same intrinsic symmetry. However, the wave-like frilled form loses this continuous symmetry and becomes N-fold symmetric. Because of the original intrinsic symmetry, there is a one-parameter family of possibilities for where the mountain and valley of the frills are located, thus the "phase" of the frills. We model such a phase shift.

We first construct an interpolated parametric surface model from the discrete simulation result. From the grid of points on the corner of trapezoids, $\mathbf{p}(i, j)$ for $i = 0, \ldots, n-1 \mod n$ and $j = 0, \ldots, m$, we interpolate them with the periodic NURBS surface $\mathbf{f}(u, v)$ for $u \in [0, 2\pi)$ and $v \in [0, 1]$, such that $\mathbf{p}(i, j) = \mathbf{f}\left(\frac{2\pi i}{n}, \frac{j}{m}\right)$ (Figure 9 (a)).

We first align the center to the z axis and use cylindrical coordinate $\mathbf{f} = (f_\theta, f_r, f_z)$. Then, the N-fold rotational symmetry of the simulated result can be verified by the following operation:

$$\begin{pmatrix} f_\theta(u + 2\pi/N, v) \\ f_r(u + 2\pi/N, v) \\ f_z(u + 2\pi/N, v)) \end{pmatrix} = \begin{pmatrix} f_\theta(u, v) + 2\pi/N \\ f_r(u, v) \\ f_z(u, v)) \end{pmatrix}. \tag{3}$$

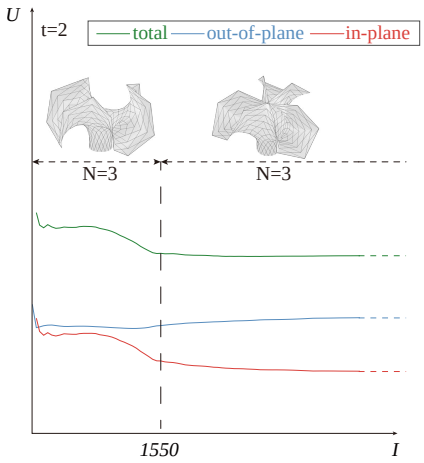

Figure 7: Plot of the potential energy U with respect to the steps of iteration for $t = 2\text{mm}$ starting from $N = 3$ initial state. The form transitions into another state with $N = 3$ symmetry.

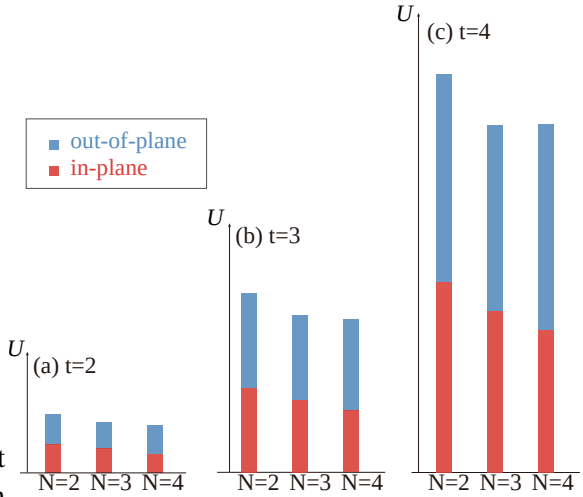

Figure 8: The potential energy of differ-ent N

Now, the phase of the frills of the interpolated surface can be shifted by angle δ by the following map $\mathbf{f} \to \mathbf{f}'$ (Figure 9 (b)):

$$\begin{pmatrix} f'_\theta(u,v) \\ f'_r(u,v) \\ f'_z(u,v)) \end{pmatrix} = \begin{pmatrix} f_\theta(u-\delta,v)+\delta \\ f_r(u-\delta,v) \\ f_z(u-\delta,v)) \end{pmatrix}. \tag{4}$$

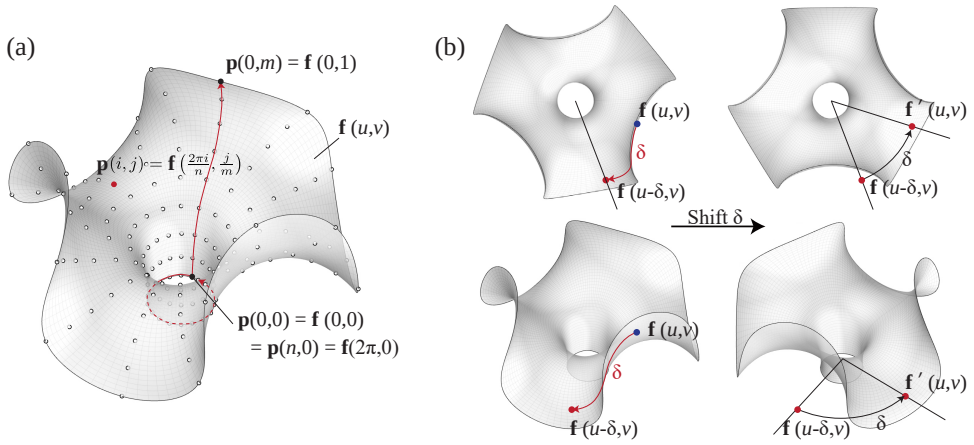

Figure 9: (a) The grid point $\mathbf{p}(i,j)$ and interpolated surface $\mathbf{f}(u,v)$. (b) Shifting the phase of the frills by angle δ by map $\mathbf{f} \to \mathbf{f}'$.

Here, we use (u,v) to keep track of the positions of the actual material, i.e., a point at $\mathbf{f}(u,v)$ moves to $\mathbf{f}'(u,v)$ by this phase shifting operation. Note that the addition of δ to the angle represents the rotation of the image of the surface, while the subtraction of δ to the parameter represents that the material itself stays not globally rotated. After this operation, we can sample the point coordinate $\mathbf{p}'(i,j) = \mathbf{f}'\left(\frac{2\pi i}{n}, \frac{j}{m}\right)$ to recover the scissors structure with a phase-shift.

We performed the bar-and-hinge simulation of Section 3.1. using the shifted scissors structure as the initial state while adding weak springs to bring the points to $\mathbf{p}'(i,j)$. Figure 10 shows the plot of the

strain energy of the structure with respect to the shift change of $\delta \in [0, 360°)$. We experimented for $N = 2, 3, 4$ cases with a fixed thickness of $t = 3\text{mm}$ with a $n = 18$ model.

We observed a nearly horizontal plot of energy with 18 bumps of in-plane energy. These bumps are attributed to the discrete structure caused by the radial division by $n = 18$ The amplitude of bumps is large for $N = 2$ and $N = 3$ and smaller for $N = 4$. The higher amplitude of the bumps in $N = 2$ and 3 may come from that n is the integer multiple of N when the hinge elements are aligned at the peaks of the ruffles, so the effect of the discretization is strongly reflected in the overall energy. It is still open if this effect is an artifact of computation or may appear in the real object; in the latter case, choosing the number of elements that are not integer multiple of N may lead to a smoother actuation.

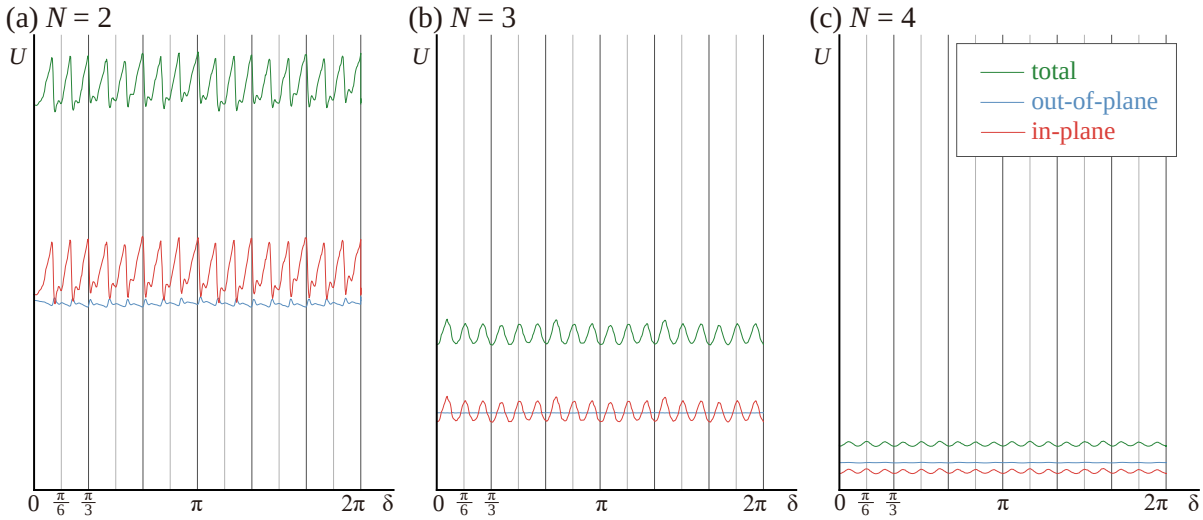

Figure 10: Plot of the strain energy with respect to the shift change of δ. (a) $N = 2$, (b) $N = 3$, (c) $N = 4$.

4. Phase change control

4.1. Concept

As simulated in Section 3.3, the wave-like frilled form after deployment is not stable in one position, allowing the frilled position to be shifted with almost zero force. This motion is a wave-like motion along the perimeter. We propose a method to control such motion by applying a tensile force to the perimeter of the structure. Specifically, the threads that pull the structure together are attached so that they connect the hinges on the perimeter with points on the central axis. We generate such motion by moving the end of the thread on the central axis side vertically to apply tensile forces.

To allow for a smooth motion, we apply the idea of a three-phase alternation. Specifically, we group the vertical movements into three groups $g = 0, 1, 2$ with different phases separated by $1/3$ of the wavelength. The threads in the same group are placed every $2\pi/N$, so there is a $3N$ threads in total (Figure 11).

4.2. Control path generation

We identify the path of the vertical movement of the endpoint on the central axis side of the thread that is required to generate a wave-like motion. We use the phase-shifted interpolated surface of a simulated

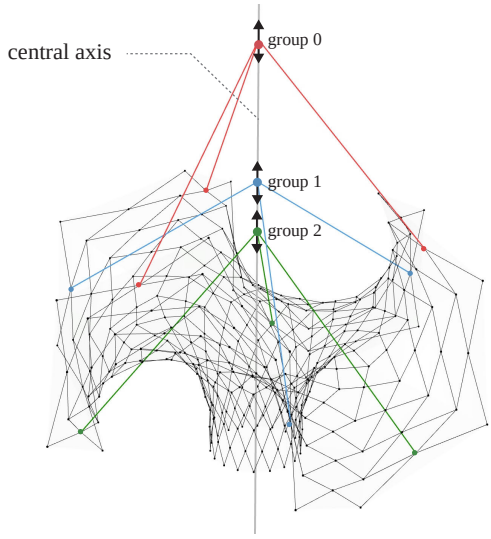

Figure 11: Vertical movements in three groups.

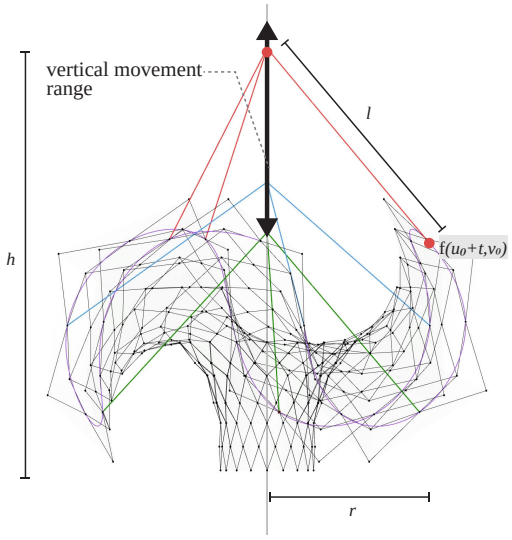

Figure 12: Notation to determine the vertical movements of the endpoints over time.

result $\mathbf{f}'(u, v)$ given in Section 3.4. The $3N$ points of control are given by

$$(u, v) = \left(\frac{2\pi}{N}n + g, 1\right), \tag{5}$$

where $n = 0, 1, \ldots, N-1$ and $g = 0, 1, 2$. Here,the height h of the endpoints on the central axis side at time t is given by the following equation (Figure 12):

$$h = \sqrt{l^2 - r_f(u_0 + t, v_0)^2} + z_f(u_0 + t, v_0), \tag{6}$$

where l is the length of the thread. Using this control, the thread is expected to be in tension at all times without sagging. The trajectory when t is varied from 0 to 2π is shown in Figure 11. By following this trajectory and moving the points on the central axis of the thread up and down, the structure can be smoothly moved in a wave motion. Note that the wavelengths of three groups with different phases are shifted by $1/3$.

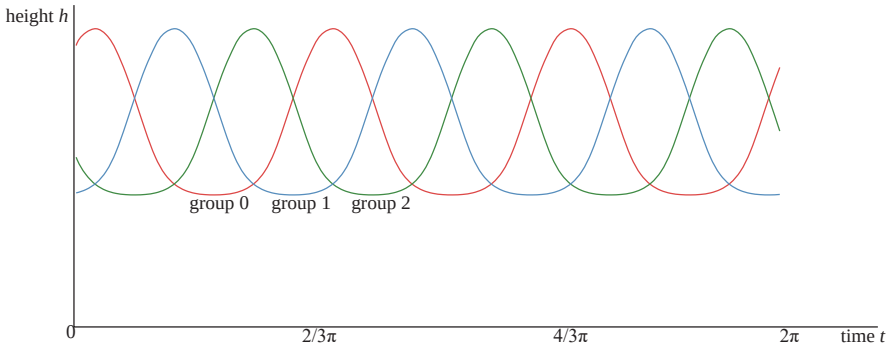

Figure 13: The height change of points on the central axis of the thread.

4.3. Evaluation by simulation

We simulate the wavy motion of the structure that is generated in the previous section. This simulation is based on Section 3.1., with the following constraints and mechanical properties added to generate such a motion. The material is assumed to be POM with Young's modulus of $E = 3 \times 10^2 \mathrm{N/mm^2}$ and the density of $1.41\,\mathrm{g/cm^3}$.

Gravitational force To approximate the deformation of the physical model, a force in the direction of gravity is applied to all pivots. For simplicity, the force applied to a single pivot is defined as the weight of the entire structure divided by the number of pivots. [load]

Tensile member A tensile member is represented as two serially connected linear springs. The middle split prevents compressive force from being applied. We used [Length(line)].

We simulated the motion for a 3-frilled model (Figure 14) and observed a continuous wave-like motion without any significant sagging of all tensile members. When actuated, the perimeter endpoints oscillate in a figure of 8.

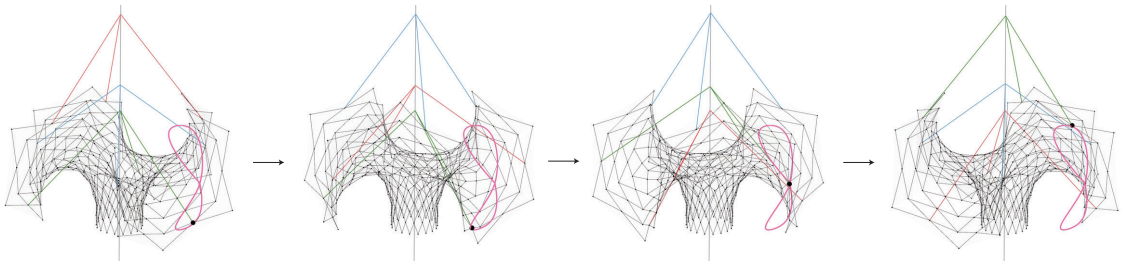

Figure 14: Sequential images of the phase change. The perimeter pivot draws like a figure of 8.

5. Fabrication / pavilion design

We designed a meter-scale pavilion that can be compactly folded and transported (Figure 1). Our structure is a 1.7 times scaled version of the simulation model shown in (1) and (2). It transforms into an elongated cylindrical shape when open, it is about $2000\,\mathrm{mm}$ in diameter, and when closed, it is about $200\,\mathrm{mm}$ in diameter. The total weight of the structure is $1.8\,\mathrm{kg}$.

We chose $1\,\mathrm{mm}$ thick sheets of vulcanized fiber (HB-77, Hokuetsu Toyo Fibre) sheets as sustainable, lightweight, and easy-to-fabricate materials. This material is made of cellulose fibers treated with chemicals to break them down to the nano-level. The fibers are tightly intertwined, making the material hard and tenacious. It is also highly biodegradable and has a smaller environmental footprint than plastics and metals. For fabrication, we utilize the property that softens and becomes plastic when moist while it hardens and becomes elastic when dry.

We made our design modular; we assembled multiple units that can be removed and added depending on the required size or partially replaced to repair the damage to the structure. All pavilion components are cut using a laser cutting machine. The maximum size of the components is determined by the size of the machine ($600\,\mathrm{mm} \times 450\,\mathrm{mm}$).

The module design is inspired by the techniques of making pivots in a pop-up book. A polar scissors unit is composed of two types of members; one is a bar-shaped member, and the other is a cross-shaped connecting member (Figure 15). The bar has three holes (top, center, and bottom) where a cross-shaped hinge slides in. The tip of the cross-shaped hinge is tapered to prevent it from falling out of the hole.

When assembling, the cross-shaped hinge is soaked in water before passing through the hole. After the joint is passed, the hinge module is dried using an iron (Figure 1) so that it becomes hard again.

The scissor units of 8 different sizes are rotationally symmetrically connected in 18 rows to form a cylindrical shape. Finally, the nylon threads are passed through the diagonals of the units, which are used to control the deployment of the pavilion (Figure 16). Note that the diagonal threading system for deployment is separate from the system that controls the wave-like motion. The control system for wave-like motion is still under development.

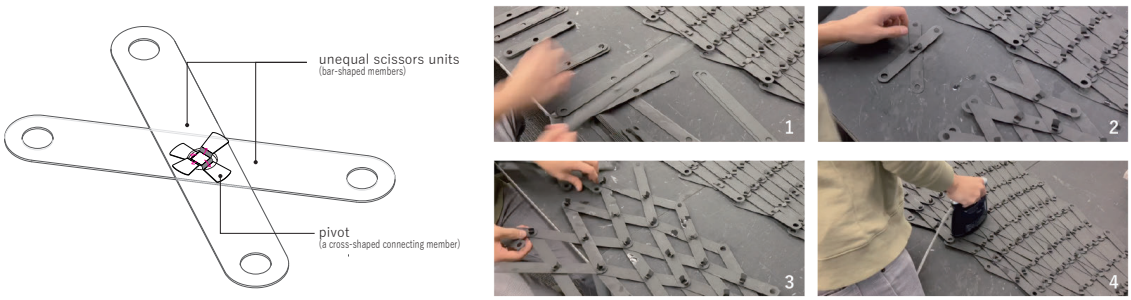

Figure 15: Joint details and assembly process.

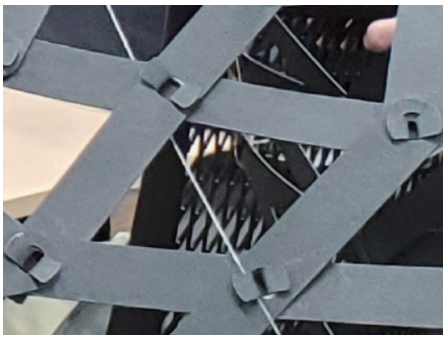

Figure 16: Diagonal threads to control the deployment.

6. Outlook

We envision that the structure we propose can be used for a variety of architectural applications, taking advantage of its characteristic movement. For example, our structure may be used as a work booth in an office space, reducing the oppression of the typical work booth closed off by walls. We hope that the bioinspired and biophilic nature of the structure improves the user's ability to concentrate, reduce stress, and increase intellectual productivity (Figure 17).

We still have future works to be done. As for theory, the metastability of the N-fold frills is still not fully analyzed. A more accurate model may be necessary to explain these interesting phenomena. As for practice, the physical control of phase-shifting motion is still a challenge we plan to accomplish.

Acknowledgments

This project is supported by NIKKEN Sekkei. We thank our colleagues who joined the brainstorming workshop for this project. We thank Shintaro Ueno, Masaharu Kii, Mei Yaya, and Hibiki Totsuka for the help in manufacturing the models.

