Abstract

This paper presents a simple method to calculate nodal displacements of kinematically indeterminate pin- jointed frameworks using matrix analysis, aiming to facilitate the early-stage design and analysis of space frames. This method can also inform a novel funicular form-finding approach by iteratively accumulating nodal displacements until reaching a new state of equilibrium. This method assumes that the framework is massless and inextensional, and requires only minimal inputs such as the frame geometry, support locations, and force vectors. The method intends to provide fast and preliminary engineering insights into the kinematic behavior of the framework, like identifying critical locations and suggesting new forms that best fit the force vectors. The proposed method can be a useful tool for designers in the early stages of design, providing them with quick and intuitive displacement results to inform design iterations. By using this method, designers can bridge the gap between early-stage designs and in-depth engineering rationalizations. The results can be used to identify potential problems or limitations in the design and suggest improvements or modifications to optimize the design. This method has been implemented as part of a Grasshopper® plug-in that is freely available for designers to explore. Several case studies are also demonstrated to show how this method can facilitate early-stage space frame designs.

Keywords: funicular form-finding, matrix analysis, kinetic indeterminacy, multi-layer space frame

1. Introduction

Space frames are commonly used in the engineering world at various scales due to their lightweight and high efficiency. Usually, the initial form-finding and schematic design requires the participation of experienced engineers with structural intuition and knowledge of structural analysis and material properties. The geometry-based structural design method based on 2D and 3D reciprocal diagrams developed since the 19th century [1–12], namely 2D/3D graphic statics (GS), allows designers without limited knowledge in the engineering field to create, manipulate, and analyze structural forms while knowing the internal force distributions. However, those preliminary structural forms are usually kinematically unstable and are generated solely based on the design loads, which only represent the equilibrium for this specific load case. That is, when the applied loads are different from the design loads, the structural form may have deflections. To ensure their safety and reliability in real-world scenarios with more complex boundary conditions and material properties, it is crucial for professionals to carefully examine and evaluate them using more rigorous engineering methods such as finite element analysis (FEA) before moving into de- sign development. The design process often requires multiple

iterations, and designers usually need to take the evaluation and analysis results to inform and adjust the forms.

There is a gap between the geometric-based form-finding process and the more sophisticated engineering rationalization. To bridge this gap, this paper proposes matrix analysis methods as an intermediate stage, which can provide designers with engineering insights while maintaining clarity and simplicity. During the matrix analysis, a structural form is simplified and abstracted as an easy-to-analyze pin-jointed inextensional framework, and its equilibrium matrix and kinematic matrix (also called compatibility matrix) can be constructed. Although space frames are often made with rigid joints, the behavior of a pin-jointed frame with the same configuration could be a good indicator and estimate of the performance of real engineering structures. By using matrix analysis methods, designers can obtain a wealth of static and kinematic information that cannot be abstracted from the conventional formulation without considerable effort [13]. It allows for a better understanding of the structure's behavior under different load cases and empowers designers to make informed decisions throughout the design process.

Focused on the kinematic aspect of matrix analysis, this paper proposes a way to calculate the nodal displacements using minimal inputs, which can then be exploited to inform a novel approach for form-finding, aiming to facilitate the early-stage design of space frames. Nodal displacements serve as an intuitive indicator and can be used for spotting critical locations for a specific load case. Moreover, the deformed configuration often represents a more appropriate form for this load case, suggesting an approach for form-finding and modification.

1.1. Related work

1.1.1. Matrix analysis on the static and kinematic indeterminacies of pin-jointed frameworks

Matrix analysis is found convenient in organizing calculations in engineering fields such as aerospace, civil, and mechanical engineering. With a focus on pin-jointed frameworks, Calladine [14], Pellegrino and Calladine [15] formulated an algorithm that evaluates the static and kinematic indeterminacies in a rapid manner by determining the rank of equilibrium and kinematic matrices and the bases of its four linear-algebraic vector subspaces. Specifically, it offers complete details of any states of self-stress and modes of inextensional deformation that a framework may possess. Lu et al. [16] adapted this method from bars to faces and applied it to the design of multi-layer sheet-based funicular structures by ensuring all mechanisms are restrained. Pellegrino [17] later presented a matrix algorithm that analyzes the mechanisms and nodal displacements of a pre-stressed network upon change of loads, which leads to a new deformed configuration and can be used for form-finding. This algorithm requires the input of material properties such as Young's modulus and cross-sectional areas of each bar.

1.1.2. Methods for calculating nodal displacements and the corresponding form-finding approaches

Existing form-finding methods of space frames based on nodal displacements can be categorized into three main clusters [18], including geometric matrix methods [19, 20], stiffness matrix methods [21], and dynamic relaxation methods [22, 23]. Geometric stiffness methods are material-independent, with only a geometric stiffness that relates the forces to the length of the edge members. Stiffness matrix methods are based on the standard elastic and geometric stiffness matrices. Both geometric and stiffness matrix methods find the equilibrium by reducing unbalanced forces. Dynamic relaxation methods, on the other hand, calculate the velocity and acceleration for each time increment, until the structure becomes static due to artificial damping. A variety of inputs need to be prepared to use such methods. For stiffness matrix methods, the elastic properties need to be provided to set up the tangent stiffness matrix. For the geometric matrix methods, a prescribed set of force densities together with the applied forces need to be provided in order to find a form. The dynamic relaxation methods also require elastic properties and masses to calculate the physical movements.

1.2. Problem statement and objectives

As stated above, an intermediate stage is desired to bridge the gap between geometric-based form-finding and engineering rationalization. Analysis of equilibrium matrix and kinematic matrix is a great candidate as it can provide a wealth of static and kinematic information without much effort, maintaining simplicity and clarity for early-stage design iterations. However, for more detailed information such as nodal displacements, it still needs to assign material-related parameters to the framework in order to carry out calculations. This paper aims to provide a simple method for calculating nodal displacements that requires minimal input such as the structural form and force vectors on the nodes, hoping to assist preliminary space frame designs and enrich the available toolset. In other words, this method can qualitatively analyze the nodal displacements given a user-defined framework with support conditions. The results can be used in the following ways:

- Display the tendency of nodal displacements if the applied force vectors cannot be balanced.
- Identify critical locations with large displacements.
- Accumulate the displacements incrementally, serving as an accurate kinematic simulation tool.
- Iteratively reverse and accumulate the displacements towards a different state of equilibrium, suggesting a new form that better fits this load case.

2. Method

The construction of the equilibrium matrix and kinematic matrix follows the convention established by Pellegrino and Calladine [15]. The framework is described as b bars (or edges) pin-jointed by j nodes (or vertices) with k supported dimensions, each supported dimension defined as constrained movement along one direction. Two kinematic variables and two static variables are considered, they are displacements of the vertices assembled in a $[3j-k \times 1]$ vector $\mathbf{d}$; elongation coefficients of the edges assembled in a $[b \times 1]$ vector $\mathbf{e}$, each entry defined as $e_i \times l_i$ where e_i is the elongation of the i-th edge, l_i is the edge length; external forces on the vertices assembled in a $[3j-k \times 1]$ vector $\mathbf{f}$; and tension densities in the edges assembled in the $[b \times 1]$ vector $\mathbf{t}$, each entry defined as t_i/l_i where t_i is the tension of the i-th edge. The elongation coefficients and tension densities can be easily turned to the actual elongations and tensions as the edge lengths are known. All forces applied to each node must be in equilibrium, written as

$$\mathbf{A} \cdot \mathbf{t} = \mathbf{f}, \tag{1}$$

where $\mathbf{A}$ is the $[3j-k \times b]$ equilibrium matrix. And all extensions in the edges must be compatible with the nodal displacements, written as

$$\mathbf{B} \cdot \mathbf{d} = \mathbf{e}, \tag{2}$$

where $\mathbf{B}$ is the $[b \times 3j-k]$ kinematic matrix, or compatibility matrix. It's easy to prove by the principle of virtual work that the equilibrium matrix and kinematic matrix are the transposes of each other [14]

$$\mathbf{B} = \mathbf{A}^{\mathbf{T}}. \tag{3}$$

2.2. Calculation of unbalanced forces

Eq.1 is helpful in terms of calculating the forces in the edges given $\mathbf{f}$. However, not all $\mathbf{f} \in \mathrm{R}^{3j-k}$ can be in equilibrium when $\mathbf{f}$ lies in the column space of the equilibrium matrix $\mathbf{A}$. Otherwise, mechanisms (pin-joints) will be activated when it lies in the left null space of $\mathbf{A}$. In such cases, if the framework has

no mass, then the least squares solution of $\mathbf{t}$, denoted as $\hat{\mathbf{t}}$, can be used to estimate the edge forces, calculated as

$$\hat{\mathbf{t}} = (\mathbf{A}^{\mathbf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathbf{T}}\mathbf{f} \tag{4}$$

when $\mathbf{A}$ has a full rank. If not, $\hat{\mathbf{t}}$ can be calculated as

$$\hat{\mathbf{t}} = \mathbf{A}^{+}\mathbf{f}, \tag{5}$$

where $\mathbf{A}^{+}$ denotes the Moore-Penrose Inverse of $\mathbf{A}$. The principle of least action can provide some evidence for it. The action S of the framework is defined as the integral of the Lagrangian L between time t_1 and time t_2, written as

$$S = \int_{t_1}^{t_2} L(t)dt \tag{6}$$

where L is the difference of the kinetic energy T and potential energy V.

$$L = T - V \tag{7}$$

For the framework, it's assumed as particles connected by massless bars. Let the mass of each particle be m, then T and V can be written as

$$T = \frac{1}{2}\sum_{a=1}^{3j-k} mv_a^2 \tag{8}$$

$$V = \sum_{i=1}^{j-k_z} mgz_i \tag{9}$$

where v_a is the velocity of the particles along each 3D Euclidean axis, z_i denotes the z-coordinate the the i-th particle, and k_z denotes the number of nodes that have their z-coordinate constrained.

Since the whole system is not in equilibrium, the velocity v_a will be determined by the summation of all external forces and all axial forces in the edge members, namely residual forces or unbalanced forces and assembled in a $3j$ - k vector $\mathbf{f_r}$, written as

$$\mathbf{f_r} = \mathbf{f} - \mathbf{A}\hat{\mathbf{t}} \tag{10}$$

where external forces $\mathbf{f}$ and equilibrium matrix $\mathbf{B}$ are known. Then the Lagrangian of the middle point is used to approximate the Lagrangian for the small time interval dt. The vertex velocities, assembled in a $3j$ - k vector $\mathbf{v}$ can be written as

$$\underset{\mathbf{t}\in\mathbb{R}^e}{\text{minimize}}\ \mathbf{L} = \mathbf{T} - \mathbf{V} = \frac{1}{2}\sum_{a=1}^{3j-k} mv_a^2 - \sum_{i=1}^{j-k_z} mgz_i = \frac{dt^2}{8m}\mathbf{f_r^2} - \sum_{i=1}^{j-k_z} mgz_i. \tag{12}$$

When the masses of the vertex particles are infinitely small, then the kinetic energy in the Lagrangian becomes dominant:

$$\underset{\mathbf{t}\in\mathbb{R}^e}{\text{minimize}}\ \mathbf{L} = \frac{dt^2}{8m}\mathbf{f_r^2}. \tag{13}$$

which is equivalent to solving for the least square solution $\hat{\mathbf{t}}$ of Eq. 1, proving that the residual forces $\mathbf{f_r}$ can be calculated by Eq. 10. When the frame is kinematically determinate, the kinematic indeterminacy *m* equals zero:

$$m = 3j - k - r_{\mathbf{A}} = 0, \tag{14}$$

where the rank of **A** is denoted as $r_{\mathbf{A}}$. This shows **A** has a full rank and Eq.1 has a solution. In this case, the unbalanced forces will be zero.

2.3. Transforming unbalanced forces to nodal displacements

As mentioned by Pellegrino [17], any infinitesimal inextensional displacement from the original configuration, while leaving the prestress unchanged, results in unbalanced loads of magnitude proportional to the size of the displacement. This is also true in our case when restress does not exist. That means the nodal displacements in the inextensional mode can be directly represented as the residual forces $\mathbf{f_r}$ multiplied by a user-specified scale factor ξ

$$\mathbf{d} = \xi \mathbf{f_r}. \tag{15}$$

This can be proved using Eq. 2

$$\mathbf{Bd} = \xi \mathbf{B} \mathbf{f_r}. \tag{16}$$

Substitute $\mathbf{f_r}$ using Eq.10,

$$\mathbf{Bd} = \xi \mathbf{B}(\mathbf{f} - \mathbf{A}\hat{\mathbf{t}}). \tag{17}$$

Then substitute $\hat{\mathbf{t}}$ using Eq.4, and substitute **B** using Eq.3,

$$\mathbf{Bd} = \xi \mathbf{A^T}(\mathbf{f} - \mathbf{A}(\mathbf{A^T A})^{-1}\mathbf{A^T f}) = \xi(\mathbf{A^T f} - \mathbf{A^T A}(\mathbf{A^T A})^{-1}\mathbf{A^T f}) = \xi(\mathbf{A^T f} - \mathbf{A^T f}) = \mathbf{0}, \tag{18}$$

which shows zero edge elongation coefficients, meaning that the nodal displacements are under inextensional mode. That is, there won't be any edge elongation during the displacement, and the result can be a good estimation of the behavior of pin-jointed rigid bars. Note that the above calculations are based on the small displacement theory. The displacement results are accurate when $\xi\mathbf{f_r}$ is small. Otherwise, matrices **A** and **B** are no longer valid and need to be updated.

2.4. Accumulation of the small displacements

Given the applied force vectors are unchanged and always attached to the nodes, the small displacements can be incrementally accumulated until the frame reaches a new form where all applied force vectors can be balanced and there is no force residual. This process simulates the more accurate kinematic behavior of the frame in response to the applied forces. Note that matrices **A** and **B** need to be updated after each step. The updated equilibrium matrix and kinematic matrix are denoted as $\mathbf{A'}$ and $\mathbf{B'}$, respectively. Again, when $\xi\mathbf{f_r}$ is small the displacements are accurate at each step and the change of edge lengths is negligible. The Moore-Penrose Inverse can be used again to determine whether the applied forces are all balanced. The deformed frame reaches a stable state only when Eq.19 holds:

$$\mathbf{f} = \mathbf{A'A'^{+}f}. \tag{19}$$

2.5. Accumulation of the reversed displacement: towards a novel form-finding approach

Instead of deforming along the displacement direction, the frame can also deform opposite to the displacement direction at each step, acting like a pre-deformation to counteract the displacements. This iterative operation is the same as the process described in Section 2.4, except that the displacements applied to the frame are reversed at each step. After reaching a new state of equilibrium, the new frame geometry will represent a new form that fits the applied load. The computational pipeline of those processes is illustrated in Figure 1.

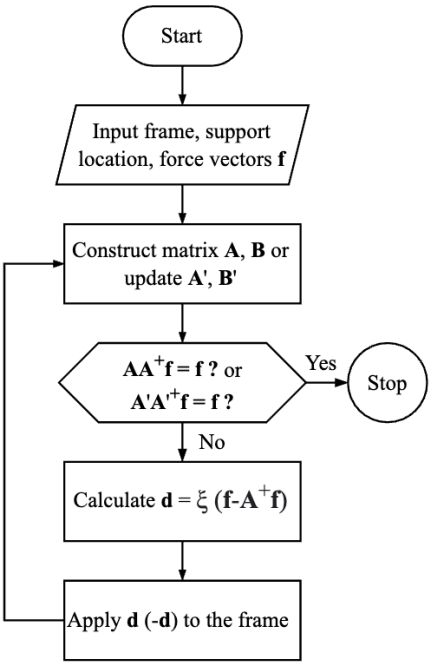

Figure 1. The computational flowchart of incremental accumulation of the (reversed) displacements.

3. Case study

The above-mentioned process has been implemented and included as part of a Grasshopper® plug-in named PolyFrame 2 [24]. The matrix computations are supported by Numpy.NET [25], a .NET binding of the scientific computing library Numpy [26]. With the help of this implementation, several studies are created to demonstrate the possible use cases.

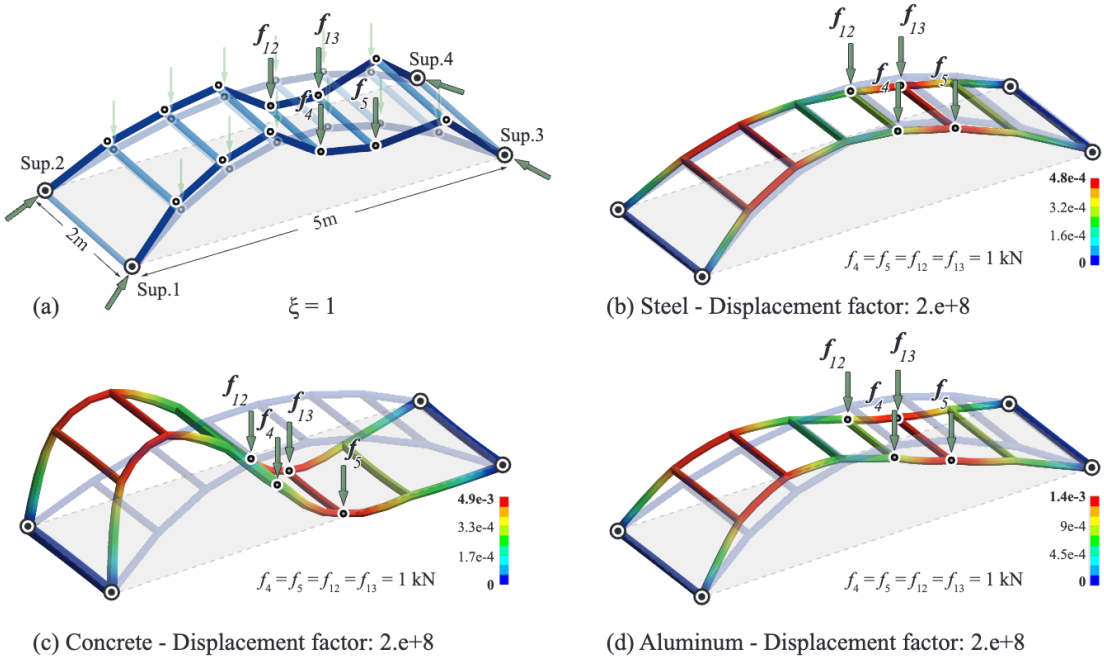

Figure 2. Compare the nodal displacement result with FEA.

3.1. Deformation estimation

Although this proposed method for calculating displacements is based on many assumptions such as massless frame, frictionless pin-joint, and rigid edge, the result can still represent a qualitative estimation of the real behavior of a structure. Figure 2 shows the comparison of analysis results between this proposed method and the finite element method (FEM). For the FEM, three different materials are simulated. The results manifest clear relevance between the simple nodal displacement results and the more rigorous FEM results.

3.2. Simulate the kinematic behavior or find a new form

Figure 3 shows the incremental accumulation of the nodal displacements from an initial flat grid network. In each step, if the displacements are applied to the previous state of the frame, the result will be a kinematic simulation in response to the external forces (Figure 3a); otherwise, the result will show a new form that better fits the applied forces (Figure 3b, 4).

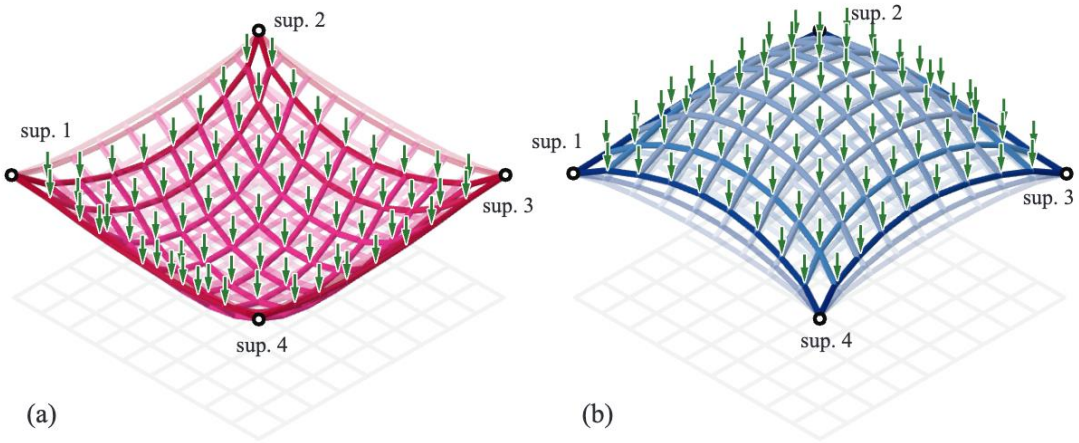

Figure 3. (a) The nodal displacements are iteratively applied to the frame, (b) The reverse of the nodal displacements are iteratively applied to the frame.

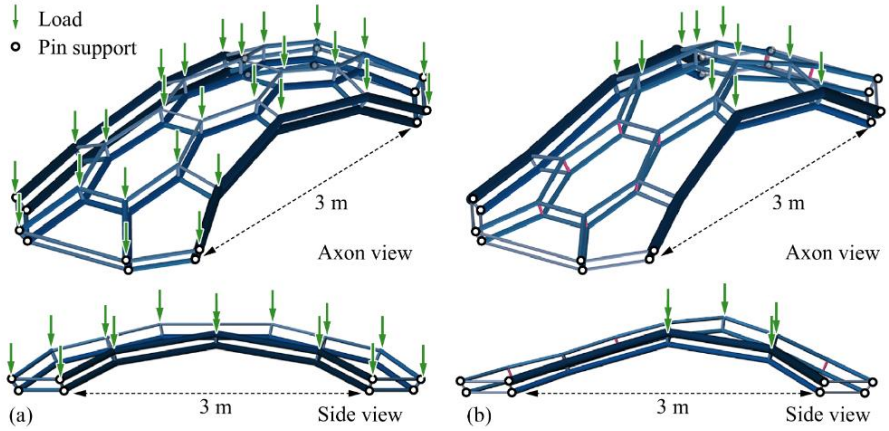

Figure 4. By applying the reverse of the asymmetrical forces, a new bridge geometry can be found that better fits the new load case.

4. Conclusion

This paper presents a simple method to calculate nodal displacements of a pin-jointed framework under a group of force vectors using matrix analysis. This method assumes that the framework is massless and inextensional, and requires only minimal inputs such as the frame geometry, support locations, and force vectors. The method intends to provide fast and preliminary engineering insights into the kinematic behavior of the framework, like identifying critical locations and suggesting new forms that best fit the force vectors. The proposed method can be a useful tool for designers in the early stages of design, providing them with quick and intuitive displacement results to inform design iterations. By using this method, designers can bridge the gap between early-stage designs and in-depth engineering rationalizations. The results can be used to identify potential problems or limitations in the design and suggest improvements or modifications to optimize the design. This method has been implemented as a software tool that is freely available for designers to explore. Several case studies are also demonstrated to show how this method can facilitate early-stage space frame designs.

In summary, the proposed method enriches the toolset for designing space frames, allowing designers to make informed decisions based on preliminary engineering analysis, and saving time and resources in the design iteration process.

Abstract

The Harmony Search (HS) algorithm, inspired by the process of tuning musical instruments, is widely used in optimizing various fields due to its simplicity and ease of use. The Binary Harmony Search (BHS) algorithm was developed to enhance search techniques in binary number optimization problems such as the knapsack problem of the decimal-based HS algorithm. In the development of BHS, it was discovered that the role of the pitch-adjust rate (PAR) operator could be improved by addressing the issue of the mutation operator. However, the success of binary-based algorithms in more complex problems heavily depends on how the PAR operator is defined. To address this issue, this study compared the characteristics of the algorithm according to the PAR operator with the decimal-based HS and bit-based algorithms and analyzed the results.

Keywords: optimization, harmony search, binary number, benchmark function, plane truss, minimum weight

1. Introduction

The term "metaheuristic" was first used in the 1980s to describe an optimization algorithm designed to find an optimal solution [1]. In the 2000s, several metaheuristic algorithms, including Particle Swarm Optimization, Ant Colony Optimization, and Harmony Search Algorithm, were developed for optimization problems. The Harmony Search (HS) algorithm is a metaheuristic algorithm that imitates the process of musical improvisation to find harmony through the combination of musical notes. It was introduced by Geem [2] in 2001. The Harmony Memory (HM) is created by selecting notes from musical instruments with a probability to achieve better harmonies. The size of the Harmony Memory Size (HMS) affects the convergence speed and precision in the search process. The HS algorithm is a stochastic search algorithm that employs a probabilistic approach to finding an optimal solution. The HS algorithm consists of several critical parameters. To find an optimal solution for the fitness function $f(x)$ subject to decision variables x_i $(i = 1,2, \dots, n)$ where n is the dimension of the problem, the Harmony Memory (HM) needs to be initialized. A new harmony is generated by the Harmony Memory Consideration Rule (HMCR) and Pitch Adjustment Rule (PAR), denoted as x_i' . HMCR is the probability of selecting a value from the HM when generating a new harmony and typically takes a value between 0.7 to 0.95. PAR controls the amount of random perturbation introduced in the selected values when generating a new harmony and usually takes a value between 0.1 to 0.5 [1]. The tune can be adjusted depending on the width of the b_w. After generating a new harmony, the Harmony Memory is updated, and the same process is repeated until the stopping criterion is met. The best harmony stored in HM is used to find the optimal solution. Figure 1 illustrates the process of the HS algorithm.

The Harmony Search (HS) algorithm is a well-known metaheuristic optimization algorithm that is primarily used for decimal-based optimization problems. However, the application of the HS algorithm to binary-coded problems is an emerging field of research. The Binary Harmony Search (BHS) algorithm was first introduced by Geem [2] to solve a water pump switching problem. Since then, various modifications to the BHS algorithm have been proposed to enhance its performance. Kong et al. [3] introduced the Hybrid BHS Algorithm, which adapts the search mechanism of the Ant System. Additionally, Ling et al. [4] proposed an Adaptive BHS Algorithm. The BHS algorithm was developed to improve search techniques in binary number optimization problems, such as the knapsack problem of the decimal-based HS algorithm. It has been widely applied in various fields, including architecture engineering, where it has been used to optimize truss topology and member sizing[5][6]. It is important to note that the optimal values of the HMCR and PAR parameters in the BHS algorithm may vary depending on the characteristics of the specific binary optimization problem being solved. Ongoing research and development in the field of metaheuristics are essential for the continued advancement of optimization algorithms. As mentioned in the abstract, the binary HS operator is more complicated to find a good solution. Thus, we will create the binary HAS according to the HMCR and PAR skills.