Abstract

The coupling of origami tubes realizes extremely stiff yet deployable structures used for temporary structures, such as emergency shelters and infrastructure. However, thickness accommodation is a crucial problem in the coupling of thick-panel origami tubes. To solve this problem, we propose the coupling of origami tubes along the creases for easy coupling of thick-panel origami tubes. As thick origami tubes can generate one-degree-of-freedom (DOF) motions based on a hinge-shift technique, coupling of origami tubes mirrored along creases also provides one-DOF motions because of the mirror symmetry along the creases. Therefore, the proposed coupling method facilitates the fabrication of coupled thick-panel origami tubes using existing hinges, such as piano hinges or fabrics. To demonstrate that the proposed coupling method contributes to the high stiffness of the coupled origami tubes, an eigenvalue analysis of linear dynamical systems defined by bar and hinge models is performed. A wide gap in eigenfrequencies is obtained between the one-DOF mode (i.e., 7th mode) and elastic modes (i.e., higher than the 7th mode), indicating that the one-DOF motion provides flexible deployment, and the elastic deformations retain high stiffness throughout the deployment process. In addition, meter-scale coupled origami tubes are fabricated based on the proposed coupling method.

Keywords: origami tubes, stiff deployable structures, bar and hinge model

1. Introduction

Deployable structures play an important role in the rapid and easy construction of contemporary structures, such as solar sails [1], emergency shelters [2], and infrastructures [3, 4, 5]. In these applications, it is necessary to design the deployable structures to have enough mechanical properties, such as load-bearing capability, after development.

Geometrical designs based on coupled origami tubes are effective in adding unique mechanical properties to deployable structures. Furthermore, coupling of Miura-ori provides lockable morphing mechanisms [6]. In previous studies, origami metamaterials with negative Poisson's ratios [7] and extremely stiff deployable structures, referred to as zipper-coupled tubes [8], were proposed based on Miura ori. Tachi-Miura polyhedra are also composed of origami tubes [9, 10, 11], which lead to auxeticity [12],

load-bearing capability [13], and high- energy absorption [14]. In these origami structures, origami tubes are coupled along origami panels. Therefore, deployability is ensured when origami tubes are fabricated using thin plates that are difficult to fabricate using thick panels.

Construction using thick panels is necessary to enhance the load-bearing capability of deployable structures [15]. In previous studies, although thickness accommodation for thick-panel origami was investigated [16, 17, 18], thickness accommodation for coupling origami tubes has not yet been fully established.

This study presents the coupling of origami tubes mirrored by creases. Using thick origami tubes that generate one-degree-of-freedom (DOF) motion based on a hinge-shift technique, the coupling of origami tubes mirrored along the creases also provides one-DOF motion because of the mirror symmetry along their creases. Therefore, the proposed coupling method facilitates the easy fabrication of coupled thick-panel origami tubes using existing hinges. Furthermore, because the rotational direction of each coupled tube is the same as that of the zipper-coupled tubes, the proposed coupling provides high stiffness. To demonstrate this observation, an eigenvalue analysis of linear dynamical systems defined by bar and hinge models [19, 20, 21, 22] was performed to evaluate the stiffness via eigen frequencies. Furthermore, the design concept for the pavilion is explained, and a prototype of a meter-scale coupled tube is fabricated using wooden panels and fabric hinges.

2. Geometry of coupled origami tubes

2.1. Miura-ori tube

This subsection describes the geometry of Miura-ori tubes. The dimensions of Miura-ori unit cell are defined as shown in Figure 1 (a). Using the length of Miura-ori a, b, the internal angle of the parallelogram α, and the half dihedral angle $\theta \in [0, \pi/2]$, the dimensions of the unit cells are defined as follows:

$$L_x = 2b\frac{\cos\theta\tan\alpha}{\sqrt{1+\cos^2\theta\tan^2\alpha}}, \tag{1}$$

$$L_y = 2a\sqrt{1-\sin^2\theta\sin^2\alpha}, \tag{2}$$

$$H = 2a\sin\theta\sin\alpha, \tag{3}$$

and

$$V = b\frac{1}{\sqrt{1+\cos^2\theta\tan^2\alpha}}. \tag{4}$$

The Miura-ori tubes were created by coupling Miura-ori to that mirrored along x-y plane, as shown in Figure 1 (b).

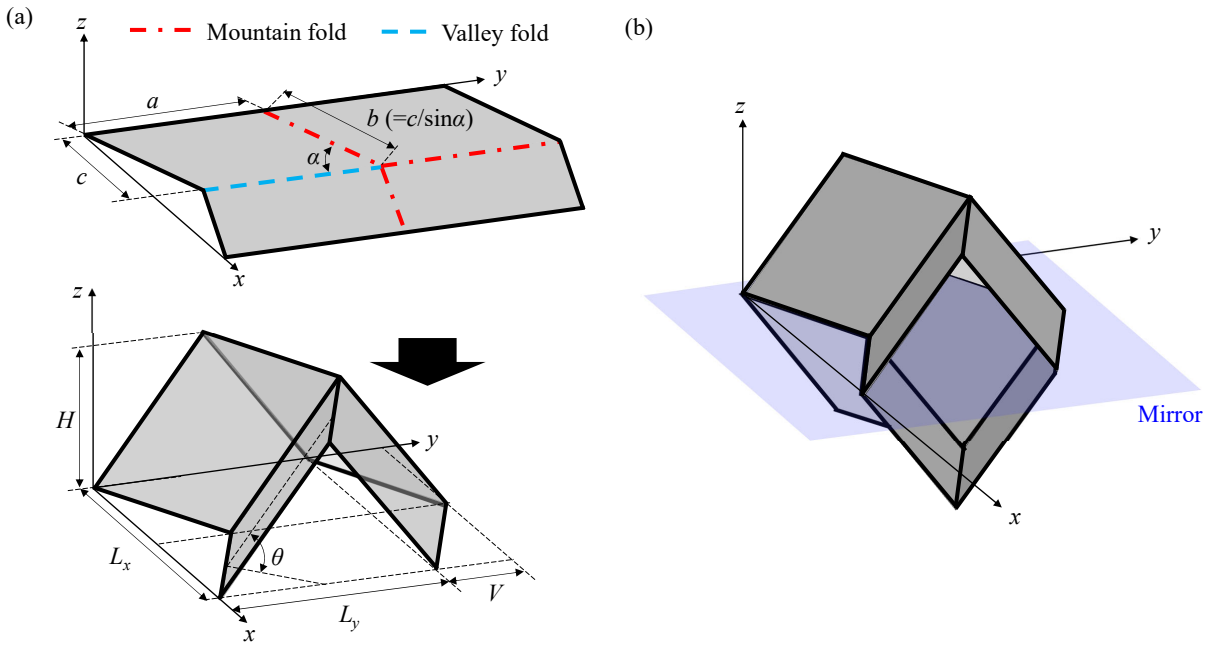

Figure 1: Geometry of Miura-ori tube (a) Unit cell of Miura-ori sheet (b) Miura-ori tube created by coupling mirrored Miura-ori sheet.

2.2. Coupled origami tubes along creases

This subsection briefly introduces the geometries of coupled Miura-ori tubes consisting of five unit cells with parameters $a = 1$, $c = 1$, and $\alpha = 55^o$. Examples of coupled tubes along faces, i.e., aligned coupled tubes and zipper-coupled tubes, introduced by Filipov et al. [8] are shown in Figure 2 (a) and (b), respectively. To avoid face contact in the coupling of origami tubes, this study proposes coupling tubes along the creases, as shown in Figure 2 (c). The coupled tubes are composed of Miura-ori tubes mirrored along the creases, providing reflection symmetry along the creases, as shown in XY-plane in Figure 2 (c).

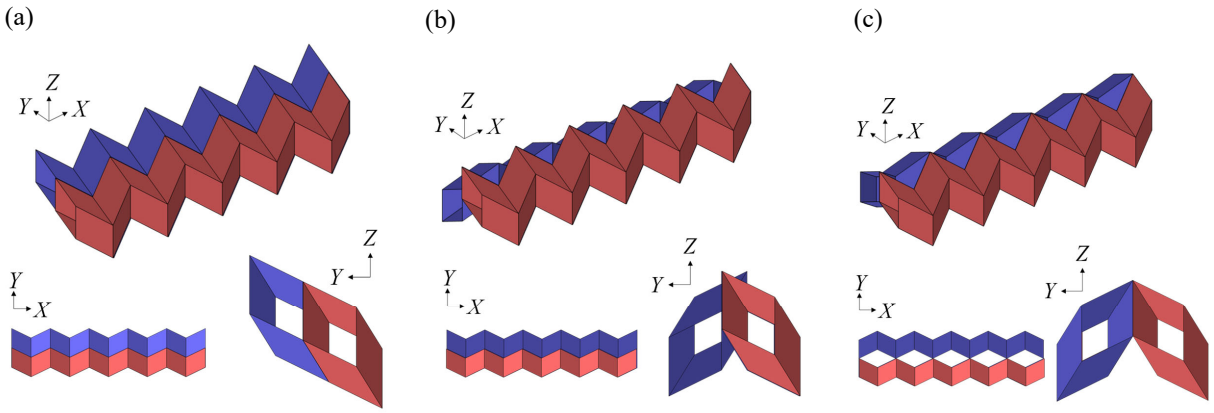

Figure 2: Geometry of coupled Miura-ori tubes. (a) Coupling aligned Miura-ori tubes. (b) Coupling zipper Miura-ori tubes. (c) Coupling mirrored Miura-ori tubes along creases.

2.3. Thickness accommodation

The thickness accommodation of mirror-coupled tubes and their motions are introduced. Tachi discussed the thickness accommodation for Miura-ori tubes using hinge-shift techniques, which provide flat foldability, rigid foldability, and one-DOF motion using thick panels [23]. Based on the thickness accommodation, the mirrored geometries along the creases in the proposed coupled tubes also retain one-DOF motion owing to the mirror symmetry along the coupled creases, as shown in Figure 3. Furthermore, the cross-sections of the coupled tubes have opposite rotations of the cross-section in the Miura-ori tubes, as shown in Figure 4. These opposite directions of rotation occur in zipper-coupled tubes and contribute to the high stiffness of coupled tubes [8]. Therefore, the proposed coupling leads to not only the realization of one-DOF motions but also the high stiffness of deployable structures.

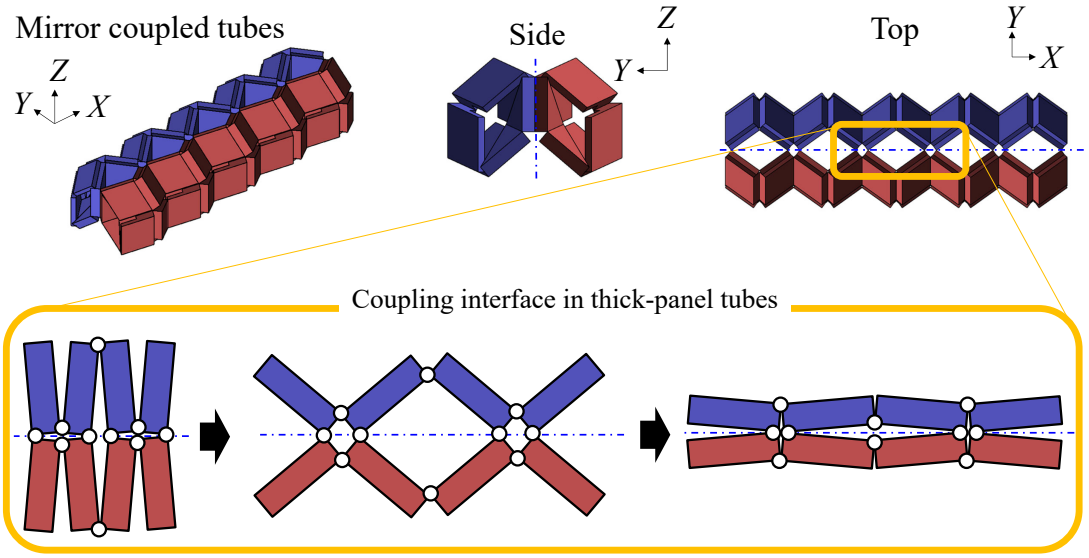

Figure 3: Motion of thick panels at the interface of coupling tubes. The mirror symmetry along the creases retains one-DOF motion after the coupling of Miura-ori tubes.

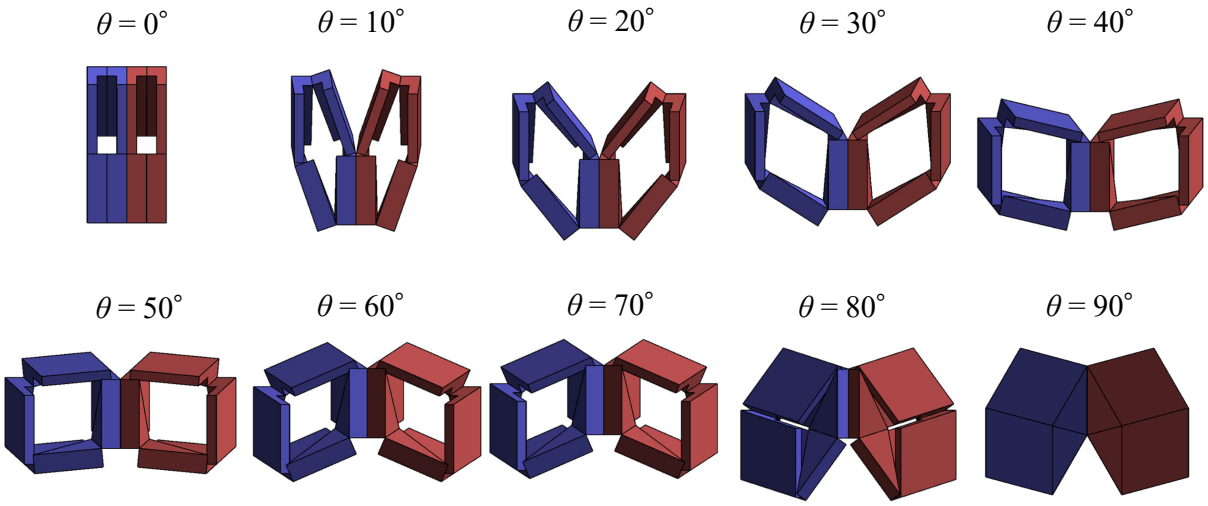

Figure 4: Motions of the cross-section of coupled tubes. The red and blue tubes rotate in opposite directions.

3. Stiffness of coupled origami tubes

3.1. Bar and hinge models for eigenvalue analysis

To evaluate the stiffness of the origami tubes, eigenvalue problem defined using the stiffness and mass matrices $\mathbf{K}$ and $\mathbf{M}$ are solved, as follows:

$$\mathbf{K}\mathbf{v}_i = \lambda_i \mathbf{M}\mathbf{v}_i, \tag{5}$$

The bar and hinge models are constructed using the N5B8 approach that expresses their panels using five nodes and eight bars. Eigenvalues λ_i and eigenmodes $\mathbf{v}_i$ are associated with the stiffness of each deformation. The mass matrix $\mathbf{M}$ is defined as a diagonal matrix composed of concentrated masses, assuming that the mass of the panels is equally distributed on each node. The stiffness matrices of the bar and hinge models are implemented based on MERLIN developed in [21, 22]. The geometry of the Miura-ori tube is presented in Subsection 2.2.. The Young's modulus, density, Poisson's ratio, and thickness of the panels are 10^6, 1, 1/3, 0.01 used in [8], respectively. The scaling factor of the stiffness of the hinges along the creases is set to 40, as used in [20].

3.2. Stiffness in basic coupled pattern

As shown in Figure 5 (a), the aligned-coupled tubes have small gaps between the one-DOF modes (i.e., 7th mode), and torsional modes appear in the 8th and 9th modes. However, zipper-coupled and the proposed coupled tubes have large gaps between the one-DOF mode and elastic modes, as shown in Figure 5 (b) and (c), because the opposite rotations of the cross-section in the Miura-ori tubes cancel each torsional deformation. The wide gaps indicate that the one-DOF motion provides flexible deployment, and the elastic deformations retain a high stiffness throughout the deployment process. Therefore, the proposed coupling method enables the easy coupling of thick-panel Miura-ori tubes without losing the unique mechanical properties of zipper-coupled tubes.

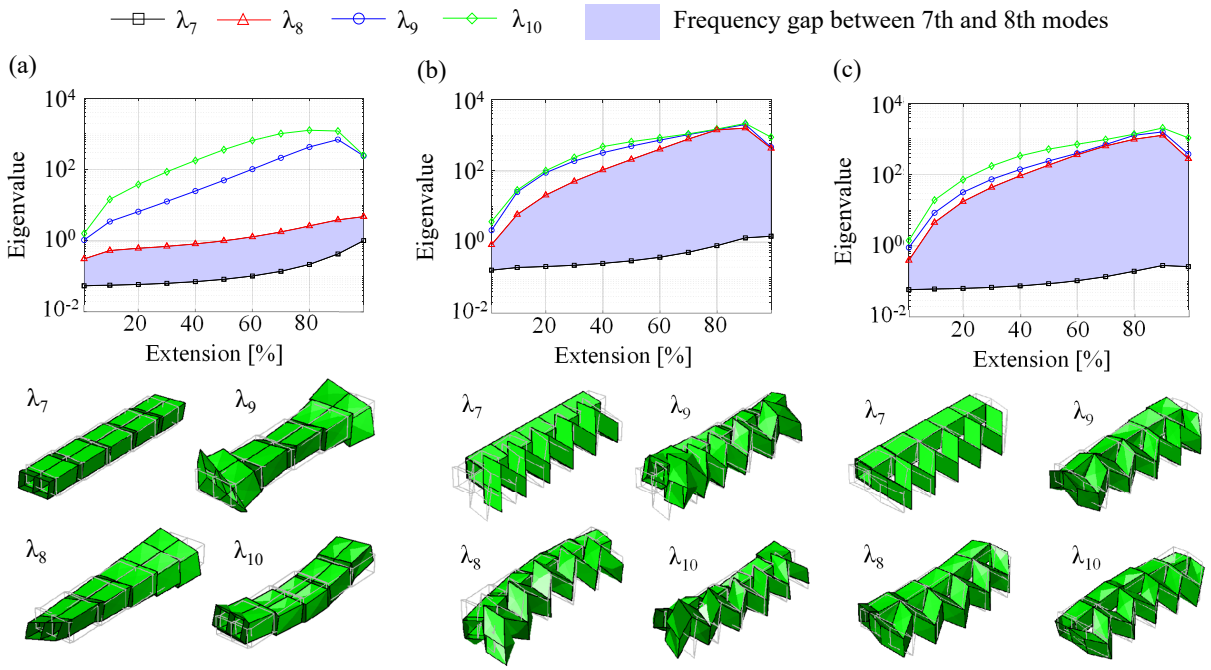

Figure 5: Eigenvalues of bar and hinge models. (a) Coupling the aligned Miura-ori tubes does not contribute to increasing the eigen frequency of torsional modes, such as 8th and 9th modes. (b) Coupling zipper Miura-ori tubes and (c) Coupling mirrored Miura-ori tubes along creases having a large frequency gap between the 7th and 8th modes.

4. Fabrication using thick panels

4.1. Concept of pavilion

As discussed in the previous section, the proposed coupling leads to high stiffness, flat-foldability, rigid-foldability, and one-DOF motions. These characteristics facilitate high transportability and the rapid construction of stiff structures. We demonstrate the deployment of 3-meter-high coupled tubes from a suitcase (Figure 6) to clearly demonstrate these key concepts to the audience in the pavilion. Although the coupled tubes are fabricated using thick panels, the one-DOF motion of the Miura-ori tubes was maintained, and the tubes were completely folded by appropriate thickness accommodation. The designed structure of the pavilion significantly affects our understanding of the compact foldability and novel mechanical properties of the proposed structures.

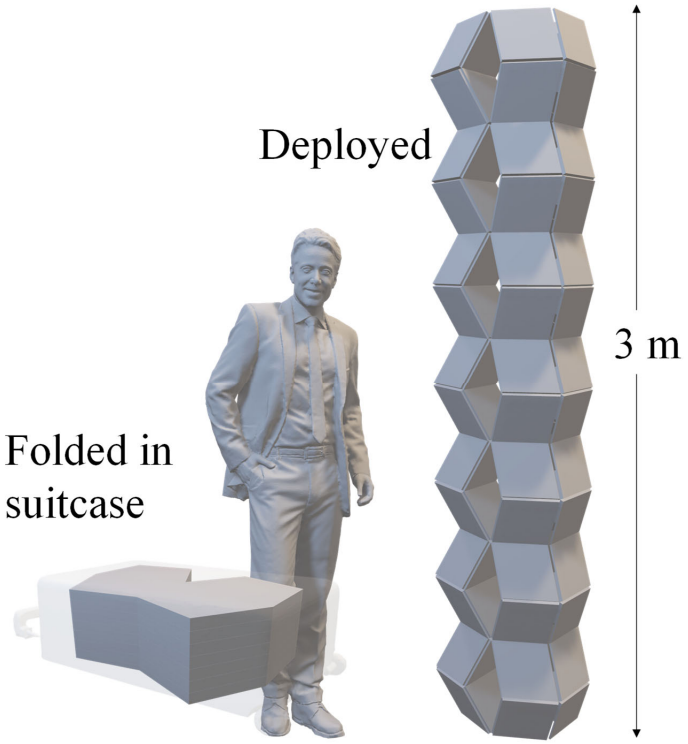

Figure 6: Design for pavilion. The deployment of 3-meter-high coupled tubes from a suitcase is demonstrated.

4.2. Prototype of fabricated coupled tubes

As a prototype of the pavilion, coupled origami tubes were fabricated on a meter scale using panels and fabric hinges. The unit of Miura-ori tube is defined by Miura ori with parameters $a = 350$ mm, $c = 350$ mm, and $\alpha = 75^o$. The tubes consisted of three Miura-ori tubes. The materials of the panels and fabric hinges were 12-mm-thick wooden panels and 0.5-mm-thick nylon sheets, respectively. The origami tubes were coupled using nylon sheets for hinges. Therefore, the coupling interfaces behave similar to hinges, and one-DOF motions are retained after coupling.

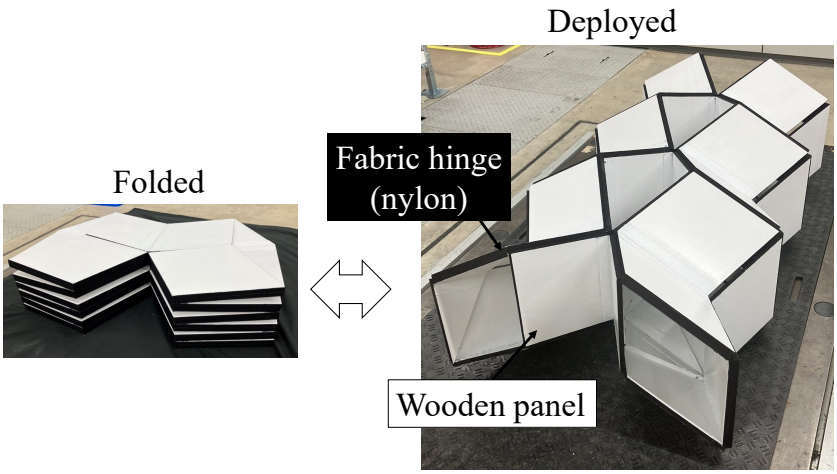

Figure 7: Coupled Miura-ori tubes fabricated by wooden panels

5. Conclusion

We present the coupling of Miura-ori tubes mirrored along their creases for easy thickness accommodation during the coupling of thick-panel Miura-ori tubes. The proposed coupling leads to high stiffness owing to the opposite rotation of the cross-sections. To demonstrate high stiffness, we indicated wide frequency gaps between the one-DOF and elastic modes via an eigenvalue analysis of the bar and hinge models. To express the compact foldability and high stiffness of the proposed structures, a pavilion design was proposed, and a proto-type of the pavilion was fabricated using thick panels and fabric hinges.

Abstract

Shellular structures, i.e., cellular structures composed of a single smooth 2-manifold surface, have recently received attention in the context of architecture, structures, and materials. This study aims to efficiently construct shellular structures using sheet materials by dividing the surfaces into a single type of piece by using the geometry of hyplanes, discrete surfaces of constant negative curvature consisting of congruent triangles. We realize the shellular structure homeomorphic to but slenderer (or thicker) than Schwarz's D-surface with a variant of the hyplanes. Each piece with integrated joints were fabricated by cutting and perforating a sandwich panel of polypropylene. We build a pavilion that can be assembled and disassembled and compactly folded for convenient storage and transportation.

Keywords: advanced manufacturing and materials, Shellular structure, tessellation, modular construction, origami

1. Introduction

Shellular structures are cellular structures consisting of a single smooth 2-manifold surface in the form of a hollow three-dimensional truss. Typical examples of such surfaces are triply periodic minimal surfaces (TPMSs) such as Schwarz's P-surface, Schwarz's D-surface, and Schoen's gyroid surface. Their high strength, low density, and property of dividing space into two portions have attracted attention in the fields of materials [1] and architecture [2]. They also have a variety of applications such as infill for 3D printing [3] and a heat-exchanger [4].

If we attempt to construct a Shellular structure from a flat panel, it needs to be divided into some pieces because of its negative Gaussian curvature. Depending on the division method, different types of pieces may be needed. For easier manufacture and construction, a method that can divide the surface into fewer types of pieces, especially into a single type, is preferred.

We propose a method for discretizing the surface of Shellular structures with a single type of piece by applying hyplanes [5], discrete surfaces of constant negative curvature ($K = -1$ surfaces) composed of congruent triangular faces. We show an immersion of a type of hyplanes in $\mathbb{R}^3$; more specifically, we give an intrinsically isometric covering of a hyplane to a surface homeomorphic to the D-surface. Similar to our study, there have been studies that divide TPMSs into one type of triangle in a smooth [6]

or a discrete sense [7]. In these examples, the surface is divided into triangular minimum units of the surface based on its global symmetry (or even subdivided). In contrast, our discrete surface has a couple of triangles corresponding to the unit of the surface by not subdivision but by adding another triangle to the original triangular unit. This resulted in a discrete D-surface with a smoother and slenderer (or thicker) form, which has the potential for architectural applications as it can reduce the proportion of space for load bearing and increase the proportion of space that people utilize.

We create this surface as a pavilion to demonstrate its application to architecture (Figure 1). The surface is divided into a type of developable piece consisting of eight triangular faces connected in a strip using its global symmetry. We fabricate the pieces with the joints attached to the boundary edges by cutting and perforating a Plapearl [8], a lightweight sandwich panel of polypropylene. The pieces can be assembled and disassembled without damage and can be reused as no additional parts are required for the joint. The pieces can also be folded compactly for convenient storage and transport.

In Section 2., we first recall the definition of the hyplane and calculate the triangle that constitutes it. Then, we show that two variants of hyplanes can construct surfaces homeomorphic to the D-surface. In Section 3., we describe our pavilion design, including modules, joint system, material, and fabrication.

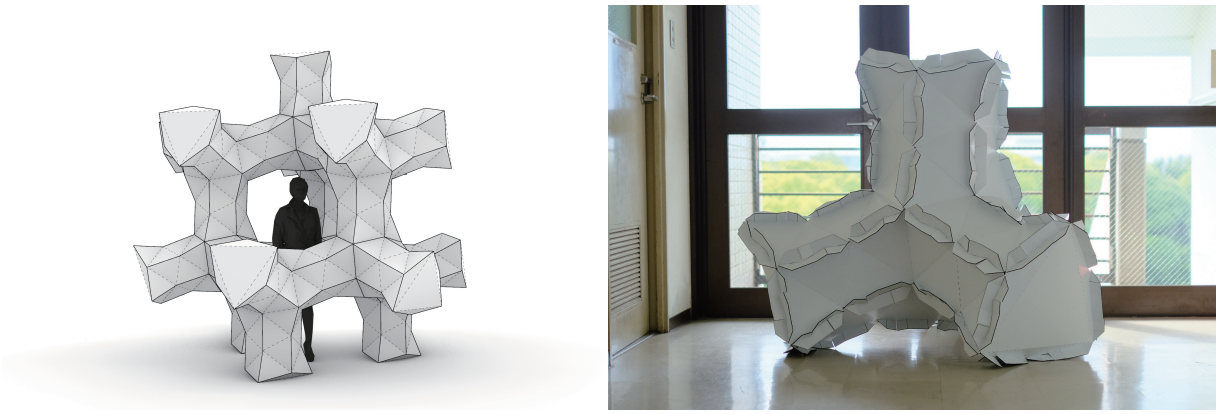

Figure 1. Left: our pavilion of a triply periodic discrete $K = -1$ surface constructed from one type of triangle, which appears to be a slender D-surface. Right: a partial mock-up of our pavilion.

2. Triply periodic discrete $K = -1$ surface

This section shows a method for dividing a surface of a Shellular structure by one type of triangle. Surfaces allowing for such division include surfaces of constant Gaussian curvature (K-surfaces), such as the sphere ($K = 1$), the Euclidean plane ($K = 0$), and the hyperbolic plane ($K = -1$), which can be tiled by one type of Schwarz triangles [9] so that adjacent triangles are mirror reflection about a plane that contains the shared edge. The immersion of the tiling of the hyperbolic plane in $\mathbb{R}^3$ creates a saddle-shaped surface, whose discrete analogue is called hyplane [5].

In Section 2.1., we recall the definition of the h yplane. In Section 2.2., we triangulate a surface homeomorphic to the D-surface so that it is an immersion of the types of hyplanes. Then we show the possibility of intrinsically isometric immersion by discussing the design freedom of the configuration of the triangles.

2.1. Hyplane

We recall the definition of the hyplane [5]. For a triad of positive integers (a, b, c), (a, b, c)-hyplane is a polyhedral surface that satisfies following conditions:

C1 $\frac{1}{a}+\frac{1}{b}+\frac{1}{c}<\frac{1}{2}$;
C2 all faces are congruent to $\triangle ABC$;
C3 any pair of adjacent faces is the mirror reflection about a plane that contains the shared edge;
C4 A, B, C create a degree-a, b, c vertex, respectively.
C5 discrete Gaussian curvature is constant on every vertex.

C1 is for the surface to have negative curvature, while C2-C4 defines the tiling structure on a surface. C3 implies that if a (b, or c, resp.) is odd, the triangle needs to be isosceles $AB = AC$ ($BC = BA$, or $CA = CB$, resp.), and thus $b = c$ ($c = a$, or $a = b$, resp.). Figure 2 shows an example of $(6, 6, 8)$-hyplane and the face triangle.

For C5, there are variations in the definition of discrete Gaussian curvature. Here, we define the discrete Gaussian curvature on a vertex as an angle defect divided by the area associated with the vertex. We divide a triangle into three kite areas by perpendicular lines from the incenter to each edge and assign each area to the vertex it contains (Figure 2 Left). This method divides the polyhedral surface into patches of regular polyhedra (Figure 2 Right).

Now we consider hyplanes composed of congruent isosceles triangles: (a, a, c)-hyplanes. Let the radius of the incircle of the triangle r and the ratio of the length of AC split by the foot of the perpendicular lines $s : (1 - s)$, where $0 < s < 1$. The triangle with $\angle A = \angle B = \theta_1, \angle C = \theta_2$ composing (a, a, c)-hyplane can be calculated by the equation about the Gaussian curvature:

$$\frac{2\pi - a\theta_1}{ars} = \frac{2\pi - c\theta_2}{cr(1-s)}, \tag{1}$$

where $2\theta_1 + \theta_2 = \pi, \cos\theta_1 = s$. This leads to

$$\frac{2\pi - a\theta_1}{a\cos\theta_1} = \frac{(2-c)\pi + 2\theta_1}{c(1-\cos\theta_1)}. \tag{2}$$

This equation for θ_1 cannot be algebraically solved as it has members of θ_1 and $\cos\theta_1$. We obtained a numerical solution of $\theta_1 \sim 0.97382$ for $(a, c) = (8, 6)$, and $\theta_1 \sim 1.12596$ for $(a, c) = (6, 8)$. The Gaussian curvature is $\sim \frac{-0.33518}{r}$ for $(a, c) = (8, 6)$, and $\sim \frac{-0.18304}{r}$ for $(a, c) = (6, 8)$.

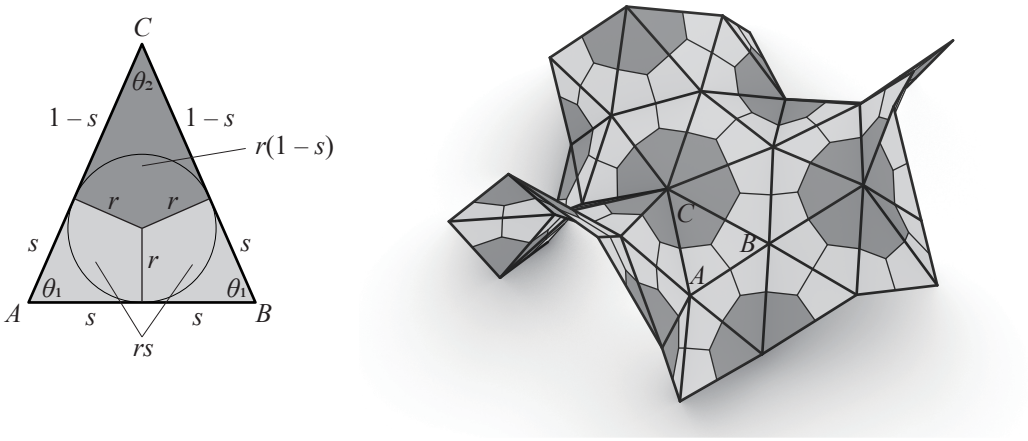

Figure 2. The geometry of (6,6,8)-hyplane. We divide the triangular face by perpendicular lines from the incenter to each edge to assign an area to a vertex. The area is used for calculating the Gaussian curvature.

2.2. Triply periodic hyplane

In this section, we show that the two types of hyplanes we obtained in Section 2.1., $(8, 8, 6)$-hyplane and $(6, 6, 8)$-hyplane, can cover a surface which is homeomorphic to the D-surface, through intrinsically isometric transformation. Figure 3 Left shows the hyplanes homeomorphic to the D-surface we obtained. We focus on the nodal module of the surface to discuss its existence (coloured in green). Figure 3 Right illustrates the conditions for the module. We divide the module into the units of $\frac{1}{24}$ by mirror planes which are determined by the global symmetry of the D-surface (shown in blue). We also provide a regular hexagonal prism on the boundary of the module which is required for the connection of the modules (shown in orange). The lines determined by the intersection of the planes and the prism are named l_1, l_2, l_3, l_4.

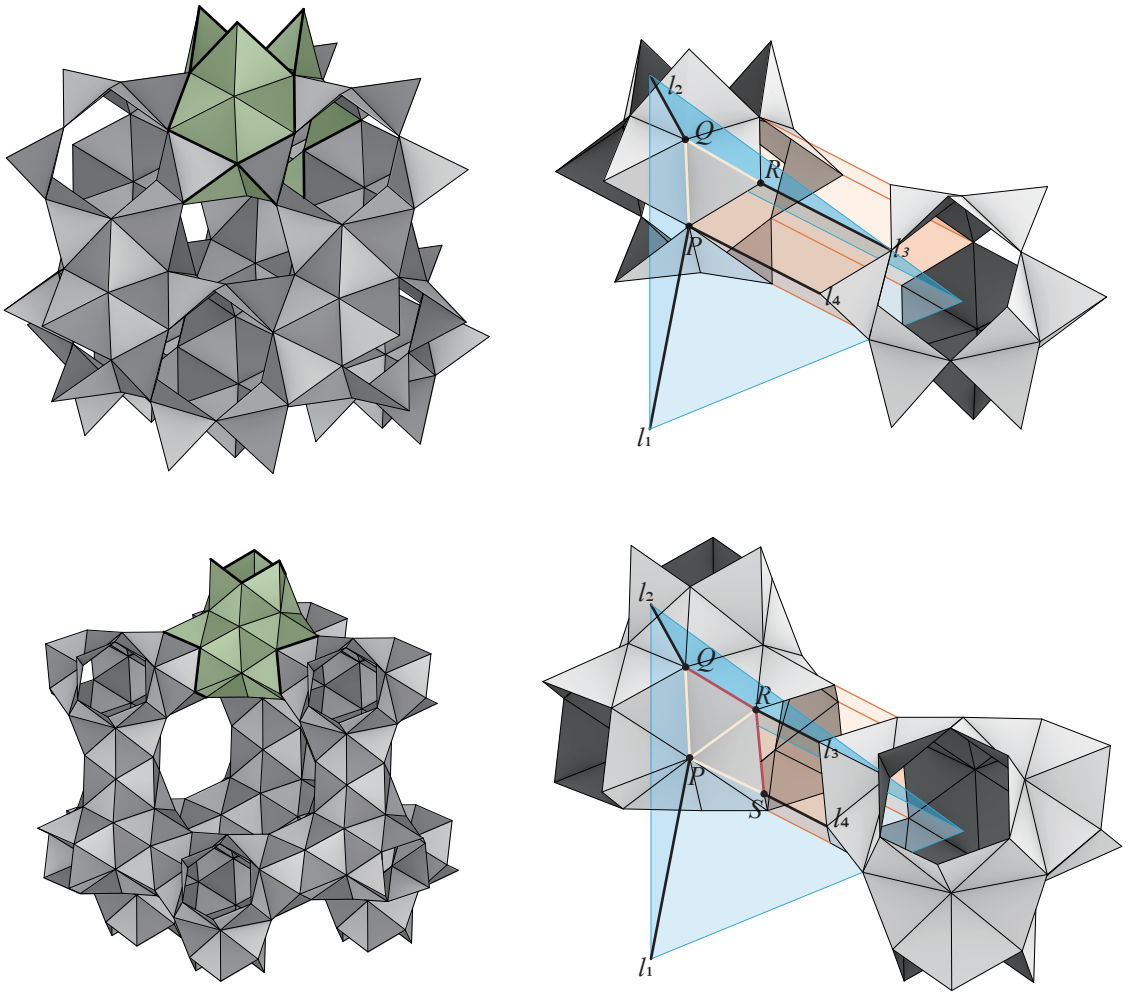

Figure 3. Left: The $(8, 8, 6)$-hyplane (Upper) and the $(6, 6, 8)$-hyplane (Lower) homeomorphic to the D-surface. We focus on the nodal module of the surface coloured in green. Right: the geometric constraints for the nodal module of the surface to have the triple periodicity.

$(8,8,6)$**-hyplane** See Figure 3 Upper. We consider the configuration of the unit $\triangle PQR$ with $PQ = QR$. P is a point that moves on both l_1 and l_4, which means it is fixed on the intersection of l_1 and l_4. Thus the variables we have are

V1 Q on l_2;
V2 R on l_3.

These variables need to satisfy the constraint:

C1 $PQ = QR$.

This system has a 1 degree of freedom with 2 variables and a 1 constraint.

$(6,6,8)$**-hyplane** See Figure 3 Lower. In this case, we consider the configuration of the unit $\triangle PQR$ with $PQ = PR$ and $\triangle PSR$ with $PS = PR$. This means the module has twice as many faces as that of the (6,8,8)-hyplane. We have the following variables:

V1 P on l_1;
V2 Q on l_2;
V3 R on l_3;
V4 S on l_4.

These variables need to satisfy the constraint:

C1 $PQ = PR$;
C2 $PS = PR$;
C3 $QR = SR$,

so that $\triangle PQR$ and $\triangle PSR$ are congruent isosceles triangles. This system also has a 1 degree of freedom with 4 variables and 3 constraints.

In the cases of both $(8,8,6)$ and $(6,6,8)$, the configuration has a 1 degree of freedom. Therefore it should include the solution of the triangle we obtained in Section 2.1., which constructs the hyplane. We obtained the numerical solution by using Kangaroo2 [10] on Rhino/Grasshopper.

Through solving in Kangaroo2, we found a surface composed of the same triangle can take different configurations while keeping its triple periodicity. Figure 4 shows the two possible configurations of the (6,6,8)-hyplane. These configurations can be switched to each other by snap-through buckling.

The D-surface, which is a minimal surface, has the property of bisecting space. In contrast, the proposed triply periodic $(6,6,8)$-hyplane has the appearance of a slenderer (or thicker) D-surface, dividing space into larger and smaller portions. The volume ratio of the two portions is calculated to be $\sim 0.757 : 0.243$, by supposing the space tessellation by rhombic dodecahedron onto the surface from its symmetry and computing the two volumes in a rhombic dodecahedron partitioned by the surface (Figure 5). This slender D-surface reminds us of triply periodic constant mean curvature (CMC) surfaces [11].