2. Binary search algorithm

The Binary Harmony Search (BHS) algorithm is a variant of the Harmony Search (HS) algorithm, which is a population-based optimization algorithm that aims to find the optimal solution through a musical improvisation process. The BHS algorithm builds upon the HS algorithm by using a binary coding process for decision variables to solve binary optimization problems, where the variables take on only two values (0 or 1). This extension allows the BHS algorithm to efficiently explore and exploit the solution space of binary optimization problems. The BHS algorithm has demonstrated its effectiveness in solving a wide range of binary optimization problems.

    end while
    Output results
end procedure
```

Figure 1. Pseudo Code of a Classic Harmony Search (HS) Algorithm

To compare the Harmony Search (HS) algorithm and the Binary Harmony Search (BHS) algorithm, the pseudo-code for each algorithm is provided in Figure 1 and Figure 2. It should be noted that the HS algorithm is based on decimal arithmetic, while the BHS algorithm employs binary arithmetic. Two types of the BHS algorithm are proposed in this section for further investigation. This comparison is essential to determine the effectiveness of the BHS algorithm and to evaluate the impact of binary arithmetic on the optimization process. By providing the pseudo-code for both algorithms, it is possible

to gain a better understanding of the differences between the two and to analyze their performance in solving optimization problems.

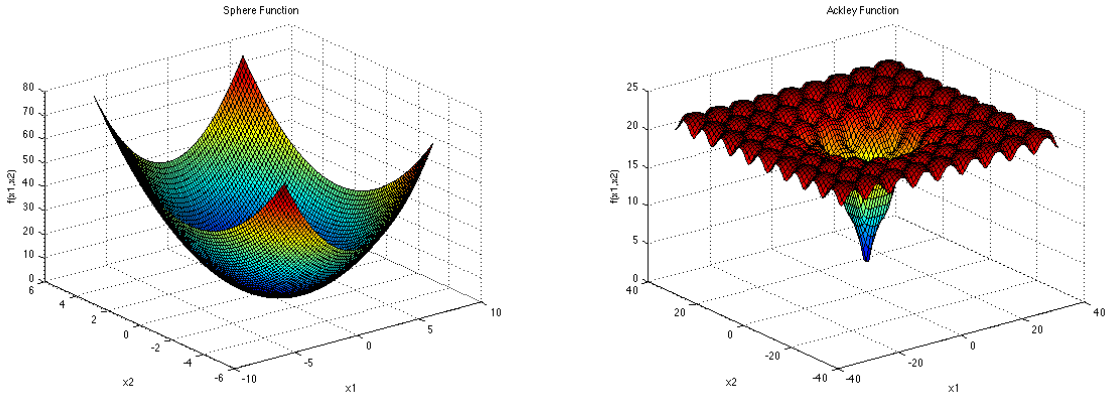
(b) Type B

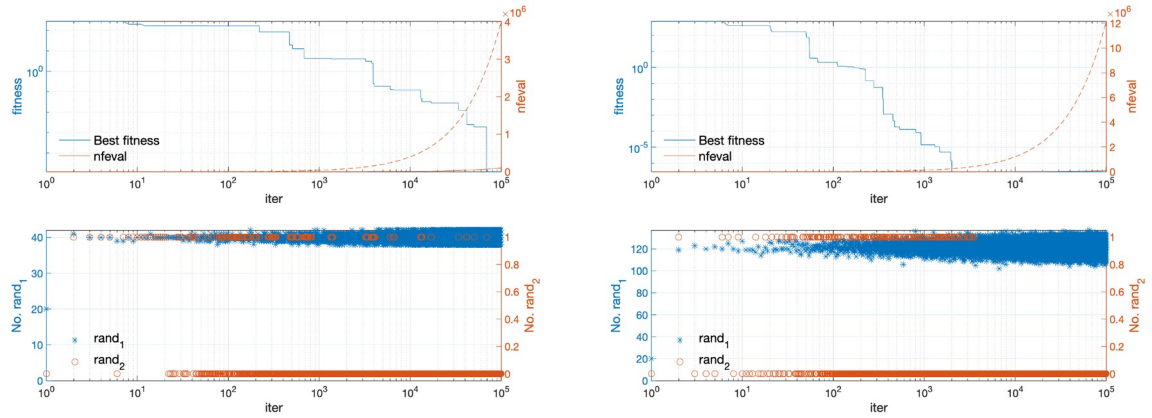
Figure 2. Pseudo-Code of a Binary-coded Harmony Search (BHS) Algorithm



To handle the binary value problem, we can consider two types of binary HS operators. One is, as Figure 2(a), binary HS based on decimal asymmetric. And the other, as Figure 2(b), is based on the binary value. In this work, we compare these types of operators.

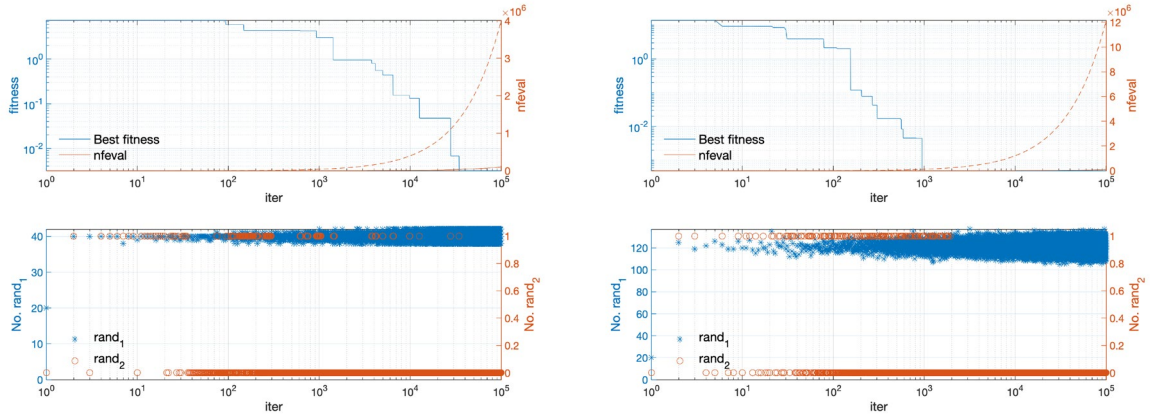
2.2. Benchmark function

This section utilized the Harmony Search (HS) and Binary Harmony Search (BHS) algorithms to optimize a benchmark function and find the optimal solution. The benchmark function was constructed based on two mathematical models: the Sphere (1) and Ackley (2) functions, which are commonly used benchmark functions in optimization studies due to their simplicity and effectiveness in evaluating algorithm performance. Figure 3 displays the graphs of each benchmark function. The Sphere function represents a convex quadratic function with a single minimum, while the Ackley function represents a non-convex function with multiple local minima. The study aimed to compare the performance of the HS and BHS algorithms in finding the global minimum of the benchmark function. We compared how well the BHS algorithm and the HS algorithm work to see if using binary code for solutions is effective.



$$f(x) = \sum_{i=1}^{n} x_i^2 \tag{1}$$

$$f(x) = -ae^{\left(-b\sqrt{\frac{1}{d}\sum_{i=1}^{n} x_i^2}\right)} - e^{\left(\frac{1}{d}\sqrt{\cos(cx_i)}\right)} + a + e^1 \tag{2}$$



(a) Sphere Function (b) Ackley Function

Figure 3. Graph of Benchmark Function

(a) Type A considering fixed b_w (b) Type B

Figure 4. Result of Sphere Function

(a) Type A considering fixed b_w (b) Type B

Figure 5. Result of Ackley Function

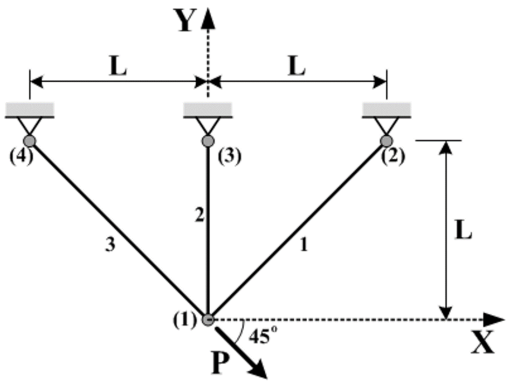
Figures 4 and 5 illustrate the results of the study, where (a), (b), and (c) demonstrate the results of type A and (d) represents the type B. In particular, (a) displays the result when b_w was not considered, (b)

shows the result when a fixed b_w was used, and (c) illustrates the result when b_w was decreased. The graph shows that as the amount of increasing generation, the optimal solution converges. By storing candidates in the harmony memory, it can be seen that Type B has excellent convergence performance. Type B has three times the amount of random generator than Type A, but its convergence performance is excellent.

3. Three bar truss optimization problem

As an illustrative example, the present study addresses the optimal design problem of a truss structure comprising three members is in Figure 6. The objective of this investigation is to optimize the performance of the truss by minimizing the weight of the structure while satisfying the design constraints. To this end, a set of benchmark functions were utilized to evaluate the convergence rate of the optimization algorithm. Figure 4 show the truss structure with three members [14], where the cross-sectional areas of member 1 and member 3 are held constant. The optimization problem is formulated with the objective function (3), in which x_1 and x_2 are the design variables representing the cross-sectional areas of members 1 and 3, respectively. The values of x_1 and x_2 are adjusted to optimize the weight of the structure. Figure 7 shows the analysis results using the BHS operator.

$$f(x_1, x_2) = 2\sqrt{2}x_1 + x_2 \tag{3}$$



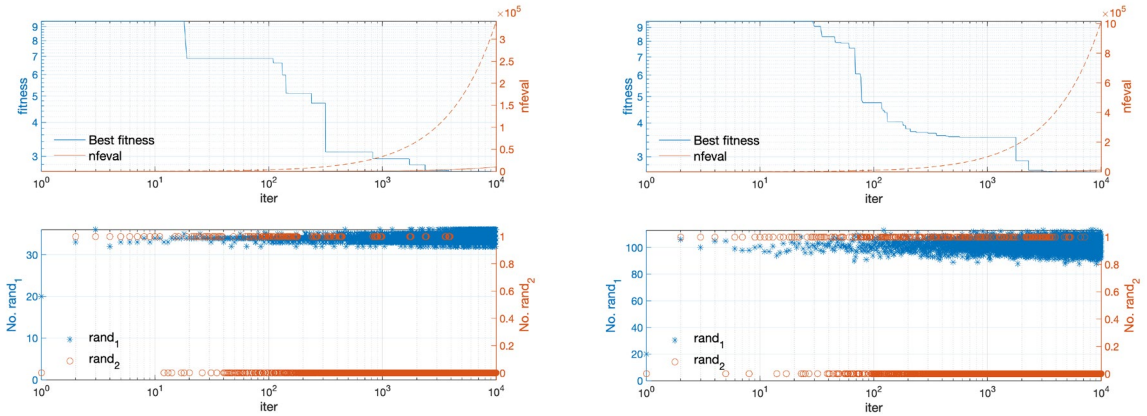


Figure 6. Three-Member Truss

4. Conclusion: submission of contributions

This work investigated the characteristic of the Binary Harmony Search (BHS) algorithm according to HS operator skill. Through experiments to benchmark function, we check the performance of the operator. Type A has a smaller number of random numbers than Type B, but Type B has better convergence performance than Type A. The results of this study indicate that the BHS algorithm is an effective method for addressing binary optimization problems and may have broad applications in various fields.

Abstract

Cold-formed steel (CFS) members are widely used in low-to-medium rise light steel building construction due to their lightweight, fabrication versatility and low production costs. Optimising the conventional CFS (CCFS) members for enhanced load-bearing capacity and less material consumption will lead to efficient and economical construction solutions. This study presents two applications of (i) an optimised folded-flange lipped channel sections for roof purlins and (ii) an optimised folded-flange "*Sigma*" sections for wall studs. The aim of this study is to minimise the cross-sectional areas of the individual shape-optimised CFS sections with the same load-bearing capacity as the corresponding CCFS ones for these applications. The optimisation process for each application results in five shape-optimised sections having 100%, 80%, 60%, 40% and 20% of the cross-sectional area of the CCFS section. The elastic buckling analyses of all the optimised CFS sections are conducted using *CUFSM* software based on the Finite Strip Method (FSM), and the obtained buckling stresses are used to determine the nominal capacity of each optimised CFS sections using the Direct Strength Method (DSM). The area-capacity curves for the five shape-optimised sections indicate that the cross-sectional areas of the optimal CFS cross-sections for a roof purlin and a wall stud are 89.2% and 52.7% of the CCFS area, respectively. Furthermore, a finite element analysis of the obtained optimal cross-sections is conducted in *Strand7* to validate the reliability of the optimisation process.

Keywords: cold-formed steel (CFS), shape-optimised sections, optimal cross-sectional area, load-bearing capacity, finite element analysis

1. Introduction

Cold-formed steel (CFS) is a kind of semi-finished or finished product made from rolled or pressed thin-walled coiled or flat bars without any heat treatment. Due to the high strength-to-weight ratio, dimensional stability, flexibility in cross-sectional profiles, and ease of fabrication and transportation, CFS is considered a more cost-effective construction material being widely used in low-to-medium rise light steel buildings and modular construction [1,2]. Conventional cold-formed steel (CCFS) members are mainly available in *Cee*, *Zed* and *Sigma* profiles with or without local stiffeners (Figure 1). They are commonly used as flexural members of structural frames for specific applications such as roof purlins, girts and wall studs [3] (Figure 2(a)). Due to its thin-walled nature, the strength and efficiency of a CFS cross-section are usually governed by a combination of three basic modes of buckling, viz. local, distortional and global buckling, which are closely related to the shape of the CFS section [4]. The Direct Strength Method (DSM) [5], by integrating the computational stability analysis into the design process, can be used to determine the capacity of members accounting for these three buckling modes. DSM is based on the elastic buckling analysis and has the advantage of dealing with the entire section of the CFS member rather than on individual elements [6].

Optimisation of CCFS members can increase load-bearing capacity and reduce material consumption. Such an enhancement at the component level can also increase the overall capacity of the CFS frame system [7]. In general, the optimisation of CFS members can be divided into two categories: (i) shape optimisation, where the profile of the cross-section is changed to obtain an innovative shape [4,8,9], or (ii) size optimisation, where the optimal dimensions of the cross-section with a predefined shape can be obtained [10,11]. The study presented in this paper is focused on the size optimisation process for two shape-optimised sections (SOCFS) applied to roof purlins and wall studs, with the aim of minimising the cross-sectional areas of the individual SOCFS section with the same load-carrying capacity as the corresponding CCFS ones for these applications. The elastic buckling analyses of all the optimised CFS sections are conducted using *CUFSM* software based on the Finite Strip Method (FSM) [12], and the obtained buckling stresses are used to determine the nominal capacity of each optimised CFS member by DSM. Furthermore, a finite element analysis of the obtained optimal members is also conducted to validate the reliability of the optimisation process.

(a) (b) (c)

Figure 1. Conventional CFS sections with or without stiffeners, (a) "*Cee*", (b) "*Zed*", and (c) "*Sigma*".

2. Structural models

Two structural models are considered to investigate the optimisation problem: (i) a 2,100*mm* span, simply supported roof purlin subjected to a nominal bending moment M_b, with a shape-optimised folded-flange lipped channel section (Figure 2(b)), and (ii) a 2,400*mm* length, simply supported wall stud subject to an axial compressive load N_c, with a shape-optimised folded-flange "*Sigma*" section (Figure 2(c)).

The reference SOCFS cross-sections (Figures 3(b) and 4(b)), produced by Wang et.al [1], were optimised from the unconstrained simply-supported CFS beams. The previously developed augmented Lagrangian Genetic Algorithm (GA) [11] was used as a "self-shape" optimisation algorithm to find the new cross-section, which aims for minimising the cross-sectional area subject to an inequality penalty function (Eq. (1)) on a uniform bending moment M^* and a compressive axial load N^*.

$$\frac{N^*}{\phi_c N_c} + \frac{M^*}{\phi_b M_b} \leq 1 \tag{1}$$

where ϕ_c and ϕ_b are the capacity reduction factors, taken as 1.0 [13].

In this algorithm, GA serves as the search algorithm by using the cross-over operator and mutation operator to generate superior offsprings, the Augmented Lagrangian (AL) method is combined as a powerful tool to avoid the ill-conditioned process by controlling the penalty factors to remain finite [14]. The fitness function suitable for GA and AL was determined as Eq. (2) and Eq. (3), respectively.

$$f(GA) = \frac{A_s}{A_{ref}} + \alpha\{\max[0, (\frac{N^*}{\phi_c N_c} + \frac{M^*}{\phi_b M_b} - 1)]\} \tag{2}$$

In Eq. (2), A_s is the cross-sectional area of the optimised cross-section, A_{ref} is the reference area of similar value to the optimised cross-sectional area, and α is a penalty factor [1].

$$f(AL) = \frac{A_s}{A_{ref}} + \frac{1}{2}\{\gamma + [\max(0, (\frac{N^*}{\phi_c N_c} + \frac{M^*}{\phi_b M_b} - 1) + \mu)]^2\} \quad (3)$$

In Eq. (3), γ is the penalty function coefficient, and μ is the real parameter to the penalty function [1].

The optimised folded-flange lipped channel section was obtained from the CCFS *Cee* section without stiffeners (Figure 3(a)), which can be characterised as a four-element (① to ④) per half cross-section type, in Figure 3(b), for the roof purlin model. The optimised folded-flange "*Sigma*" section was obtained from the CCFS *Cee* section with stiffeners (Figure 4(a)), in which the eight elements (① to ⑧) per half cross-section is the fittest to the wall stud model (Figure 4(b)).

The CCFS *Cee* cross-sections with and without stiffeners considered in this study were chosen from the design manuals *Rondo* [15]and *LYSAGHT* [16], respectively. The area of a cross section can be simply determined by multiplying its thickness by its perimeter. Note that the area and the thickness of the initial SOCFS (e.g. Figure 3(b)) are the same as those of the CCFS (e.g. Figure 3(a)). Note also that the aspect ratio remains the same for CCFS and SOCFS. Thereafter, the total length of all the elements in an individual SOCFS can be derived. Then the length of each element that forms the cross-section can be mathematically calculated based on the element's orientation [1]. Since the aspect ratio and the thickness of the cross-section remain constant, reducing the length of each element in the initial SOCFS (e.g. Figure 3(b)) with the same proportion can result in a correspondingly reduced cross-sectional area of the subsequent SOCFS (e.g. Figures 3(c) to (f)). In this study, the cross-sectional area of the SOCFS is gradually reduced to 80%, 60%, 40% and 20% of the CCFS section (A_{CS}), for both roof purlin and wall stud members.

3. Numerical analysis

3.1. Elastic buckling analysis

Elastic buckling analysis is a technique for determining the buckling loads and deformed shapes when a structure becomes buckled and unstable. It allows to obtain the buckling stress f_o under the corresponding buckling modes, which can subsequently be used to determine the bearing capacity of the CFS cross-sections. In this study, the elastic buckling analyses were carried out using the software *CUFSM*, which was developed based on the Finite Strip Method (FSM) and can provide a quick analysis to obtain the buckling load factors by entering the basic parameters, such as the element coordinates, dimension and thickness, and the expected loads of the CFS sections. The obtained buckling load factors are expressed as the ratio of the elastic buckling stress f_o to the steel yield stress f_y. The principles for distinguishing and determining the three buckling load factors, viz. f_{oe}/f_y (global buckling), f_{ol}/f_y (local buckling) and f_{od}/f_y (distortional buckling), are described in detail in Section 4.2. Table 1 and Table 2 list the obtained local (f_{ol}/f_y) and distortional (f_{od}/f_y) load factors for each cross-section of the roof purlin and wall stud members. The buckling stresses f_{ol} and f_{od} can then be determined which are also given in Tables 1 and 2.

3.2. Bearing behaviour

The Direct Strength Method (DSM) was used in this study to calculate the bearing capacity of all cross-sections. It is based on AS/NZS 4600 [13] and employs the strength curves on the entire CFS member rather than the isolated cross-sectional elements [17]. The DSM allows the calculation of the nominal bearing capacities under local, distortional and global buckling modes by using the corresponding buckling stresses and the design bearing capacity is determined as the minimum of these three values. In this study, the design bending moment applied to the roof purlin structural model can be determined as

$$M_b = \min (M_{bl}, M_{bd}, M_{be}) \tag{4}$$

where M_{bl}, M_{bd}, and M_{be} are the nominal bending capacities for local, distortional, and global buckling modes, respectively.

Similarly, the design axial compressive load applied to the wall stud structural model was expressed as

$$N_c = \min (N_{cl}, N_{cd}, N_{ce}) \tag{5}$$

where N_{cl}, N_{cd}, and N_{ce} are the nominal axial compressive capacities for local, distortional, and global buckling modes, respectively.

The calculated M_b and N_c for the roof purlin and wall stud cross-sections are also summarised in Table 1 and Table 2, respectively.

4. Results and discussion

4.1. Optimal cross-sectional area

According to Table 1 and Table 2, the piecewise linear area-capacity curves for the five SOCFSs can be plotted for the roof purlin and the wall stud structural models, respectively, in Figures 5(a) and (b). It can be seen that the initial SOCFS with a cross-sectional area of $100\%A_{CS}$ (e.g. point B1 in Figure 5(a)) has a greater bearing capacity than the CCFS (e.g. point A1 in Figure 5(a)) for both roof purlin and wall stud sections, which validates the shape optimisation outcomes that the SOCSF has a higher strength than that of the corresponding CCFS with the same cross-sectional size [1]. By drawing a horizontal line from the CCFS point (e.g. point A1), an intersection point with the plotted area-capacity curve, denoted as a blue triangle in the diagram, was obtained indicating that the optimal SOCFS has the same load carrying capacity as the CCFS. Given the linear relation between every two adjacent SOCFS points on the area-capacity curve, the cross-sectional areas of the optimal SOCFSs for the roof purlin and wall stud sections can be determined by linear interpolation.

Specifically, for the roof purlin member, the optimal SOCFS point in Figure 5(a) falls between points B1 and C1, on a linear line which can be expressed as

$$y = 0.0214x\text{-}1.65 \tag{6}$$

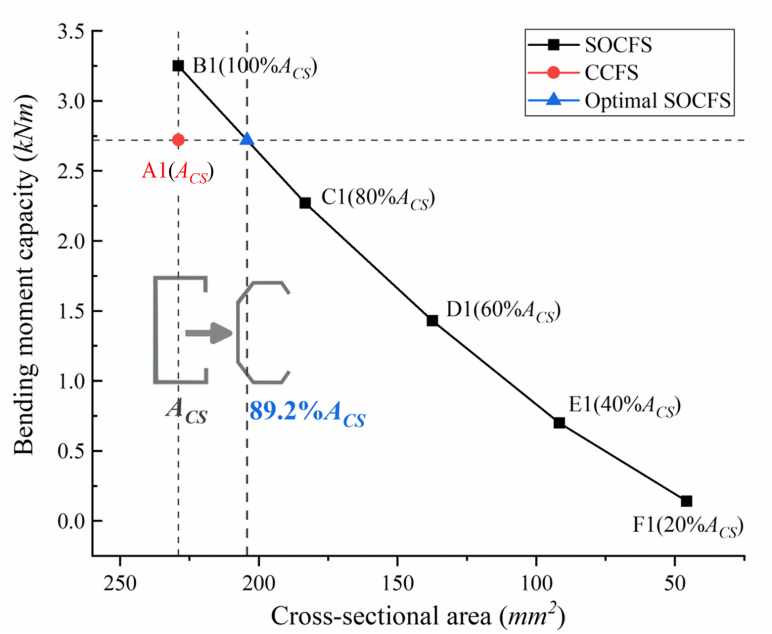
where x is the cross-sectional area and y is the bending moment capacity.

By substituting the same bending moment capacity of 2.72 *kNm* as the CCFS into Eq. (6), the optimal cross-sectional area of the roof purlin member is determined to be $204.2mm^2$, which is only $89.2\%A_{CS}$.

Similarly, the optimal SOCFS point for the wall stud member falls between points D2 and E2 in Figure 5(b), also on a linear line which can be expressed as

$$y = 0.1646x+3.1872 \tag{7}$$

where x is the cross-sectional area and y is the axial compressive capacity.



Taking the same axial compressive capacities of the SOCFS and CCFS of 10.73kN, the optimal cross-sectional area of the wall stud member can be calculated using Eq. (7) as 45.85mm^2, which is only 52.7%A_{CS}.

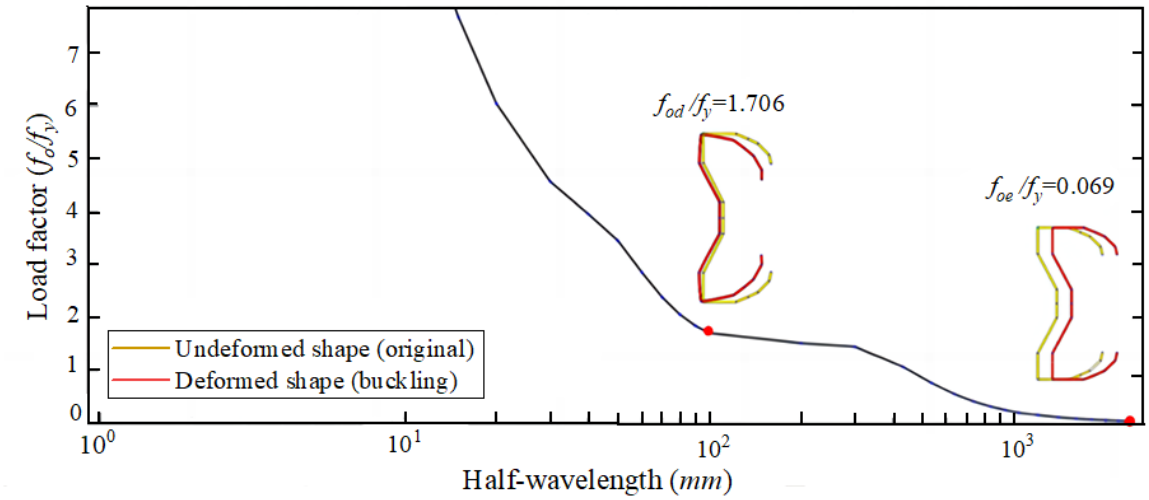
4.2. Validation of CUFSM results using finite element analysis

In order to verify the accuracy of the optimal SOCFSs for the roof purlin and wall stud members as described above, a finite strip analysis in *CUFSM* and a finite element analysis in *Strand7* were performed. Note that the elastic local and distortional buckling modes cannot be distinctly identified in *Strand7*. Therefore, this validation study only focused on the global buckling mode which is readily obtainable in *Strand7* and *CUFSM*.



For the individual optimal roof purlin and wall stud sections, the buckling load factor (f_o/f_y) versus the half-wavelength (1/2 sine wave) from *CUFSM* is shown in Figure 6 in the form of the "signature curve". Ideally, each signature curve contains two local minima, the first one of which is usually considered to be the local buckling load factor (f_{ol}/f_y), and the second is the distortional buckling load factor (f_{od}/f_y) [12]. In the case where only one local minimum exists on this curve (Figure 6(b)), Gilbert et al. [4] suggested that if the buckling occurs at a half-wavelength being less than the perimeter length of the cross-section, this single minimum is regarded as the local buckling load factor; otherwise, it is deemed as distortional. Due to the simply-supported boundary condition, the global buckling generally exists at the end of the member, as shown in the elastic buckling analysis. Thus, the global buckling load factor (f_{oe}/f_y) is usually obtained when the half-wavelength equals the member length. Based on the above descriptions, the local, distortional, and global buckling modes for the optimal roof purlin cross-section can be clearly identified in Figure 6(a). However, no local buckling was identified on the signature curve for the optimal wall stud cross-section (Figure 6(b)), but only distortional and global buckling modes were distinguished.

The global buckling analysis in *Strand7* for the optimal roof purlin section resulted in a load factor equalling 0.48*MPa*, which is slightly higher that the corresponding *CUFSM* value of 0.35*MPa* (Figure 6(a)). Similarly, the load factor for the optimal wall stud section is 0.082*MPa* from *Strand7*, also slightly higher than the *CUFSM* value of 0.069*MPa* (Figure 6(b)). The disparity in the predicted load factors from the two analysis methods is due to the different ways they simulate the members, i.e., finite element versus finite strip. Nevertheless, such a discrepancy can be considered acceptable.

Figure 7 and Figure 8 show the *Strand7* initial shape and the corresponding deformed shape under the global buckling mode for the optimal roof purlin and wall stud structural models, respectively. The global buckling deformation of the roof purlin model is an apparent tilt of the whole CFS section (Figure 7(b)), while the deformation of the wall stud model is primarily a lateral movement of the web along the *x*-axis (Figure 8(b)). Compared to the global buckled shapes obtained from *CUFSM* as shown in Figure 6, the deformed shapes from *Strand7* are rather consistent. Therefore, the buckling analysis results of the optimal cross-sections obtained from *CUFSM* are well validated by *Strand 7*.

5. Conclusion

This paper presents the size optimisation process of the individual shape-optimised cold-formed steel sections (SOCFSs) for roof purlin and wall stud structural models. For each model, a series of elastic buckling analyses and bearing capacity calculations were carried out using *CUFSM* and DSM, leading to an optimal SOCFS with a reduced cross-sectional area whilst maintaining the same load bearing capacity as the equivalent conventional CFS (CCFS). The cross-sectional areas of the optimal roof purlin and wall stud members are found to be 89.2% and 52.7% of that of the corresponding CCFS, respectively. Finite element analyses were also performed in *Strand7* on the two structural models with the optimal cross-sections, which verified the accuracy of the entire size optimisation process for SOCFSs using the finite strip method in *CUFSM*.

Abstract