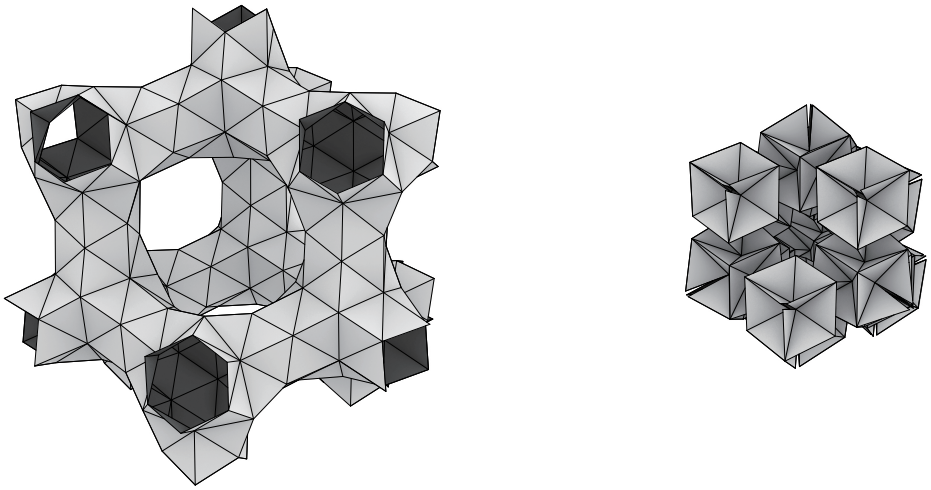

Figure 4. Two possible configurations of the $(6, 6, 8)$-hyplane with triple periodicity. They can be switched to each other through snap-through motion.

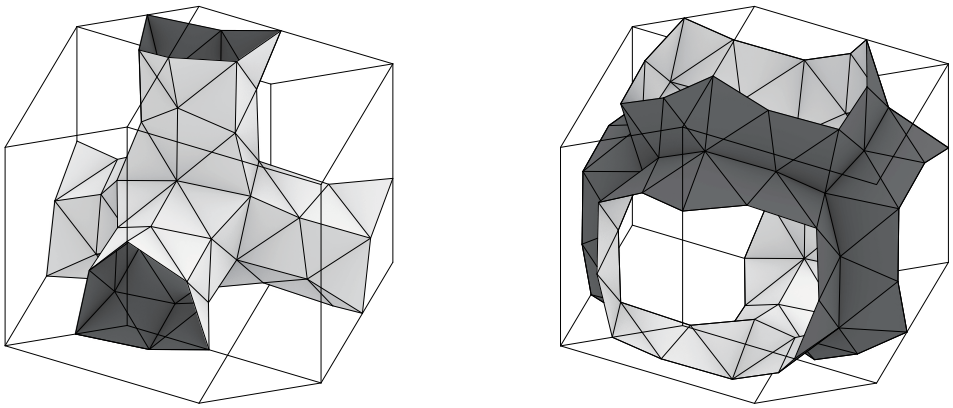

Figure 5. The part of (6,6,8)-hyplane with a triple periodicity which corresponds to the unit of space tessellation by rhombic dodecahedra.

3. Pavilion design

In Section 2., we obtained the slenderer D-surface composed of a single type of triangle by applying $(6, 6, 8)$-hyplane. This enables the construction of the surface from one type of triangular piece with improved manufacturability. Compared to $(8, 8, 6)$-hyplane, the structure will behave more like a shell due to the smoother discretization. In addition, the surface divides space into larger and smaller portions, reducing the space for load bearing and increasing the space that people utilize. We demonstrate this potential for architectural application through the practical building of the pavilion.

We construct a part of the surface with an infinite extent in space. Figure 6 shows two possible trimming of the surface we considered for design. The front side of the surface is more visible in one design and the back side is more visible in the other design. We chose the left one with fewer naked boundary edges to reduce the number of degrees of freedom of the structure. We determined the dimension of the pavilion so that a side of the space is large enough to accommodate a person on one side (Figure 1).

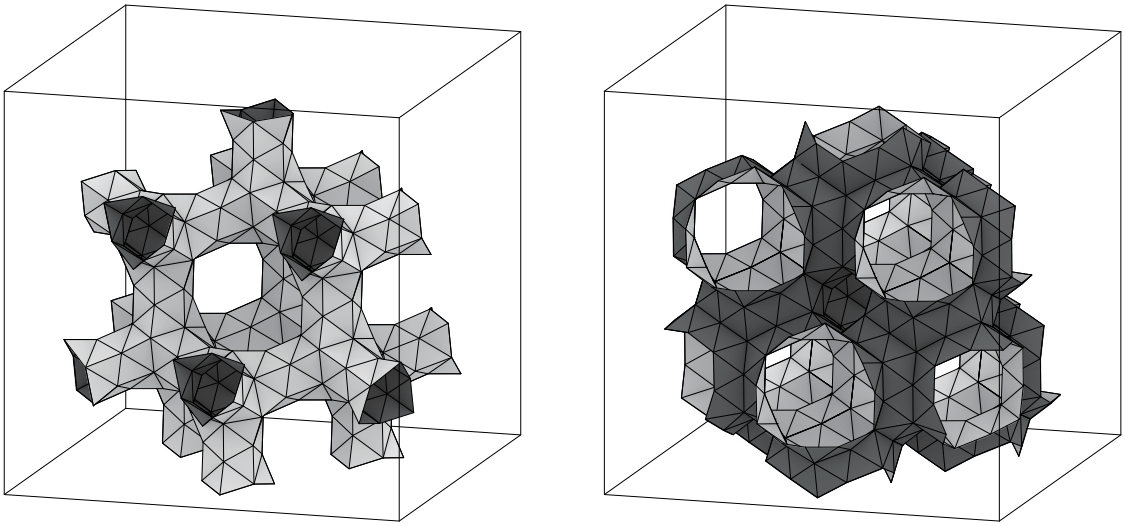

Figure 6. Two possible designs of our pavilion in the box of $3\,\mathrm{m} \times 3\,\mathrm{m} \times 3\,\mathrm{m}$.

3.1. Module

Figure 7 shows the modules of our pavilion. Although each triangular face of the surface could be a single piece, for more efficient construction, the piece should consist of several faces connected at edges as fold lines and still be developable. Therefore, using the global symmetry of the surface, we divide the surface into pieces with eight faces connected in a strip (A). Near the boundary of the surface, there are half-trimmed pieces composed of four faces (B). Caps are also provided to close the boundary of the surface to stabilize the structure (C).

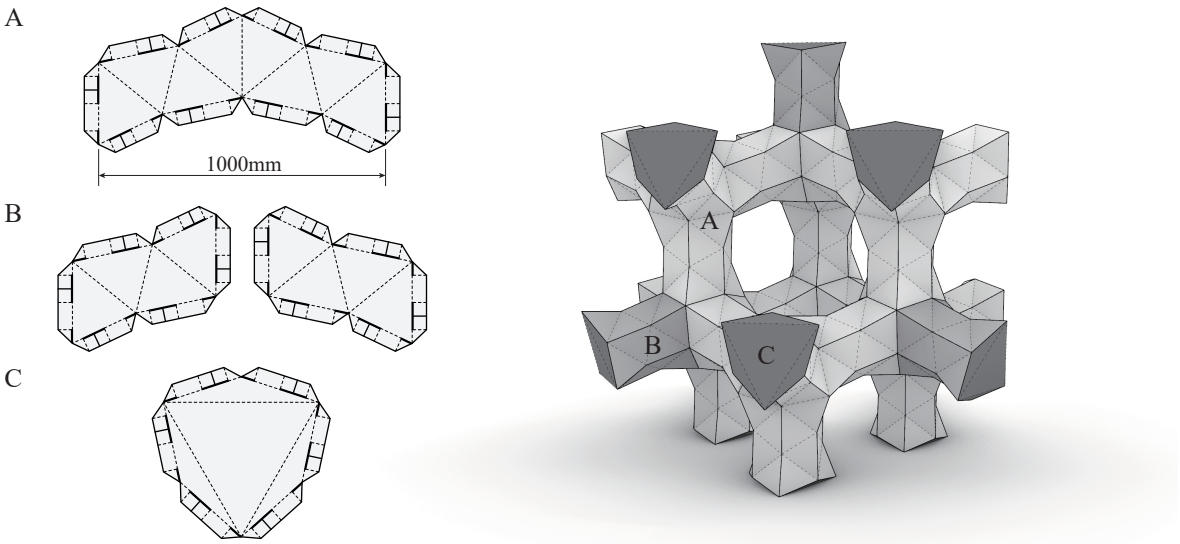

Figure 7. The pieces of our pavilion. A: a Strip of 8 faces (72 pieces), B: a mirrored pair of half-trimmed strips (12 pieces for each), and C: a cap for stabilizing the structure (16 pieces).

3.2. Joint and material

In order to join the modules together, we add regions for joints on the boundary of the pieces (Figure 7). We adopted a paper-craft technique for the joints (Figure 8). The regions for joints have cut lines, fold lines, and clearances for accommodating the thickness of the material. We fold the fold lines to make fingers (Left), then engage the fingers (Middle), and finally open the fold lines again to fix the joints (Right).

The material we use is Plapearl [8] produced by Kawakami Sangyo Co., Ltd., a three-layer polypropylene board consisting of an air bubble sheet sandwiched between two flat sheets. Plapearl is capable of cutting and embedding living hinges by perforation using CNC. Though the board has a thickness of $3\,\mathrm{mm}$, we need a minimum thickness accommodation of the joint due to the material's elasticity. The structure of the board containing air allows its lightweight of $0.5\,\mathrm{kg/m^2}$. The entire pavilion weighs about $17.6\,\mathrm{kg}$.

This construction system allows the components to be manufactured by creating cut lines and fold lines on one type of material. The pieces can be repeatedly assembled and disassembled without damage because they do not require additional parts for the joint. They can also be folded compact enough to pack in suitcases, enabling convenient storage and transport. The structure can also be grown by increasing the number of strips.

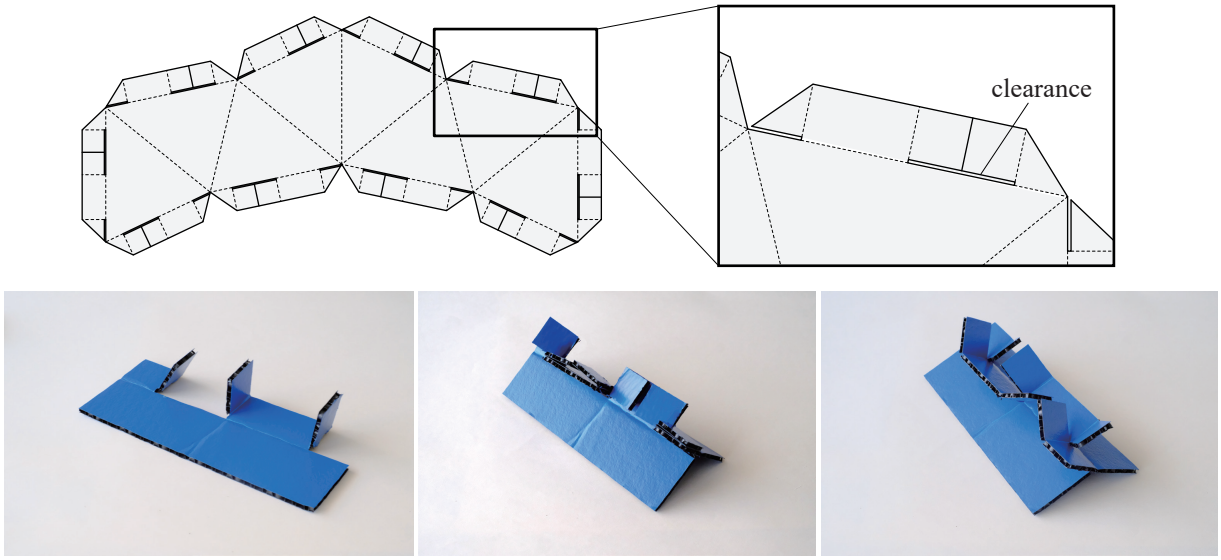

Figure 8. Paper-craft joint method with Plapearl. Upper: clearances for accommodating the thickness of the board. Lower: the process of joining. Fold the fold lines to make fingers (Left), engage the fingers (Middle), and develop the fold lines to fix (Right).

4. Conclusion

This paper showed $(8, 8, 6)$-hyplane and $(6, 6, 8)$-hyplane can construct a surface homeomorphic to Schwarz's D-surface. In the case of $(6, 6, 8)$-hyplane, the surface forms a slenderer D-surface with smoother discretization, dividing space by the ratio of $\sim 0.757 : 0.243$. We also described the design of the pavilion we construct. We divide the surface into one type of developable strip based on the global symmetry of the surface. The pieces with integrated joints are fabricated by cutting and perforating a Plapearl. The paper-craft technique is adopted for the joint, which does not require additional parts to join the pieces.

Future work includes the identification of the bending stiffness of the hinge by perforation of Plapearl, the structural analysis of the pavilion as a shell structure, and the generalization of the discretization method into other types of TPMS or Triply periodic CMC surfaces.

Abstract

Rammed earth (RE) is a traditional building technique that has been gaining popularity as a sustainable and low-cost alternative to conventional building methods. However, the lack of established processes for constructing free-form rammed earth structures, as well as the increasing cost of labour, hinder its uptake in contemporary design. This research proposes an innovative method of rammed earth manufacturing that combines modular design and digital fabrication techniques to leverage the potential of mass customisation and mass production. A production system for modular RE tiles with intricate curvatures is introduced, where the tiles can be aggregated to create continuous free-form RE walls. The tiles are computationally designed to allow variations through rotation and/or flipping of tiles. The aggregation of 16 identical tiles yields 128 wall design variations with continuous curved designs. Moreover, the number of potential variations rises to 512 when using four different tile designs. This encompasses both customisation of the overall system and standardisation of the module. This method merges the benefits of rammed earth construction with those of modular integrated construction (MiC), which involves off-site production of fully completed 3D modules. The new system also enables improved mobility and manageability, which elevates transportation and assembly efficiency. The proposed system offers a novel approach that can provide an alternative to conventional RE construction processes, offering higher productivity, sustainability and efficiency of the built environment.

Keywords: rammed earth, mass customization, mass production, modular design, free-form, 3D tile aggregation, digital fabrication, modular integrated construction (MiC)

1. Introduction

Rammed earth (RE) is an ancient building method that utilises natural resources such as aggregate, clay, lime and sand to construct walls [1, 2] Earth is one of the oldest construction materials that has been utilised in architecture for millennia due to its abundance, low cost and bioclimatic qualities that withstand harsh weather [3]. RE is an earth-based construction technique that has been utilised for ages in many parts of the world. It entails combining dry soil with water then compacting the mixture into successive lifts within a formwork to produce structures. Because of the near-dry state of the mixture and the creation through compression process, RE has the highest mechanical and structural strength among the many earth construction techniques [4, 5]. In terms of compression strength and erosion resistance, stabilised RE compares favourably to masonry or concrete blocks, while its raw material is less expensive. The entire cost of rammed earth building varies depending on geography and labour cost [6]. RE constructions have been witnessing an increased interest and development lately. Since 1970, Western Australia has led the world in the development of cement-stabilised rammed earth (CSRE), which is now considered an established construction method in that region. Yet, there is a considerable

Copyright © 2023 by Ahmed ABDELAAL, Mohamed GOMAA and Yi Min XIE. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

lack of utilising advanced construction techniques to manufacture free-form RE geometries. This research aims to investigate and introduce a novel method for manufacturing rammed earth walls that can substantially enhance the conventional practice of RE construction through overcoming major drawbacks in design versatility and on-site process efficiency. This research comes as a part of a large project at RMIT University's Centre for Innovative Structures and Materials (CISM) that aims to harness the qualities of digital manufacturing technologies to efficiently produce novel free-form earth construction.

2. Rammed earth construction

In rammed earth construction, walls serve as the primary structural elements. The soil used in RE mixture is subsoil excavated at a depth of more than 1 m below ground. Subsoil consists of gravel, sand, silt and clay. Particle size distribution classifies the quantity and ratios between components. A good range of particle sizes is recommended to contain a balanced mix of coarse and fine aggregates [7]. To ensure the quality of the rammed earth mixture, on-site testing and/or lab analysis is required. A good mixture should have a high sand percentage (30–50%) and no more than 8% clay. Clay is a natural binder that improves compaction and mechanical performance of soil. Other binders such as cement are also used to strengthen the construction [8]. RE offers various benefits in the built environment such as sustainability, energy efficiency, durability and aesthetic appeal, while it utilises natural and locally accessible resources with minimal embodied energy use and high recyclability [9, 10]. However, there are significant drawbacks to rammed earth in a modern context. The construction process is labour-intensive and requires highly experienced workers, which leads to higher costs compared to standard building methods [10]. Moreover, the maximum allowable structural height is relatively low [4, 11]. On the other hand, the time-consuming process of constructing, aligning, inspecting, stripping, cleaning, relocating and storing the formwork often exceeds the time spent on transporting and compacting the raw earth [12]. Despite these challenges, recent advancements have improved the quality and efficiency of rammed earth production, such as using metal formwork and pneumatic rammers [12–14].

3. Modular systems

Modular integrated construction (MiC) is a method of producing finished modules in off-site facilities and transporting them to the construction site for installation. Off-Site Construction (OSC) technologies such as prefabrication, panelisation and hybrid-construction utilise this technology [15]. MiC method was significantly leveraged and presented in two major projects in 2019. The first project is a 40-storey residential skyscraper built in Singapore using concrete MiC modules with a height of 140 m, which is considered the tallest MiC-based tower in the world. The second project is a 135 m high tower in Croydon, UK, which stands as the world's second tallest MiC-based tower [15]. MiC's popularity and rising use are attributed to its proven advantages in increasing the construction process efficiency and improving building quality. MiC encourages on-site and off-site work overlap which minimises the risk of delay. In addition, it eliminates 90% of on-site tasks [16] , while it reduces accidents by 80% [17], capital costs by 10% [18] and waste by 76% [17]. Over the past decade, the use of MiC modules has increased. This growth is demonstrated by developments such as modular buildings [22], positive impact evaluations of government initiatives to promote MiC [23], increased effectiveness of MiC module installation [24]. By utilising a 3D modular method (Figure 1), productivity can be improved by 25% to 50% [25]. However, this technology has various problems such as the high initial investment costs [19, 20], possible challenges in transportation and logistics of the modules [20].

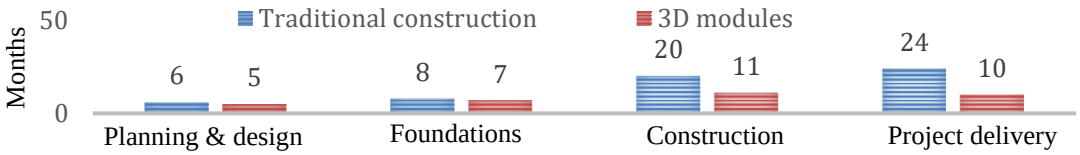

Figure 1. Example project construction duration (Months) [25].

4. Modular rammed earth

Modular rammed earth is an innovative construction technique that merges the environmentally friendly principles of rammed earth with the efficiency of modular building methods. This method involves prefabricating rammed earth wall sections in a controlled environment, which ensures consistent quality and reduces the impact of weather on the construction process. Once completed, these sections are transported to the construction site and assembled using heavy machinery, offering a faster, more efficient and more sustainable construction process compared to traditional rammed earth techniques. Hence, modular rammed earth construction offers benefits in terms of scalability, flexibility and cost-effectiveness, making it easy to rearrange or expand structures to accommodate changing needs or preferences. Moreover, the reduced construction time and labour costs associated with prefabricated components further enhance its appeal for projects with tight deadlines or budget constraints. As a result, modular rammed earth is gaining popularity in sustainable construction projects worldwide for both residential and commercial applications [2, 4, 26].

4.1 Introducing modular systems to rammed earth

Both monolithic/linear formwork and modular form work systems have similarities and distinctions where they offer various benefits to different building types. Monolithic/linear formwork refers to the use of multiple form work parts, usually in the form of boards or sheets, to construct a continuous and monolithic building components on site. On the other hand, modular formwork refers to the use of similar or identical mould units that generate sections or blocks of a large building through assembly. Integrating modular systems with RE can enhance the construction process through offering higher accuracy, better quality control, reduced waste and shorter construction timeframes compared to conventional on-site procedures. Also, modular construction could potentially overcome some of the limitations associated with rammed earth, such as the skilled labour requirements, since it requires less trained labour and can be utilised in any environment [30]. Current methods of RE prefabricated walls are often produced off-site and then transported to the installation location [26]. This is similar to the part-to-module prefabrication in modular construction, which refers to the process of producing individual components that are later assembled into larger modules for easy transportation and installation on-site [31]. However, rammed earth walls are generally larger and heavier than components of modular systems, and their construction requires special equipment and experienced workers. Modular systems, on the other hand, are more transportable and adaptable to a wider variety of architectural demands and designs [2, 32–34]. Introducing a modular system to rammed earth construction can help overcoming some of its limitations while maintaining the unique characteristics and benefits of rammed earth.