Computer-aided optimization algorithms in structural engineering have historically focused on the *structural performance* of generated forms, often resulting in the selection of a single 'optimal' solution. However, *diversity* of generated solutions is desirable when those solutions are shown to a human user to choose from. Quality-Diversity (QD) search is an emerging field of Evolutionary Computation which can automate the exploration of the solution space in engineering problems. QD algorithms, such as MAP-Elites, operate by maintaining and expanding an archive of diverse solutions, optimising for quality in local niches of a multidimensional design space. The generated archive of solutions can help engineers gain a better overview of the solution space, illuminating which designs are possible and their trade-offs. In this paper we apply Quality Diversity search to the problem of designing shell structures. Since the design of shell structures comes with physical constraints, we leverage a constrained optimization variant of the MAP-Elites algorithm, FI-MAP-Elites. We implement our proposed methodology within the Rhino/Grasshopper environment and use the Karamba Finite Element Analysis solver for all structural engineering calculations. We test our method on case studies of parametric models of shell structures that feature varying complexity. Our experiments investigate the algorithm's ability to illuminate the solution space and generate feasible and high-quality solutions.

Keywords: evolutionary algorithm, evolutionary computation, quality diversity, optimisation, multi objective optimisation, conceptual design, shell structures, spatial structures

1. Introduction

A frequently encountered problem within the AEC industry is the design of efficient shell structures. Such structures–in which architectural form is inextricably linked to structural behaviour and performance–require a close collaboration between architect, structural engineer and other AEC consultants to find a shape that is acceptable to all parties and their separate demands. Historically, many of these shells were conceived as form-active structures, and thus their final shape was ascertained through form-finding techniques–first physically [1],[2], then digitally [3]. These digital simulations are remarkably flexible, and able to incorporate a range of physical input constraints, such as ensuring structural efficiency (e.g. axial loading only) or geometric rationalisation (e.g. avoiding panel warp). However, for a single set of inputs (materials, loading and support conditions) form-finding algorithms only generate a singular solution, rather than a range of potential solutions. As such, it can be difficult for the designer to evaluate potential trade-offs between the desired criteria and propose new weightings of them.

We see similar limitations in evolutionary computation (EC) algorithms, such as Divide-and-Conquer or Hill-Climbing. These algorithms are Single Objective Optimisation (SOO) approaches, and as such they too suffer from a difficulty in weighting and combining output values to achieve a well-balanced fitness evaluation for the variants. More sophisticated EC approaches include Multi Objective Optimisation (MOO) or Pareto optimisation algorithms, such as SPEA-2 and HypE. These MOO algorithms have been implemented in AEC digital design toolkits for several years now [4],[5], and allow substantially more detailed exploration of the solution space.

Quality Diversity (QD) search is a family of EC algorithms that simultaneously maintain the quality and diversity of solutions [6] by rewarding *divergence* of the population according to some ad-hoc measure of difference between the actual artefacts rather than the genotypic information. *Quality* can be a secondary objective to this divergence [7], act as a constraint on minimal quality [8], or as a survival criterion between similar artefacts [9]. Algorithms such as MAP-Elites can illuminate the search space, maintaining and evolving in parallel different solutions in different behavioural niches (i.e. with similar design characteristics orthogonal to quality). MAP-Elites and its variants has been a popular algorithm for problems where the "optimal solution" is subjective, such as evolutionary art [10] and game content generation [11].

This paper presents a constrained variant of the MAP-Elites algorithm for QD search and tests it in a set of shell structure optimization tasks ranging from simple to complex. While shell structure optimization has received attention in the past through evolutionary approaches [12], here we propose a QD method that explicitly produces a large archive of potential solutions and visualizes their trade-offs. The FI-MAP-Elites algorithm, proposed here, leverages two archives evolving in parallel: one archive of solutions that fail a constraint on maximum allowed displacement, and another archive of solutions that satisfy this constraint and search for optimal elastic energy of the structure. The algorithm is integrated into Grasshopper and allows engineers to specify the structure of possible solutions and the dimensions towards which FI-MAP-Elites should explore. Comparisons against a baseline SOO algorithm available in Grasshopper show that the proposed constrained QD search algorithm produces far more diverse solutions, while SOO typically converges towards a single type of solution. This paper, therefore, argues that QD search algorithms that illuminate the solution space and show trade-offs between different designs will help engineers interface with the subjectivity of the AEC design process.

2. General methodology for constrained quality diversity search

Feasible-Infeasible Multidimensional Archives of Phenotypic Elites (FI-MAP-Elites) is a hybrid of the MAP-Elites [11] and the FI-2Pop GA [13] algorithms. Its main goal is to combine the illumination capabilities of the former with the constraint-solving capabilities of the latter. Its operation is controlled by the following hyperparameters that are problem-specific: **(1) Representation:** refers to how the algorithm stores the artefacts in a compact genotype [14]. **(2) Initialization:** refers to how the initial population is formed. In many cases initialization of the genotype is as simple as generating a random list of numbers. More complex representations, however, may require a more elaborate scripted initialization [15]. **(3) Variation:** refers to the genetic operators applied while evolution is carried out to produce offspring from selected individuals. While traditional EC operators include recombination and mutation [16], FI-MAP-Elites only uses mutation of one individual. **(4) Infeasible fitness (F_i):** measures how many constraints are failed by the solution and to which degree. The infeasible population aims to minimise the distance to feasibility; to convert this into a maximisation task, we consider that an infeasible fitness below a threshold (usually $F_i < 1$) means that the individual is *infeasible* (i.e. at least one constraint is not satisfied). Ad-hoc heuristics are designed per constraint and added together to form the infeasible fitness score. **(5) Feasible fitness (F_f):** is a problem-specific measure of the desirable property of the final artefact. Feasible fitness is only calculated if the individual is feasible, as failed constraints in some problems render calculating the feasible fitness impossible [17]. **(6) Behaviour characterizations (BCs):** refer to quantifiable characteristics of the artefact. BCs are orthogonal to

quality and artefacts of both high and low BC scores should be desirable. These BCs define the dimensions of exploration and diversity and should be of interest to the designer. While most MAP-Elites implementations use two BCs, the algorithm can operate with any number of BCs but this may impact the computational cost of evolutionary search.

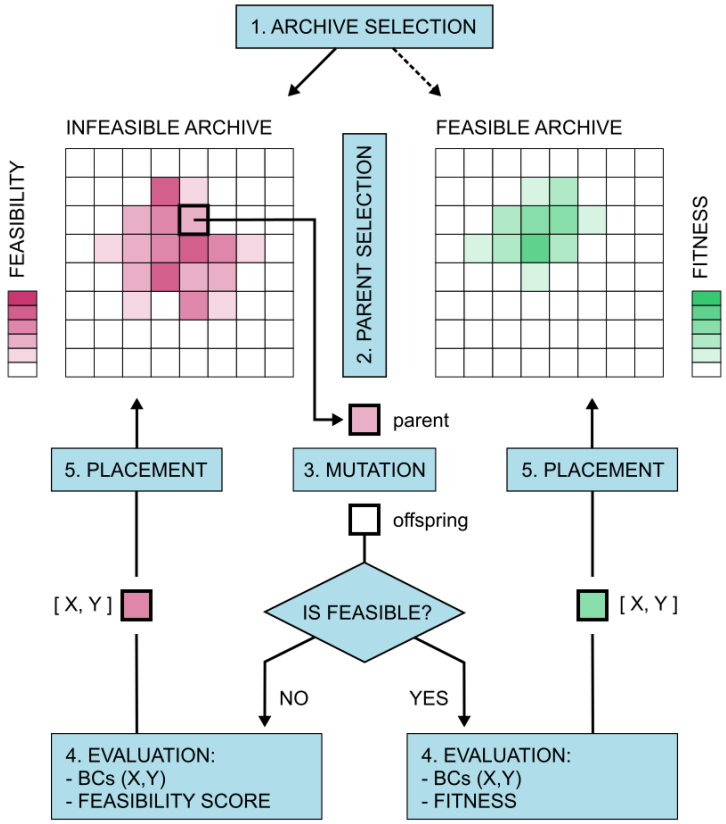

Figure 1. Functional diagram showcasing the operation of the FI-MAP-Elites algorithm, for two BCs.

The FI-MAP-Elites [15] algorithm, visualised in Fig. 1, maintains two separate archives for feasible and infeasible solutions, organised in an n-dimensional grid based on the problem's BCs. Each grid cell contains a single elite with specific BC values. An initial population seeds the archives according to feasibility. The algorithm randomly selects an individual, mutates and evaluates it, and places it in the proper archive and cell based on feasibility and BCs. Offspring replace current elites if their fitness is higher. Through repeated iterations, the algorithm fills the archives with solutions that approach locally maximum fitness, providing a diverse set of fit and feasible solutions for users.

3. Applied methodology & experiment protocol

To efficiently test FI-MAP-Elites in shell structure design tasks, a series of parametric shell models were defined in Rhino's visual programming interface, Grasshopper, based on SubDivision (SubD) surfaces. SubD surfaces have the advantage of being derived from a low polygon control mesh that is easy to manipulate through adjustment of its vertices (control points). This gives them geometric flexibility and makes them suitable for representing a wide range of forms. Furthermore, the resulting surfaces are generated through iterative Catmull-Clark subdivisions [18] of the input mesh which guarantees a smooth, continuous curvature. SubD-based approaches have been successfully utilised by AKT II on a series of built and unrealised projects over the last decade [19],[20].

3.1. Algorithmic parameters

Based on Section 2, there are several problem-specific hyperparameters to the algorithm. We elaborate the parameters for the shell use case here.

- **Representation:** The parametric shell model is manually defined by the designer in Rhino/Grasshopper [21]. This includes a definition of a SubD surface, several constraints on its control points' variability, as well as a number of control parameters that affect the points' movement along specified vectors. Any point on the SubD control polygon selected as a *support* by the designer is defined as 'creased' to ensure that the point that is constrained exists on the smooth shape. The genetic algorithm only stores (and manipulates) the values of the control parameters.
- **Initialization:** When initialising the population for evolution, control parameters are assigned a random value within a designer-specified value range.
- **Variation:** Variation occurs solely through the mutation operator that iterates over all the control parameters defined in the model and changes their values according to two parameters: *Max Step Size* (i.e. the maximum distortion allowed per mutation step) and *Mutation Rate* (i.e. the probability that this control parameter will be changed).
- **Infeasible fitness:** The only constraint in this use case is an upper limit on displacement (d), i.e. the distance between the point in the original model and the deformed model. The upper limit on displacement is specified by the designer (C_d). Equation (1) calculates the infeasible fitness for this problem (F_i), which is bound in the value range of [0,1] and feasible individuals always have $F_i = 1$.

$$F_i = \begin{cases} \frac{C_d}{d} & \text{, if } d > C_d \\ 1 & \text{, if } d \leq C_d \end{cases} \tag{1}$$

- **Feasible fitness:** For feasible individuals, quality is ascertained based on the total elastic energy (U) of the structure. The value for U measures how much energy is stored in the structure based on its elastic deformation. The feasible fitness (F_f), as shown in shown in Equation (2), is bound in the value range of [0,1] with higher values being preferred (lower elastic energy). FI-MAP-Elites calculates F_f only for individuals that satisfy the constraints ($d \leq C_d$); the score of $F_f = 0$ for infeasible individuals is calculated only for the baseline single-objective algorithm in the experiments of this paper.

$$F_f = \begin{cases} 0 & \text{, if } d > C_d \\ \frac{1}{1+U} & \text{, if } d \leq C_d \end{cases} \tag{2}$$

- **Behaviour characterizations (BCs):** Two formulas based on control point coordinates are explored as BCs in this work: (1) *Edge Point Coordinate Average*, as the average coordinate value of a set of parametric points on a series of edges in the SubD geometry (either X, Y, or Z, determined by the user); (2) *Edge Point Coordinates Deviation*, calculated as the difference between the average value and the coordinate (X, Y, or Z, determined by the user) of each point on a series of edges in the SubD geometry, divided by the number of points.

3.2. Rhino implementation

In order to apply FI-MAP-Elites to structural engineering problems, we exploit the parametric design capabilities of the Rhino/Grasshopper design environment. Within this environment, we developed a set of components which allow the structural engineer to (1) define the structural parametric model, (2) select the algorithmic parameters and (3) run the FI-MAP-Elites algorithm and generate an optimised (in terms of quality and diversity) set of variations of the parametric model.

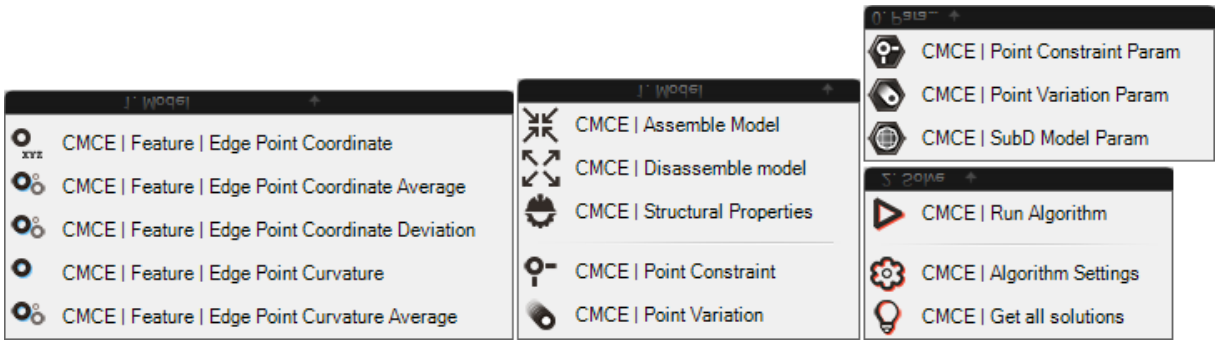

Figure 2. Grasshopper toolbars for the FI-MAP-Elites implementation of shell design.

Customization of the algorithm is done through parameters (on the point constraints, its variation range, and parameters of the SubD model) and through details on the physics model and BC characterizations (see Fig. 2 for a summary of the components available). The solver toolbars provide the settings and components to run the process, along with tools to retrieve results. The components can be combined to produce a pipeline to initialise and evaluate solutions.

As soon as the algorithm's operation is over, a Grasshopper component outputs the data of all elites in both archives, as well as their positions on the archive's grid (based on their BCs). Each one of the generated variations includes various meta-information, including: (1) its Karamba [22] model, (2) its Rhino geometry, (3) its genome (parameter values), (4) its elastic energy and (5) its BC scores. Based on these outputs, the archive's contents can be visualised in Rhino's viewport, in a customised manner. Fig. 6. illustrates an example of such a visualisation of the feasible archive, which includes a visual (by vertex colours) indication of the parametric model's fitness.

3.3. Hyperparameters and baseline algorithms

For all experiments with FI-MAP-Elites in this paper, we use an initial population of 100 random individuals, a mutation rate of 50% and mutation step of 20%, a grid of elites of 16 by 16 (BC1 by BC2) for both feasible and infeasible archives, and results are collected after 50,000 evaluations.

As a baseline to test the performance of FI-MAP-Elites, we use a single-objective optimizer (SOO) of the Galapagos library within Grasshopper. This simple algorithm aims to maximise a single-objective fitness (F_b) computed as the average of the infeasible and feasible fitness; see Eq. (3). Therefore, it overlooks diversity dimensions but tackles constrained optimization.

$$F_b = \frac{1}{2}(F_i + F_f) \tag{3}$$

The evolutionary solver of the Galapagos optimizer within Grasshopper is used for this baseline, with the following settings: a *population* of 256 individuals, an *initial boost* of 1 (the initial population size is 256), an *elitism* of 5% (the 13 fittest individuals are retained across generations) and an *inbreeding rate* of 50% (slightly favours the selection of similar parents during crossover). The population evolves for a number of generations resulting in a comparable number of evaluations as FI-MAP-Elites. We collect solutions from the final population on the last generation to derive SOO performance metrics.

3.4. Hypothesis and performance metrics

Our hypotheses in the experiments described in Chapter 5 can be summarised as follows:

- The two-population approach of FI-MAP Elites will discover more feasible solutions faster.
- Evolution will focus on the feasible population earlier and lead to higher quality solutions in FI-MAP-Elites compared to single-population approaches.
- As a QD algorithm the variety of solutions (in terms of the chosen BCs) will be higher.

- It is expected that more high-quality solutions that are structurally different will emerge from the QD search process that favours local competition within the same behavioural niche.

Following the literature in QD search [9], we evaluate the following metrics: (1) **maximum performance**, as the lowest elastic energy (U_{min}) score and lowest displacement (d_{min}) among feasible individuals of the SOO population or the feasible archive, (b) **coverage**, as the ratio of all cells in the feature map occupied by feasible solutions[1], (3) **QD score**, as the sum of feasible fitness scores among all elites in the feasible archive (of feasible individuals in the SOO population). The maximum performance assesses whether at least one solution is well-performing, while coverage assesses whether a large behavioural variety of solutions is found. Finally, the QD score assesses a combination of the above, with higher scores achieved when the algorithm produces many behaviourally diverse individuals of high quality. In addition, we measure the **fitness deviation** (σ_U and σ_d) as the standard deviation in terms of the elastic energy and displacement (respectively) of all feasible solutions. This measure captures the uniformity of designs when exploring along different BCs.

Moreover, we assess constraint satisfaction and constraint optimization performance through the following metrics: (1) **feasible ratio**, as the ratio of solutions that satisfy all constraints against all solutions in the final population(s); (2) **infeasible coverage**, as the ratio of all possible cells in the feature map that are occupied by infeasible solutions (i.e. the infeasible archive for FI-MAP-Elites).

4. Results

To evaluate the proposed algorithm's performance, we use three different test cases: two variants of a simple test case, and a complex test case comparable to real-world engineering problems.

4.1. Simple test case

Fig. 3 shows the parametric surface model of the simple test case, based on a square SubD surface subdivided into 9 patches and 16 points. The algorithm varies the height of each point in order to optimise the shape. Each point is given a variability in Z-direction from 0 to 5, which is represented by the green arrows at each control point.

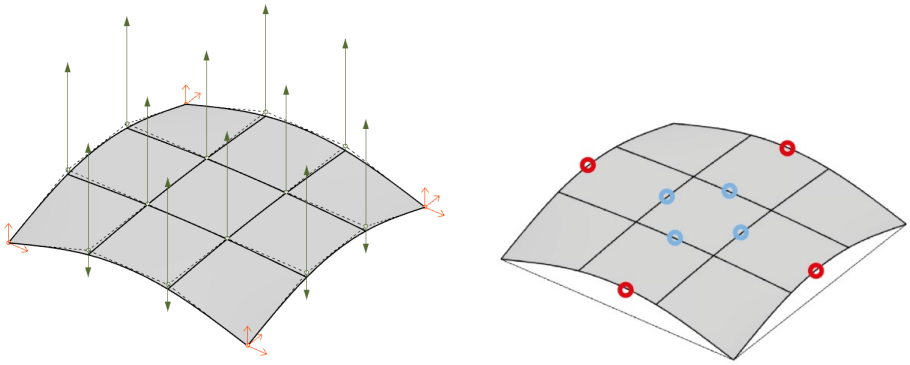

Figure 3: The simple test case with the square base, with the height variability range (left), and the BCs calculated based on the average height of the centre points (blue dots in right image) and height difference between arches (red dots in right image).

Diversity dimensions (BCs) focus on two target areas, namely the central region and the arches (blue and red dots, respectively in Fig. 3). BC1 is taken as the average Z coordinate of the edges of the central face, to capture the height at the middle of the shell. BC2 is the Z coordinate deviation between the midpoints of the side arches, in order to capture asymmetric aspects of an otherwise symmetrical problem. High performing solutions for this form are largely known beforehand, so these two case

[1] For the SOO baseline, all solutions are processed and only feasible ones are placed on the feasible feature map along the two BCs of FI-MAP-Elites (with only the fittest solution retained in each cell).

studies act as benchmarks to ensure that the solutions provided by the QD algorithm are as expected. Based on preliminary experiments, the value ranges for each BC were specified by the structural engineers at BC1$\in$[0,1.3] and BC2$\in$[0.5,3.5], forming the design space that QD should illuminate.

Experiments conducted with this structure assume a base of 16m by 16m, made of grade C16/20 concrete, and a thickness of 7cm, a mesh resolution of 2 subdivisions, and applied loads of 2kN/m^2. For the FI-MAP-Elites hyperparameters, we use an initial population of 100 random individuals, a mutation rate of 50% and mutation step of 20%, a grid of elites of 16 by 16 (BC1 by BC2) for both feasible and infeasible archives, and a total of 50,000 iterations of parent selection. The upper threshold for displacement (C_d) is set to 5cm.

We test two versions of this simple test case (Case 1 and Case 2). In both cases an identical input geometry is used, but they are given two different support constraints. Case 1 has all translations (X, Y, Z) constrained at the four corner points, while Case 2 has the X direction free. This means that Case 1 can transfer horizontal forces in two directions to the supports, while Case 2 can only transfer the horizontal forces in one direction. This should force the same patch into two different structural behaviours, thereby rendering different resulting shapes in the two maps.

Table 1. **Simple Test Case**: Comparing the final archive of QD with the final population of SOO, for Case 1 and Case 2. Results are averaged across 10 experiment repetitions. Error signifies a confidence interval of 95%.

	Case 1		**Case 2**	
	FI-MAP-Elites	**SOO**	**FI-MAP-Elites**	**SOO**
Feasible Coverage	94.3% ± 2.1%	0.6% ± 0.3%	88.9% ± 0.6%	0.7% ± 0.1%
Feasible QD-Score	110.37 ± 1.20	1.12 ± 0.51	75.32 ± 0.91	0.44 ± 0.11
Feasible U_{min}	0.38 ± 0.00	0. ma34 ± 0.01	0.72 ± 0.02	3.01 ± 0.74
Feasible σ_U	1.16 ± 0.08	0.00 ± 0.00	1.82 ± 0.04	0.02 ± 0.01
Feasible d_{min}	0.37 ± 0.04	0.13 ± 0.02	0.44 ± 0.06	2.08 ± 0.35
Feasible σ_d	0.62 ± 0.03	0.03 ± 0.01	0.76 ± 0.02	0.03 ± 0.01
Feasible Ratio	48.5% ± 0.6%	100.0% ± 0.0%	47.1% ± 0.2%	100.0% ± 0.0%
Infeasible Coverage	100.0% ± 0.0%	0.0% ± 0.0%	99.8% ± 0.3%	0.0% ± 0.0%

Table 1 shows the different performance metrics (see Section 3.4) for both Case 1 and Case 2. Results are averaged from 10 independent runs of both FI-MAP-Elites and SOO per case. A first observation for both cases is that the final SOO population contains exclusively feasible individuals, and those individuals have almost identical scores in elastic energy among them (very low σ_U). Moreover, based on the very low coverage when these solutions are mapped in the FI-MAP-Elites feature map, the solutions are geometrically very similar. Unsurprisingly, FI-MAP-Elites is designed to explore the BCs specified by the designer and reaches very high scores in both feasible and infeasible coverage. Case 2 seems to be more challenging for EC to optimise, as evidenced by the much higher elastic energy in the best solution for both SOO and FI-MAP-Elites. While for Case 1 the SOO manages to converge towards a solution with a U score lower than the best U score found in FI-MAP-Elites, this is not true in Case 2. We presume that SOO converges early to a *local optimum* and does not explore the search space enough in order to find a better solution. The QD algorithm unsurprisingly does explore along the BCs and thus finds (many) better solutions. However, both the lower coverage and lower QD-score of FI-MAP-Elites in Case 2 compared to Case 1 shows that the freedom of changing the corner points' coordinates makes the problem more difficult.

Fig. 4 shows how the feature map of some indicative runs of FI-MAP-Elites differ between Case 1 and Case 2. It is evident that better solutions (with lower elastic energy) can be found in different parts of the design space (for these BCs), thus indicating different trade-offs between geometric designs. It can be seen that the change in support conditions leads to different solutions for each location in the map,

as the shapes with the lowest fitness go from two-directional compression shells in Case 1 to single-span shell topologies in Case 2. This can be seen as the fittest individuals in Case 1 are the ones with a high middle height, regardless of symmetry, whereas in Case 2 the fittest solutions have moved to the spots with high single-axis symmetry (barrel vault forms) and two-axis symmetric solutions are not observed. Moreover, in Case 2 we also see a different class of fit individuals in the middle of the map as the lower middle height of these shells allows them to develop some synclastic curvature, which further increases stiffness.

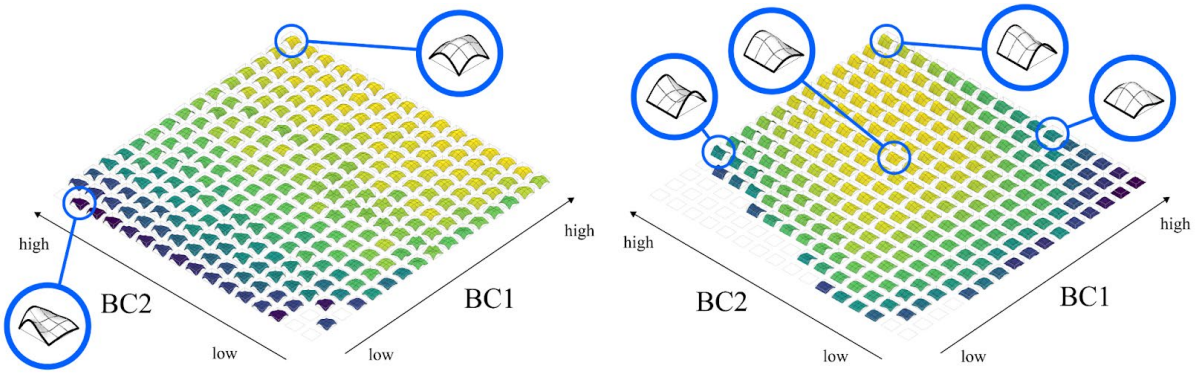

Figure 4: Indicative archives of feasible solutions from a single run of FI-MAP-Elites for Test Case 1 (left) and Test Case 2 (right), collected after 50,000 evaluations. Yellow shapes have higher feasible fitness.

4.2. Complex test case

The complex case study focuses on a more detailed four-arch vault shell which is initially mirror symmetrical in the XZ and YZ planes (as seen in Fig. 5). This form comprises 16 patches, and has 29 control points adjusted by the optimisation algorithms. The shell has a base boundary of 20m by 10m, is formed in grade C16/20 concrete with a thickness of 10cm, a mesh resolution of 3 subdivisions, and only self-weight (no applied loads). The upper threshold for displacement (C_d) is set to 6cm.

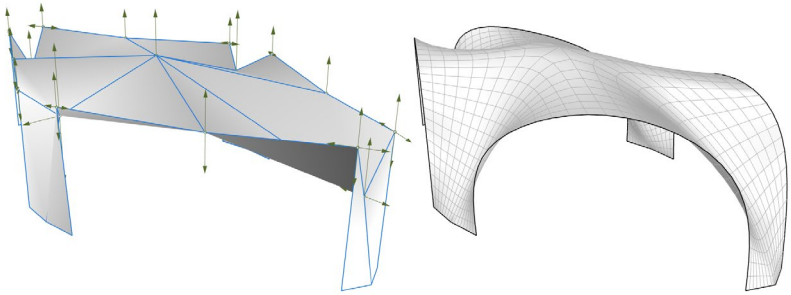

Figure 5: Inputs for complex case study: control mesh and control point variation vectors (left, vectors in green), and resulting smoothed mesh that is structurally analysed (right).

Diversity is defined using two *Edge Point Coordinates Deviation* BCs: BC1 is the Z coordinate deviation between midpoints of the four external arches, BC2 is the Z coordinate deviation between midpoints of the four axial iso-curves that meet at the centre of the vault. The problem-specific value ranges for the BCs in this case are found through trial and error at BC1$\in$[0,1.0] and BC2$\in$[0,1.15].

Table 3 shows the performance metrics on the complex test case, averaged from 8 independent runs. The increased complexity of this test case impacts the feasible coverage of the FI-MAP-Elites approach. However, more than half of the examined domain has been covered with feasible solutions in this approach (64%). On the other hand, the SOO's feasible coverage remains at a very low value, suggesting that solutions discovered in SOO are very similar to each other in every run. Furthermore, the feasible population discovered by the QD approach exhibited better performance in terms of both elastic energy

and displacement, in comparison to SOO. This observation is aligned with the general notion that diversification in evolutionary approaches is a means of achieving better fitness.

Table 3. **Complex Test Case**: Comparing the final archive of QD with the last population of SOO. Error signifies a confidence interval of 95%. Displacement (d) is reported in centimetres.

	FI-MAP-Elites	SOO
Feasible Coverage	66.9% ± 1.5%	0.8% ± 0.3%
Feasible QD-Score	110.66 ± 2.18	1.46 ± 0.56
Feasible U_{min}	0.34 ± 0.01	0.45 ± 0.02
Feasible σ_U	0.21 ± 0.02	0.01 ± 0.00
Feasible d_{min}	0.15 ± 0.01	0.27 ± 0.02
Feasible σ_d	0.11 ± 0.01	0.01 ± 0.00
Feasible Ratio	49.5% ± 0.4%	100.0% ± 0.0%
Infeasible Coverage	68.3% ± 1.7%	0.0% ± 0.0%

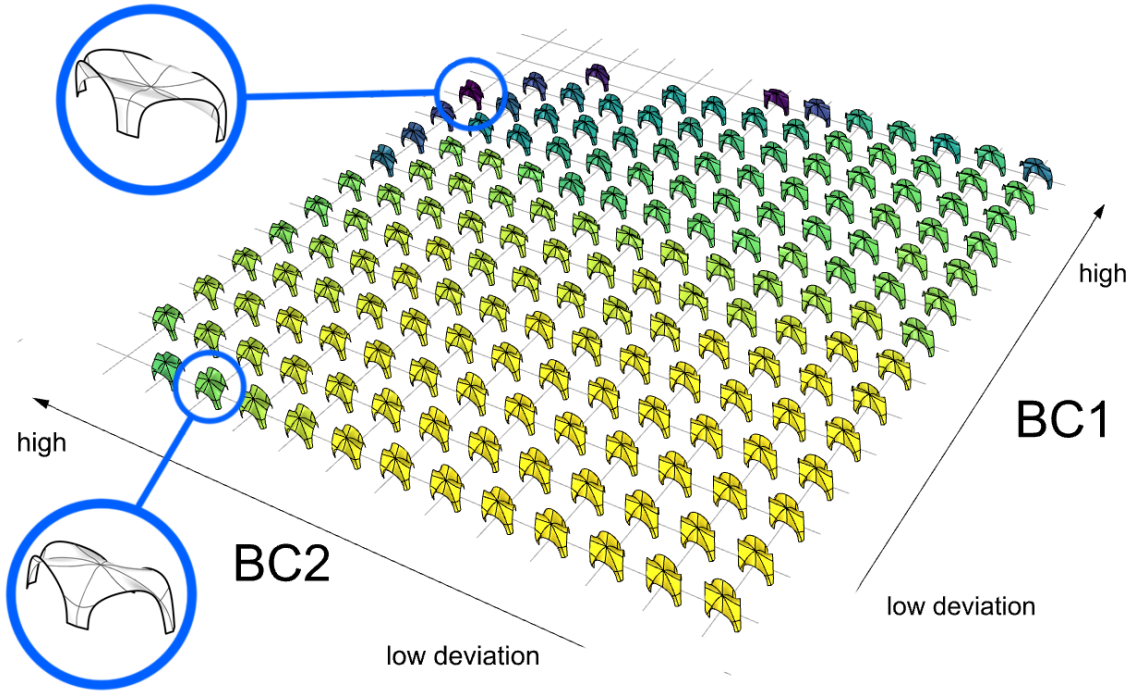

Figure 6: Visualisation of all feasible solutions found in a single run of the FI-MAP-Elites algorithm on the Complex Test Case. Meshes in yellow have a higher fitness (i.e. lower elastic energy). All feasible designs are found in the first 13 by 14 cells (BC1 by BC2) of the feature map; empty cells beyond this range are omitted.

As seen in Fig. 6, the fittest solutions are concentrated in regions of low deviation for both sets of control points. Furthermore, we observe a clear gradient that starts from this point and diminishes the further away we move from it. This observation is aligned with an engineering intuition that more symmetric solutions will exhibit better structural properties. Despite this fact, it is worth noting that all presented solutions are feasible and locally optimised, rendering them potential candidates for further investigation.

Finally, Fig. 7 visualises the best individual solutions found by FI-MAP-Elites and SOO approaches, for a detailed examination. In these examples the QD algorithm found a lower deformation solution than the SOO. The QD optimal solution has sharper curvature at the two supports [20] in the short-span axis but achieves a shallower angle into the two long-axis supports. As these results suggest, the best range

of solutions for high-dimensional problems like this can often not be easily intuited by the engineer, unlike the simple test cases.

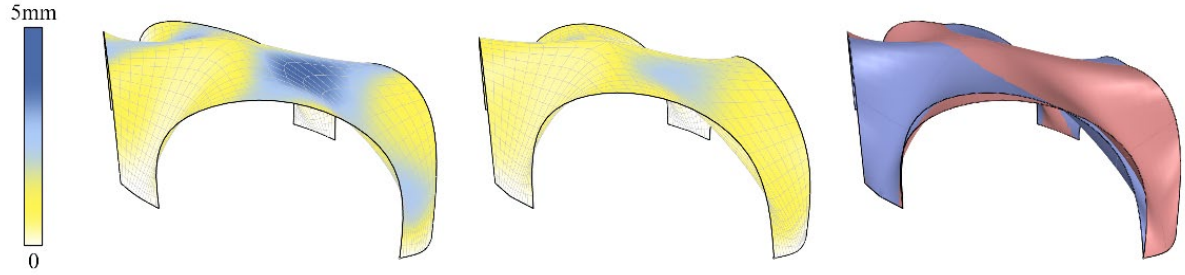

Figure 7: Best solution found by the SOO (left) and by FI-MAP-Elites (middle), with blue regions representing high displacement. Both solutions overlaid (right) with blue colour for FI-MAP-Elites and red colour for SOO, to highlight their difference.

5. Discussion

This paper introduces a constrained Quality-Diversity evolutionary approach in structural engineering and tests it on the problem of designing shell surfaces. Unlike traditional evolutionary optimization, which converges towards similar solutions, our method produces many diverse solutions and improves them throughout evolution. It uses a two-population approach to explore the design space efficiently and discover feasible solutions. It produces many individuals, with a high coverage of the design space of geometric properties specified by the designer. The produced visualisation of all possible layouts can provide important feedback to engineers and inspire future iterations. As shown in some use-case example shell structures, this approach can offer many good alternatives for an engineer to choose from, compared to the single design produced by single-objective evolution.

The experiment setup included three test cases: two variants of a simple problem and a more complex problem closer to the real-world structural engineering problems encountered by AKT II [19],[20]. We compared the output of FI-MAP-Elites against designs collected from a traditional single-objective optimization (SOO) method available to all engineers through the Galapagos optimizer (in Rhino/Grasshopper). While the objective function included both the design goal and the constraints, through a form of fitness penalty typical in constrained optimization [17], other evolutionary approaches may perform differently. For instance, a two-population approach such as FI-2pop GA is expected to find feasible individuals even in the complex case study, where SOO struggled. Moreover, traditional genetic diversity preservation mechanisms such as the Fitness Uniform Selection Strategy [23] could also lead to more diverse results. Finally, a multi-objective approach [24] where the BCs are used as objectives alongside the SOO objective function (F_b) may lead to a more diverse population. On the other hand, since the best solutions were found at specific BC coordinates, sometimes with low BC scores, optimising towards high BCs may not lead to any improvements at a higher computation cost. Such more complex baselines will be explored in future work, where more complex structural engineering problems will be tested with FI-MAP-Elites.

Results of FI-MAP-Elites as a method of illuminating the design space and generating many good alternatives is promising for the structural engineering test cases, including the complex one which is close to real-world problems faced by professionals. However, there are many other problems within the AEC domain that could benefit from FI-MAP-Elites and could be explored in future work. Preliminary studies in illuminating the space of stick models for structural engineers with FI-MAP-Elites [25] have shown that the method is valuable for simple test cases but does not scale for more complex problems due to the additional burden on designers to define the entire range of allowed designs. FI-MAP-Elites has also been tested for MEP engineering towards designing ventilation shafts

[25], operating under strict design spaces provided by the designers; this allows designers to ensure that solutions satisfy their ad-hoc constraints but limits the potential of QD search to provide truly surprising solutions to the designers. Beyond testing FI-MAP-Elites in other engineering tasks, a more ambitious avenue for future work is testing the output of the algorithm (e.g. the feature maps of Fig. 4) in real-world, everyday workflows of a professional setting and their applicability as inspiration for engineers, for communicating between disciplines (e.g. showing a feature map of alternatives to other AEC stakeholders, such as architects), and for communicating with clients. This ambitious direction of inquiry would shed more light on the potential of Quality-Diversity search and the improvements needed to the algorithm, visualisation, explainability [26], and tools (e.g. Rhino plugin).

6. Conclusions

This paper presented a novel approach to structural engineering, testing a new algorithm that takes advantage of recent advances in constrained optimization and quality-diversity (QD) evolutionary search. The method shows promise in both simple and complex test cases and can produce a range of geometrically diverse high-quality solutions, which can be beneficial during conceptualization stages and when exploring alternatives with different stakeholders. The algorithm is integrated into the Grasshopper visual programming environment within Rhino, which makes it both easily accessible and customizable by engineers, and also provides tools to intuitively visualise and inspect all generated solutions. Compared to a traditional single-objective optimization method currently available in Rhino, our constrained QD approach can find feasible solutions more easily and produce far more viable alternatives, compared with a single optimum that the single-objective approach converges to. Future work will explore converting FI-MAP-Elites into a plugin available for everyone via online repositories (e.g. food4rhino.com) and assessing its applicability further in everyday structural engineering workflows.

Abstract

Applying prestress to concrete structures makes it possible to redirect forces, thus increasing their efficiency by optimizing their structural behaviour and durability. This paper proposes an efficient and practical tendon optimization method that allows engineers to find an optimal tendon layout in spatial beamlike structures. It is based on the minimization of strain energy, while also taking geometrical boundary conditions into consideration. The constrained optimization problem is solved using approaches from variational calculus, including the Rayleigh-Ritz method and Lagrange multipliers. The consideration of practical boundary conditions and the precise polynomial solution reduce post-processing and facilitate an easy implementation of the method in the structural design process. Numerical examples that apply the method to thin-walled beamlike structures demonstrate its flexible applicability for both simple and complex systems with a variety of support conditions and design constraints. The proposed method is efficient, flexible, and accurate, thus improving the tendon layout optimization process with respect to past approaches and equipping structural engineers with a powerful, yet user-friendly tool for designing more sustainable and lightweight concrete structures.

Keywords: prestressed concrete, post-tensioned concrete, structural optimization, tendon layout optimization, strain energy minimization, folded slabs, concrete shells, thin-walled structures, Hangai Prize applicant

1 Introduction

Reducing the amount of concrete in structures is indispensable in order to contribute to more sustainable construction, since concrete production is an extremely resource-intensive process. Optimizing the structures' geometry according to the principle of *form follows force* leads to slenderer and filigree structures such as folded slabs or shells. Moreover, using the concept of prestress makes it possible to optimize the structural behaviour and durability of concrete structures. As the effect of prestress depends heavily on the tendon, finding an optimal tendon layout is a crucial step in the design process. Conventional methods for the design of an optimal tendon layout require engineering experience and frequently the use of complex methodologies, thus making it difficult to apply them in practice.

Most previous studies on optimizing tendon layouts minimize the costs or material usage in simple beams with two-dimensional tendon layouts. In early papers by Kirsch [1] the tendon was optimized using linear programming. Subsequent studies used projected Lagrangian algorithms, among others, to optimize several objectives such as minimum cost, weight, or initial camber simultaneously [2]. An energy-based optimization method was proposed by Eurviriyanukul and Askes [3] who optimized the tendon layout by minimizing the residual of the configurational forces in simple and continuous beams. Avelino et al. [4] and Hymans et al. [5] used topology optimization and gradient-based optimization methods to optimize spatial tendon layouts in concrete slabs. They showed that the optimization of

structural behaviour also results in a reduction of costs. Their approaches have recently been developed further by Zelickman and Amir [6], [7] by using B-splines in order to gain more freedom with respect to the tendon layout and reduce post-processing. Whilst those studies successfully optimize the tendon layout, the methods all include elaborate iterations and FE analysis. Moreover, extensive post-processing is required to obtain tendon layouts that comply with practical boundary conditions such as continuity above supports.

The method proposed in this paper contributes to solving the problems mentioned above. The authors of this work developed a method to optimize tendon layouts based on the minimization of strain energy at the Technical University of Berlin [8]. Minimizing the strain energy minimizes the deflection and maximizes the stiffness, therefore allowing for the design of slenderer and more efficient structures. By considering geometrical boundary conditions during the optimization, post-processing is reduced and the efficiency of the structural design process increased.

The model for a prestressed spatial beamlike thin-walled structure and the resulting internal forces are visualized in Figure 1 and Figure 2. The tendon layout is defined by its eccentricity to the centroid of the beam described by the three-dimensional curve $\boldsymbol{r}: \mathbb{R} \to \mathbb{R}^3, t \mapsto \boldsymbol{r}(t)$. It is assumed that deformation resulting from prestressing is not restrained (statically determinate), which means that the secondary effects of prestressing thus do not need to be taken into account. Note that the subsequent addition of static constraints still allows statically indeterminate systems to be achieved. The global stress resulting from prestress is then given by:

$$\sigma_P(x,z) = \frac{N_P(x)}{A} + \frac{M_P(x)}{I} z \tag{1}$$

Where $N_P(x)$ is the axial force in the structure's cross section due to prestressing and $M_P(x)$ is the bending moment about the y-axis resulting from prestressing.

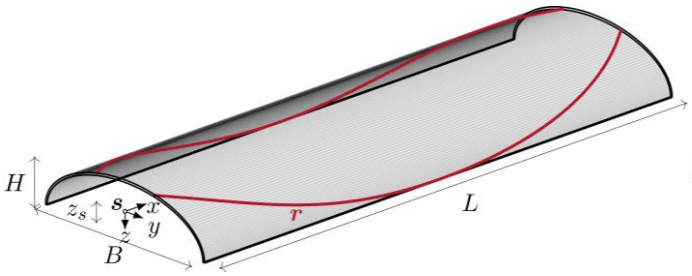

Figure 1 Model for a prestressed beamlike spatial structure

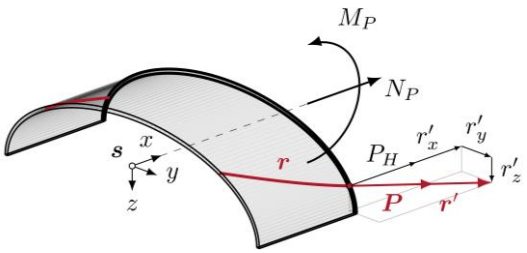

Figure 2 Internal forces due to prestress

2 Tendon layout optimization as a constrained optimization problem

The energy required to deform a prestressed body depends on the structure's geometry, material, and external loads, as well as the tendon layout. Hence, minimizing the strain energy reduces the deflection and optimizes the tendon layout for the structure and loads being considered. The objective of the optimization problem considered in this paper is thus as follows:

The tendon layout is considered optimal if the vertical deflection under a certain external load is zero, i.e., the strain energy is zero.

The optimization problem is characterized as follows:

Variable	Tendon layout
Objective function	Strain energy
Constraints	Geometrical boundary conditions
Method	Rayleigh-Ritz method with Lagrange multipliers
Solution	Polynomial

2.1 Objective function derivation

Strain energy is the potential energy stored in a body as a result of its deformation by external loads. For a beam with isotropic elastic materials, the strain energy from axial and bending stresses σ_x (assuming $\sigma_y = \tau_{xy} = \tau_{yx} = 0$) is defined as:

$$\Pi_i = \frac{1}{2E} \int_V \sigma_x^2 \, dV \tag{2}$$

The strain energy in a prestressed beam depends on the elasticity modulus E and the stress resulting from external loads and prestress. Here only normal stresses resulting from bending moments due to external loads M_E and prestress M_P are considered, as they are responsible for the vertical deflection of a beam.

$$\sigma_x = \sigma_E + \sigma_P = \frac{M_E \, z}{I} + \frac{M_P \, z}{I} \tag{3}$$

Assuming a constant cross section and substituting σ_x from equation (3), equation (2) thus yields:

$$\Pi_i = \frac{1}{2E} \int_V \sigma_x^2 \, dV = \frac{1}{2EI^2} \int_H \int_B \int_L (M_E + M_P)^2 \, dx \, dy \, z^2 \, dz \tag{4}$$

As shown by Osman-Letelier [8] minimizing the strain energy in equation (4) leads to the following expression, stating that the strain energy is minimized by minimizing the integral of the squared sum of moments over the beam length.

$$\Pi_i = 0 \Rightarrow \min \Pi_i \equiv \min \overbrace{\int_L \overbrace{(M_E + M_P)^2}^{\mathcal{H}} \, dx}^{\mathcal{J}_P} \tag{5}$$

This term is called J_P and serves as the objective function for the proposed optimization method.

$$\mathcal{J}_P = \int_L \mathcal{H} \, dx = \int_L (M_E + M_P)^2 \, dx \rightarrow \min \tag{6}$$

M_E depends on external loads and the system considered while M_P depends on the tendon layout.

2.2 Solution with the Euler-Lagrange equation

In analogy to differential calculus, which addresses the change of a function that depends on a scalar variable, the change of a functional that depends on a function, is addressed by variational calculus. To find an optimal tendon layout, a function $\boldsymbol{r}(t)\colon \mathbb{R} \rightarrow \mathbb{R}^3 \, , t \mapsto \boldsymbol{r}(t)$ that extremizes the objective function

$$\mathcal{J}_P\colon \mathbb{R}^3 \rightarrow \mathbb{R}, \boldsymbol{r}(t) \mapsto \int_{t_1}^{t_2} \mathcal{H}\big(t, \boldsymbol{r}(t), \boldsymbol{r}'(t)\big) \, dt, \tag{7}$$

with $\mathcal{H}\colon \mathbb{R}^3 \rightarrow \mathbb{R}, \boldsymbol{r}(t) \mapsto \mathcal{H}\big(t, \boldsymbol{r}(t), \boldsymbol{r}'(t)\big)$ depending on the unknown function $\boldsymbol{r}$ and its derivative $\boldsymbol{r}'$, can be found by solving the Euler-Lagrange equation:

$$\delta \mathcal{J}_P = 0 \Leftrightarrow \frac{d}{dt} \frac{\partial \mathcal{H}}{\partial \boldsymbol{r}'} - \frac{\partial \mathcal{H}}{\partial \boldsymbol{r}} = 0 \tag{8}$$

As demonstrated by Osman-Letelier [8] optimizing the tendon layout by using the Euler-Lagrange equation leads to highly complex non-linear differential equations, which could not be solved. The design space is thus restricted by applying the Rayleigh-Ritz method.

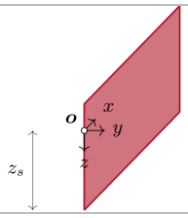
2.3 Design space

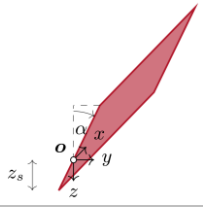
The design space of the curve $\boldsymbol{r}$ is restricted in two ways in order to ensure that the tendon is located inside the structure's cross section and to reduce the complexity of the optimization problem. Table 1

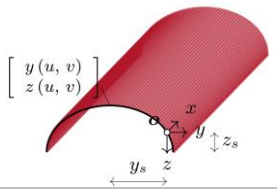
shows various cases of tendon layouts in beamlike structures. To ensure that the tendon is located inside the concrete, the placement of the tendon needs to be constrained to the possibly curved neutral surface of the thin-walled structures cross section. Consider the curve $\boldsymbol{r}$ and surface $\boldsymbol{S}$:

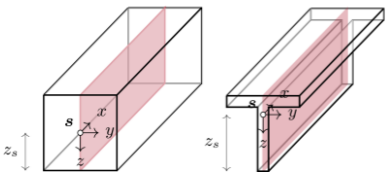
$$\boldsymbol{r}(t) = \begin{bmatrix} r_x(t) \\ r_y(t) \\ r_z(t) \end{bmatrix} \tag{9}$$

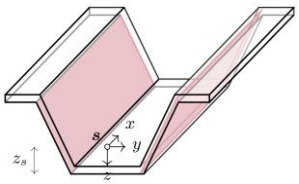
$$\boldsymbol{S}(u,v) = \begin{bmatrix} u \\ f_y(u,v) \\ f_z(u,v) \end{bmatrix} \tag{10}$$

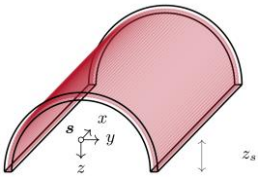












The curve $\boldsymbol{r}$ lies on the surface $\boldsymbol{S}$ between t_1 and t_2 if their minimal distance vanishes for all $t \in [t_1, t_2]$.

$$\boldsymbol{r} \subset \boldsymbol{S} \iff \forall\, t \in [t_1, t_2]\ \exists\, (u,v) \in \mathbb{R}^2 \mid 0 = \boldsymbol{r}(t) - \boldsymbol{S}(u,v) \tag{11}$$

In order to restrict the tendon to the cross section, $\boldsymbol{r}$ is projected onto $\boldsymbol{S}$, so that the following statement, which is derived from equation (11), applies:

$$\begin{bmatrix} r_x(t) \\ r_y(t) \\ r_z(t) \end{bmatrix} = \begin{bmatrix} u \\ f_y(u,v) \\ f_z(u,v) \end{bmatrix} \tag{12}$$

Table 1 Parametrized surfaces for spatial tendon layouts with examples

	Planar tendon layouts	Spatial tendon layouts in planar surfaces	Spatial tendon layouts in curved surfaces
Surface			
Example	Simple beams 	Folded slab 	Cylindrical shell 

A second restriction of the design space is introduced in order to reduce the complexity of the equations by applying the Rayleigh-Ritz method. Instead of searching for entirely unknown functions for the components of $\boldsymbol{r}$, an approximation $\tilde{\boldsymbol{r}}$ that satisfies

$$\lim_{n\to\infty} \tilde{\boldsymbol{r}} = \boldsymbol{r} \tag{13}$$

and depends on the coefficients $\boldsymbol{a} \in \mathbb{R}^n$ as well as on the shape functions $\boldsymbol{\phi} \in \mathbb{R}^n$ is defined as follows:

$$\tilde{\boldsymbol{r}}\colon \mathbb{R} \to \mathbb{R}^3, x \mapsto \boldsymbol{r}(\boldsymbol{a}^T\boldsymbol{\phi}) = r\left(\sum_{i=1}^{n} a_i \phi_i(x)\right) \tag{14}$$

In this paper a polynomial approach has been chosen, thus restricting the design space to polynomials which are described by the shape functions

$$\phi_i = x^{i-1} \tag{15}$$

Combining both design space restrictions by substituting

$$u = t = x \tag{16}$$

$$v = \boldsymbol{a}^T \boldsymbol{\phi}(x) \tag{17}$$

in equation (12), the approximation of a spatial tendon layout that is restricted to a surface that is described by the functions $f_y(u, v)$ and $f_z(u, v)$ is defined by:

$$\tilde{\boldsymbol{r}}(\boldsymbol{a}, x) = \begin{bmatrix} r_x \\ r_y \\ r_z \end{bmatrix} = \begin{bmatrix} x \\ f_y\big(x, \boldsymbol{a}^T \boldsymbol{\phi}(x)\big) \\ f_z\big(x, \boldsymbol{a}^T \boldsymbol{\phi}(x)\big) \end{bmatrix} \tag{18}$$

The curve $\boldsymbol{r}$ in equation (9) consists of three entirely unknown functions, whereas the approximated curve $\tilde{\boldsymbol{r}}$ in equation (18) contains one unknown polynomial that depends on the scalar coefficients $\boldsymbol{a}$. Hence, replacing $\boldsymbol{r}$ with its approximation $\tilde{\boldsymbol{r}}$ results in the objective function $\mathcal{J}_P$ being dependent on the unknown scalar coefficients $\boldsymbol{a}$ instead of on an unknown three-dimensional function $\boldsymbol{r}$.