4.2 Case studies

Over the past two decades, efforts have been made to create prefabricated RE wall components off-site. This prefabrication process can offer enhanced quality control through factory production, reduce construction time and make RE construction more feasible in densely populated areas. However, the current prefabricated RE wall sections are large and require special equipment for assembly, leading to increased shipping and handling costs that can make the overall project cost more expensive. Several case studies have explored the use of prefabrication for both stabilised and unstabilised rammed earth structures [35]. For instance, since 1997, numerous prefabricated unstabilised rammed earth buildings and projects have been documented in the literature [36, 37]. One notable example is the work of Lehm Ton Erde, which has constructed buildings using prefabricated rammed earth panels. Figures 2 and 3 demonstrate the installation process of these prefabricated rammed earth panels.

In 2020, an Australian start-up firm ‘Form Earth’ unveiled a modular system prototype for automated production of RE walls. That system uses a compact unit with a material hopper, compaction device, and slip formwork. It is transportable and can function both off-site and on-site. The material hopper spans the length of the slip form and adds a complete layer of rammed earth mixture for each load. The compaction tool moves

within the formwork to undertake the ramming operation. The formwork slides higher with each completed lift and the process is repeated to construct succeeding lifts (Figure 4).

Figure 2. Alnatura Campus by Lehm Ton Erde [38].

Figure 3. Prefabricated rammed earth panels delivered and assembled on-site by Lehm Ton Erde [38].

Figure 4. Prefabricated rammed earth panels by Form Earth [39].

Another approach was presented by Hurtado and Eloualid in 2016, which is considered one of the early attempts to bring digital fabrication into RE modular manufacturing. The project utilises CNC laser cutting to create metal and plywood formwork components. The metal mould is retrieved from a single sheet and folded and tack-welded into the correct geometry before being placed within a plywood box to form the final brick mould (Figure 5). The additional soil mixture is rammed to make a rammed earth brick and the bricks are arranged to create the appropriate wall height. This concept provides a modular method for constructing a self-shading wall with enhanced thermal efficiency and intriguing appearance. However, material feeding, compaction and assembly are fully dependent on human labour [40].

In 2017, a project under the name of 'Community action walls' was presented by a team from Istanbul Bilgi University [41]. This project marks the first documented attempt to use digital manufacturing in the creation of formwork for modular rammed earth. The mould was carved from hard Styrofoam blocks using a robotic hot-wire cut process and the soil mixture was manually compacted. The manufactured rammed earth blocks were assembled into wall panels (Figure 6).

Figure 5. Modular prefabricated brick using a folded mould [40].

Figure 6. Modular rammed earth using hard styrofoam blocks as mould [41].

The presented case studies demonstrate the viability of using modular systems for RE architecture, such as prefabricated walls, or small forms such as blocks, which highlighted the potential to achieve different architectural forms and improve construction efficiency. These studies emphasise the need to investigate the design and manufacture of free-form, movable walls.

5. Novel modular system for freeform rammed earth

This research introduces an adaptable modular system for rammed earth that merges the qualities of RE with the efficiencies of MiC. The proposed system uses a collection of modular RE tiles with intricate curvatures for off-site manufacturing. This facilitates mass customization and large-scale production while ensuring consistent quality and reducing construction waste and on-site labour. The modular design allows flexibility in design, manufacturing and construction processes. This fusion between RE construction and MiC lays the groundwork for more sustainable, visually appealing and versatile building solutions.

5.1 Free-form Surfaces design process

The design of the modular rammed earth tiles is encompassed by an array of design variables (Figure 7), offering a multitude of possibilities for modifications through the simple acts of rotation and/or flipping. This flexibility empowers architects and designers to craft a diverse range of creative, visually intriguing structures tailored to their demands and unique vision. Through offering such versatility, the system can accommodate various design elements and respond to the ever-changing demands of the construction industry, making it a highly sought-after solution by architects, designers and clients alike. Furthermore, a seamless integration into various architectural contexts, from contemporary applications to traditional techniques, is facilitated by the inherent flexibility of the modular rammed earth tiles. By streamlining the design process and fostering seamless integration into different contexts, this innovative construction solution is poised to redefine the way sustainable, aesthetically appealing and customisable building projects are approached.

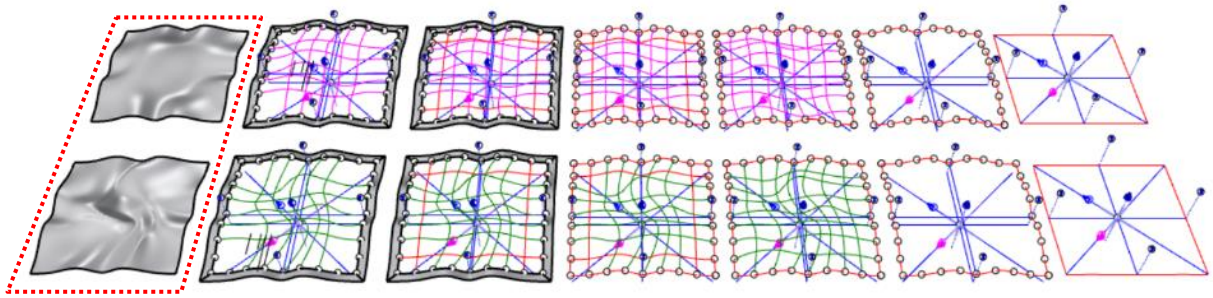

Figure 7. Design variables control of the tile itself.

The design of the tile commenced with a planar rectangle (Figure 9-a), symbolising one of the two primary faces of the tile. The aim was to create its edges as eight matching segments, which would enhance the potential for producing curvature and assist in aligning the geometric side edges. In more detail, the plan involved constructing each side edge from two segments that are mirrored around the

four-sided edges of the geometry. Subsequently, these eight mirrored edges were modified by moving their control points in the Z direction, creating a curved boundary that would become the surface edge and the main elements for the curvature. To accomplish this, it was necessary to reposition the curve's control points, which would be part of the continuous curvature (Figure 9-b). Following the division of each edge into a specified number of divisions, which was carried out for all eight edges, a set of points was constructed to designate them. Utilising these points as anchors for the control point curve along the U and V directions of the surface, the network representing the surface's curvature started to be constructed. As a result, the seamless connection of these curvatures was ensured by the precise alignment of their control points. Each of the curved edges of the tile is formed from a pair of symmetrical segments.

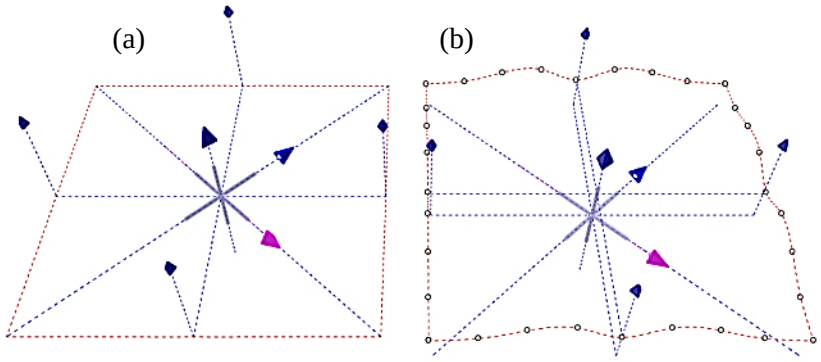

Figure 9. Deforming the boundary: (a) Tile baseline, (b) Modified boundary in Z direction.

Following that, a network of curves was established between the U and V axes of the surface, uniformly dividing the four curved planar edges. At this stage, two distinct curvature networks were generated while maintaining identical edges, resulting in continuous curvature between them. To generate the surface, the first UV curve in the network from all around the edges was to be disregarded in the subsequent step, allowing the curvature network to relax more towards the boundary. The primary objective, ultimately, was to achieve continuous curvature between the tiles (Figure 10).

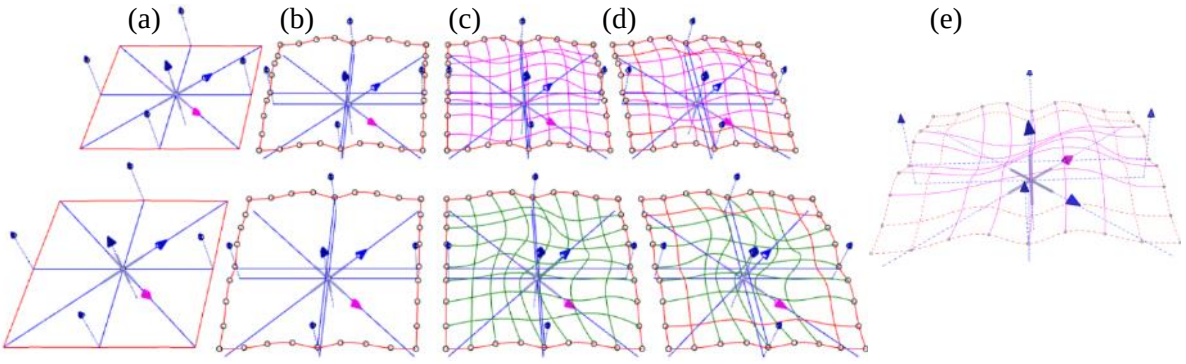

Figure 10. Surface network of curves: (a, b) Edge curvature processing (c) Curvature network creation (d) Removing curves in U and V direction for curvature relaxation (e) Final curvature network.

The aim is to produce two distinct surfaces with matching edges and continuous curvature across all transformations. Although removing the first curve in the network around the edges assists in relaxing the curvature towards the edge, it may not be sufficient. The more complex the curvature at the centre of the surface is, the greater the distance for relaxation is needed. To address this, a secure tangency guide is incorporated (Figure 11). This guide is a single curved surface perpendicular to the edges, which acts as a boundary to direct the curvature relaxation during surface creation.

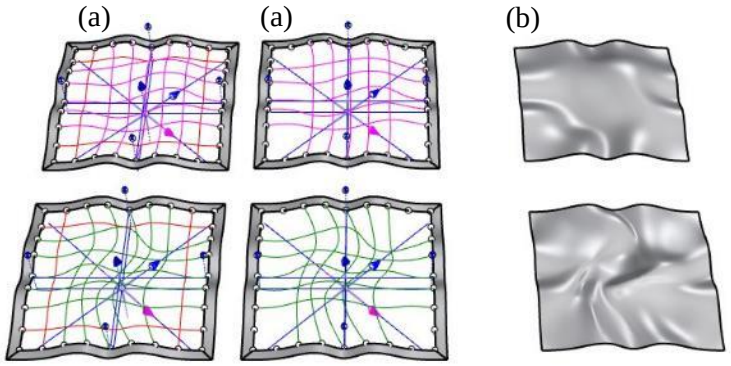

Figure 11. (a) Tangency guide (b) Final surface.

5.2 Tiles Aggregation and Assembly process

The outcome of the previous steps was a tile featuring two unique faces with four identical boundaries. When positioning the tiles adjacent to each other, the variables that affect the final wall design change from manipulating the curvature network to rotating and/or flipping the tile. Consequently, the continuity of the curvature can be transformed to change the final appearance of the wall, leading to a unique design with a continuing curvature each time the assembly order is manipulated (Figure 12). These modular tiles can be manufactured off-site with minimal equipment and required labour, then easily transported to the construction site. Also, this approach allows for modifications and repairs to be conducted more efficiently, contributing to the system's sustainability.

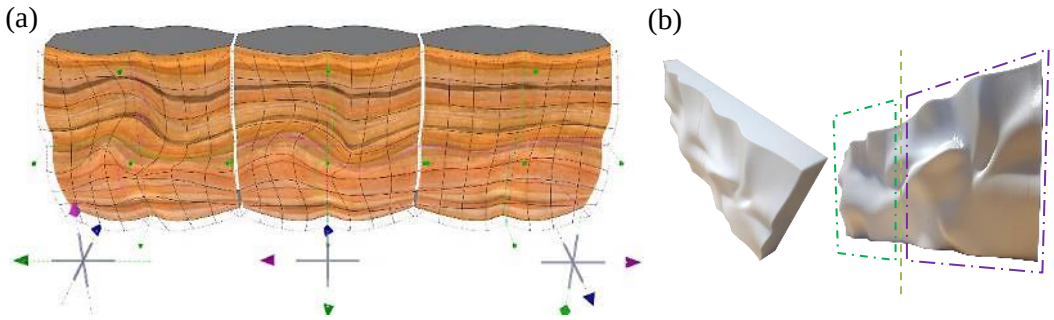

Figure 12. Tiles aggregation: (a) Same tile but flipped and rotated (b) The two distinct tile faces (the dotted lines represent the planes between the two distinct tile faces).

The tile concept can be realized in one of two ways (Figure 13). The first possibility involves creating two unique parts that are rammed as separate tiles and then attached together. The second possibility follows the same idea but includes the addition of insulation material between the tiles to enhance their thermal performance. This approach, which features two connected parts, is inspired by the sandwich structure concept [42].

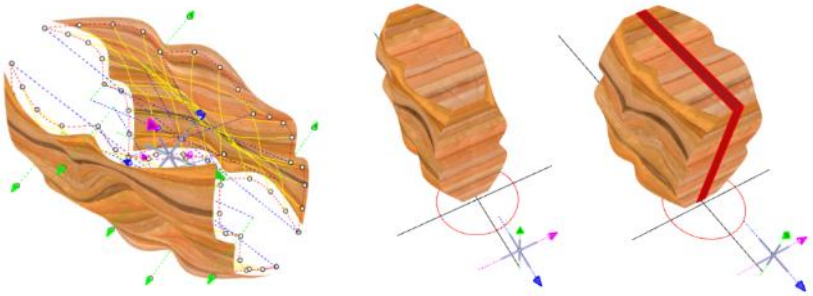

Figure 13. The envisaged design of the 3D tile.

Two design proposals were envisaged using the new 3D RE modular tiles to generate a 200 cm × 200 cm wall, with each tile measuring 50 cm × 50 cm and featuring two distinct faces. The first proposal involved using two different tiles to generate 128 wall design alternatives upon aggregation. The second proposal involves using four different tiles, resulting in 512 wall design alternatives (Figure 14).

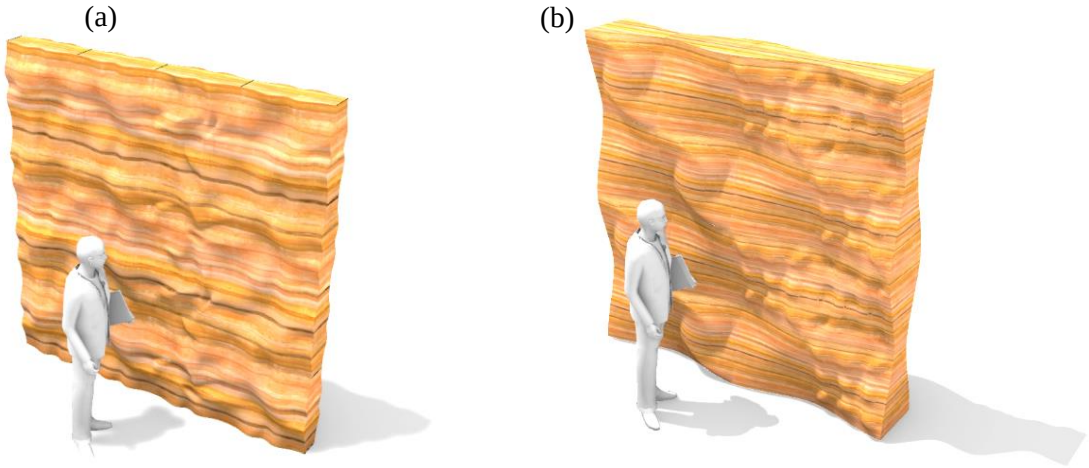

Figure 14. The envisaged two design proposals: (a) using two different tiles, (b) using four different tiles.

5.4 Fabrication Process

The formwork is composed of a curved base and a cubic frame/enclosure. The curved base is digitally manufactured through computer numerical control (CNC) milling from hardwood. The tile creation starts by adding fresh earth mixture inside the cubic mould and onto the curved base, followed by ramming the mixture manually for the first layer of soil, then with a pneumatic rammer for the remaining layers (Figure 15). This method ensures that the modular rammed earth tiles will have precise and intricate curvatures. The produced RE tile has dimensions of 50 cm × 50 cm and the depth of the produced RE tile can be easily adjusted through the cubic frame to serve various architectural requirements and construction purposes (e.g., structural, non-structural elements). The fabrication process also considers the incorporation of necessary additives, such as binders, to enhance the strength and durability of the modular RE tiles. The integration of these materials is carefully balanced to preserve the sustainability benefits of the rammed earth system while achieving the required structural performance (Figure 16).

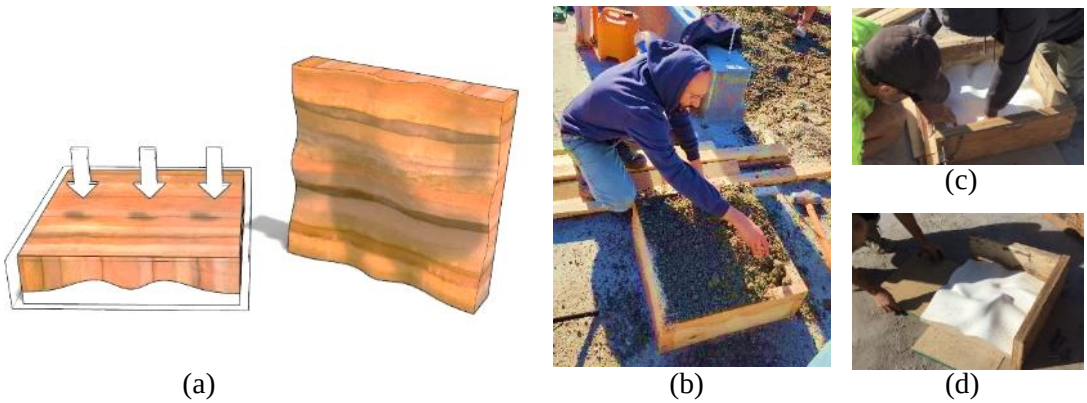

Figure 15. Fabrication process: (a, b) using the hybrid mould (curved CNC milled base and the cubic wooden boundary), (c, d) assembling the cubic wooden boundary of the hybrid mould.

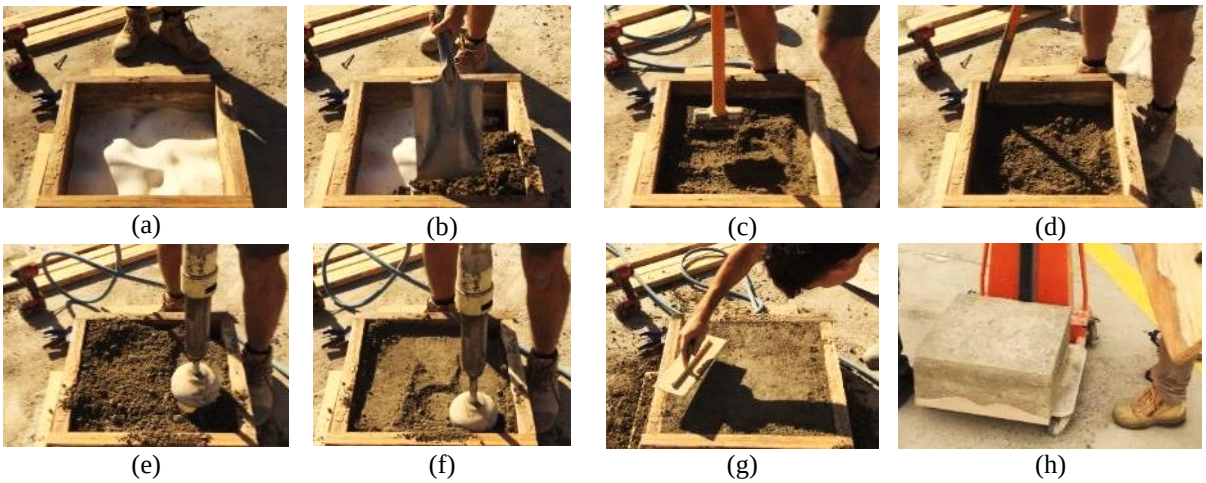

Figure 16. Tile production: (a) the hybrid mould, (b to d) manual ramming, (e to f) pneumatic ramming, (g) finishing, (h) disassembling the hybrid mould's cubic boundary.