$$\mathcal{J}_\mathrm{P}\colon \mathbb{R}^3 \to \mathbb{R}, \boldsymbol{a} \mapsto \int_{x_1}^{x_2} \mathcal{H}\big(x, \tilde{\boldsymbol{r}}(\boldsymbol{a}, x), \tilde{\boldsymbol{r}}'(\boldsymbol{a}, x)\big)\, dx = \int_{x_1}^{x_2} \mathcal{H}(\boldsymbol{a}, x)\, dx \tag{19}$$

This restriction of the design space reduces the complexity of the equations and the processing time.

2.4 Constraints

To eliminate extensive post-processing and obtain realistic tendon layouts, practical boundary conditions such as continuity above supports, tendon curvature, concrete cover depth, or anchor positions should be fulfilled. Consider the boundary conditions $\boldsymbol{g}\colon \mathbb{R}^n \to \mathbb{R}^m, \boldsymbol{a} \mapsto g(\boldsymbol{a})$. By introducing the Lagrange multipliers $\boldsymbol{\lambda} \in \mathbb{R}^m$, the Lagrange function $\mathcal{L} \in \mathbb{R}$ is defined

$$\mathcal{L}(\boldsymbol{a}) = \mathcal{J}_P(\boldsymbol{a}) + \boldsymbol{\lambda} \cdot \boldsymbol{g}(\boldsymbol{a}) \tag{20}$$

and the constrained optimization problem can be solved by minimizing the Lagrange function

$$\mathcal{L} \to \min \Rightarrow \nabla \mathcal{L} = \boldsymbol{0} \tag{21}$$

2.5 Summary

The complete constrained optimization problem for spatial tendon layouts is defined as follows:

Minimize $\boldsymbol{r}$	$\mathcal{J}_P$	subject to	$\boldsymbol{g} = \boldsymbol{0}$

The solution algorithm is described as follows:

Find	$\tilde{\boldsymbol{r}} \in \mathbb{R}^3$	with	$\lim_{n\to\infty}(\tilde{\boldsymbol{r}}) = \boldsymbol{r}$
by solving	$\nabla \mathcal{L} = \boldsymbol{0}$	for	$\boldsymbol{a} \in \mathbb{R}^n$
		with	$\mathcal{L}(\boldsymbol{a}) = \mathcal{J}_P(\boldsymbol{a}) + \boldsymbol{\lambda} \cdot \boldsymbol{g}(\boldsymbol{a})$
			$\mathcal{J}_P = \int_L \big(M_E(x) + M_P(\boldsymbol{a}, x)\big)^2\, dx$
			$\tilde{\boldsymbol{r}}(\boldsymbol{a}, x) = \begin{bmatrix} \tilde{r}_x \\ \tilde{r}_y \\ \tilde{r}_z \end{bmatrix} = \begin{bmatrix} x \\ f_y\big(x, \boldsymbol{a}^T \boldsymbol{\phi}(x)\big) \\ f_z\big(x, \boldsymbol{a}^T \boldsymbol{\phi}(x)\big) \end{bmatrix}$
			$\phi_i(x) = x^{i-1}$

3 Study cases

3.1 Optimization of planar tendon layouts in simple beams

The optimization of planar tendon layouts can be described by a simplified formulation of the optimization problem, as they are a special case of spatial tendon layouts. In a simple beam with a constant rectangular cross section, the tendon lies on the XZ plane. The tendon layout is defined by its vertical eccentricity to the x-axis $r_z \in \mathbb{R}$, with $r_x = x$ and $r_y = 0$. In order to define $\boldsymbol{r}$, we solely need to find the term r_z. Hence, the optimization problem and solving algorithm for planar tendon layouts is simplified as follows:

Minimize r_z	$\mathcal{J}_P$	subject to	$\boldsymbol{g} = \boldsymbol{0}$
Find	$\tilde{r}_z \in \mathbb{R}$	with	$\lim_{n\to\infty}(\tilde{r}_z) = r_z$
by solving	$\nabla\mathcal{L} = \boldsymbol{0}$	for	$\boldsymbol{a} \in \mathbb{R}^n$
		with	$\mathcal{L}(\boldsymbol{a}) = \mathcal{J}_P(\boldsymbol{a}) + \boldsymbol{\lambda} \cdot \boldsymbol{g}(\boldsymbol{a})$
			$\mathcal{J}_P(\boldsymbol{a}) = \int_L \left(M_E(x) + M_P(\boldsymbol{a}, x)\right)^2 dx$
			$\tilde{r}_z(\boldsymbol{a}, x) = \boldsymbol{a}^T \boldsymbol{\phi}(x),\ \phi_i(x) = x^{i-1}$

As the tendon is located on the XZ plane, the resulting moment is calculated as follows:

$$M_P(x) = -P_H(x)\, r_z(x) = -P \frac{r_z}{\sqrt{1 + r_z'^2}} \tag{22}$$

Numerical examples for the optimization of planar tendon layouts are presented by Osman-Letelier [8].

3.2 Optimization of spatial tendon layouts in folded slabs

To validate the proposed optimization method, three numerical examples of spatial tendon layouts in folded slabs as shown in Figure 3 and Figure 4 are presented. The results are obtained by implementing the algorithm described in section 2.5 in MATLAB (©MathWorks, Version R2020b). The built-in functions *vpaintegral* and *vpasolve* are used to solve the integral $\mathcal{J}_P$ and the system of equations $\nabla\mathcal{L} = \boldsymbol{0}$.

Figure 3 Prestressed folded slab [9]

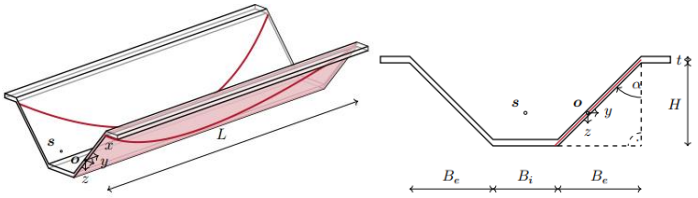


Figure 4 Model of a folded slab

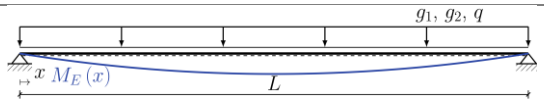
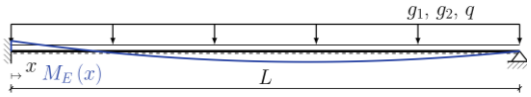
The tilted plane of a folded slab as in Figure 4 is described by the functions $f_y = -\tan(\alpha)\, v$ and $f_z = v$. With equations (16), (17), and (18), that leads to the following approximation for the tendon:

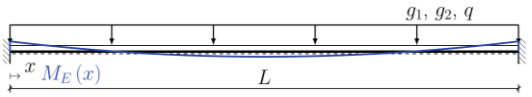
$$\tilde{\boldsymbol{r}}(x) = \begin{bmatrix} u \\ f_y \\ f_z \end{bmatrix} = \begin{bmatrix} u \\ -\tan(\alpha)\, v \\ v \end{bmatrix} = \begin{bmatrix} x \\ -\tan(\alpha)\, \boldsymbol{a}^T \boldsymbol{\phi}(x) \\ \boldsymbol{a}^T \boldsymbol{\phi}(x) \end{bmatrix} \tag{23}$$

In this paper, only the moment about the y-axis is considered. It is assumed that the tendons are arranged symmetrically along the y-axis, so that no moment occurs about the z-axis.

$$M_{P,y}(x) = -P_H(x)\, r_z(x) = -P \frac{r_x'\, r_z}{\sqrt{r_x'^2 + r_y'^2 + r_z'^2}} \tag{24}$$







The additional term $r_y'^2$ in the denominator of equation (24) compared to equation (22) reduces the moment resulting from the change in the tendon's horizontal eccentricity. In the context of this paper, this effect will be called geometrical loss. Geometrical losses occur for the change in vertical ($= r_z'$) as well as in horizontal ($= r_y'$) eccentricity.

A quasi-permanent load combination of uniformly distributed loads composed of self-weight g_1, additional dead loads g_2, and live loads q is considered. At the time of prestressing, the beams under self-weight g_1 are simply supported (statically determinate), while the additional dead and live loads are applied to the system in its final state, which might be statically indeterminate. Applying prestress while the system is statically determinate and subsequently adding static constrains to achieve statically indeterminate systems is commonly seen in precast concrete elements. Under this assumption, indirect moments from prestressing do not need to be taken into account.

For all the beams considered, the following parameters concerning geometry, loading, and degree of the polynomial are defined: $L = 20\,m$, $H = 4\,m$, $B_i = 3\,m$, $B_e = 0{,}5\,m$, $\alpha = \pi/4$, $g_1 = 3\,kN/m$, $g_2 = 4\,kN/m$, $q = 2\,kN/m$, $n = 15$.

Three different static systems are considered: simply supported beam (SSB), beam fixed at one end (BFOE), and beam fixed at both ends (BFBE). The beams considered might represent a singular field of a continuous beam. To ensure a continuous geometry of the tendon above the supports, a constraint $\boldsymbol{g}$ is defined in such way that that the tendon arrives at the end of the fixed supports horizontally. To fully utilize the vertical space available, an optimal prestressing force P is chosen for each beam.

Table 2 Static systems of study cases

	System	Constraints
Simply supported beam (SSB)		$g \coloneqq \emptyset$
Beam fixed at one end (BFOE)		$g \coloneqq r'(0) = 0$
Beam fixed at both ends (BFBE)		$\boldsymbol{g} \coloneqq \begin{bmatrix} r'(0) \\ r'(L) \end{bmatrix} = \mathbf{0}$

The quality of the optimized tendon layout is evaluated by the achieved minimal value of the objective function $\mathcal{J}_P$. Moreover, the effectiveness of the optimized tendon layout is compared to two alternative approaches for the design of tendon layouts. First, a simplified solution that ignores the gradient of the tendon ($r_i'(x) \approx 0$ for slender beams) is introduced:

$$\boldsymbol{r}_{simp}(x) = \begin{bmatrix} x \\ f_y(x) \\ M_E(x)/P \end{bmatrix} \tag{25}$$

Second, the tendon layout r_{xz}, which is optimized without considering geometrical losses, is introduced. Instead of using the definition of $\tilde{\boldsymbol{r}}$ in equation (23) and considering the decrease in the tendon's effectivity due to its horizontal eccentricity during the optimization process, the tendon is optimized according to the simplified algorithm in section 3.1 and projected horizontally onto the tilted plane of the folded slab afterwards.

$$r_{xz}(x) = \begin{bmatrix} x \\ f_y(x) \\ \boldsymbol{a}^T \boldsymbol{\phi}(x) \end{bmatrix} \tag{26}$$

3.2.1 Simply supported beam (SSB)

The static system of a simply supported beam (SSB) at the time of prestressing does not differ from its system in the final state. Thus, the moment $M_E(x)$ due to the loads g_1, g_2, and q in the final state is:

$$M_E(x) = M_{SSB}(g_1 + g_2 + q) = \frac{1}{2}\,(g_1 + g_2 + q)\,x\,(L - x) \tag{27}$$

Figure 5 shows the optimized tendon layout considering a prestressing force of $P = 294\,kN$. The objective function has been minimized to a value of $\mathcal{J}_P = 1{,}917 \cdot 10^{-7}\,(kN\,m)^2 m$.

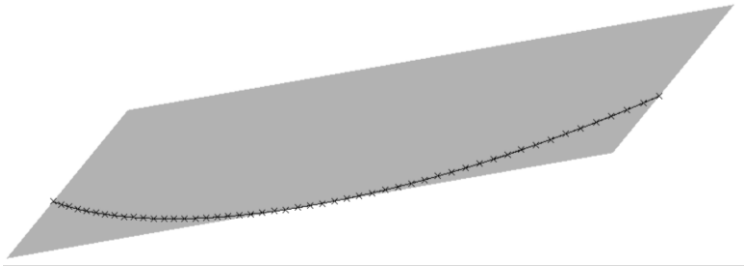


Figure 5 Optimized spatial tendon layout in a simply supported beam (SSB)

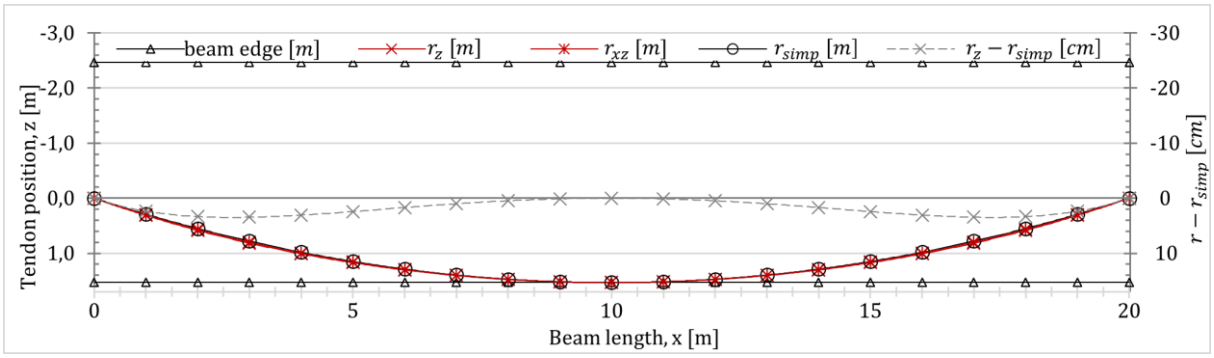

Figure 6 Vertical component r_z of the optimized spatial tendon layout in a simply supported beam (SSB), with and without considering geometrical losses in comparison to the simplified approach

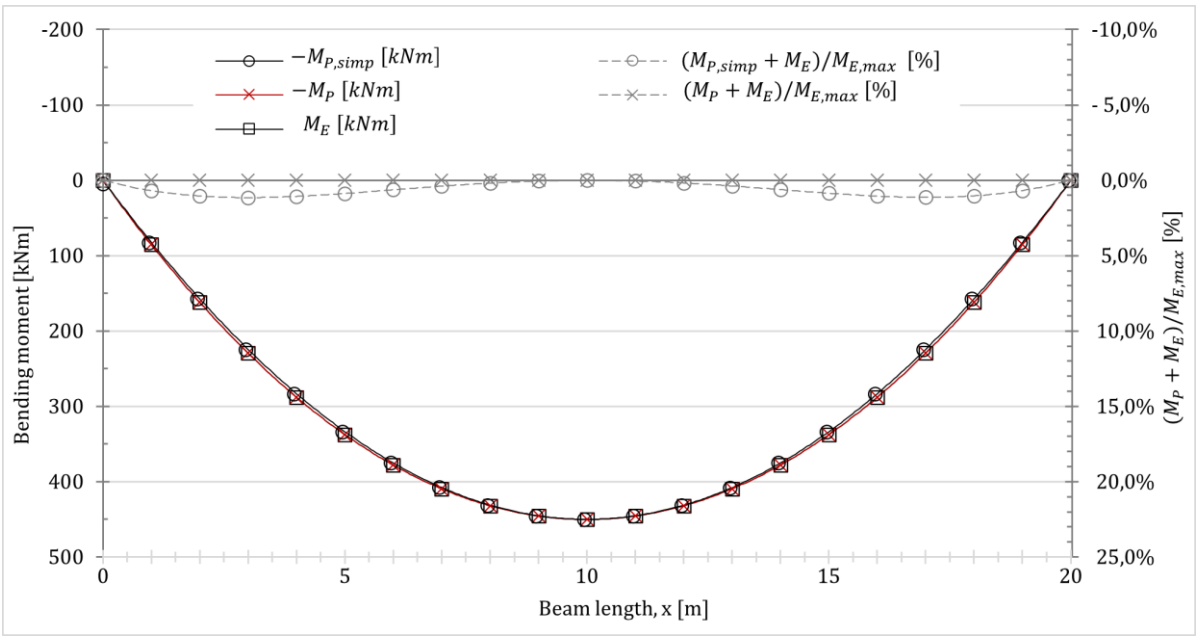

Figure 7 Bending moments due to external loads and prestress in a simply supported beam (SSB)

3.2.2 Beam fixed at one end (BFOE)

The static system of a beam fixed at one end (BFOE) at the time of prestressing is an SSB. Only in the final state is the system of a BFOE valid. Thus, the moment $M_E(x)$ resulting from the loads g_1, g_2, and q in the final state is:

$$M_E(x) = M_{SSB}(g_1) + M_{BFOE}(g_2 + q) = \frac{1}{2}\, g_1\, x\, (L - x) - \frac{1}{2}(g_2 + q)\left(x^2 - \frac{5}{4}\, L\, x + \frac{1}{4}\, L^2\right) \qquad (28)$$

Figure 8 shows the optimized tendon layout considering a prestressing force of $P = 204\ kN$. The objective function has been minimized to a value of $\mathcal{J}_P = 6{,}859 \cdot 10^0\ (kN\ m)^2 m$.

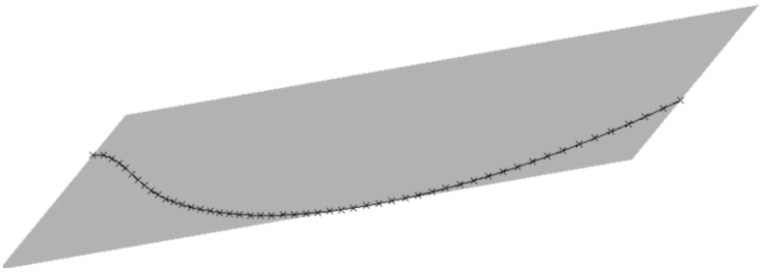

Figure 8 Optimized spatial tendon layout in a beam fixed at one end (BFOE)

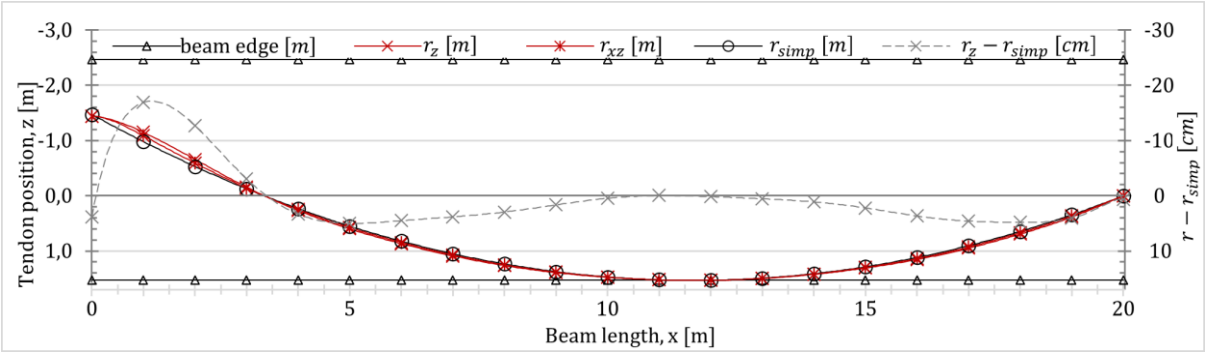

Figure 9 Vertical component r_z of the optimized spatial tendon layout in a beam fixed at one end (BFOE), with and without considering geometrical losses in comparison to the simplified approach

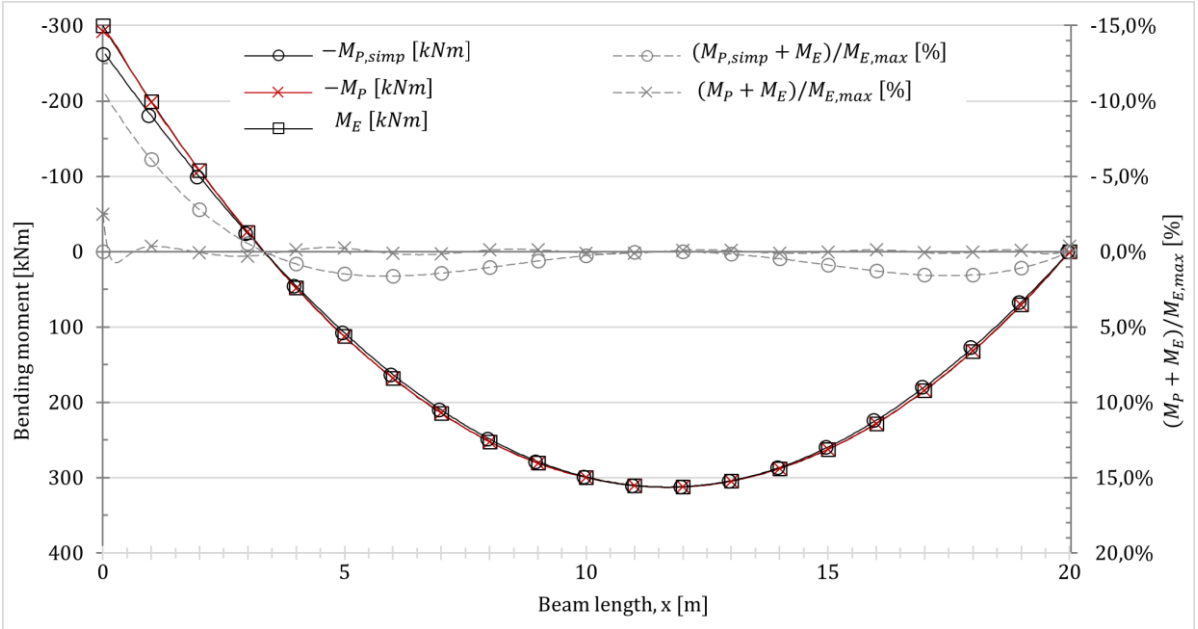

Figure 10 Bending moments due to external loads and prestress in a beam fixed at one end (BFOE)

3.2.3 Beam fixed at both ends (BFBE)

In the case of a beam fixed at both ends (BFBE), the static system at the time of prestressing is an SSB. The system of a BFBE applies in the final state. The moment $M_E(x)$ resulting from the loads g_1, g_2, and q in the final state is thus:

$$M_E(x) = M_{SSB}(g_1) + M_{BFBE}(g_2 + q) = \frac{1}{2}\, g_1\, x\, (L - x) - \frac{1}{2}(g_2 + q)\left(x^2 - L\, x + \frac{1}{6}\, L^2\right) \qquad (29)$$

Figure 11 shows the optimized tendon layout, considering a prestressing force of $P = 193\, kN$. The objective function has been minimized to a value of $\mathcal{J}_P = 1{,}387 \cdot 10^1\ (kN\ m)^2 m$.

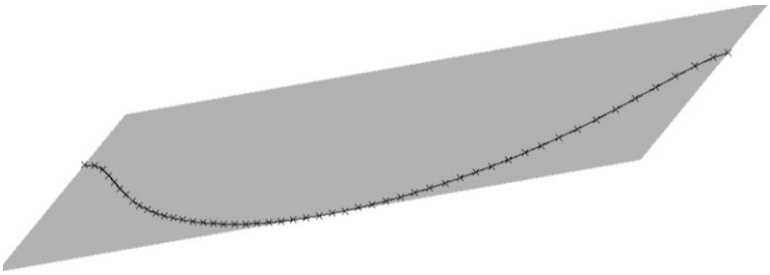

Figure 11 Optimized spatial tendon layout in a beam fixed at both ends (BFBE)

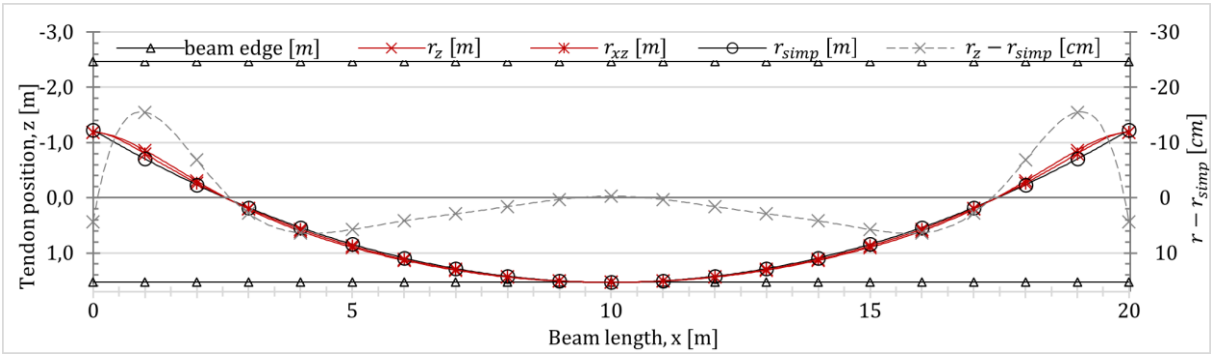

Figure 12 Vertical component r_z of the optimized spatial tendon layout in a beam fixed at both ends (BFBE), with and without considering geometrical losses in comparison to the simplified approach

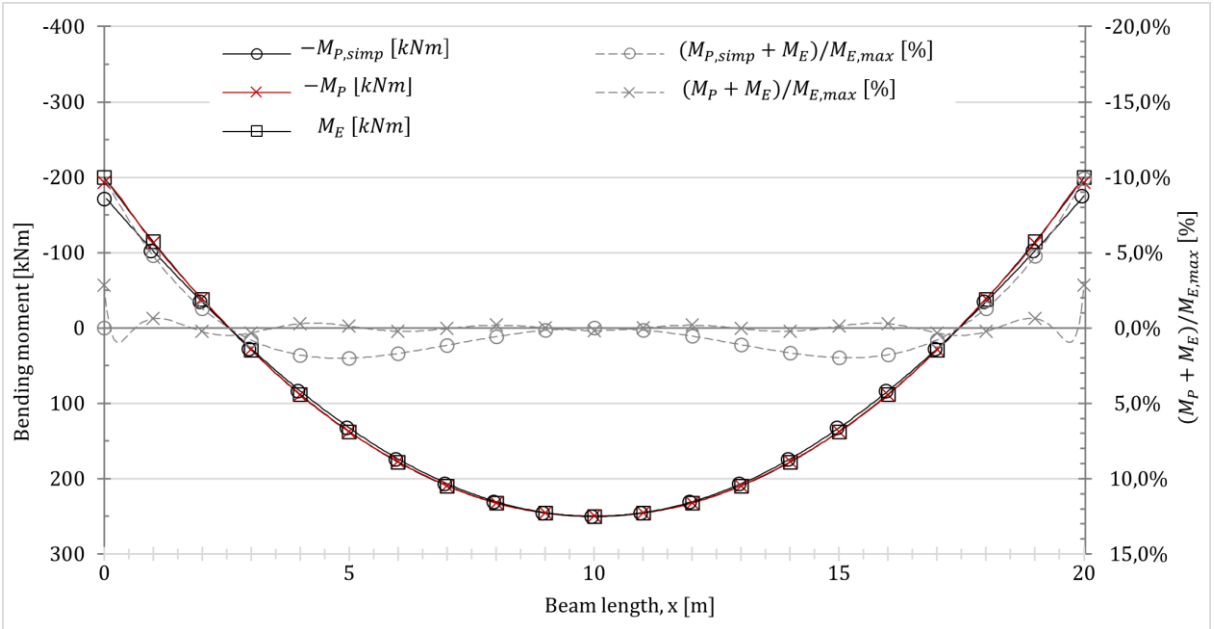

Figure 13 Bending moments due to external loads and prestress in a beam fixed at both ends (BFBE)

3.2.4 Analysis and comparison of the results

The z-components of the optimized tendon layouts in Figure 6, Figure 9, and Figure 12 show that the geometrical boundary condition of arriving horizontally at the fixed support was satisfied in every case. For an SSB, the simplified approach already results in very good compensation of the external moments. The improvement of the optimization is almost invisible in Figure 7. Figure 10 and Figure 13, by contrast, show for a BFOE and a BFBE that 99 % of the moment due to external loads M_E was compensated by the moment induced by the optimized tendon layout M_P, while the moment induced by a tendon designed with the simplified approach (see equation (25)) $M_{P,simp}$ compensates only up to 90%. As expected, the improvement is particularly visible in regions where there is a steep slope close to the fixed supports, where the geometrical loss due to the gradient of the vertical eccentricity r_z' is highest.

The comparison of the optimized tendon layout r_z to r_{xz} (see equation (26)) demonstrates the influence of the decrease in the tendon's effectiveness due to its horizontal eccentricity. The consideration and compensation of the change in horizontal eccentricity r_y' leads to an increase in vertical eccentricity r_z of the optimized tendon in comparison to r_{xz}. This demonstrates that it is necessary to consider the horizontal placement during the optimization process, instead of projecting the tendon onto the desired surface afterwards.

The achieved values of the objective function $\mathcal{J}_P$ differ between the three examples. The lowest value of $\mathcal{J}_P = 1{,}917 \cdot 10^{-7}\ (kN\,m)^2 m$ was achieved for the SSB, while for the BFBE a minimal value of $\mathcal{J}_P = 1{,}387 \cdot 10^{1}\ (kN\,m)^2 m$ was achieved. This demonstrates that with the same degree of the polynomial, the quality of the solution obtained for an SSB without constraints is higher than for a BFBE with two constraints. In order to satisfy the additional constraints during the optimization, additional turning points in the tendon layouts are necessary, requiring a higher degree of the polynomial.

3.3 Optimization of spatial tendon layouts in shells

To demonstrate the flexibility and potential of the proposed optimization method, the geometrical model of spatial tendon layouts is applied to a shell as shown in Figure 14 and Figure 15.

Figure 14 Prestressed cylindrical shell [10]

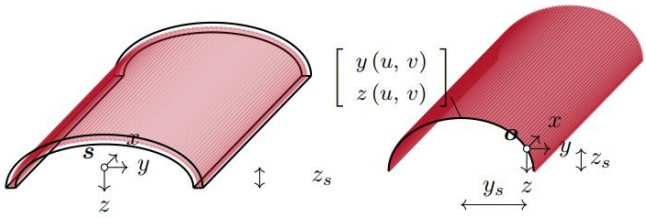

Figure 15 Geometric model of shells

The curved surface of an elliptical shell is described by $f_y = R\cos(v) - y_s$ and $f_z = -R\sin(v) - z_s$. With equations (16), (17), and (18), that leads to the following approximation for the tendon:

$$\tilde{\boldsymbol{r}}(x) = \begin{bmatrix} u \\ f_y \\ f_z \end{bmatrix} = \begin{bmatrix} u \\ a\,R\cos(v) - y_s \\ -R\sin(v) - z_s \end{bmatrix} = \begin{bmatrix} x \\ a\,R\cos\left(\boldsymbol{a}^T\boldsymbol{\phi}(x)\right) - y_s \\ -R\sin\left(\boldsymbol{a}^T\boldsymbol{\phi}(x)\right) - z_s \end{bmatrix} \tag{30}$$

More in-depth examinations of local effects that influence the mechanics and structural behaviour of shells need to be conducted based on the geometrical model for tendons in shells.

4 Conclusions and outlook

This paper proposed a novel method for optimizing tendon layouts in spatial structures. The optimized tendon counteracts the deflection of beamlike spatial structures resulting from external loads, while complying with practical boundary conditions. It is defined as a three-dimensional curve that is restricted

to the cross section of the thin-walled spatial concrete structure. The examples presented here provide evidence of the effectiveness and flexibility of the approach.

The proposed method employs analytical solving and approximation techniques rather relying on elaborate iterations. Incorporating design space restrictions immensely reduces the complexity of the solving algorithm, resulting in a significant reduction in processing time. The solution obtained is fully defined by a precise polynomial that takes into account any desired geometrical boundary conditions. This approach greatly facilitates easy implementation of the method and more efficient structural design.

The formulation of the objective function also allows for varying loads or the consideration of prestress losses during the optimization process. Notably, the geometrical model of a spatial tendon was successfully applied to a shell, which shows the potential for the proposed method to be applied to a wide range of spatial structures. Further examinations should nonetheless be conducted in order to examine if tendon layouts in more complex structures with non-prismatic cross sections or multidimensional stresses can be optimized by basing the objective function on stresses instead of bending moments. Additionally, the secondary effects of prestress in statically indeterminate systems should be examined to determine how they can be taken into account during the optimization process.

In conclusion, the proposed optimization method for tendon layouts in spatial structures represents a significant advancement in the field of structural engineering. Its flexibility, efficiency, and accuracy make it a powerful tool for designing more sustainable and lightweight concrete structures.

Abstract

This paper describes a novel approach to structural optimisation based on learning design strategies rather than searching for optimal solutions. In the proposed approach, an AI agent is trained through Reinforcement Learning (RL) to explore a 3D modelling environment and iteratively morph a flat NURBS surface into a doubly-curved shell structure. At each iteration of the 3D modelling process, the agent computes the maximum structural displacement through FEM analysis: it learns to select modelling actions through this feedback and progressively improves the performance of the input surface. Unlike current applications of RL in structural design, where the AI agent generates design options by recombining a predefined set of design variables, our approach aims to create structural forms through the interaction of a designer and an AI agent within a 3D modelling environment. An application illustrates that our agent can interpret a preliminary structural form defined by a designer and iteratively transform such a form to improve its structural performance. The trained agent can hence transform the geometry and improve the structural performance of any open surface that features a square footprint and is defined through a sequence of modelling commands. Preliminary results suggest that this AI agent can be used for the development of more interactive tools for structural design and optimisation.

1. Introduction

In 1995, John Fraser wrote that "space, structure and form are the traditional outward expressions of an architectural concept which has developed in the mind of the architect" and that "architectural concepts are expressed as generative rules so that their evolution may be accelerated and tested. […] Computer models are used to simulate the development of prototypical forms which are then evaluated on the basis of their performance in a simulated environment." Regarding the role of computers in the creative/generative process of architectural form, Frazer stated that they are "slaves of infinite power and patience" and "are not without their dangers. If used unimaginatively, they have a tendency to: dull critical faculties, induce a false sense of having optimised a design which may be fundamentally ill conceived" [1]. On the one hand, these statements lucidly explain how aware Frazer was of the limits of using optimisation algorithms as an integral part of the architectural design process. On the other hand, these sentences denote an unbridgeable gap in the interface between humans and machines – a separation and a consequent interruption of the workflow between the conception and implementation of design ideas that still exists today every time one formulates the invariants and design variables of a parametric model for optimisation purposes.

Contrary to what one might intuitively think, computational and performance-oriented design workflows based on classical parametric modelling and optimisation algorithms disrupt rather than support the spontaneous and mostly unconscious human process of synthesis: what we generally refer

to as the holistic creation of an architectural idea. Human designers do not need an explicit and analytic definition of design spaces to be able to explore and test formal solutions within such spaces. Expert designers rarely constrain themselves to search for creative design solutions within a single design space. The processes of human thoughts are complex and flow more like a river than follow a set of instructions. The emergence of unexpected architectural forms through optimisation is, therefore, a clear illusion because it is always an expert designer to call the shots throughout the process [2]. Mutsuro Sasaki wrote that structural forms designed through optimisation are mutable, fluid and organic and can hence be called *flux structures*, but he also described in his book how critical it is that architects and engineers collaborate throughout the optimisation process to create such fluid structural ideas [3].

The problem does not lie in the workflow or efficiency of the tools used: the problem is the interface between human thought processes and the internal functioning of computer programs.

To an extent, this might explain why it is easier for architecture students to learn structural design strategies based on physical form-finding models: the workflow presents fewer interface issues, allowing young designers to synthesise ideas entirely within the analogue domain. Unfortunately, classical form-finding is not plague-free and has many other limits that might impact human creativity, such as the impossibility of generating non-optimal structural forms or simulating more than one physical phenomenon at a time [4].

We believe there is a better way to approach structural optimisation through Reinforcement Learning (RL), and we quantify 'better' as enhanced interactivity between human designers and computers. The paper illustrates this approach, which allows designers to conceive, model, morph, and explore structural forms in a CAD environment without requiring an analytic problem formulation, as is the case for classical optimisation processes. Section 2 briefly introduces RL applied to structural design and highlights the differences between RL and other machine learning algorithms for structural optimisation. Section 3 describes how we conceived our RL application as the definition of a *design game*. It also provides details on the AI agent training and evaluation. Section 4 focuses on the key aspect of this paper: interactivity between a human designer and the AI agent. In the concluding section, we reflect on the limits and potential of our application, noting that, in this field, innovation is achieved through a series of small results. Such results do not provide readers with tools that are readily available to use in practice. However, they aim to indicate a path to follow, whose originality can be better understood if read in parallel with a more theoretical article on optimisation, creativity and AI that we published in 2022 [5].

2. Reinforcement learning in structural design