The proposed modular rammed earth system in this research combines the sustainability of rammed earth construction with the efficiency of modular integrated construction (MiC) to create a novel approach to sustainable and efficient building practice. By using locally abundant materials, the system reduces environmental impact through off-site production and assembly. Furthermore, the mass customization and mass production aspects of the system offer a scalable solution to accommodate growing market demand. as all tiles have matching edges from all sides (Figure 17).

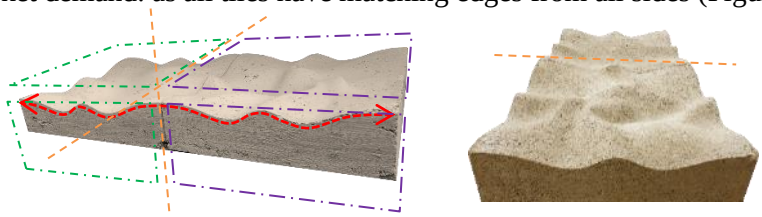

Figure 17. Rammed earth aggregated two distinct tiles (the dotted lines representing the planes between the two distinct tile faces).

6. Discussion and concluding remarks

The proposed system in this study offers a promising approach to manufacturing free-form rammed earth walls. It addresses the challenges associated with both rammed earth construction and modular integrated construction (MiC). By combining the sustainability of rammed earth with the efficiency of MiC, this innovative approach has the potential to contribute significantly to a more sustainable and efficient built environment. Further research and development are needed to refine the system and validate its effectiveness in full-scale construction. This includes replacing the cement in the soil mix with bio-binders. Future improvements are planned to enhance the workability and adjustability of the hybrid mould. These enhancements will include testing the feasibility of ramming both sides of the tile at the same time (Figure 18).

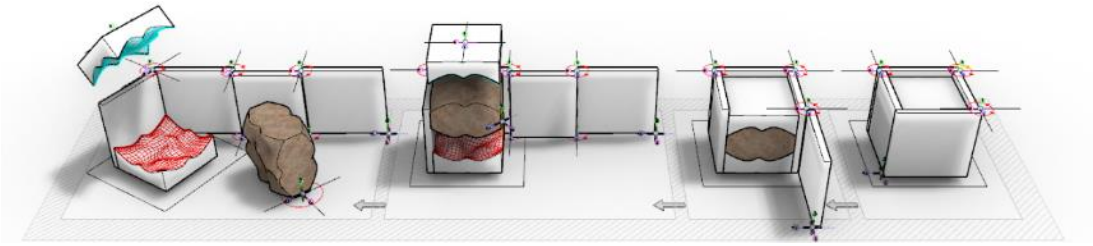

Figure 18. Further mould development to be tested.

Complex digital modelling for low-cost construction of East African vernacular architecture

Joanna Maria LESNA[a], Xavier de KESTELIER[a,*]

[a,*] Hassell Studio
London, United Kingdom
xdekestelier@hassellstudio.com

Abstract

The technological advances in computer-aided design allow architects to digitally model and fabricate complex structures. However, these are typically utilised within large, well-funded teams in developed countries. Drawing on a philanthropic partnership between creative activists TO:, international architecture studio Hassell and Ugandan based architecture firm Local Works, this project demonstrates the potential for utilizing cutting-edge technology to construct buildings using the most suitable materials, thereby maximizing performance and sustainability in even the most remote locations.. This aims to provide equal opportunities to support the most vulnerable. The Bidi Bidi Music Academy and Art Centre project merges the use of sophisticated design tools with traditional construction methods to develop a complex structure in one of the largest refugee settlements worldwide. The intricate geometry of the building addresses three primary design objectives: (1) creating a culturally significant structure that instills pride in the local community and establishes a sense of identity for the area, including the inclusion of an education space with excellent acoustic properties; (2) providing environmental protection through the creation of shaded and naturally ventilated communal spaces; and (3) supporting life by incorporating a water collection system for drinking and sanitation. The paper describes process of developing and evaluating the pre-defined global geometry of the Academy (top-down) for the bespoke functions in relation to the local material properties and fabrication methods (bottom-up). The project emphasises the translation of complex elliptical global form into simple elements and guides for the construction by newly trained local workers of the refugee settlement. This publication aims to expand the use of computer-aided techniques for digital modeling in the architectural industry, particularly within impoverished urban areas. Addressing global social and environmental challenges calls for innovative approaches that uplift local communities and inspire the world. The project proves that eco-friendly building materials and construction technologies can be cost-effective while adhering to stringent building standards. Complex and optimized digital models can be translated into straightforward components that local labor can produce and assemble, thereby minimizing the carbon footprint.

1. Introduction

1.1. Context

1.1.1 Bidi Bidi refugee settlement

Bidi Bidi refugee settlement is the largest refugee settlement in Africa, the second largest in the world. A small village on the South Sudan border, Bidi Bidi became officially recognized as a refugee settlement in August 2016. According to UNHCR statistics, as of August 2019 Uganda was hosting over 1.3 million refugees, making it the largest host country in Africa. Since then, Bidi Bidi has grown to cover nearly 250 km and is now home to a population of nearly 250,000 refugees - over 42,000 households, the majority of whom are South Sudanese refugees forced to flee their homes due to violent conflict. (UNHCR 2020) The Bidi Bidi Music and Arts Centre will provide a platform for gifted artists based in the Bidi Bidi settlement, and their facilities will aid in healing process for a community that has suffered in immerse trauma.

1.1.2 Local climate

Northern Uganda is located a few hundred miles north of the equator, the area is hot and dry throughout the year and particularly in the winter. The key environmental challenge of the designing in this climate is to provide an efficient protection from the sun as well as heavy rainstorms, including driving rain at almost horizontal angles.

1.1.3. Context of Music and Arts Centre

The objective of the Music and Arts Centre is to offer a space for music, art, and various cultural activities for the Bidi Bidi refugee settlement community. The facility comprises a performance area, recording studio, music classroom, changing rooms, and storage space. Recognising the central role of music in South Sudanese culture and the settlement's current lack of resources to foster such programs,

the centre will serve as a crucial hub for creative expression and individual empowerment, contributing to the healing process for a community that has endured immense trauma.

1.2. Local resources

1.2.1. Compressed Stabilized Earth Blocks

In Uganda, locally produced bricks require a substantial amount of wood as fuel for the firing process. The supply of wood near the Bidibidi settlement is limited due to deforestation for firewood. Scarcity of firewood is also a common source of conflict between refugees and host communities in Northern Uganda. Implementing alternative technology could help preserve the environment.

Compressed Stabilised Earth Block (CSEB) technology is one such alternative that has gained increasing recognition, particularly in East Africa (UN-HABITAT, 2009). CSEBs are construction blocks made from a mixture of soil and a stabilizing agent, compressed using various types of manual or motor-driven press machines. Compared to alternatives like fired bricks, CSEBs offer lower construction costs at similar quality levels and significantly reduce environmental impact. The blocks are fabricated on-site and cured over time, eliminating the need for fuel such as wood and thereby preventing environmental degradation.

1.2.2. Water

Bidi Bidi lacks a general water supply. Near the site, there is a manually operated borehole from which the community collects water for drinking and sanitation purposes. However, the water is contaminated due to limited sanitation infrastructure. Uganda frequently experiences intense tropical storms. Meteorological data for Northern Uganda indicates that there are 31 rain events per year, with each releasing over 10mm of precipitation within 15 minutes.

One of the primary design objectives was to harvest rainwater and provide water storage that would last throughout the dry season. By employing digital tools, the designers could calculate, visualize, and optimize the amount of water collected from the building's roof. This process allowed for predictions of water usage within the facility, and the excess collected water is intended to be shared with the community.

2. Methodology

Since the advent and widespread availability of parametric 3D modeling software in the early 2000s, architects have been able to design and realize complex forms. The utilization of computational methods in architectural design has become commonplace in practice, incorporating performance analysis as an integral component of the design process (Kolarevic and Malkawi, 2005).

However, the employment of these advanced tools and the development of complex geometric shapes has typically been limited to larger projects with substantial budgets. In contrast, the Music and Art Centre project, characterized by its high cultural aspirations, was undertaken pro bono by the architectural firm Hassell Studio and engineering firm Arup. In this instance, parametric design and digital analysis tools were utilized to minimize the need for an extensive design team. Design development and optioneering were efficiently carried out through iterative modifications of the parametric model. Early integration of wind and solar analysis during the design process facilitated the optimization of the overall design. Additionally, augmented reality (Hololens) and virtual reality (Twinmotion) technologies were employed for community engagement within the camp.

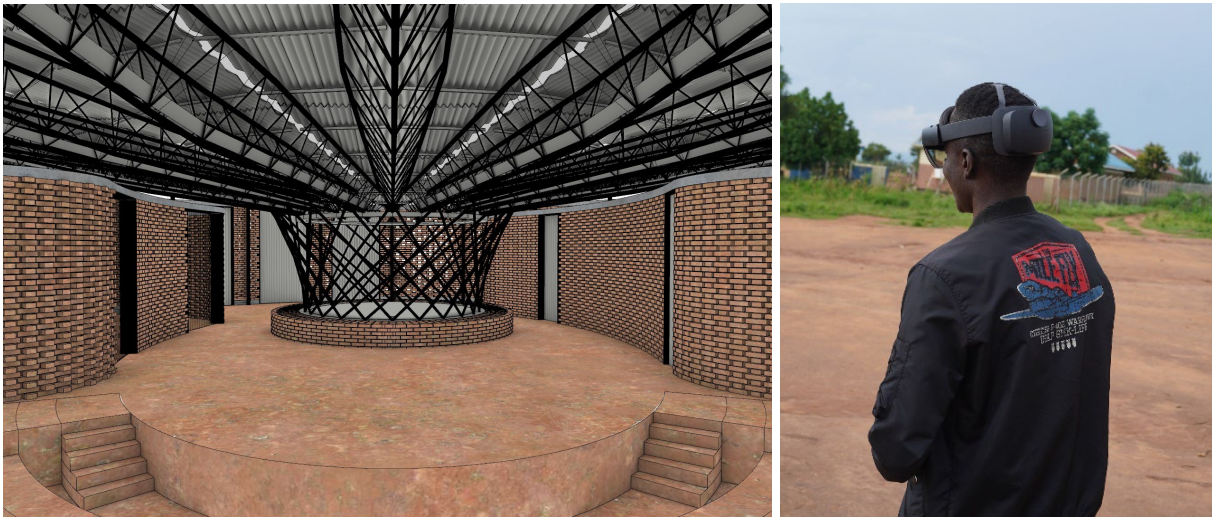

Figure 2. Visualising the project on site through Microsoft Hololens

3. Geometry

3.1. Planning and form development

The building's overall plan is elliptically shaped, a geometry derived from its relationship to the site. Situated along the existing footpath leading to a borehole, the structure serves as a creative and social hub for the local community, inviting individuals to pass straight through the building or walk along its curved façade.

An ellipse features two foci, each of which holds not only mathematical significance but also essential architectural functions in this design. The first focus, an oculus, permits daylight to enter and channels rainwater from the expansive roof to water collection tanks. The second focus serves as a stage for the amphitheatre, accommodating local artist performances and community events.

The amphitheatre constitutes the primary design function and is accessible from the south, facilitating community gatherings and spotlighting performing artists. The building's design follows the terrain's slope to utilize the natural gradient for amphitheatre seating.

Additional rooms are situated along the ellipse's short axis: a music classroom featuring a translucent polycarbonate corrugated pivoting door for natural light is located to the left of the amphitheatre, while changing rooms for performers, storage for music equipment, and a recording studio are found to the right. As visitors proceed towards the northern exit along the long axis, they pass through the multifunctional foyer-art exhibition space and oculus.

Eliptical-like ase constructed on 3 arches

3.2. Structure and roof

The roof geometry adheres to the building's elliptical shape, extending approximately 2 meters beyond the building envelope. This overhang serves to protect the brick wall against erosion caused by heavy rainfall. Furthermore, the roof safeguards the interior from rainfall and direct sunlight.

3.2.1. Roof geometry

The roof is designed as a large funnel, collecting rainwater at the centre of the building. To facilitate proper flow on the roof surface, a minimum slope of 6% is required. The oculus, symmetrically positioned within one of the two foci of the elliptical curve, results in a roof slope varying between 6% and 11% due to differing distances from the roof's edge and the oculus.

Initially, the roof's geometry comprised a double-curved surface, which precluded a quadrilateral flat panel solution. To reduce costs and simplify manufacturing and assembly, the double-curved geometry needed conversion into a developable surface, enabling mapping onto planar quadrilateral panels. This optimization was achieved through torsal ruling of the surface, ensuring the same tangent plane at all points of the same ruling. One geometry capable of utilizing torsal ruling for isometric mapping is a cone (Pottmann et al., 2007). Given the planar curved external profile of the roof based on three arcs and the oculus's centre, the geometry can be translated into a basic cone.

The oculus's opening was fashioned by removing surfaces near the cone's vertex, resulting in a truncated cone geometry. The geometry was then transformed into a skewed cone by shifting the vertex along the ellipse's long axis, as the oculus resides in one of the ellipse's two centers. This alteration rendered the geometry reflexively symmetrical along the long axis. Subsequently, the cone was inverted, employing its lateral faces to direct rainwater towards the oculus. Analogous to the roof's edge, the oculus's curve is based on an ellipse composed of three arcs with varying radii and identical lengths. Consequently, three distinct truncated, skewed, and inverted cones were utilized to

construct the roof's form, symmetrical along the long axis.

3.2.2. Structure and construction strategy

Due to lack of wood in Bidi Bidi, the roof structure is made of light weight steel which is pre-fabricated in Kampala, the capital of Uganda. The roof decking is made out off widely available corrugated panels.

The geometry of the roof was divided based on the 3 arches into 24 parts, which 12 of them are symmetrical. Then, the parts were divided into groups of two, and the corrugated aluminium cladding was positioned parallel to the common edge of the 2 parts. This way the corrugation guides the rainwater in one direction, directing it to the oculus. (Figure 6)

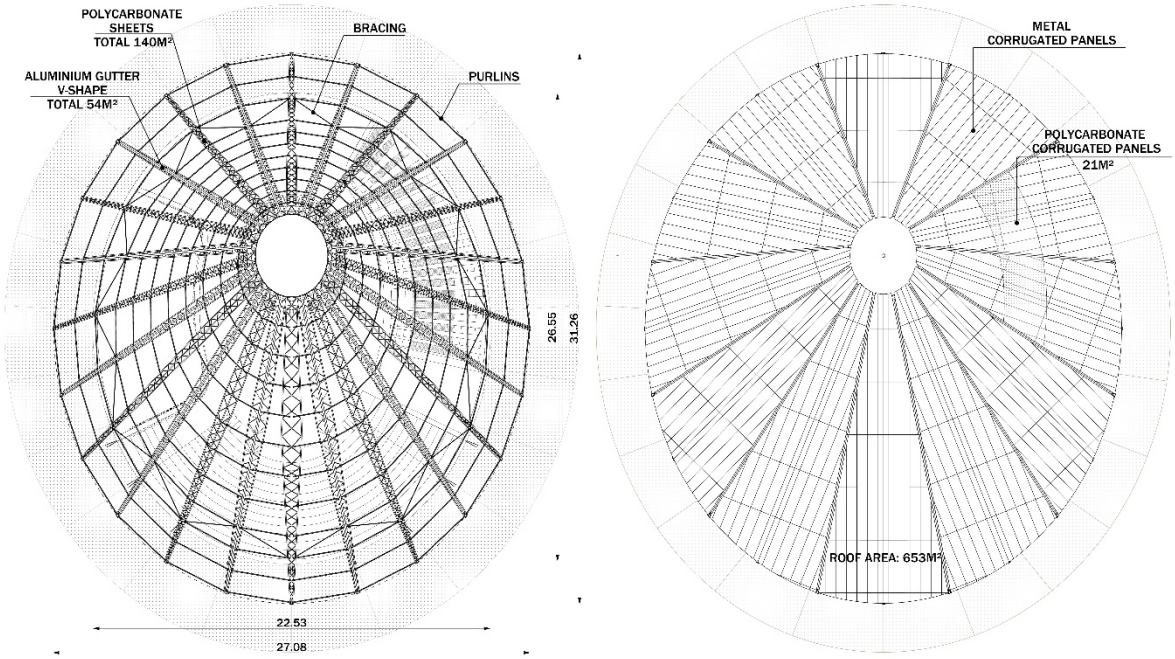

Figure 4. Drawings of the roof structure

However, due to the conical shape of the roof and corrugation pattern, one of the edges would need a drainage. Therefore, the gutters in-between every second roofing part were introduced. V-shaped gutter lying in the truss is partially made of aluminium, and partially made of polycarbonate. This allowed an additional indirect daylight to enter the interior space.

The truss structure follows the edges of the bespoke roofing parts, and it is organised radially to the oculus. It lays on columns attached to the external brick wall and central hyperbolic paraboloid column around the oculus. By using hyperbolic paraboloid one can produce the structure out of straight steel elements (Whitehead 2003).

Figure 5. Full scale mock up of structure and CEB wall at the offices of Localworks.

Figure 6. Interior render of the performance area

3.3. Brick walls: daylight, ventilation and acoustic performance

Integration of the multiple scales, geometrical and material performance as well as fabrication process constrains into early-stage design allows to create complex architectural model. However, this complexity doesn't need to be reflected in the fabrication and assembly processes. To reduce the costs, only one module of CEB with the dimensions 250x120x90mm is used for the wall construction. By changing the position and pattern of the CEB unit, we are designer is able to create a wall which varies in performance: acoustics, natural ventilation, daylight diffusion but also aesthetics. The performative variety of the predefined rooms according to the specific usage is possible to program using a multi-

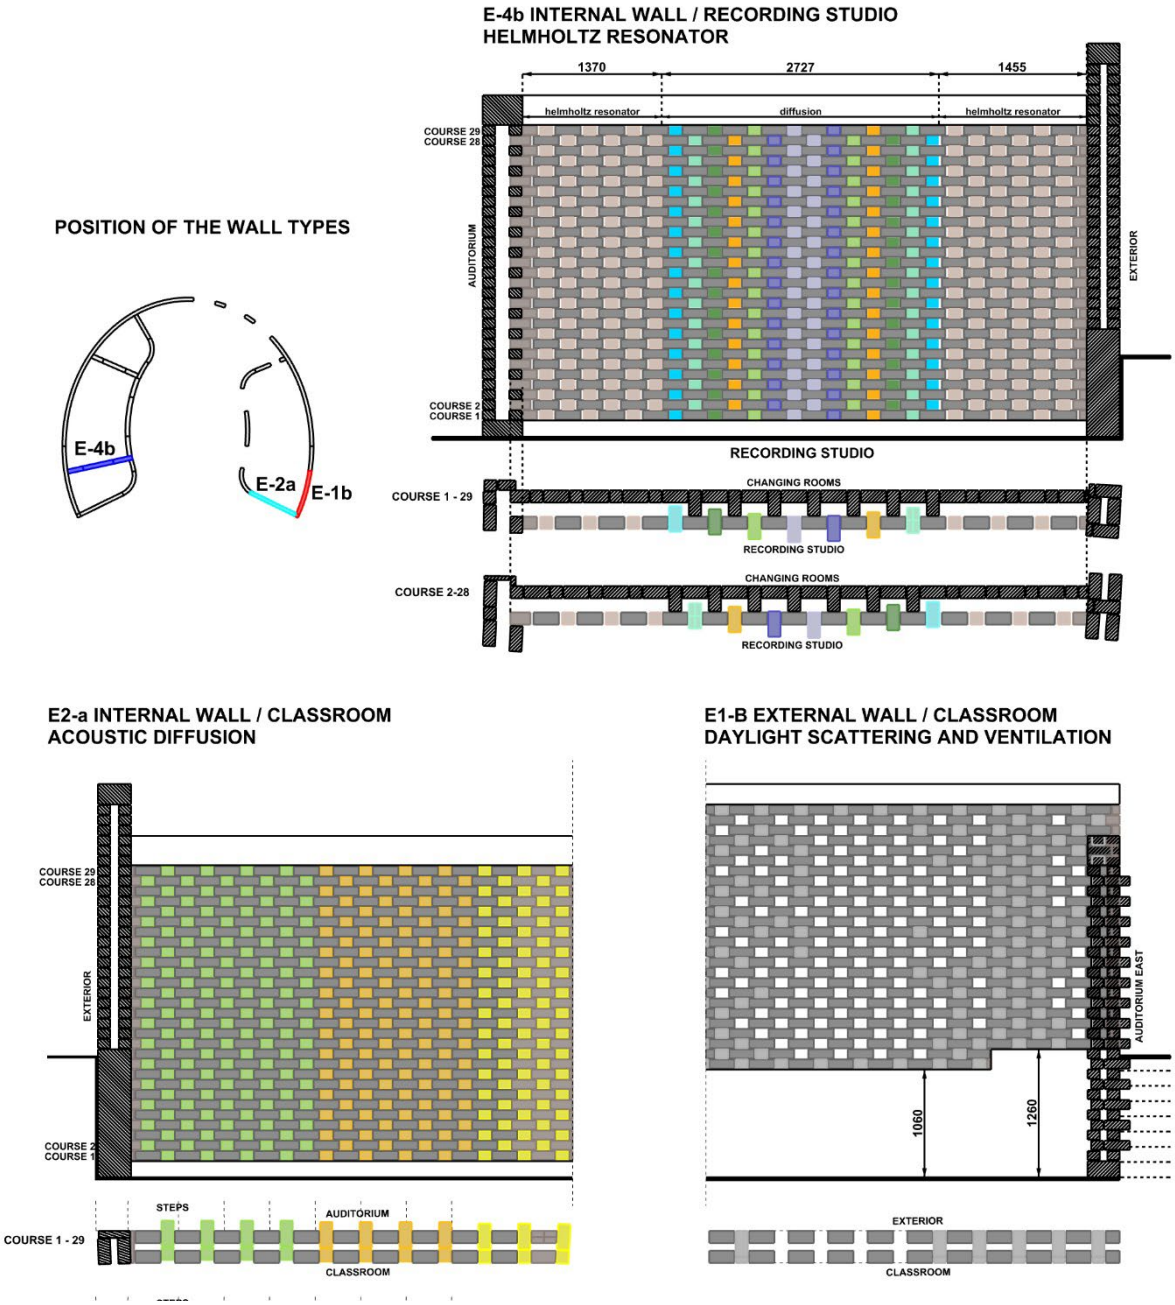

Figure 7. Drawings of the different brick patterns.

scalar approach of digital modelling and generation of bricks in various arrangement. This is followed by digital simulations and consultations with local architect and an engineer.