Artificial intelligence (AI) has become increasingly popular in structural design and optimisation, with many approaches focusing on prediction tasks. For instance, AI has widely been used to predict the behaviour of structures based on large datasets. In a previously published work, we demonstrated that generative models based on AI, such as Variational Autoencoders (VAE) have advantages over traditional methods based on parametric modelling in structural optimisation applications [6]. We also used generative models to synthesise new structural forms by recombining features extracted from existing design precedents [7]. These approaches have something in common: they all rely on large amounts of data. In contrast, AI models trained through RL do not require datasets and can be applied to a broader range of problems, particularly those where data is scarce or unavailable.

RL relies on the Markov Decision Process (MDP), a mathematical framework that formalises decision-making problems as the interaction between an agent that takes actions and an environment in which such actions are performed. An MDP unfolds as a sequential process: at each iteration of the decision process, the agent performs an action, which modifies the subsequent state of the environment, and collects a reward, i.e. positive or negative feedback that indicates whether the agent is moving towards or away from its goal.

In structural optimisation, the agent may represent a designer, whereas the environment can be a digital representation of a preliminary structural form. The objective of the decision-making problem can be to adjust the design to improve its structural performance. To achieve this objective, the agent needs to learn a strategy or *policy* to select actions, in this case, local adjustments of the structural form, that lead to a structural improvement. In the real world, an expert designer would already know the best course of action to produce a structurally sound design option. Conversely, an AI agent cannot rely on an existing body of knowledge: it needs to acquire such knowledge from experience.

RL can be used to teach an AI agent how to discriminate between actions and select only those that lead to a successful outcome. The objective of the training process is to learn a function that for each state of the environment, e.g. any partially defined structural form, returns the action which leads, in expectation, to the highest possible structural improvement. A popular approach computer scientists use consists of modelling the agent as an Artificial Neural Network (ANN) and training such a model to perform the mapping between state observations and actions.

RL has historically been applied to teach AI agents how to play video games [8] and control robots [9]. In the design fields, RL has instead been applied for optimisation and has thus been tested as an alternative to other computational techniques for performance-driven design.

Mandow et al. [10] described an application of RL for the spatial planning of single-family dwellings. The application was aimed at optimising such performance requirements as habitability and energy consumption and was based on a previous work by Ruiz-Montiel et al. [11], which only considered functional requirements. In that study, the researchers used a representation scheme based on shape grammar, in which actions corresponded to the selection of a design rule from a predefined set. The agent was trained to find any sequence of rules that produced an optimal planning solution.

Similar performance-driven approaches have been used to address such engineering design problems as the optimisation of combustion systems for coal-fired boilers [12], traffic flow optimisation [13], and waterflooding optimisation [14]. In these applications, the agent observed simplified representations of the state space – i.e., feature vectors representing design attributes – and performed actions that involved the adjustment of predefined variables. Yonekura and Hattori [15] used a different representation of the state space for turbo-machinery optimisation. In that case, the state space was represented by coloured contour images of pressures around an airfoil – therefore pixels rather than features – although the action space was still described by a limited set of design variables.

Hayashi and Ohsaki [16] used RL in structural design for the optimisation of 2D steel frame structures of buildings under static loads, where each structure was parametrised by a set of design variables. They also tested RL for 2D topology optimisation, where the representation of each structure was a connectivity graph [17]. RL has also been applied to optimise the design of truss structures for a set of boundary conditions [18, 19].

All the applications described above were successful because of the suitability of treating performance-driven design as an RL problem. Like other optimisation approaches, RL frameworks allow design problems to be formalised in terms of design variables – or design rules – and objectives.

The main difference between RL and other machine learning algorithms for structural optimisation, such as GAs, is that the former can be used to train an AI agent to learn an optimisation strategy. In other words, an agent trained with RL can solve an infinite number of optimisation problems by finding optimal or sub-optimal solutions for previously unseen boundary conditions. Conversely, each optimisation run with a GA requires the statement of a fixed set of boundary conditions. GAs can learn the best action to take – i.e., how to update the design variables – albeit only for those specific initial conditions, which means that the algorithm cannot reuse the experience acquired during each optimisation run to solve analogous problems.

Another characteristic of RL algorithms is that they can effectively learn decision-making strategies by exploring large action spaces. Although this creates an opportunity to enhance the capabilities of computational tools, in terms of design exploration, this feature has not been fully harnessed in current applications, which involve defining small action spaces consisting of a limited number of design variables. Such spaces are designed to ensure that the agent always produces solutions that satisfy a given set of design constraints, thereby minimising the time spent evaluating unfeasible design options. However, like other optimisation approaches, this prevents the agent from exploring solutions that lie outside the solution space considered by the designer.

A computational model that learns to optimise structural forms should explore large action spaces, just as humans do. Through the exploration of large action spaces, the agent is expected to gain sufficient knowledge to assist designers during the development of a preliminary structural design proposition, where such a proposition can be freely modelled in a CAD environment without the need to select a limited set of variables for the construction of a design space.

The following sections describe how an AI agent that interacts with a 3D modelling environment can be trained to learn sequences of actions or commands that maximise the structural performance of a preliminary design proposition. They also present an AI-CAD interface whereby the trained agent can interpret the 3D modelling actions taken by a designer and suggest additional actions to improve the performance of the design.

3. An AI agent for structural optimisation in CAD

Unlike conventional approaches for structural optimisation, which explore local adjustments of a single predefined design, the application described here involved training an AI agent to learn a design strategy that transformed any input design – constructed by moving the control points of a square surface – into a structurally sound design option. The agent developed this strategy by balancing the randomness involved in the action selection process with the maximisation of a structural performance reward.

3.1. The design game

The application required developing a *design game*, i.e. a simulation in which the AI agent could generate and assess the performance of a shell structure. During the game, the agent received feedback in the form of a reward based on how well the design performed according to a specified criterion. The *design game* comprised: (1) a 3D modelling environment, which allowed the agent to observe and manipulate 3D geometries, (2) a procedure that converted a 3D form produced by the agent into a structural model, and (3) a FEM solver that analysed a structural model to inform the agent about its structural performance.

The agent collected information about a specific state of the 3D modelling environment as a 2D image, hereafter referred to as ‘canvas’, whereas it performed 3D modelling actions by selecting points on a discrete 2D grid named ‘canvas grid’. The canvas grid consisted of an 8 × 8 matrix of values, representing the z-coordinates of 8 × 8 equally spaced control points used to construct a degree 7 NURBS surface. Given a canvas grid configuration, the environment first generated the NURBS surface (Figure 1, stage 1) and then sampled 16 × 16 points from such a surface to produce the canvas observation (Figure 1, stages 2-3). The canvas observation stored information about the height of the NURBS surface at the sampled point locations, which could therefore be visualised as a depth map. Height information was normalised from [-8, 8] to [0,1] so that the flat surface generated from a canvas grid initialised with zeros was rendered in the canvas observation space as a solid mid-grey image (v = 0.5). Moreover, any point z-coordinate outside the [-8, 8] range was clipped to keep the NURBS surface within a 20 × 20 × 16 3D volume. For instance, if the z-coordinate of a NURBS surface sample point was equal to 10, it was clipped to the upper bound of 8 and rendered in the canvas observation space as a white pixel (v = 1).

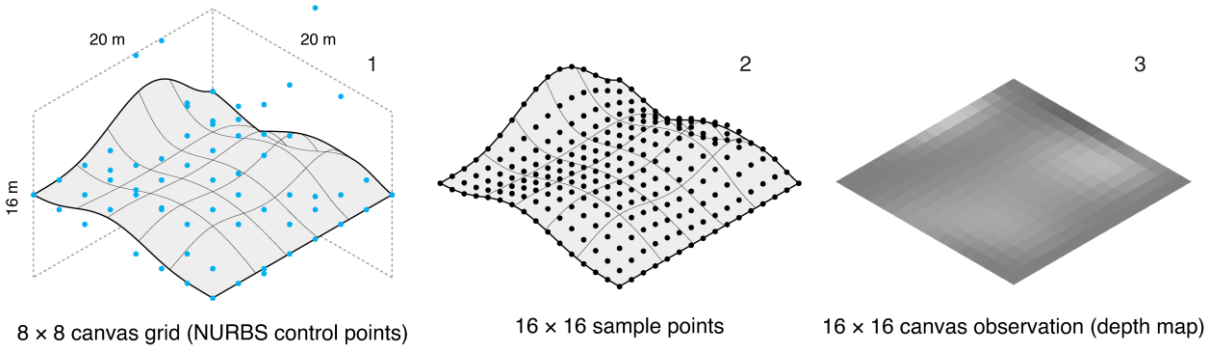

Figure 1. The three stages used to convert the canvas grid into the canvas observation space.

A design action modified the state of the canvas grid by updating one of its values, i.e. changing the z-coordinate of one control point. The agent selected a control point and applied a translation vector to perform this action, meaning it had to perform a sequence of sub-actions. The first sub-action was selecting a vector location point (*P*) from the 8 × 8 available control points. Having chosen a control point, the agent first decided on the vector direction *(d)*, which could be either -1 or 1, and then on the vector length (*l*), i.e., to what extent the control point had to be moved along the z-axis. The vector length was defined as an array of 10 values, where each value represented a 1-step increment in the [0,10] range. A design action was therefore characterised by a tuple of three elements (*P*, *d*, *l*) of (64, 2, 10) sizes.

After the agent performed the complete sequence of sub-actions described above, the environment updated the z-coordinate of a control point, generated a new NURBS surface, and produced a new canvas observation. Figure 2 shows a sequence of three actions performed by the agent in the canvas grid and the canvas observation space.

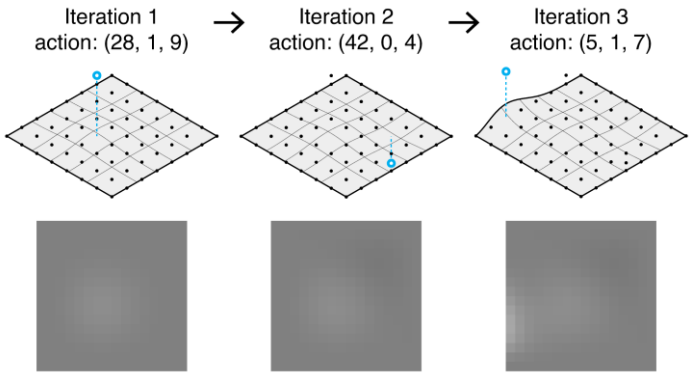

Figure 2. Sequence of three design actions performed in the environment development for the shell design application. At the top: drawing instructions in the canvas grid; at the bottom: canvas observations constructed from the canvas grid.

The structural model for FEM analysis was constructed from the data stored in the canvas observations. A 16 ×16 point grid spaced by 1.3 m in the x and y directions was first built to produce a 20 × 20 m shell footprint. Then the unnormalised height values of the canvas observations were assigned – in the [-8, 8] m range – to the z-coordinates of the point grid. Finally, a NURBS surface was interpolated from the resulting 3D point grid and transformed into a triangulated mesh, ready for the mechanical properties to be assigned.

All the mesh faces were converted into shell elements, and 5 cm thick C35/45 material concrete was assigned. The mesh corners were used as fixed support nodes, whereas a uniformly distributed gravity

load of 2 kN/m^2 was applied to the shell elements. The structural reward R_{str} was computed from the maximum displacement of the shell as follows:

$$R_{str} = 11 - min\left\{1, \frac{d}{m}\right\} \times 10 \quad (1)$$

with $m = 500$

where: d is the maximum displacement of a shell structure designed by the agent, and m is a positive margin representing the maximum allowed displacement.

Figure 3 shows the structural model of a shell structure constructed from a canvas observation, according to the abovementioned process.

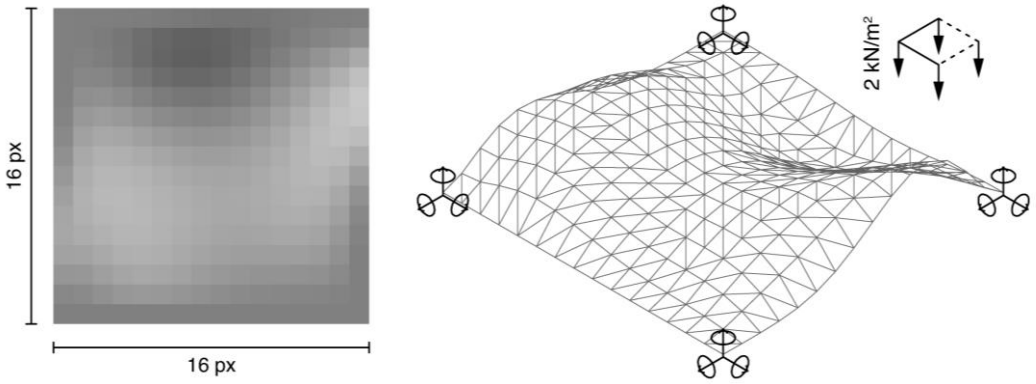

Figure 3. Conversion of a shell structure representation from the observation space (on the left) to a geometrical and mechanical model for FEM analysis (on the right).

3.2. Training and evaluation

The AI agent was modelled with an ANN – called policy network – and trained using an RL approach named Policy Gradients (PG). The training process works as follows: the agent takes a canvas observation as input and outputs a probability distribution p over actions. Then, it selects a modelling action with probability p, performs such an action in the environment and collects a structural reward. The scope of the training process is to compute a probability distribution that leads to the selection of actions producing increasingly higher structural rewards for every canvas observation.

PG can be implemented using different algorithms. The one used here is a variant of the REINFORCE algorithm called advantage actor-critic (A2C) [20]. The first author of this paper adapted the model architecture and training process from a previous work by Ganin, et al. [21]. Details about the network architecture can be found in Mirra [22]. The policy network was used to generate sequences of actions and, therefore, full design episodes and to produce the loss terms necessary for the training process.

Figure 4 illustrates how the agent interacted with the environment to produce shell design options. The episode length was set to 20 iterations, during which the agent observed the shell geometry – as a depth map – and decided how to modify it to improve the structural performance. At the end of an episode, the structural rewards, R_{str} were transformed into 1-step reward increments as follows:

$$R_{t(step)} = R_t - R_{t-1} \quad (2)$$

This reward redistribution allowed the agent to observe how much reward it received after performing an action compared to what it had achieved in the previous time step. In the context of the shell design task, this reward represents to what extent a design action contributed to reducing the maximum displacement of the shell.

As Ganin, et al. [21] suggested, an entropy loss term was included in the definition of the PG standard loss terms. This term penalised the agent for shrinking the probability distribution of each sub-action too soon, i.e., it introduced a degree of randomness into the action selection process by increasing the smoothness of the probability distributions.

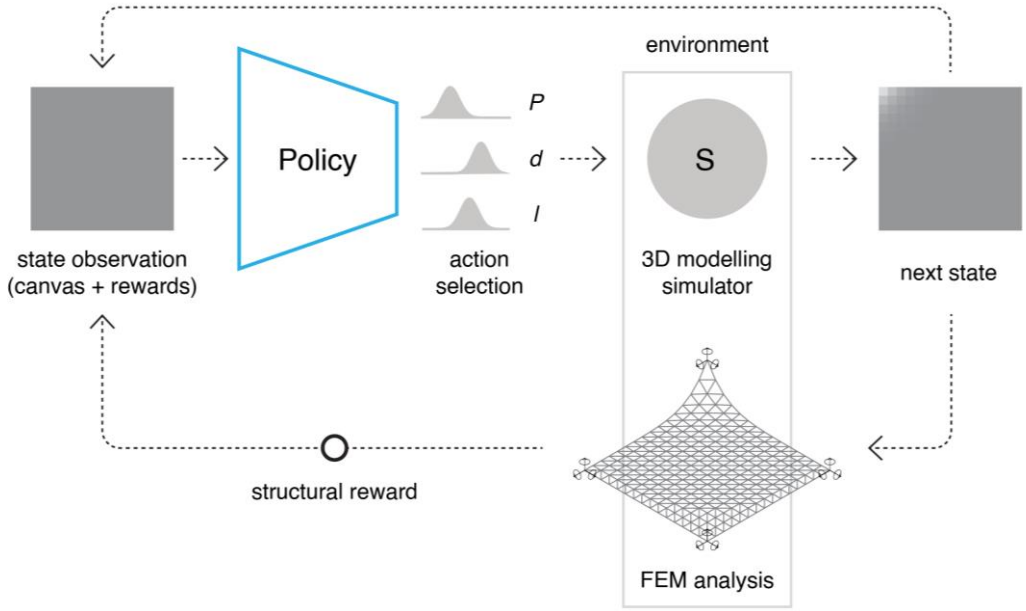

Figure 4. Interaction of the policy network with a 3D modelling simulator.

The agent was trained for 25,000 episodes, using a learning rate of 1e-4. Figure 5 (at the top) shows the structural reward collected by the agent at the end state, averaged for groups of 50 consecutive episodes. In contrast, Figure 5 (at the bottom) illustrates the canvas observation and corresponding NURBS surface at the end of some episodes produced during the training process. The reward graph in Figure 5 demonstrates that, by e_{50} = 100, the agent had already converged to a good-performing policy, achieving a reward of over 9. The trend slightly increased over the next episodes and peaked at 9.5, around e_{50} = 350. The end states in Figure 5 reveal that, between e = 250 and e = 5000, corresponding to e_{50} = 100, the agent learned to move most of the control points upwards, thereby producing depth maps with an average grey value $v > 0.5$, which led to progressively more convex surfaces. The agent also developed partially concave surfaces in e = 15,000 and e = 17,500 by either moving the internal control points to different heights or those on the edges to create openings.

The training process results demonstrate that the agent learned to solve the design task in the early iterations. However, it never reached a higher average reward than 9.5. This result was expected, considering the definition of the loss terms. Since the agent was trained to minimise the entropy of each sub-action probability distribution, it tended to produce variations of sub-optimal solutions rather than converging on a single optimal one.

The training process was further validated through a design generation task. The agent was run for 1000 episodes, and the rewards collected at the end state were plotted onto the histogram shown in Figure 6 (on the left). Since the agent always produced solutions with a score higher than 5, and most of the solutions fall into the three last bars of the graph, this test suggests that the agent successfully learnt to morph a flat surface into a performative shell structure.

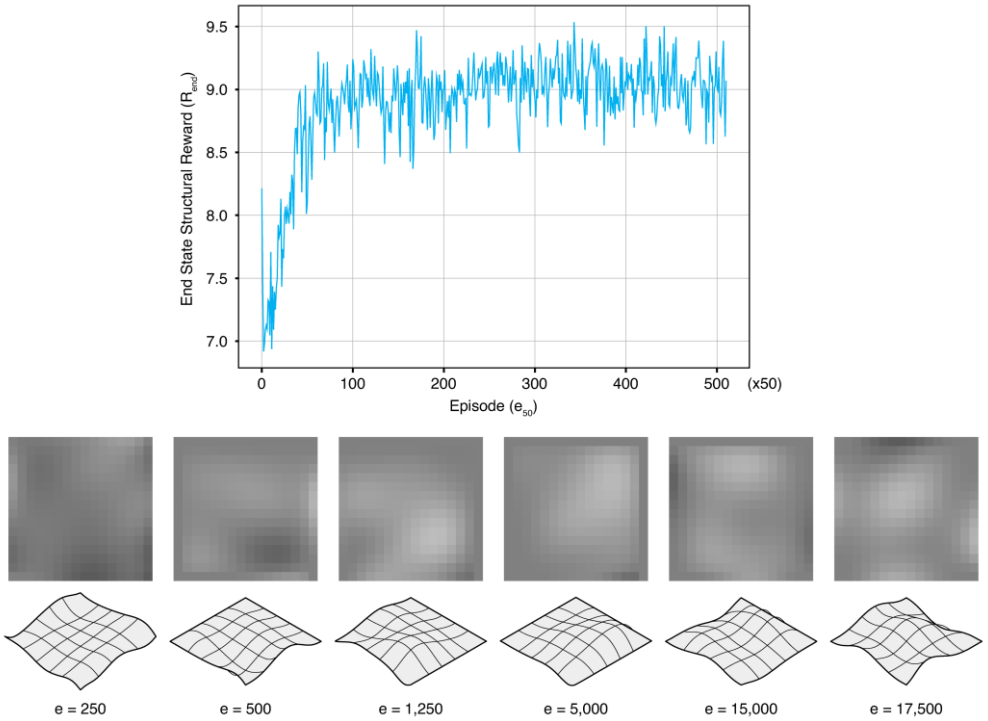

Figure 5. Results from the training process. At the top: trend of the structural rewards at the end-state averaged for groups of 50 consecutive episodes; at the bottom: End states achieved by the agent during the key stages of the training process visualised as depth maps (canvas observation format) and NURBS surfaces.

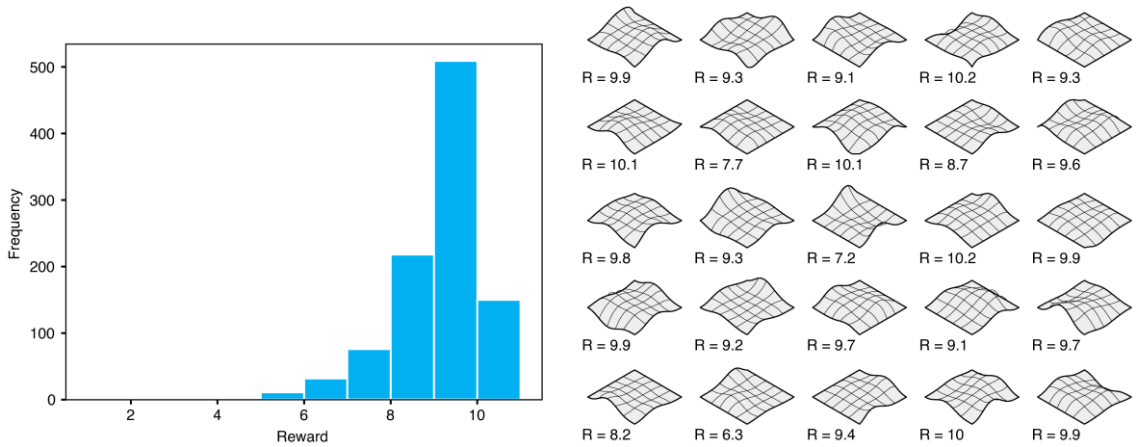

Figure 6. Results of the design generation task. On the left: distribution of the structural rewards collected by the agent at the end of the 1000 episodes; on the right: some of the shell design options generated by the agent at the end of the 1000 episodes.

Figure 6 (on the right) illustrates 25 solutions generated by the agent during the design generation task. Most of these shell structures are shallow and characterised by one or more openings, which is one of the strategies that the agent developed towards the end of the training process. The analysis of the mean structural reward per iteration collected by the agent at the end of the 1000 episodes of the design generation task (Figure 7, on the left) shows how the agent applied this strategy after training. The agent exploited all 20 available actions to progressively increase the performance of the flat surface used as input. Moreover, the trend of the 1-step structural reward can be seen to increment (Figure 7, on the

right), thus demonstrating that the agent performed the most valuable actions within the first five iterations and spent the remaining iterations refining the design. This, in turn, led to increasingly minor structural improvements.

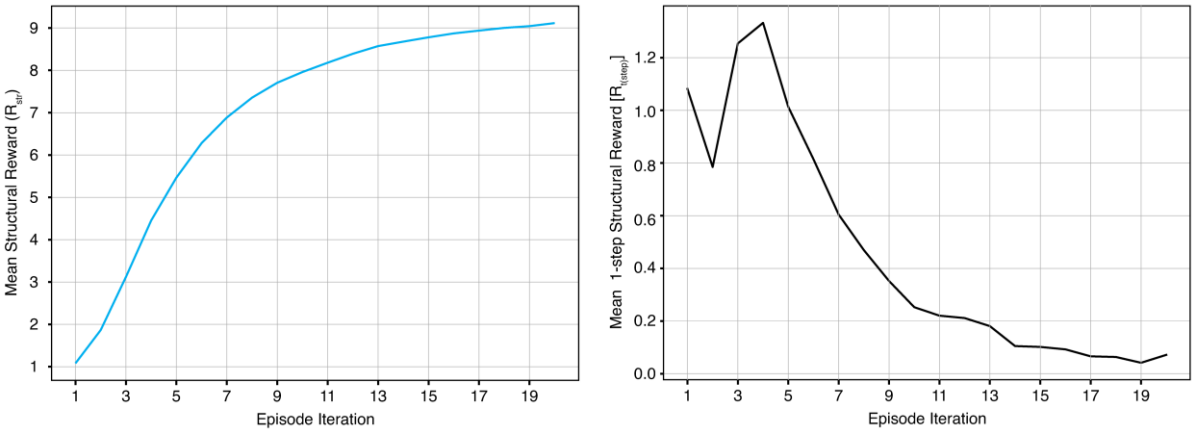

Figure 7. Detailed analysis of the average rewards collected by the agent during the 1000 episodes of the design generation task. On the left: mean structural reward for each episode iteration; on the right: mean 1-step structural reward increments for each episode iteration.

4. Interaction with the AI agent

A design completion test was used to assess how the agent could interact with a designer through CAD software and to what extent it could use the knowledge acquired during the training process to support the exploration of design options.

An AI-CAD interface was implemented in *Grasshopper* for *Rhinoceros 3D* to manage the exchange of information between the agent and the designer. Communication occurred through the specification of 3D modelling instructions, or commands, in the same format used for the training process. Therefore, a designer could transform a flat surface by moving the control points in the z-direction. Each time a control point was moved, the action was recorded and converted into a tuple (P, d, l) (see Section 3.1). After N transformations, the sequence of actions was sent to the agent, which then completed the design by performing additional actions (Figure 8).

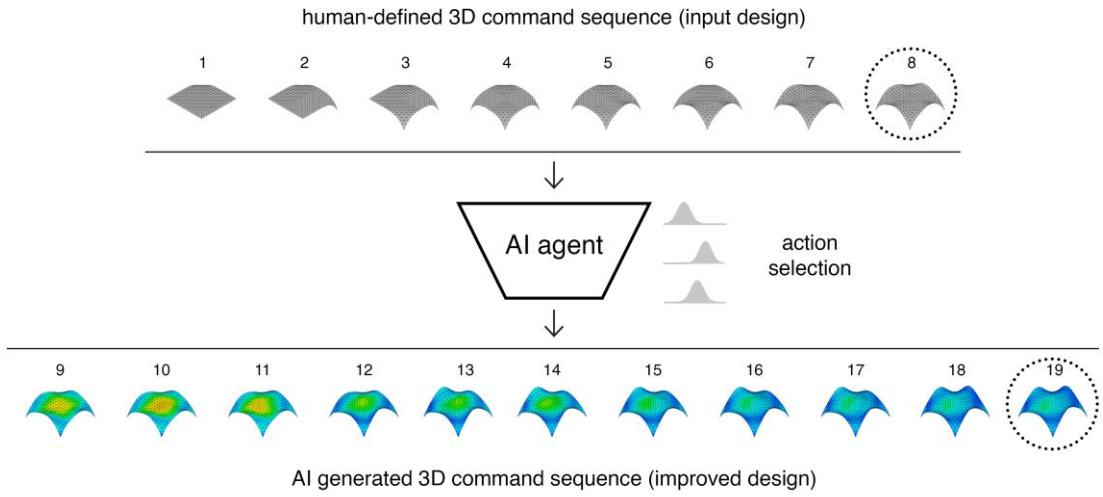

Figure 8. Human-AI interaction workflow for the structural optimisation of shell structures based on the exchange of 3D modelling commands.

Figure 9 shows three forms used as input and a set of outputs (a to e) produced by the agent after completing the 3D modelling sequence. The three forms reproduce a preliminary design for (1) a dome, i.e., a shell with four openings and two symmetry axes, (2) a barrel vault, and (3) an anticlastic shell.

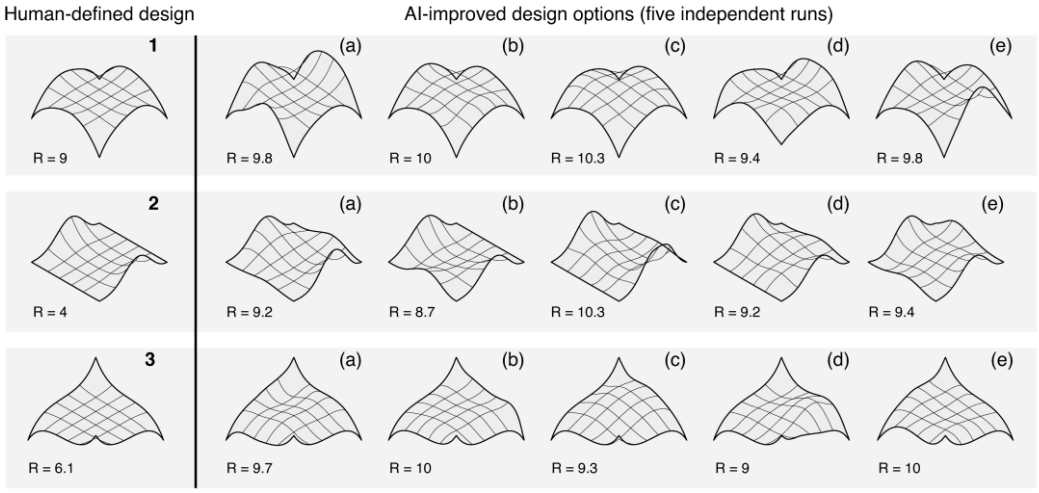

Figure 9. The three input shell designs used for the design completion task and the set of design options (a-e) generated by the agent at the 20th iteration.

Input design 1 (Figure 9, at the top) was constructed from a sequence of 8 modelling actions: the four control points at the corners of the surface were moved downwards, whereas the four control points at the centre of each edge were moved upwards. The resulting form achieved a structural reward of 9. The sequence was sent to the agent five times to produce five different design options. The agent processed the input sequence and performed additional actions until iteration 20. Overall, the five solutions produced by the agent preserved the main features of the form generated using the input sequence, i.e., a shell with four support points and four openings, but improved its structural performance. The agent completed the sequence by either increasing the height of the openings (solutions a, d, and e) or moving the internal control points (solutions b and c).

Input design 2 (Figure 9, in the centre) was generated from a sequence of four modelling actions. The control points in the centre of two opposite edges of the flat surface were moved upwards. There were four modelling actions because each point had to be moved twice: the maximum value of the sub-action l (vector length) did not allow sufficiently tall openings to be produced by a single modelling action. In this case, the agent was also able to improve the structural performance, but the main features of the input design were not preserved. The agent introduced at least one another opening for all the solutions, except for solution c, by moving the external control points.

Input design 3 (Figure 9, at the bottom) was also constructed from a sequence of four actions. The two control points at the end of each diagonal of the flat surface were moved upwards and downwards. The agent completed the design by mainly moving the internal control points, which produced high-scoring solutions while preserving the main features of the input design.

The test illustrates that a designer can interact with the agent by specifying a sequence of 3D modelling commands. The agent could produce more than one solution for each input, allowing multiple design options to be evaluated. This behaviour is possible because the agent did not output a single action for each state observation, but rather a probability distribution for selecting actions that maximised the reward. This can be seen as a way of steering a structural optimisation process towards design options with desirable features, such as the position of support points and openings. By interpreting an input form – resulting from a sequence of modelling actions – defined by a designer, the agent produced a design option that maximised the structural performance reward. It did this by adjusting the input design, thus simulating a process of form improvement.