The spaces of recording studio, amphitheatre area and music classroom need specific acoustic performance embodied in the geometry. The complexity of the surfaces was created by altering the geometry of the wall by changing the arrangement and patterns of the CEB units. Walls of recording studio consist of two types: 1) Sound diffusers- these are made by altering protrusion distance between 70-30mm and are located in the middle of the wall length; 2) Sound absorber using Helmholtz resonator brick array, located in the corners of the room. This type consists of 3 brick layers as in the top view from inside: 1) brick layer with 3mm holes to get the sound wave into the resonator; 2) cavity gaps with fibrous absorber, 1m wide divided with unit of brick; 3) flat and closed brick layer based on Flemish bond. In a wide frequency range, the resonators have insufficient performance. Hence, the suitable size for each resonator needs to be studied and tested to widen the frequency range of sound absorption (Basirjafari 2020).

Recording studio needed to be design as a closed space, because of noises. However, walls in the music classroom and amphitheatre have additional functions.

To prevent the low but intense morning and evening sun from penetrating deep into the building – and their sides facing north and south as transparent as possible – to maximise on natural daylight and airflow. The bricks are arranged in the way that the header in the Flemish bond is removed to allow daylight to the room and naturally ventilate the space. The pattern was programmed based on the daylight analyses and users' experience and combined with acoustic patterns.

The project uses physical prototypes, mock-ups and mixed reality smart glasses as a means to explore and evaluate the methods presented. The workflow creates opportunities for feedback across the design chain and increased flexibility in effecting changes.

4. Conclusion

This publication is intended to broad the application of computer aided techniques for digital modelling in the architectural industry of the urban poor. The world's social and environmental challenges require novel approaches that elevate the local and inspire the global. The project demonstrates that environmentally friendly building materials and construction technologies can be made more affordable while still meeting rigorous building standards. Complex and optimised digital model can be translated to simple elements which the local labour is able to produce and assemble, which results in reducing the carbon footprint to minimum.

Translation of the complex elliptical and double curved geometry is a result of the fabrication possibilities in the refugee settlements and digital optimisation followed by structural analyses. Geometry of elliptical skewed cone is translated by using 3 arcs as a base instead of ellipse. Therefore, the planar tessellation of metal roof elements was possible for low-cost construction.

Furthermore, the digital tools present the opportunity for incorporating performance analysis into the architectural design process. This paper proves that this can lead to a complex performance by using simple materials and fabrication techniques.

Abstract

This research focuses on designing and constructing a unique extension space using a 60-meter-long and 6-meter-wide curve ruled glass shell structure. The project implemented a well-coordinated data flow across various stages from design to construction, utilising digital design techniques and robotic technology. A digital model of the shell structure was created in the Rhinoceros 3D environment to facilitate the data distribution between design software and construction machines, particularly for the robot system. U-shaped glass panels were used to achieve this innovative space for both interior and exterior surfaces, with a steel structural frame embedded in the U-shaped glass modules. An on-site robot arm system was employed to assist human workers in ensuring the accuracy of the installation of the steel frame, contributing to cost savings in building materials and time efficiency. This experimental project investigates the potential of automation in construction for free-formed buildings in different stages of project delivery. This paper highlights the benefits of using advanced manufacturing and digital design techniques, specifically in complex shell structures, and discusses future developments in the industry.

Keywords: complex shell structure, digital design and fabrication, on-site robotic construction, advanced manufacturing, U-shaped glass panel, collaboration in human and robot, automation in construction

1. Introduction

In the past decade, digital design data has rapidly developed and is widely deployed in the building industry. Building Information Modelling (BIM) [1] is the dominant platform for delivering design data to construction. In addition, multiple types of computer numerical control (CNC) activities take place to address conventional tasks such as laying bricks [2], pouring concrete [3], and surveying construction [4]. Despite these advancements, there are still gaps in accuracy control and flexibility management when transferring information from digital design models to machinery, specifically for in-situ construction and assembly. For instance, if multiple teams and construction materials are not well considered in the programming phases, delays or additional costs might occur due to the automatic machines encountering unforeseen obstacles. Moreover, if the steel structure is deformed slightly by temperature changes or applying payload, but the machines still run the code with un-updated information, accidences such as collision and property damage will occur at a high percentage rate. Human experts' involvement is required to avoid these discrepancies. Consequently, managing the data flow and implementing software to hardware becomes a critical challenge for researchers and practitioners.

Copyright © 2023 by Lei YU and Guanqi ZHU. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

The building industry recognised the value of using industrial robot arms designed for versatility and adaptation to various applications. Researchers and stakeholders realised that these potential advancements, such as improved accuracy, reduced safety hazards, saved cost, and shortened delivery timeframe [5], offer significant benefits. With a large category of robot modules and configurable end effectors, a single robot arm station or multiple robot arms as a team can execute various jobs on demand. A robot arm system can overtake or reduce conventional construction machines, increasing efficiency and sustainability. Furthermore, robot arm systems can be easily reprogrammed in case of construction deviations from the digital model during a real-time site survey [6], which helps bridge the gaps between design and construction. This advanced solution prevents unexpected time costs in construction and allows architects and contractors to maintain projects' quality as it happens.

This research examined an experimental project to integrate the design and construction process by encouraging collaboration and coordination between human experts and robots. It involved schematic design, design development, project management, prefabrication, and on-site construction. These processes brought together architects, structure engineers, computer programmers, construction workers and a robot arm system in a tightly organised effort. As a result, the U-shape glass panels and steel frame were assembled to form a transparent shell structure that reflects the proposed architectural design scheme. During the shell installation, the capacity of a robot arm system was also enhanced for a broader coverage on a pair of rails to allow its end effector to reach any location as demanded. Furthermore, the industry robot arm can be configured to perform distributed roles in different construction positions. For instance, before moving onto the rails, this robot station was also hired to fabricate 1339 U-shaped glass panels, each with different lengths and edge angles.

2. Design concept, methodology and approach

Figure 1. An adaptive reuse by U-shaped glass shell and steel frame, completed in 2022 (Photo by Yuguang Liu)

2.1 Design concept

The project is an adaptive reuse of an existing building (Fig 1) in an obsolete industrial area. The client was interested in adapting robotic technology with a glass panel system. We took this opportunity to play a complete role in managing design data flow through all phases with a single design team. The existing brick house stands at the site's entrance, where they expected the new building to be intricately connected to the 50-year history of this community, with two sets of abandoned railways running through it. The project aims to turn this area into a modern cultural and art centre. We designed a transparent glass shell that expanded from the existing brick house to metaphorise the transition from the past to the future. This glass shell blends naturally into the old house on one side and is free-standing

on the other side, resulting in a smooth, spiral transition in the middle.

Additionally, the glass wall contrasts sharply with the existing brick wall, creating an inspiring landmark for attracting visitors. The new extension also contributes an open plan space of 310 sqm. The design objective is to seamlessly integrate the new with the old house with the latest design and create a particular sunny space that is visually stunning and functional for its intended purpose (Fig 2).

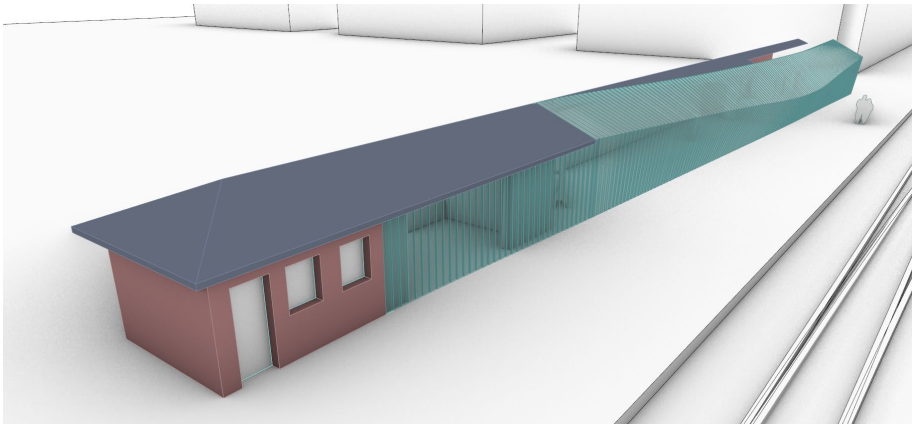

Figure 2. Concept - a transparent shell expanded out from the existing building

2.2. Building material and structure design

To construct glazing space and form the shell, U-shaped glass panels were chosen because it is a popular choice for modern building facades. Compared to the planar glass panel [7] [8] [9], U-shaped glass can provide a simple and cost-effective solution for a curved façade without the need for a mullion system [10]. The manufacturer of the U-shaped glass, ASG, provides specifications that were used in our calculations, which demonstrated that a simple support beam could have a maximum length of 6.47m. This equation assumes I (inertia) is set as 1/100, reflecting the local structural code, E is the Young's Modulus of their U-shape glass panel provided by ASG, and *w* is the wind load set as 0.5n/m. This result is particularly well-suited for our design since the top level of this shell structure is not taller than 5m, and the roof span is no longer than 6m.

$$Lmax = \sqrt[4]{\frac{384*E*I}{5*w}} \tag{1}$$

The curved façade and roof surface can be achieved by using a method called section multiplication. It involves dividing the curved surface into small sections and creating each section by slightly modifying its profile by changing the previous one's shape, foot location, and joint angle. This process is repeated from one end to the other, with gradual variations of the glass modules spacing every 275mm. Consequently, it creates a 10mm seam between the two modules because the U-shaped glass panel is 265mm wide. To meet the aesthetic requirement and provide thermal insulation during winter, the U-shaped glass panel is double-sided on interior and exterior surfaces. Two panels are placed face to face to create a single module, and their bent sides meet each other to form a hollow core with a clearance of 250*120mm.

SGI, the structure consultant, has embraced this approach and is committed to concealing the structure within the glass wall (Fig 3). To reach this goal, we have decided to insert the steel frame by fitting the customised steel studs (120*90mm) inside the hollow core of U-shaped glass panels every 12 modules. In addition, two round beams underneath each side of the north and south roof connect these sectional steel frames into a cohesive structure. The design and development of the structure system follow the design principle of ensuring that the top corner of the glass shell is free from any visual obstacle, maintaining a clear and crystal effect on the other two side corners as well.

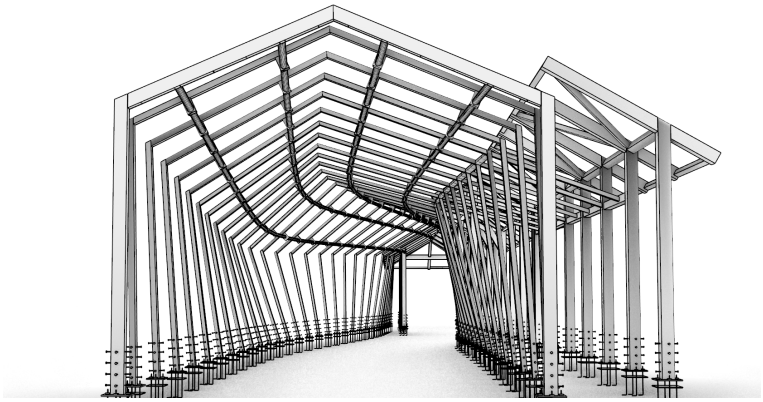

Figure 3. Steel frame structure

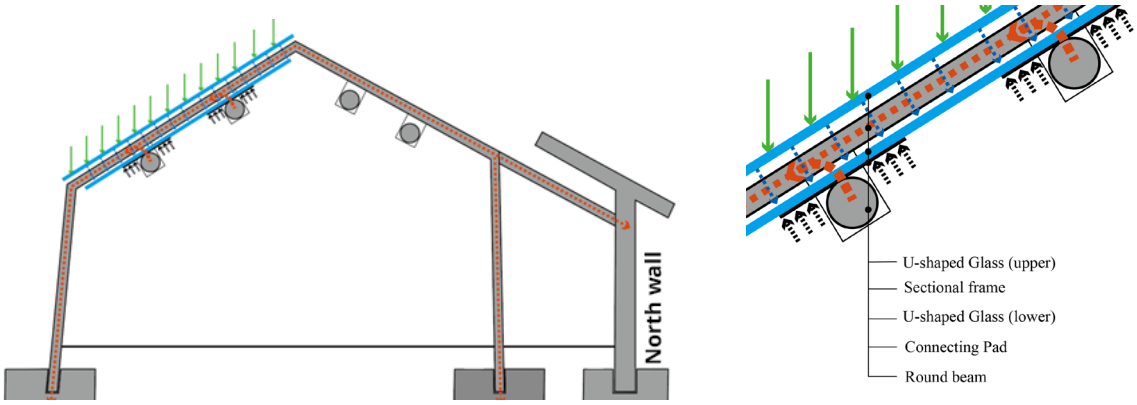

Figure 4. Section of steel design for permanent structure load and force

Four circular beams are responsible for bearing all roof loads, including the dead loads of U-shaped glass panels, metal connectors, lighting fixtures, ventilation system, and the live loads of moisture precipitation such as rain, snow, and ice together with wind loads (Fig 4). The roof steel frames in the glass core supported the loads on the four beams. Ultimately, the side steel frames transfer the upper load from the top steel frame downwards to the foundation. The glass modules in the façade and the interior partition wall are mostly self-supporting and occur in two positions: leaning inwards and outwards. The ones leaning inwards do not need any structural treatment. However, for the other position, a prestressed stainless-steel cable is anchored between the upper corner of the glass module and the lower round beam to prevent glass panels from falling outwards. The steel frame is secured by a series of connecting beams welded to the northern wall's primary columns.

2.3. Prefabrication

The primary challenge in constructing a glass shell structure is ensuring that the U-shaped glass panels and the steel frame are appropriately coordinated to prevent damage to the glass panel. Despite the structure engineer's best effort to reduce the section size of the steel studs embedded in the hollow space, there is only 20mm between the glass panel and the steel frame. This narrow space raises a challenge because the glass panels must be produced and toughened before the completion of the steel frame's construction, leaving no room for modification if the steel frame is installed below the required tolerance level. Any deviation of the steel frame from the digital model beyond +/-10mm will result in a smaller space (of less than 10mm), where a collision with glass panels could occur and damage the glass. Therefore, all U-shaped glass panels should be prefabricated precisely to follow the design data, leaving the challenge entirely in the steel frame construction.

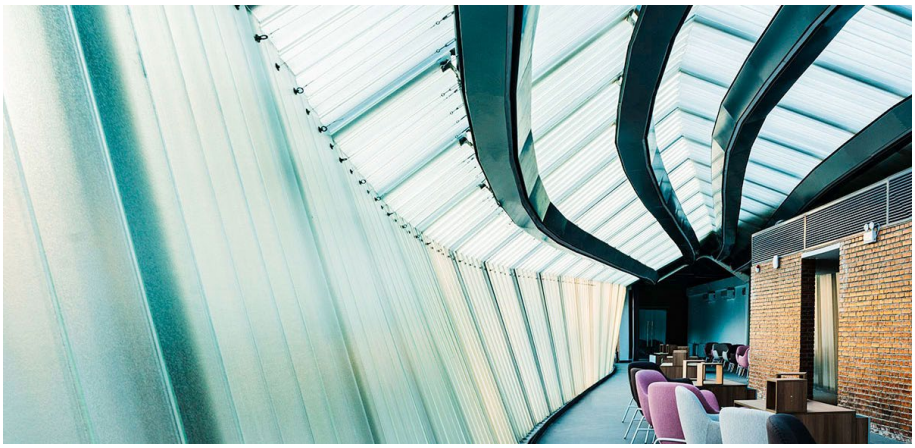

Figure 5. Interior view of the glass shell space

Figure 6. Robot system cuts U-shaped glass panels in the manufacturer site. (Photo by Ji Shi)

U-shaped glass panels can be engineered and tested to comply with various building codes and safety standards, such as ASTM E3100 for glass strength and ASTM E2353 for hurricane resistance [11]. The typical supplied U-shaped glass panel is 7mm thick, 6000mm long, 265mm in outer width and has two 65mm folded rims. We developed and test-proven a robotic glass-cutting technique from previous projects. We adopted the grinding-through technique with a diamond blade to fabricate the unique panels. Cutting U-shaped glass panels in irregular angles and shapes, especially in sharp corners at the edge of folded rims, can result in high-rate failures using the general cutting method by the stroke cutter. The grinding speed control in different cutting stages is also critical to minimise breakage because the inappropriate speed will cause cracks due to microscopic crevices and stress points. The whole prefabrication statistically has a 10% failure rate in the cutting and toughening process compared to a 3-5% loss in the general cutting technique. We also invited the skilful glass-cut expert to manually make the panels in this project. It turned out to be a 50% failure, and it took an undetermined amount of time to fix the edges to the suitable shapes with the angled grinder by hand - the same task took at most 5 minutes for each panel by the robotic cutting station. This 'on-site' prefabrication, where we moved our robot station to ASG's factory (Fig 6), also helps reduce material waste, as glass cullet can be returned to raw supply immediately.

We hired a KUKA KR120 R3900 prime to produce these unique glass panels, which fully packed a 25m cargo truck. In addition, an 8mm seam is offset for every mitre joint of the glass panels, which is used for inserting the connecting pad and leaving some space to cope with the deviation during installation.

The robotic cutting system can produce every panel with an accuracy of +/-0.5mm in length and +/-0.1 in angles, satisfying the design requirements.

2.4. Project Integration

2.4.1. Digital Workflow

Designing and constructing this project was managed and executed through a digital workflow [12]. A central model was created using Rhinoceros 3D + Grasshopper software environment that generated, optimised, extracted, and streamed data to link every project delivery phase. The dataset worked dynamically across different phases [13], progressive developments, and various tasks, such as site planning, design and development of architecture and structure, robot and CNC coding, project management, and fabrication.

At the beginning of managing the project, we found limited reference to the U-shaped glass mitre joints with fractal angles and no examples of installing the steel structure inside the core of the glass panels. As a result, we decided to make a 1:1 mockup of a typical portion of this project with technical support from ASG. After successfully proving this structural solution worked well through this mockup, we finalised the digital model, generated the final version of the data set and moved on to the fabrication phase.