5. Discussion and conclusions

The application described in this paper illustrates a novel manner of approaching structural design through AI, whose originality lies in a level of human-machine interactivity that cannot be seen in classical computational models for structural form-finding and optimisation. Our approach is not based on the definition of a design space like other optimisation procedures and, therefore, it is intrinsically more interactive and aims to open a research path for future AI applications.

It is worth noting that the test considered in this paper does not provide sufficient evidence that a trained AI agent can recognise specific structural performance issues in each input configuration and respond accordingly. It might have consistently applied the same strategy, which may have worked equally well regardless of the input sequence. In fact, due to the high degree of the NURBS surface, with which the agent interacted, moving the control points only generated a local deformation, thus producing flat regions in the centre of the input shell. Increasing the curvature in the centre is always expected to increase the structural performance of the shell, which might explain why the agent managed to produce high-scoring solutions consistently.

Another issue of the application described is that a designer must provide the 3D modelling commands by following the definition of the action space used for training the agent: this is a clear limit for the designer's freedom and flow of thoughts, particularly during the early design stages. With the current application settings, a designer cannot just produce a preliminary shell design using any geometric transformations the CAD software allows. For instance, they cannot move the control points in a direction other than z or exceed the maximum vector length per iteration. Furthermore, any input design must be provided as instructions that transform a flat surface since the agent always took this configuration as the initial state.

Future developments of this specific application should focus on providing the AI agent with examples of structural typologies to narrow down the search process and improve the quality of the feedback to the designer.

Abstract

This research paper presents a computational method for designing architectural elements using functionally graded cementitious materials, with the aim of reducing embodied carbon and mass. Functionally graded materials, commonly found in nature, are materials that have a graded variation in their composition or properties, which can be tailored to specific structural requirements [8]. In this case, the material used is CharCrete, a cementitious material that includes biochar, a type of carbon-sequestering material made from biomass. The CharCrete material system includes five grades with varying quantities of biochar that attain a range of structural performances and carbon footprint. Topology optimization is used in architectural design to reduce the material while optimising the structural performance and is a common approach for designing geometrically complex structures. However, topological optimization is typically more suited to homogeneous material systems [20]. In contrast, the method proposed in this research additionally transfers complexity to the material allocation instead of, solely, to the geometry, and is specifically tailored to heterogeneous material systems. The finite element analysis (FEA) method is used to optimise the distribution of different grades of CharCrete according to structural requirements. By maximising the use of carbon-negative biochar in the CharCrete, the method aims to minimise embodied carbon and mass while maintaining structural integrity. The method is implemented using FEA within the Grasshopper environment with the Karamba3D plug-in, and multi-objective optimization is used to find the optimal material grade allocation on a case study of flat and vaulted slabs. The results are compared to homogeneously distributed standard concrete. The research results show that the developed computational method is effective in generating carbon-offsetting digital designs while maintaining structural integrity. The research suggests that optimisation techniques and generative design methods can be integrated into architectural design to address the challenge of decarbonisation from a material perspective.

Keywords: functionally graded concrete, bio-inspired design, vaulted slab, optimisation, carbon sink, biochar, charcrete, embodied carbon, decarbonisation

1. Introduction

The view that most carbon is produced during the "life" of a building, and only 11% of the total carbon was embodied is shifting as research from 2017 suggests that the gravity and time sensitivity of embodied carbon in the building sector has been significantly underestimated. Although our contemporary practices and policies primarily focus on reducing the energy consumption of buildings to lower the CO_2 emissions during their operation, the biggest challenge lies in decreasing the embodied carbon of the building industry.

In terms of computational design different approaches responding to the challenge of embodied carbon reduction have been explored. The accessibility to computational tools has empowered designers and

architects to generate data driven solutions for the build environment that have the potential to generate designs with optimised embodied carbon considering both material and geometry.

From the material side, the interest towards performance optimisation has resulted in the rise of applications for highly engineered multi-materials in various domains, such as the automobile, aeronautics, and energy industries. In the field of architecture this knowledge has been translated in development of structurally optimised composited. Developing new structural materials often involves trade-offs, especially with traditional design and fabrication methods that result in homogeneous materials with uniform composition, even though many real-world applications require heterogeneous materials. There is an opportunity to tailor the local properties of the material to meet specific requirements by optimising the composition and architecture in specific regions.

The mechanical performance of structural materials can be improved by designing higher strength in regions that are under higher stress. This method allows materials to have region-specific properties by combining varying degrees of heterogeneity or gradients. The term "gradient" refers to the non-uniform nature of materials instead of strict homogeneity. Creating variable properties or functionally graded materials (FGMs) offers a promising solution to meet the demands for emerging applications of materials. Furthermore, as the research on FGMs is gaining traction, it is important to include the environmental considerations as part of their optimisation criteria.

Reinforced concrete, as the most used construction material, offers versatility, resilience, and cost-efficiency due to its composite nature. However, the environmental impact, particularly in terms of embodied carbon and resource depletion, has become a major concern in new construction. To address this issue, the concrete industry is evolving to incorporate more sustainable construction methods, material compositions, and design solutions. With its composite nature and the ability to design mixtures with varying properties, concrete is an ideal candidate for exploration in optimization not only in geometric design but also in graded material allocation.

FGMs have been researched extensively with an engineering approach towards material reduction. Although there is a connection between the reduction in material mass and the reduction of the environmental impact, the link between the two is not always apparent. The research on FGMs until now has never been purely focused on reducing environmental impact or embodied carbon, in particular. This research gap has been addressed through the incorporation of biochar, a carbon-negative material, into the cementitious material family. The result of this research is the development of CharCrete, a net embodied carbon-optimized cementitious material system with various grades.

The paper discusses the development of a computational method which informs the allocation and distribution of various graded of CharCrete developed in the prior stages of the research. High quantities of biochar in the material mixture led to a decrease in mechanical properties but increased carbon sequestration and therefore lowered embodied carbon. Functionally grading the quantity of biochar in CharCrete composites results in a lower carbon footprint without compromising the structural properties of building elements.

2. Background

Currently, there is little research on how to inform the graded material composition within from a design perspective when focusing on embodied carbon and structural performance of cementitious composites. From a structural engineering perspective there are studies and sophisticated finite element analysis tools that would allow for simulation graded materials, however they are often inaccessible to architects and designers.

Providing a workflow which allows the optimisation of material allocation of a range of grades of cementitious materials within building elements, such as slabs, in a computational environment which is commonly used in the design practice, opens up the possibility for informed conceptual designs of building elements with reduced embodied carbon without compromised structural performance. The

biggest challenge addressed by the research is determining the optimal distribution of materials and properties within the structure to achieve the desired gradation layout.

2.1. Functionally graded materials

Functionally graded materials (FGMs) are a type of composite material that possess unique properties due to their gradual transition between two or more constituents. This results in variations in composition and structure, leading to improved durability and mechanical performance when compared to laminated composites. The concept of FGMs has been inspired by the naturally occurring heterogeneities found in high-performance biological materials, which have evolved over time to optimize their strength and functionality.

In nature, soft-to-hard variations and thermal gradings are common in the composition and structure of materials. Some examples of functionally graded natural materials include human and animal bones, human skin, horse hooves, bamboo stems, tree bark, and palm tree stems. These materials exhibit a range of density and composition throughout the cross-section, resulting in maximized strength with minimized density.

The principles of FGMs have been extensively studied in aerospace and alloy engineering since the 1980s [20], [15]. However, there has been a recent wave of research on how to translate these principles from material science to architecture and design. FGMs offer a novel method of material optimization that could link mechanical performance to environmental impact, potentially resulting in a new aesthetic expression. Although architecture and design tend to be slow in adopting new technologies compared to aerospace engineering, efforts have resulted in the development and application of pioneering multi-material design and fabrication tools, albeit to a limited extent [6], [9].

In her 2010 doctoral thesis, Neri Oxman discusses the significance of materials engineered with spatial gradients in composition and structure, which have applications in a variety of design disciplines. Oxman's work serves as a foundation for exploring the use of FGMs in architectural design, where digital fabrication is inspired by nature and driven by maximal performance with minimal resources through local material property variation.

Due to its applicability to an architectural scale, research on Functionally Graded Concrete (FGC) has gained traction. FGC can be classified into two categories: layered and continuously graded. Layered FGC can be manufactured by casting, which does not require complex fabrication.

Researchers at the University of Stuttgart have pursued collaborative research on the topic of FGC following the development of variable-density graded concrete by Oxman and her team at MIT. In particular, the Institute for Lightweight Structures and Conceptual Design (ILEK) have consistently pursued the development of FGCs however the work focuses on the development of continuous grading through robotic deposition of a foaming agent [1], [12]-[13].

Researchers at Concrete Infrastructure Research Group (CIRG) at the University of Cambridge have identified the potential to obtain FGC through a "Fresh-to-fresh" method of casting that leads to well-bonded graded materials and does not require robotic set-up. Their studies reveal a relationship between system stability, geometry, and material parameters. Both vertical and horizontal casting present challenges however there are clear guidelines published on how to work with this method of graded casting [5], [31] – [33]. The work developed by CIRG is proving that the use of functionally graded layered cementitious composites can be used to optimise the material allocation and reduce the need for cement in the regions of the structural element and has been demonstrated through a case study of a functionally graded concrete beam [34]. However, there is no defined workflow that can be used to inform the material allocation and simulate the correlation between embodied carbon and mechanical performance of graded elements.

2.2. Computing graded materials

Three main obstacles that must be identified when designing with FGMs, including the inaccessibility of scientific information, limitations in design software, and the gradient extent of digitally fused materials [9]. While computational methods such as voxel editing, finite elements, and particle systems allow for multi-materiality that is spatially varied, they do not consider material behaviour, which is of central value to the design process. To attribute gradients based on physical properties, simulations must be used to allow for the gradients to be computationally calculated. This enables the designer to evaluate any relevant design projects through comprehensive design theory or criteria, rather than relying solely on aesthetics with conventional design processes.

Recent studies have demonstrated the effectiveness of Topology Optimization (TO), Voxel-Based Methods (VBM), and Finite Element Methods (FEM) in designing with FGMs [14], [16]. Kaijima's work, for instance, combined structural optimization with design aesthetics by using von Mises stress as the initial design input and carefully shaping the resulting streamlines. These methods provide designers with different levels of control over the final design.

TO is typically used to minimize the mass of a design object given external loading, boundary conditions, and constraints. Various algorithms have been developed for TO to determine the material distribution within a given design domain, though it is typically applied to isotropic or homogeneous materials. However, with some adjustments, it is possible to use TO to inform variable structural distribution on a predetermined volumetric model. In contrast, VBM allows for more design geometry freedom and the creation of graded structures with heterogeneous material properties, but this approach can be computationally intensive.

The field of computational design methods for FGMs is rapidly evolving, providing ample opportunity for further development and refinement. These methods facilitate an efficient workflow for generative design, streamlining the process and making it easier to achieve desired outcomes. Although significant progress has already been made, there is still much potential for further improvement. State-of-the-art methods provide a good understanding of the tools that can be used to generate and evaluate elements with FGMs, including simulation, optimization, and analysis tools. These methods have the potential to revolutionize the design and use of FGMs across a wide range of applications, from construction and architecture to aerospace and beyond. With technology advancing and new computational methods emerging, the possibilities for innovative and sustainable design solutions with FGMs are endless.

3. Methodology

In this research, a case study approach is taken to investigate the performance of Functionally Graded CharCrete slabs with varying geometries and curvatures. The aim of the research is to examine the potential of functionally grading CharCrete to optimize material allocation based on structural loads and reduce the embodied carbon of concrete structures.

Floor slabs are selected as the case study due to their significant contribution to the total structural mass and the availability of opportunities for material optimization. Nine conditions are examined, with varying spans ranging from 2.5 to 7.5 meters and curvatures from flat to doubly curved. The computational workflow is developed using Rhino's Grasshopper with the Karamba3D structural analysis library. The study is conducted in three phases.

In the first phase, the nine conditions are tested using standard concrete, lightweight concrete, and the designed CharCrete mixtures. This is done with homogeneous material distribution to establish a comparative baseline.

In the second phase, a duo-material grading approach is tested, with all possible combinations of three CharCrete grades (25/75, 50/50, 75/25) to determine the most effective combination for reducing embodied carbon and optimizing structural performance.

In the third phase, all three grades of CharCrete are graded to determine the optimal proportions for reducing embodied carbon and optimizing structural performance. Two proportions are tested: 25/25/50 and 50/25/25 of BCM20, BCM40, and BCM50 respectively.

The study is conducted with fixed thickness for each geometry, and the mass, utilization, and embodied carbon of each morphology are recorded. Based on this, potential optimization possibilities are identified. The fixed proportions and thickness limit the optimization possibilities. At the final stage of the study, the nine conditions are examined using the multi-objective optimization solver Wallacei. The genes of the optimization are the partitioning and thickness, and the objectives are mass, displacement, and embodied carbon reduction. The focus is on the utilization domain related to compressive performance.

The computational workflow developed in this study allows for further optimization of slabs in terms of conceptual design. It enables designers and architects to extract data on environmental performance and test geometries with different structural conditions, spans, and curvatures.

Overall, the methodology presented in this study aims to provide a comprehensive analysis of the potential of Functionally Graded CharCrete for optimizing material allocation and reducing the embodied carbon of concrete structures.

3.1. CharCrete Grades

For the purpose of this research, CharCrete is referred to type of cementitious mortar which incorporates biochar, a carbon sequestering material which is produced during the pyrolysis of agricultural and forest management waste. As part of a larger research the author has developed a range of grades of CharCrete with a varying quantity biochar, resulting in a range of mechanical properties and embodied carbon [22]. In this paper three grades of CharCrete are examined in more detail in functionally graded material composition. The three grades BCM20, BCM40 and BCM50 are tested in a laboratory and have the compressive strength of 34MPa, 15MPa and 7MPa respectively. The results obtained by the material tests are computed in the computational environment of Rhino's Grasshopper and more specifically for the Karamba3D structural analysis plug-in (Figure 1.). This method allows for generating custom materials with big degree of freedom. Additionally, the embodied carbon of each mixture is added to their digital material data repository.

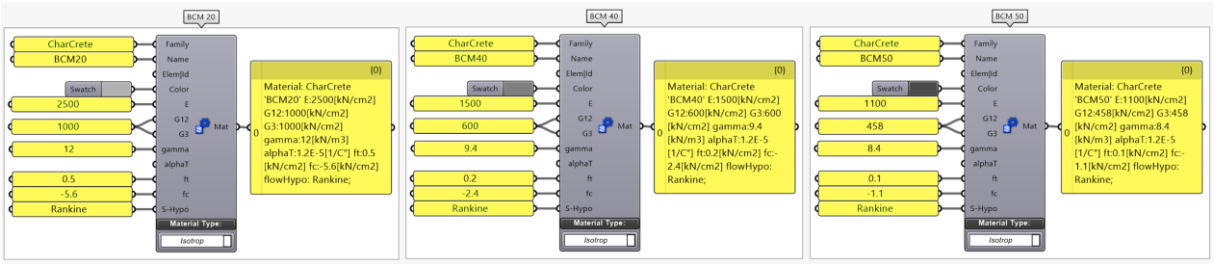

Figure 1. Material specification of the three grades of designed CharCrete mixtures examined in the research, with 20, 40 and 50 percent biochar concentration (left to right).

3.2. Computational Workflow

Computational design tools, such as Rhino's Grasshopper, offer infinite possibilities, limited only by the designer's imagination and skill. Through data-driven designs and complex optimisation processes, these tools are reshaping not only the design process but also the performance of the resulting geometries. The increasing accessibility of incorporating structural analysis, material optimisation, generative design, and performance data is transforming the role of architects and designers. New solutions to global environmental challenges can be proposed by adapting computational and data-driven design tools.

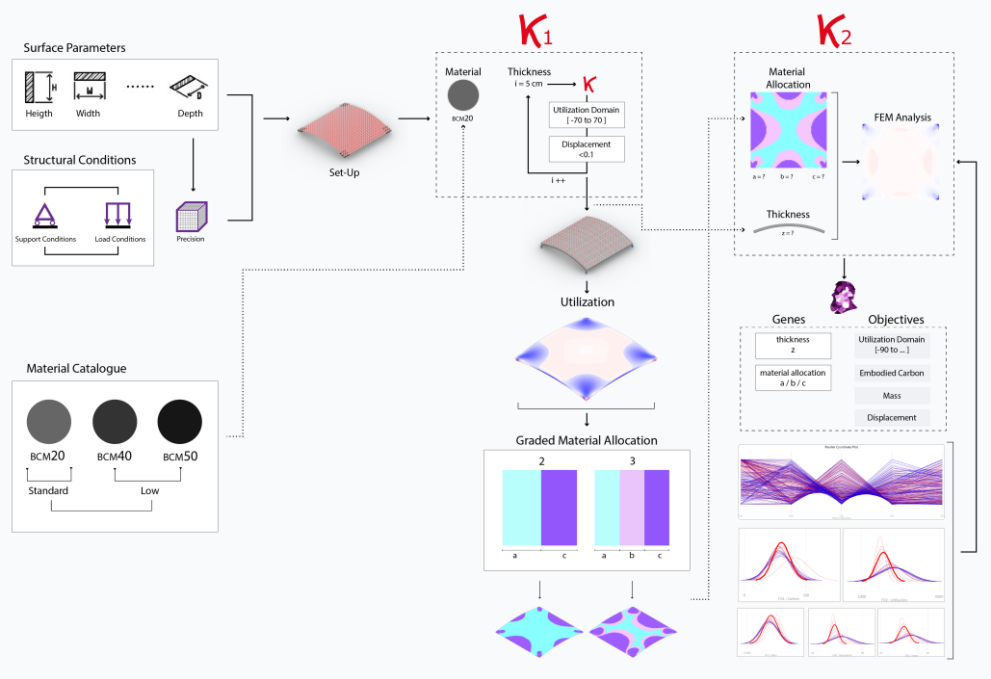

Figure 2. Computational design workflow for optimisation of functionally grading building elements.

This paper discusses the first iteration of a computational design method for generating optimised functionally graded slabs. In particular, the Karamba3D structural analysis plug-in is used to inform and test the impact the material allocations have on the structural performance. The Wallacei multi-objective solver is used to further optimise the slabs with respect to embodied carbon.

The main contribution of this computational workflow is the translation of a topologically optimised model with multi-material allocation, into a finite element model (FEM) that can be structurally tested in Karamba3D. This allows for the encoding of various BCC mixtures and their properties into the FEM mesh. Initially, a geometry is defined based on its surface parameters, including width, height, depth, or any other deformations. With this method, free-form geometries can also be used as inputs. The structural conditions, including supports and loads, are also defined, and the mesh resolution is set. The mesh resolution plays a crucial role and must follow a rule of thumb. In the first explorations, a lower resolution can be used to decrease the computing time. However, later, the resolution can be increased to improve accuracy.

The first stage of optimisation takes the input geometry and conditions, as well as the BCM20 material, which, according to material tests, meets structural regulations for cementitious materials used in building elements. Following that, the initial thickness of the shell is defined through an iterative process where the utilisation and displacement serve as criteria, allowing us to achieve optimal thickness for the geometry.