This project comprised 31 sectional steel modules covered by 1339 unique U-shaped glass panels. The steel frame installation was carried out with a precision of +/- 10mm to guarantee all glass panels can be placed appropriately above the steel frame without any apparent visual flaw across the geometrical transition. This data set was subdivided into two streams: a subcontractor will fabricate the steel components manually. At the same time, our team used a robotic cutting system to automate the fabrication of U-shaped glass panels. Once both groups had delivered the structural components to the construction site, we used a mobile robotic island to assist with precisely installing the steel structure as a collaborative process. Compared to the regular steel structure, this steel frame had a data set of unaligned positions and fractal angles that were hardly measured by conventional construction techniques. Therefore, we introduced an on-site robot arm system to transform this complex data set into reachable locations with an accurate industrial standard.

The toughened U-shaped glass is fragile and easily breaks under impact around a sharp corner. In the final installation stage, after the steel frame was built, a team of skilled workers safely installed the panels (Fig 12 &13). A total station, a surveying instrument that combines the functionality of an electronic theodolite and an electronic distance meter (EDM), was used in this stage to ensure every joint of the glass panels matches the data set within a tolerance of +/-5mm. Construction silicone gel was applied to seal the seams between glass panels manually.

Due to our design team being involved in this construction, the digital workflow implemented for this project was highly flexible, allowing for seamless synchronisation of every process. The robot workflow can automatically convert the dataset to accurate installation activities in the software environment, making the construction process more efficient and controllable. Consequently, using robot arm systems as collaborative co-workers facilitates instant response to unforeseen problems when the design and programming teams operate as one team during construction. For example, if the site-survey feedback indicated that the digital model did not accurately reflect the site condition, the support team immediately fixed the data set and reprogrammed the robot system to enable a smooth workflow without delay. An assessment will also be generated instantly and visually to evaluate if these changes will affect the following tasks and give responsive adjustments to the data flow.

2.4.2. Tooling – robot implementation in different roles

The robot end effector can perform tasks with the same effect as human hands but sometimes with better results. The potential benefits of reducing human activities in construction work are also recognised.

We have been exploring robotic technology to streamline the data from the BIM model to the robot end effector to minimise human interference that can cause errors. KUKAprc, a plugin of Grasshopper, is used to generate robot code directly from the up-to-date 3D model, consisting of a data package of the working path and actuation for the end effector.

During construction, the robot arm was outfitted with various end effectors and received different sets of codes to perform specific tasks. The locations of each building component were defined in a Cartesian coordinate, along with the locations where the end-effectors completed their assigned functions. There were two tasks for developing the end effectors in this project: cutting the U-shape glass panels with various lengths and side angles; assisting workers with placing steel structural components in unique locations. Both benefit from the robot system's native flexibility and accuracy.

Figure 7. Robot end effector design and application for assisting with steel-frame construction.

The first effector was designed using a spindle router and a circular diamond blade for cutting glass panels. Each U-shaped glass panel was secured in a 3D printed fixture, and the robotic system completed two cuts as one task. This task occurred in the glass manufacturing site because the glass panel can only be shaped before the toughened process; a post-treatment of U-shaped glass is only available at ASG throughout the country. The second end effector, comprised primarily of pneumatic actuators and a servo motor, gripped and aligned two steel components at each connecting joint for designated angles(Fig 7). The lower pneumatic actuator first grabs the side column's top point firmly at the specific location; then, the servo motor drives the upper pneumatic actuator to the exact angle to await the upper steel beam. After both beams contact at the correct position and the fold angle, a professional welder will fuse them into a single piece. This task was processed one after another, with each section module secured by temporary bracings in case of any deformation before the circular connecting beams connected them into a uniform frame. This task only required three people at most (one for operating the robot system, one for welding work and one crane driver) to be involved with the robot station as a work unit, which was more cost-effective and safer than the general method using additional workers to locate the building components and necessary fixtures hold it in place during the welding process.

2.4.3 Site challenge and mobilised robot island.

Due to the complexity of construction sites, it was not feasible to level the ground to an industrial standard for robot islands, such as those seen in prefabrication factories or automobile assembly lines [14], to expand the working coverage. To solve this problem, we installed a pair of rails to enable the robotic end effector to reach every upper joint of the shell structure's 60m-long steel frame(Fig 8). The KUKA KR150 R3100 prime robotic arm was deployed again to take over the mobile island. It was a customised trolley on rails powered by a 3000W servo motor, capable of carrying the 1500Kg robot arm and stabilised by a 2000Kg sand tank as a counterweight. In case of any vibration during the operation

resulting in unstable end effector functions, the trolley was equipped with two brakes on each side, controlled by pneumatic actuators to firmly lock it on the rails as needed. The robot arm was programmed with its end effector's payload at a maximum weight of 150kg and a full speed of 0.5m/s.

There were discrete marks on the top rail surface under every other steel frame(Fig 9), indicating the positions where the robot arm was programmed to execute relative actions. Once the robot island was aligned at a mark point and its breaks were fully engaged, the corresponding codes were launched to assist with steel frame installation accordingly. This process ran one after another until the last steel frame was completed. This simple and cost-effective mechanism provided a solution for reaching a big construction site with complex terrain conditions. However, these rails must be technically levelled to allow an ideal working environment for the robot and removed after the construction. Nevertheless, in our design, this pair of rails can still serve the customised trolleys with various functions, such as coffee tables, bookshelves, billboards, etc., allocated across the shell space.

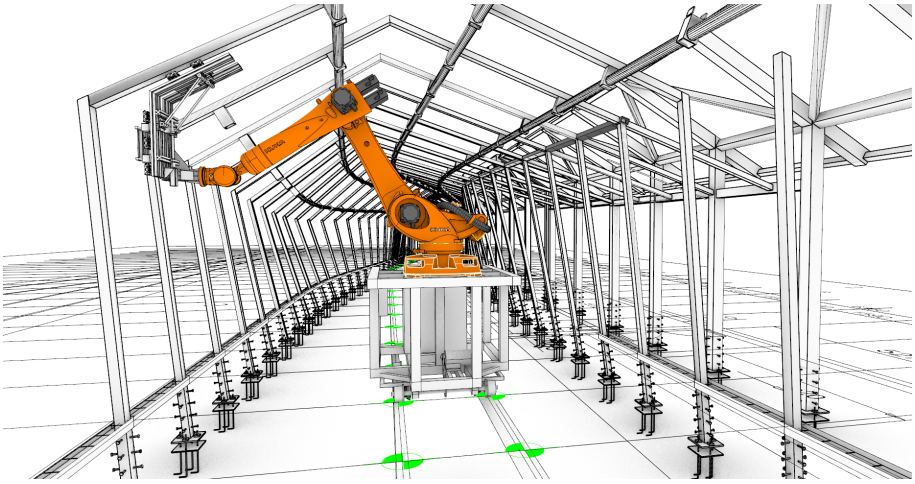

Figure 8. KUKA robot island driving on a pair of rails.

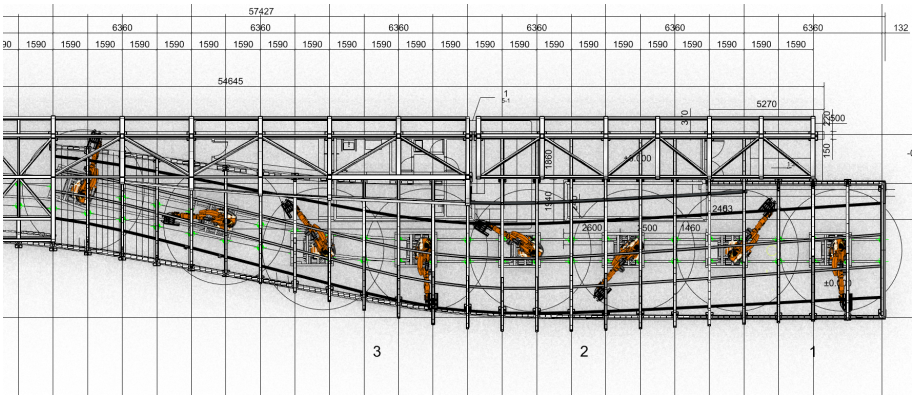

Figure 9. Marked spots for locating mobile robot island to enlarge its working coverage

2.5. Robot and Human Collaboration in Construction

Construction work is a multifaceted process that demands various skills and techniques. Each project presents unique challenges that require individualised solutions. In the context of this project, welding the steel frame was an essential aspect that must be executed to a high standard to meet the strict requirement for installing U-shaped glass panels. As such, every mitre joint of the steel frame was welded within the specified tolerance. Given numerous angles and locations, the robot arm was introduced to grip and secure the frame components in the right places before the welder started work. With a payload of 150 kg, the robot arm can carry most steel components over 4m from the ground

level. If some components exceed this payload, a crane truck can hang it into a position where the robot arm gripped the joint position firmly, ready to weld the top part. Situated in a queue of referred points robotic system runs a robotic G-code [15] to assist human workers in assembling the steel structure more efficiently and confidently(Fig 10).

Figure 10. Robot assists in structure installation.

This experiment illustrates how robots can collaborate with humans on construction sites in an extended mode other than working in factory conditions. In this productive environment, the robot arm functions as a partner that can exactly give a response to the G-code for finishing tasks. It facilitates a straightforward and highly coordinated workflow with fewer transformation procedures than the general process. This is because this work mode deals with specific problems in the environment where all immediate conflicts happen in real-time, which can be simulated, assessed, and resolved by robotic workflow.

This reciprocal teamwork promotes a new construction mode in the building industry. The project contractor manages how to coordinate human workers and robots to complete various tasks by reloading different robotic end effectors and managing correspondent silked workers and technicians. This flexible combination has merits to take over the transition in different stages of the digital workflow for high productivity and safety management, particularly for on-site construction.

However, we must also recognise that the industrial robot arm has been developed for the automatic assembly line where no people can have overlapped working space with these heavy-load machines. Therefore, a safety conduct code must also embrace robots working on the construction site with human workers in proper safety control management. Additionally, the industrial robot arm system should be modified to fit the building industry once the manufacturer and stakeholders believe the building industry will contribute a valuable share to the significant market.

Finally, it is essential to note that this research is an experimental practice by our team, who have years of experience and knowledge in robot technology. We won't encourage duplication of this research without sufficient preparation and skill in this field.

3. Conclusion

This project serves as a combination of research and practice, providing a case for the following:

- Creating a ruled surface shell structure using U-shaped glass and steel frame.
- Employing industrial robot arm technology to perform multiple roles from fabrication to installation.

- Using digital dataflow to manage design, fabrication and construction in a straightforward process and at all possible chances is a primary goal to experiment with the benefit of digital design and fabrication.
- Encouraging the collaboration between robot systems and people to deliver flexible solutions for complex design on the construction site.

Automation in construction [16] is a rapidly growing field with multi-facets to revolutionise the industry, making construction processes faster, safer, and more efficient. Digital design techniques and robotic technology are two aspects of automation that are particularly important in this regard. This project proves how these methods can turn concepts into physical outcomes. Usually, these technologies can help regular projects with more predictable efficiency. The linear process to deliver this glass shell structure demonstrates an integrated solution with structural engineers, manufacturers, and construction workers, offering insight into the potential of automation in construction for leveraging innovative and sustainable buildings.

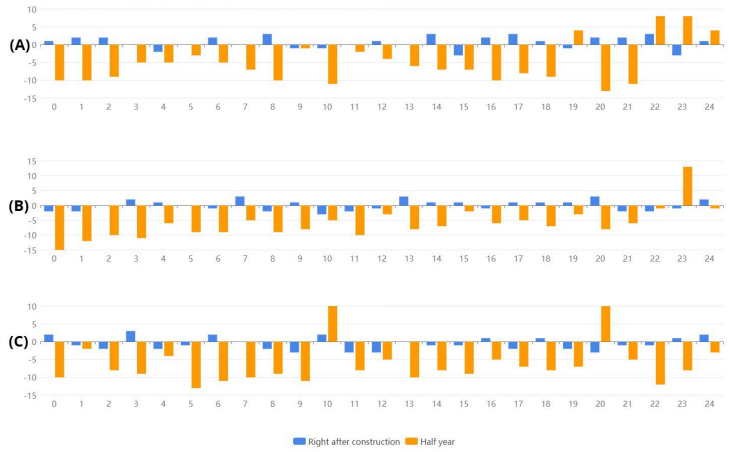

Figure 11. Steel frame survey for joints deviation in mm, vertical axis – deviation, horizontal axis – sectional frame sequent number (1 month & 6 months after).

Despite the fact that this glass shell structure has a positive outcome in reflecting the digital model, there are still some aspects that require further developments for future projects:

- The robot arm system needs to be more flexible to adapt to site conditions. In this project, we must hold the entire team to wait for any modification of robotic code on the construction site, resulting in some unexpected low-efficiency moments. We consider an advantage if tasks can be synchronised between the designer and the site manager for a forehead problem-solving mode.
- The construction materials, particularly steel, need more consideration and pre-calculation. Steel is susceptible to temperature and easily deformed over time. From two sets of surveys on the upper three corners of each sectional steel frame, significant changes occurred in 6 months during the Covid19 lockdown. Due to the distortion caused by temperature change and gravity, some of the joints sagged more than 10mm(Fig 11). A few even broke the tolerance limit, resulting in extensive efforts to revert the bias while installing glass panels.
- Instant site surveys technology, such as GPS and 3D scanning, is an advanced option for achieving better dynamic dataflow. Any conflict or deviation from the centre model can be predicted, assessed and resolved beforehand.

Abstract

Timber truss systems are very efficient load-bearing structures. They allow for great freedom in design and are characterised by a high material utilisation in combination with a low environmental impact. Unfortunately, the extensive effort in design and production have made the manufacturing and application of these structures, at this day and age, a rarity. The authors' goals are to industrialise the design and optimise the production process in order to compete with plate girders, which are characterised by an easy production yet comperatively low material utilisation. The housing of the new robot laboratory of the Institute of Green Civil Engineering at BOKU Vienna is considered a special use case for their current research activities regarding resource-efficient wooden truss structures. In addition to optimising the structure to minimise the environmental impact the production process was performed by the robot building its own house. The main support structure was designed inspired by the work area of the robot resulting in a curved wooden truss. The two research areas: (1) Optimisation of the truss geometry and (2) Optimisation of the joints by using solely wood-wood connections, are addressed in this paper. The numerical optimisation strategy is based on a parametric design of the truss and the use of a genetic solver for the optimisation regarding a minimal material consumption. Furthermore, results of the tensile and compression behaviour of the chosen wood-wood connections are presented.

Keywords: industrialised production, resource-efficient timber structures, structural optimisation, genetic optimisation algorithm, timber trusses, wood-wood connections, engineered wood products

1. Introduction

Wood is a natural inhomogeneous anisotropic material with discontinuities due to defects as for example pitch pockets, branches, fibre twist etc. When used for building construction the original material undergoes multistage sorting and processing [1]–[3]. These processes, and, if applied, gluing, allow for a compensation of the defects resulting in smoother and consequently better material properties. In addition, subsequent geometry changes due to an adjustment of the equilibrium moisture can be reduced. The drawback regarding these products is that the production process is accompanied by many subtractive machining operations. The yield rate sinks to 25 - 35% within the processing of the tree trunk into the finished building component. Consequently, good mechanical properties and advantageous behaviour regarding geometric deformations are the opposite of a low yield of the raw material.

Based on these facts, it can be clearly shown that structural optimisation of building components is of highest importance for an efficient use of the material. Unfortunately, this basic principle is being partly ignored by the wood construction industry in the industrialised countries, which currently clearly focuse on saving costs rather than natural resources, since material costs are (still!) low in comparison to those for personnel. Elements produced using industrialised manufacturing processes are cheaper and therefore preferred to resource-saving yet more complicated structures. Wooden trusses, for example,

are rarely implemented nowadays having been replaced by plate girders, especially for shorter spans, due to economic reasons even though the material yield rate is comparatively lower. [4]

The aim of the authors is to industrialise the design and production process of wood structures in order to allow for a more efficient usage of the valuable material wood while still being economically feasible. The authors split the research development in three subprocesses: (1) Optimisation of the geometry of the supporting structures, (2) Optimisation of the joints, (3) Optimisation of the production technology and the interface between the Computer Aided Design (CAD) and the Computer Aided Manufacturing (CAM). Subprocesses (1) and (2) are addressed within this paper. Work performed in area (3) can be for example found in [5]–[8].

In the robot laboratory of the newly-founded Institute of Green Civil Engineering at BOKU Vienna investigations of different numerical controlled subtractive and additive manufacturing processes can be investigated. The housing of the robot laboratory was part of the currently pursued research strategies and served as the first prototype application.

2. Parametric design and optimisation

The fundamental idea for the new robot laboratory was for the robot, which was set up first, to build its own housing. The shape of the housing was inspired by the work area of the robot, as shown in Section A-A in Figure 1. The main supporting structure was executed as a curved truss solely made from wood and wooden materials without using any steel components. To design the construction, the plug-in Grasshopper [9] for the CAD software Rhinoceros [10] was used, allowing for the creation of a parametric model with variables which were changed throughout the optimisation process in order to obtain different configurations of the truss. The following parameters were defined as variable: number of subdivisions, distance between subdivisions, alignment of the diagonal members and cross section of the members of the truss. The main goal of the optimisation was to minimise the environmental impact while still obtaining the desired load-bearing behaviour.

2.1. Evolutionary algorithm

The Grasshoppers evolutionary solver was used to determine the most efficient truss by varying the previously mentioned geometric parameters. The optimisation strategy of the solver is based on the principle of genetic evolution and consists of five steps to optimise a so-called fitness value [11]. The fitness value represents the numerical parameter which can be optimised by the solver. The goal is to either minimise or maximise the fitness value. In this project a single-objective optimisation was applied, with only one numerical value being optimised in the calculation process at a time.

Subsequently the five optimisation steps of the evolutionary solver are explained. (1) An initial population (different trusses) is randomly assembled by the algorithm from the single slider variables. (2) The fitness values of the resulting trusses are evaluated and qualitatively ranked according to their performance. (3) Trusses are chosen by the algorithm according to a determined selection procedure for further analysis. (4) The variables of the selected trusses are recombined similar to genetic reproduction, to obtain better solutions for the structure. (5) Steps (3) and (4) are repeated until one of the three abort criteria (calculation time exceeded, no improvement, best result achieved) is reached.

2.2. Evolutionary optimisation algorithm

The aim of the optimisation was to achieve the lowest possible wood consumption while maintaining the required static load-bearing capacity while simultaneously complying with the requirements regarding serviceability (deformation). The internal forces of the structure were calculated using the plug-in Karamba3D [12]. The static calculation was conducted according to Eurocode 5 (EN1995-1-1:2019-06-01) and the current Austrian application document within a separately integrated self-programmed tool box. In addition to the calculation of the deformation of the truss, buckling and cross-

section analysis were carried out. The calculation focused on the individual truss members based on a two-dimensional model which prohibits any global buckling of the structure (the nodes were modelled in 2D and therefore fixed out-of-plane).

3. Results

3.1. Reference model

At the beginning a first version of the truss, as shown in (left), was conceptualised based on the authors' engineering know-how. The predefined floor area, the existing roof of the hall as well as the working area of the robot served as boundary conditions. All results of the optimisation are compared to this first reference truss (12 segments, alternating diagonal struts and regular spacing between the subdivisions).

3.2. Boundary conditions

The geometry of the truss is determined by the available area in the existing hall where the robot laboratory is located. It spans from the middle of the hall, where it is fixed directly to the floor, to a support attached to the wall at a height of 4.92 m, resulting in a truss span of 8.20 m.

The geometry of the upper and lower chord is affected by several boundary conditions. The accessibility to the robot laboratory through a 3.20 m high sliding door made it necessary for the truss to not be curved up to that height. The upper part of the truss on the other hand had to follow the shape of the glulam beam of the roof construction of the hall. Based on these limitations the authors decided to focus on the optimisation of the inner structure as well as the cross section of the truss itself. Consequently, the global geometry was not part of the optimisation and the geometries of the upper and lower chords were set as fixed curves.

The applied loads for the supporting structure consist of the dead weight plus the load of the board panelling with 1.0 kN/m, which is applied to the truss at the nodes. The truss is situated inside a machine hall, therefore weather influences like snow and wind are neglected. An additional load of 3.0 kN is applied between 2.0 m and 3.2 m from the existing machine hall wall (the wall to which the right end of the truss is attached). This load is also introduced into the truss via a node and is intended to allow the attachment of cables of possible future experimental setups.

3.3. Optimisation results

Within the optimisation single parameters can be selected individually in order to be changed by the algorithm. The results are summarised in Table 1. Depending on which fitness value is defined and which parameters are released for optimisation, different truss configurations are generated.

Table 1. Results with different fitness values (optimisation with constant cross section).

Fitness value	Reference model	Deformation	Normal force	Mass