Through this process, the input that allows us to define the graded material allocation becomes crucial. Various types of inputs were tested, including user input attractor points, utilisation, stress and strain per node and stress lines defined through Karamba3D. The utilization calculations per node are selected as a method for obtaining the material allocation with the graded distribution. Following that, the number of grades that would be associated with the geometry can be tested, as well as the different proportions in proximity to the stress lines that they would take. As this whole process is done parametrically, those can afterwards be used as parameters for optimisation in a multi-objective optimisation engine.

The second stage allows for the material allocation, as well as the initial thickness, to be tested through Karamba3D structural analysis. This enables us to structurally test the heterogeneous or graded material

allocation on the initial geometry. Following that, the utilisation, and the formation of this structural analysis, together with the embodied carbon calculation as well as the mass calculation, can be used as inputs within a multi-objective optimisation solver; in this case, Wallacei was utilised. For the optimisation, the parameters were set to be thickness, as well as the material partitioning, and the objectives are to minimise the compression utilisation domain, the embodied carbon and the overall mass of the element. The computational workflow is graphically represented in the figure bellow (Figure 2.).

4. Data collection

The material combinations and allocations examined on the flat, singly curved and doubly curved slabs with dimensions 2.5 by 2.5 meters and 5 by 5 meters are represented in Figure 3. and the 5 by 7.5 meters in Figure 4. By comparing the homogeneous and graded possibilities of material allocation, the method allows to make informed decisions and optimise the slabs.

The different geometries are examined separately. In terms of utilization all flat floor slabs with span of 2.5 by 2.5 meters are underutilized allowing for weaker material and for the purpose of the study the optimal material is identified based on minimal embodied carbon to be homogeneous BCM50 (Figure 5). Furthermore, flat slabs with the medium span of 5meters can be attained when a dual material composition is used. Comparing the utilization and the embodied carbon, the medium span of 5 by 5 meters slabs would have the optimal condition of 50% BCM20 and 50% BCM40 material distribution as represented in Figure 3.

Studies conducted at ILEK on 5-meter span flat floor slab where graded optimisation was achieved by adding a foaming agent showed mass reduction by 43% and 62% [12]- [13]. Similarly, the CharCrete graded approach allow for 43% mass reduction but additionally it allows for a net negative embodied carbon value.

The singly curved slabs use the strength through geometry method which is allows for further reduction in thickness from 20cm to 15cm. Small and medium slabs with dual material exhibit sufficient performance in terms of both utilization and embodied carbon. The medium span with 20% BCM20 and 75% BCM40 is the most optimised in the study of singly curved slabs. The singly curved large span slabs have better utilization in comparison to the flat slabs however the utilisation values still go above 100 which indicated failure (Figure 5).

Finally, the doubly curved slabs are studied, and their structural performance is superior to the flat and singly curved slabs. When examining the doubly curved slabs all spans can be achieved with some material conditions. The double material allocation in the proportion of 25% BCM 20 and 75% BCM 40 is optimal in all the geometrical studies. However, there is room for further improvement when the thickness and material partitioning are examined further.

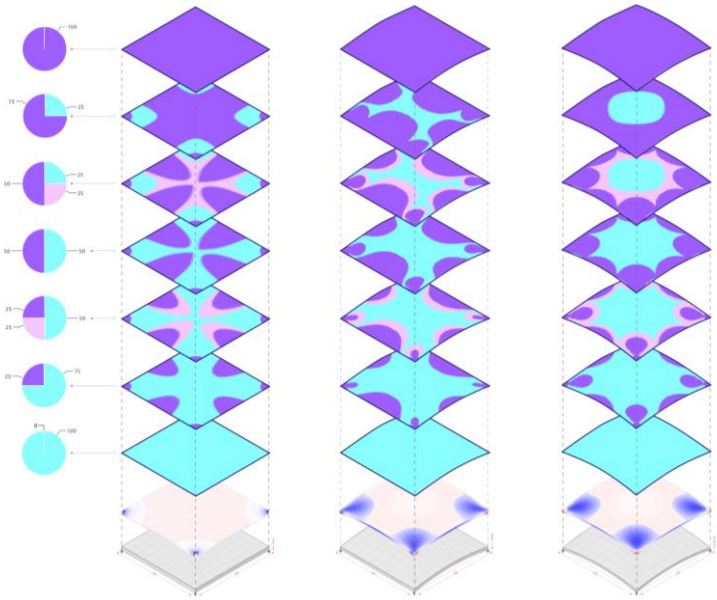

Figure 3. Slab case study with dimensions 2.5x2.5 and 5x5 meters with three geometrical variations: flat, singly curved and doubly curved (from left to right). The range of material conditions examined in the study derived by the utilization of the elements are presented with various quantities of graded – from 1 to 3 grades.

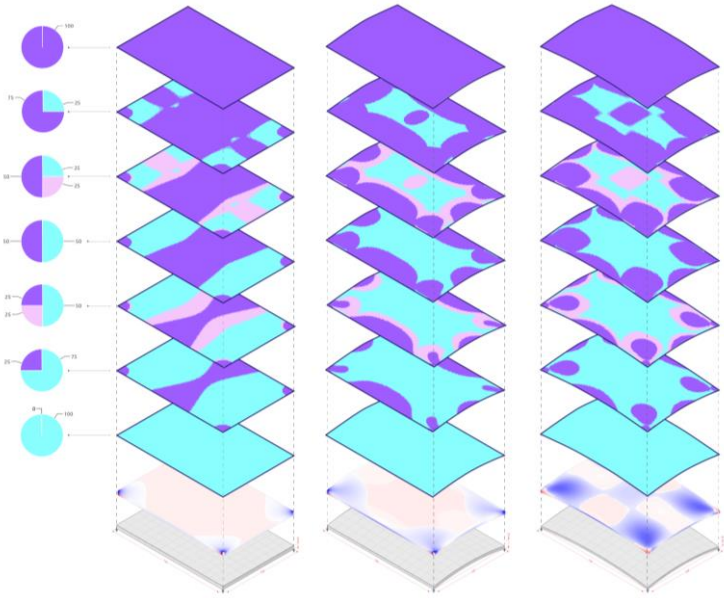

Figure 4. Slab case study with dimensions 7.5x5 meters with three geometrical variation: flat, singly curved and doubly curved (from left to right). The range of material conditions examined in the study derived by the utilization of the elements are presented with various quantities of graded – from 1 to 3 grades.

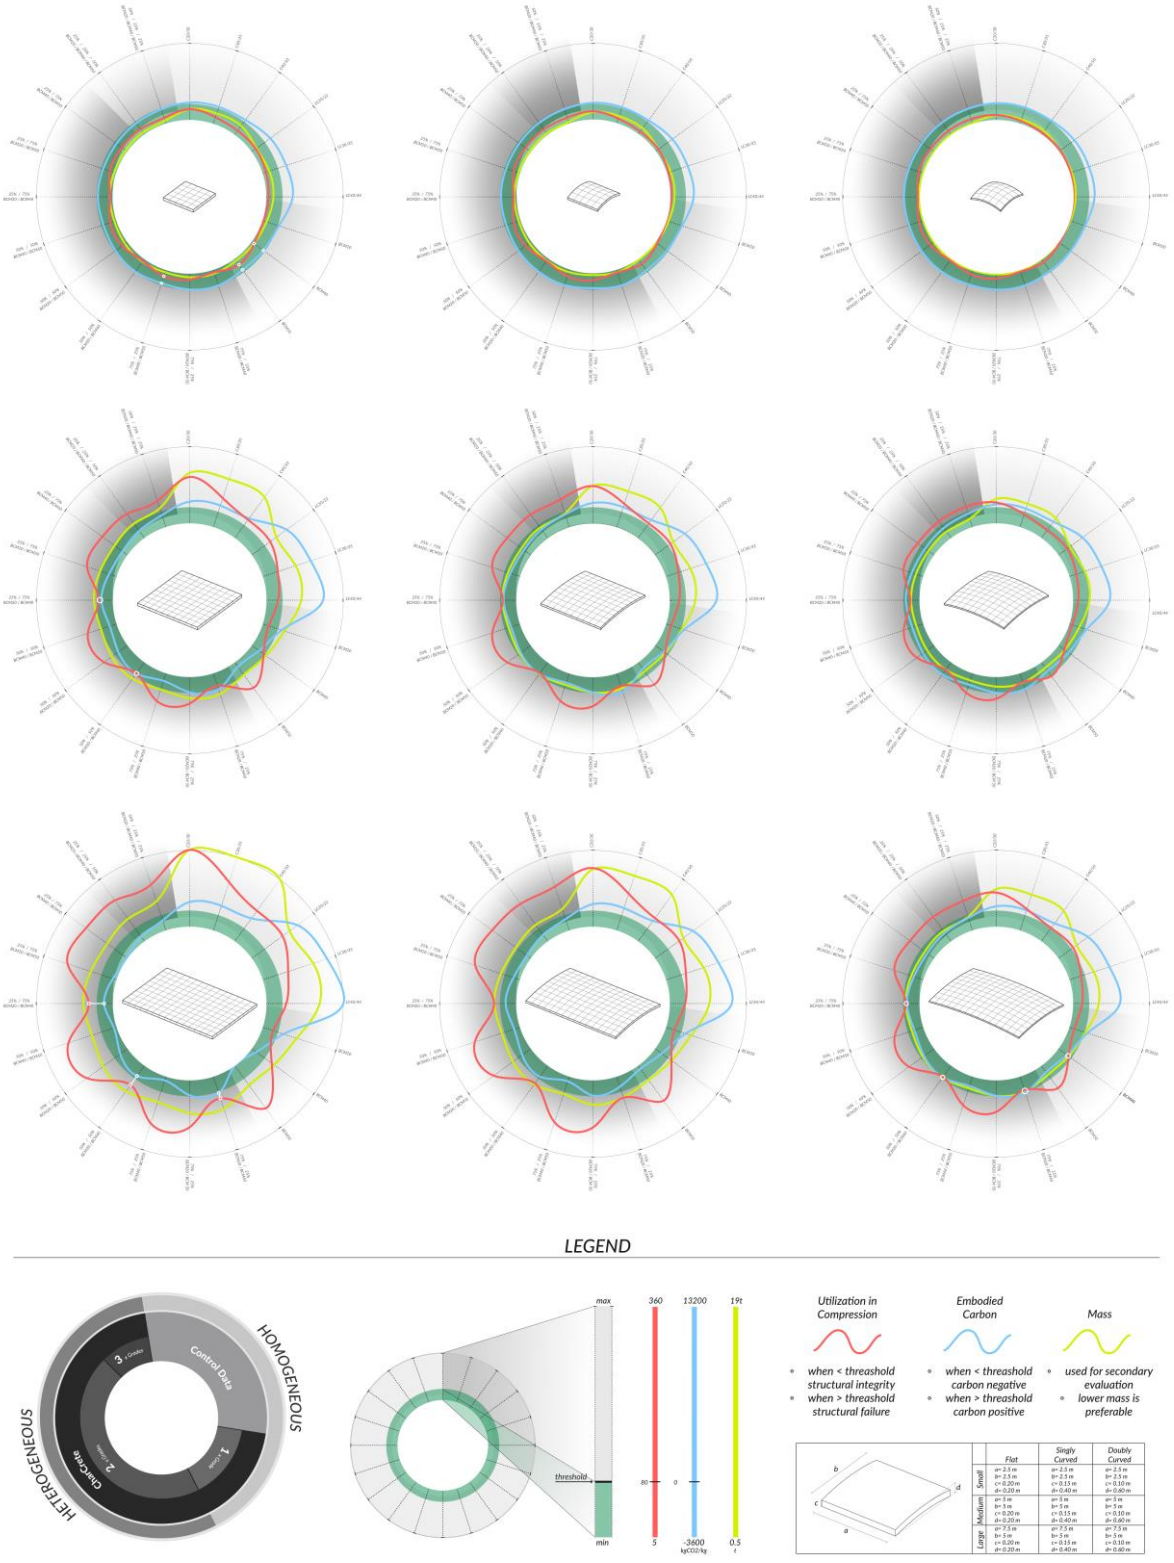

Figure 5. Remapped data of utilisation in compression (red), embodied carbon (blue) and mass (yellow) for all slab case studies.

The optimisation with Wallacei allows for vast numbers of conditions to be examined and analysed. Based on a study on the large span flat slabs, it was demonstrated that a range of possible slabs with span of 5 by 7.5 meters can be generated (Figure 6.). The study shows that graded material allocation cab be beneficial in reducing the embodied carbon without compromising structural integrity, however the work is only developed in a conceptual stage and further studies have to be conducted.

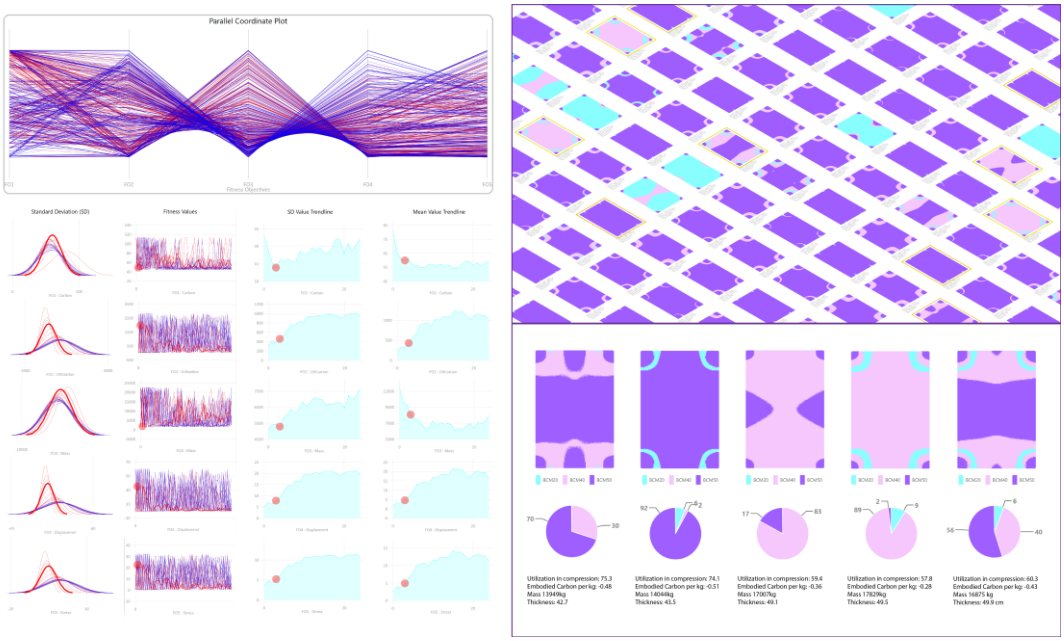

Figure 6. Flat slab case study with dimensions 7.5x5 meters optimised in terms of material allocation and thickness. The example shows the range of genes and optimisation criteria as well as a pool of slabs with ranging material allocation and a selection of five possible conceptual slabs generated using the optimisation method.

5. Conclusion

In conclusion, this paper introduces a computational workflow for informing and simulating performance graded slabs with various spans and geometrical typologies. This workflow is based on a finite element analysis conducted with the Karamba3D structural simulation plug-in within the Grasshopper environment. The method allows for the generation of conceptual digital models with graded material allocation, enabling designers and architects to incorporate environmental considerations into the design process with respect to embodied carbon. The method is tested with a CharCrete material system, which is part of a larger research project aimed at developing elements with negative embodied carbon due to the carbon sequestering nature of biochar.

The paper also highlights future directions for the method, including the case study of a load-bearing wall and testing the method with tensile strength mixtures that include fibres. As the material catalogue is enriched and developed further, the computational method will be developed to incorporate more material variations and optimization parameters. The main contribution of the research presented in this paper is the computational method and the generated data on graded slabs. The demonstration of the CharCrete material system as a case study for carbon-optimized building elements also highlights the potential for this method to impact the design of sustainable building elements. Overall, the presented computational workflow offers a promising approach for designers and architects to incorporate sustainability considerations into the design process of building elements by addressing the composition and allocation of heterogeneous material systems.

Abstract

In general, it is known that the topology optimization problem of steel structures can be formulated as a mixed-integer second order cone programming problem (MISOCP), when the compliance is minimized and the cross-section of each member is chosen from a set of predetermined candidates. On the other hand, real-world building structures should be considered not only structural performance such as compliance but also constructability. Hense, previous studies have demonstrated the effectiveness of the topology optimization method formulated as MISOCP which are considered constructability like the number of nodes and joint angles [1] [2].However, the analytical model of these studies is two-dimensional steel structures and constructability of obtained solutions cannot be evaluated only by them. Therefore, in this paper, the conventional MISOCP method is extended to 3D lattice shells. Additionally, a new constraint on the connection relationships between members that affect welding difficulty and cost is considered.

Keywords: lattice shell, topology optimization, constructability, global optimal solution, misocp

1. Introduction

It takes a lot of effort to find an optimal design by considering the shape and the section-type distribution of steel structures simultaneously using only the designer's experience and intuition. In previous studies, many methods for rational structural design have been proposed by solving the optimization problem for minimizing compliance. One of them is known that the topology optimization problem of steel structures can be formulated as MISOCP, when the compliance is minimized and the cross-section of each member is selected from a set of predetermined candidates [3] [4]. However, real-world steel structures are required not only high structural performance but also constructability. Consequently, a topology optimization method formulated as MISOCP which is considered the number of nodes and joint angles as indices for evaluating constructability was proposed [1] [2], nevertheless the analytical model of these studies is two-dimensional steel structures.Therefore, in this study, the topology optimization method in which structural rationality and constructability are simultaneously considered is applied to a three-dimensional lattice shell, and the effectiveness of that method is verified.

However, constructability cannot be evaluated only by the number of nodes and joint angles, which have been considered in previous studies. For example, Welding is an essential process in construction phase for steel structures and the number of members at each node have a significant impact on the difficulty of welding. Therefore, in this study, in order to prevent the concentration of members at each node, a new constraint that limits the number of members connected to each node is considered in the previous optimization method.

In this paper, a three-dimensional lattice shell is used as the analytical model and the topology optimization by MISOCP with a constraint on connection relationships of members to consider not only structural performance but also constructability simultaneously. Furthermore, the topology optimization is performed not only proposed constraint but also various constraints on constructability considered in previous studies, such as upper bounds for the number of nodes and lower bounds for joint angles of members are simultaneously considered.

2. Formulation of MISOCP

2.1. Minimizing compliance of lattice shells

$$\text{minimize} \quad \sum_{e=1}^{m}\sum_{l=1}^{6} 2w_{el} \tag{1a}$$

$$\text{subject to} \quad w_{e1} + a_e \geq \left\| \begin{pmatrix} w_{e1} - a_e \\ q_{e1}\sqrt{\dfrac{2l_e}{E}} \end{pmatrix} \right\|, \quad e = 1, \ldots, m \tag{1b}$$

$$w_{e2} + J_e \geq \left\| \begin{pmatrix} w_{e2} - J_e \\ q_{e2}\sqrt{\dfrac{2l_e}{\bar{G}}} \end{pmatrix} \right\|, \quad e = 1, \ldots, m \tag{1c}$$

$$w_{e3} + I_{ze} \geq \left\| \begin{pmatrix} w_{e3} - I_{ze} \\ q_{e3}\sqrt{\dfrac{6l_e}{E}} \end{pmatrix} \right\|, \quad e = 1, \ldots, m \tag{1d}$$

$$w_{e4} + I_{ze} \geq \left\| \begin{pmatrix} w_{e4} - I_{ze} \\ q_{e4}\sqrt{\dfrac{2l_e}{E}} \end{pmatrix} \right\|, \quad e = 1, \ldots, m \tag{1e}$$

$$w_{e5} + I_{ye} \geq \left\| \begin{pmatrix} w_{e5} - I_{ye} \\ q_{e5}\sqrt{\dfrac{6l_e}{E}} \end{pmatrix} \right\|, \quad e = 1, \ldots, m \tag{1f}$$

$$w_{e6} + I_{ye} \geq \left\| \begin{pmatrix} w_{e6} - I_{ye} \\ q_{e6}\sqrt{\dfrac{2l_e}{E}} \end{pmatrix} \right\|, \quad e = 1, \ldots, m \tag{1g}$$

$$\boldsymbol{p} = \sum_{e=1}^{m}\sum_{l=1}^{6} q_{el}\boldsymbol{b}_{el} \tag{1h}$$

$$\sum_{e=1}^{m} l_e a_e \leq \bar{V} \tag{1i}$$

$$a_e = \sum_{j=1}^{r} \bar{a}_j t_{ej}, \quad e = 1, \ldots, m \tag{1j}$$

$$I_{ye} = \sum_{j=1}^{r} \bar{I}_{yj} t_{ej}, \quad e = 1, \ldots, m \tag{1k}$$

$$I_{ze} = \sum_{j=1}^{r} \bar{I}_{zj} t_{ej}, \quad e = 1, \ldots, m \tag{1l}$$

$$J_e = \sum_{j=1}^{r} \bar{J}_j t_{ej}, \quad e = 1, \ldots, m \tag{1m}$$

$$\sum_{j=1}^{r} t_{ej} \leq 1, \quad e = 1, \cdots, m \tag{1n}$$

$$t_{ej} \in \{0, 1\}, \quad e = 1, \ldots, m \quad j = 1, \ldots, r \tag{1o}$$

In this paper, a lattice shell with n nodes, m elements, and D degrees of freedom for node displacement is optimized by MISOCP. According to the previous study [4], for the structural model of a lattice shell

with external nodal load $\boldsymbol{p} \in \mathbb{R}^D$, the topology optimization problem for minimizing compliance in which the optimal sections are selected from the list of the combinations of the member cross-section performances can be formulated as problem (1).

In problem (1), E, a_e, I_{ye}, I_{ze}, J_e and l_e are Young's modulus, section area, cross-sectional secondary moment of Y and Z-axis, torsional constant, and length of e-th member, respectively.

$\{(\bar{a}_1, \bar{I}_{y1}, \bar{I}_{z1}, \bar{J}_1), \cdots, (\bar{a}_r, \bar{I}_{yr}, \bar{I}_{zr}, \bar{J}_r)\}$ is the list of the combination of the member cross-section performances and t_{ej} is a 0-1 variable for selection of member section from the list. The design variable of problem (1) is t_{ej}, q_{el} and w_{el}. In the global optimal solution, $q_{e1}, q_{e2}, q_{e3}, q_{e4}, q_{e5}$ and q_{e6} are internal forces about axial, share, and bending, respectively and $\sum_{e=1}^{m}\sum_{l=1}^{6} 2w_{el}$ is consistent with compliance.

2.2. The constraint on intersection of members

Intersecting members, or even if not intersecting, overlapping cross sections, is not acceptable when considering actual construction. In this study, members that intersect in the plane are treated as intersecting members to avoid proximity or overlap of members when considering cross sections, even though the members do not intersect as lines in three-dimensional space. Pairs of member indexes of intersection of members is expressed as follows:

$$(C_{11}, C_{12}), \cdots (C_{x1}, C_{x2}) \tag{2}$$

where, x is the number of pairs of intersection of members. Then, intersection of members can be avoided by adding the constraint Eq. (3) to the problem (1):

$$\sum_{j=1}^{r} t_{\alpha j} + \sum_{j=1}^{r} t_{\beta j} \leq 1, \qquad \begin{array}{l} \alpha = C_{k1}, \quad \beta = C_{k2} \\ k = 1, \ldots, x \end{array} \tag{3}$$

2.3. The upper limit constraint on the number of nodes

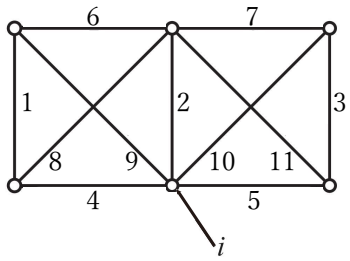

Figure 1: Node i and its surrounding members

Next, the upper limit constraint on the number of nodes is added to the problem (1). First of all, a set of indexes of members connected to node i is defined as $S(i) \subseteq \{1, \cdots, m\} (i = 1, \cdots, n)$ (In the example of Fig. 1, $S(i) = \{2, 4, 5, 9, 10\}$). Subsequently, the variable z_i is defined as follows:

$$z_i = \sum_{e \in S(i)} a_e, \quad i = 1, \cdots, n \tag{4}$$

For node i, the 0-1 variable $s_i \in \{0, 1\}$ is used to indicate the existence of that node. If setting the minimum length in the analytical model to $l_{\min}$, the following equation always holds under the upper volume constraint:

$$\sum_{e=1}^{m} a_e \leq \frac{\bar{V}}{l_{\min}} \tag{5}$$

Therefore, the relationship between s_i and z_i can be written as follows (where $0 \leq z_i$ is trivial):

$$0 \leq z_i \leq \frac{\bar{V}}{l_{\min}} \cdot s_i, \quad i = 1, \cdots, n \tag{6}$$

Also, the constraint on the number of nodes can be written as follows:

$$\sum_{i=1}^{n} s_i \leq \bar{n} \tag{7}$$

where, $\bar{n}$ is the upper limit value of the number of nodes.

2.4. The lower limit constraint on the joint angle

In order to prevent the members from connecting at extremely sharp angle, a constraint such that all joint angles are larger than or equal to the lower limit value $\bar{\theta}$ are considered. In this paper, pairs of member indexes connected at an angle less than $\bar{\theta}$ is expressed as follows:

$$(D_{11}, D_{12}), \cdots (D_{y1}, D_{y2}) \tag{8}$$

where, y is the number of pairs of members connected at an angle less than $\bar{\theta}$. Sharp connection can be avoided by adding the following constraint to the problem (1):

$$\sum_{j=1}^{r} t_{\alpha' j} + \sum_{j=1}^{r} t_{\beta' j} \leq 1, \qquad \begin{array}{l} \alpha' = D_{k'1}, \quad \beta' = D_{k'2} \\ k' = 1, \ldots, y \end{array} \tag{9}$$

2.5. The upper limit constraint on connection relationships of members

Welding is an essential process in steel construction and the number of members connected to each joint has a significant impact on the difficulty of welding. In order to consider constructability dependent on connection relationships of members, the following constraint which limit the number of members connected to each node is additionally considered to the problem (1):

$$\sum_{e \in S(i)} \sum_{j=1}^{r} t_{ej} \leq \bar{j} \quad i = 1, \ldots, n \tag{10}$$

where, $\bar{j}$ is the upper limit of the number of members connected to each node.

Finally, the following constraints are added to the problem (1):

$$\sum_{j=1}^{r} t_{\alpha j} + \sum_{j=1}^{r} t_{\beta j} \leq 1, \qquad \begin{matrix} \alpha = C_{k1}, \quad \beta = C_{k2} \\ k = 1, \ldots, x \end{matrix} \tag{11a}$$

$$z_i = \sum_{e \in S(i)} a_e, \quad i = 1, \ldots, n \tag{11b}$$

$$0 \leq z_i \leq \frac{\bar{V}}{l_{\min}} \cdot s_i, \quad i = 1, \cdots, n \tag{11c}$$

$$\sum_{i=1}^{n} s_i \leq \bar{n} \tag{11d}$$

$$\sum_{j=1}^{r} t_{\alpha' j} + \sum_{j=1}^{r} t_{\beta' j} \leq 1, \qquad \begin{matrix} \alpha' = D_{k'1}, \quad \beta' = D_{k'2} \\ k' = 1, \ldots, y \end{matrix} \tag{11e}$$

$$\sum_{e \in S(i)} \sum_{j=1}^{r} t_{ej} \leq \bar{j} \quad i = 1, \ldots, n \tag{11f}$$

2.6. Introducing the penalty function

When optimization is performed under the above constraints and there is margin for the volume constraint, it is possible to obtain multiple global optimal solutions with different volume.For example, when optimization is performed with $\bar{j} = 3$ for a anaiytical model in Fig. 2, there exist global optimal solutions with the same compliance as shown in Fig. 2. In that case, it is desirable to select the solution of (a) which has the smallest volume.

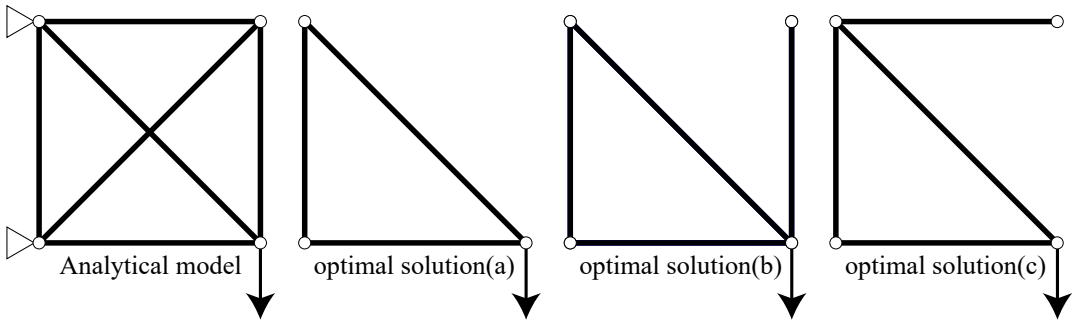

Figure 2: Examples of multiple global optimal solutions

In this study, to remove solutions other than the best solution in advance, the penalty functions are imposed to the volume by adding βV to the objective function using sufficiently small positive constant value β.

Therefore, in the optimal problem (1), the objective function is changed as follows:

$$\sum_{e=1}^{m} \sum_{l=1}^{6} 2 w_{el} + \beta V \tag{12}$$

3. Numerical examples

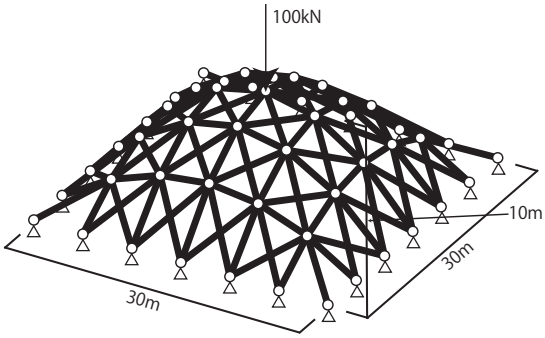

Figure 3: Analytical model

Table 1: The list of cross-sections (steel pipe)

j	1	2	3
outer diameter [mm]	216.3	216.3	216.3
width [mm]	4.5	7.0	12.7
$\bar{a}$ [$\times 10^{-3}$m^2]	2.99	4.60	8.12
$\bar{I}_y, \bar{I}_z$ [$\times 10^{-5}$m^4]	1.68	2.52	4.23
$\bar{J}$ [$\times 10^{-5}$m^4]	3.36	5.05	8.45

The optimization problem, where constraints Eq. (11a) to Eq. (11f) are additionally considered in the problem (1), is applied to the following analytical model with concentrated load shown in Fig. 3. In each numerical examples, Young's modulus and Poison's ratio are set to E=205[GPa] and $\nu = 0.3$, respectively. Member cross-sections are selected from the given list (Tab. 1). All joints are rigidly connected and boundary conditions are pinned support in circumference. The upper volume limits are set to $\bar{V}$=3.5[m^3]. In addition, in order to obtain the more realistic optimal solution, the number of design variables is reduced by considering the symmetry and analyzing the quarter region of its design area. We used PICOS ver. 1. 2. 0 [5], a Python interface to diverse optimization solvers. MOSEK ver. 8.0 [6] was used as the optimization solver. Computation was carried out on Intel (R) Core (TM) i7-1165G7@2.80GHz with 16GB RAM.

The optimal topologies are shown in Figs. 4. Changes in compliance were compared while optimization for various constraints on the maximum number of members to be connected to each node, the number of nodes, and the lower limit of joint angles. Fig.4 (a) shows the optimal solution obtained by solving a pure compliance minimization problem without any restrictions on the number of nodes, joint angles, or the number of members connected to each node. It can be confirmed that the volume constraint is satisfied and a high concentrartion of members at the load point, so this optimal solution is not always an appropriate design solution when considering constructability. Since the maximum number of members connected to each node is 8 in this optimal solution, optimization with member connectivity limit constraint of $\bar{j} \leq 7$ is iteratively carried out, the results of which are shown in Figs.4 (b) to (d), respectively. Since the optimal solution cannot be obtained with $\bar{j} = 3$ for half a day, the analysis is terminated. In each case, optimization with joint angle constraint is performed for the case where a frame including a joint smaller than $\bar{\theta} = 40^\circ$ is obtained, the result of which are shown in Figs. 4 (e) to (h). Furthermore, optimization with node constraint is performed for the topology in Fig. 4 (f) is obtained, the results of which are shown in Figs. 4 (i) to (o). In this paper, since optimization is considered the symmetry, optimization while reducing $\bar{n}$ by 4 from 41 to match the number of nodes. Since the optimal solution cannot be obtained with $\bar{n} = 9$ for half a day, the analysis is terminated. Mechanical quantity and computational time of global optimal solutions are shown in Tab. 2.

It can be confirmed from the optimization result that no intersecting members exist in each optimal solution because of the constraint Eq. (3). Any topologies can be confirmed that the solutions have a margin in volume constraint. Hense, in the case of this analytical model, any members that do not contribute to the stiffness may be used. However, these members are removed in optimal solutions due to the effect of the penalty functions about the volume.

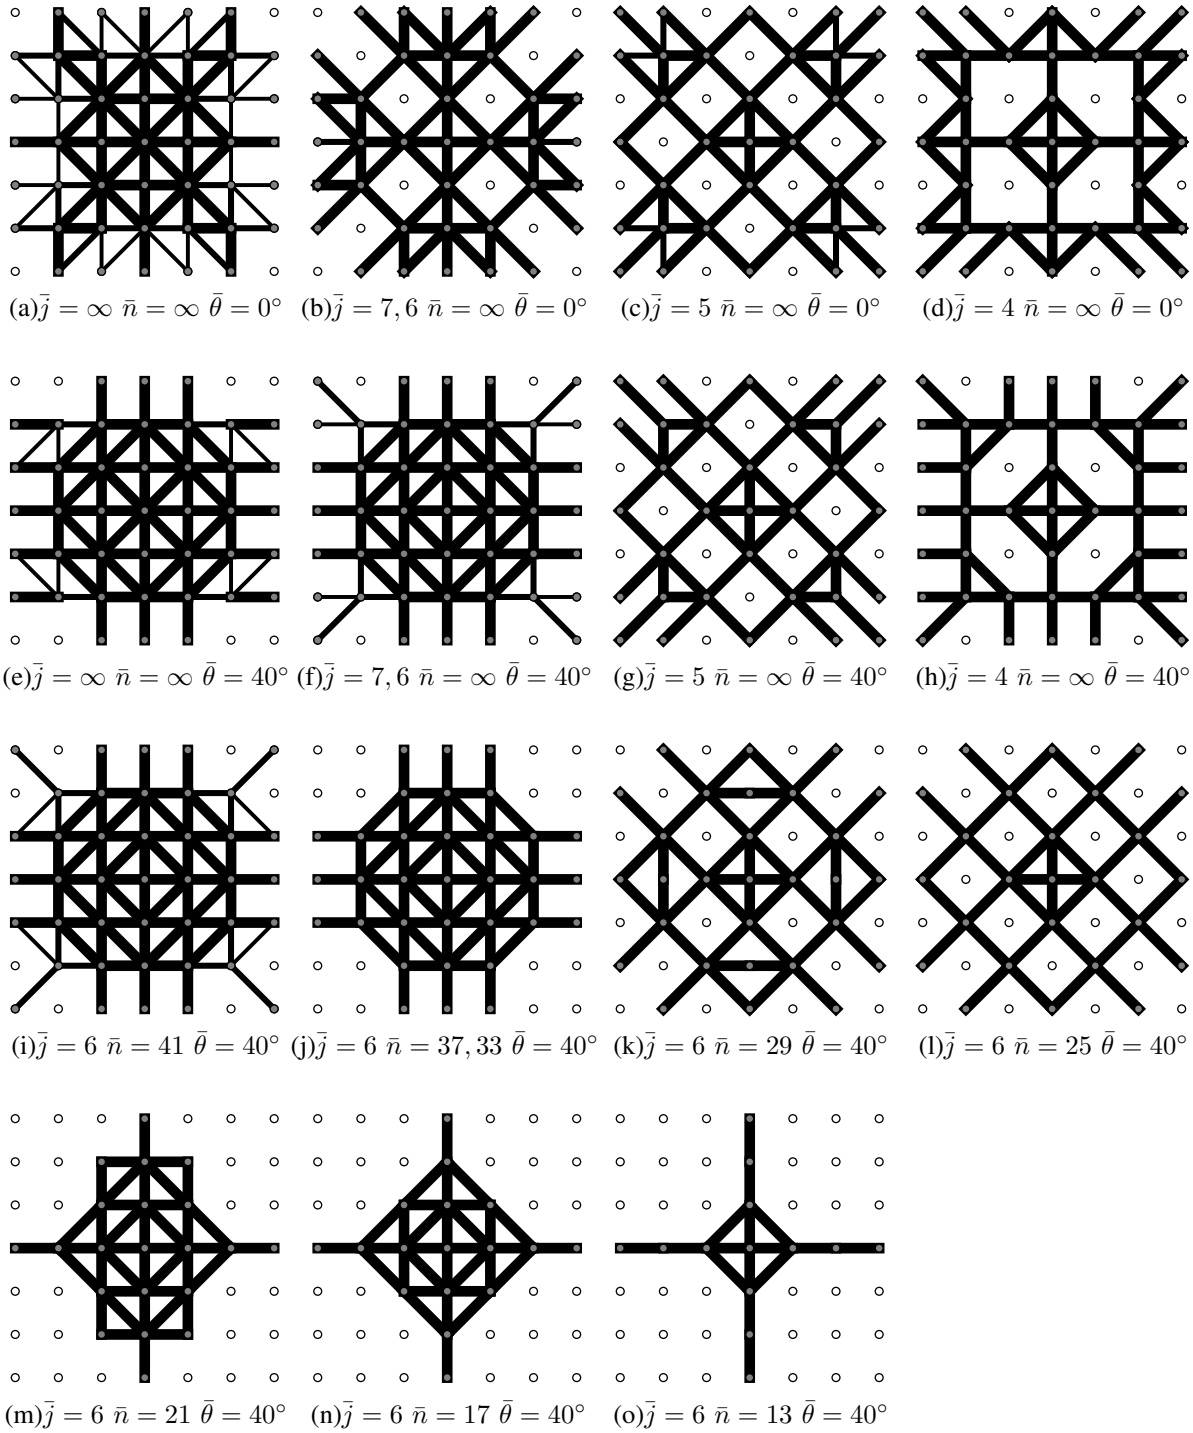

Figure 4: Global optimal solutions

Table 2: Mechanical quantity and computational time of global optimal solutions

※ a: $\bar{j} = 7$, b: $\bar{j} = 6$, c: $\bar{n} = 37$, d: $\bar{n} = 33$

	(a)	(b)	(c)	(d)	(e)	(f)	(g)	(h)	(i)	(j)	(k)	(l)	(m)	(n)	(o)
Compliance [kJ]	0.148	0.242	0.268	0.555	0.150	0.263	0.273	0.978	0.263	0.263	0.274	0.275	1.524	1.845	4.942
Volume [m^3]	3.493	3.465	3.086	3.070	3.495	3.448	2.869	2.635	3.470	3.040	2.560	2.272	2.001	1.649	0.834
Maximum number of members connected to each node	8	6	5	4	8	6	5	4	6	6	5	5	6	6	4
Number of nodes	45	37	33	37	41	45	33	41	41	33	29	25	21	17	13
Minimum joint angle [°]	33.78	33.78	37.43	35.57	40.40	40.40	42.06	40.40	42.08	42.45	46.35	46.35	42.44	42.86	46.35
Computational time [s]	163.1	157.1[a] 77.81[b]	83.54	388.2	7.722	508.5[a] 209.5[b]	55.21	2093	176.6	264.8[c] 619.2[d]	303.1	314.6	96.20	29.27	136.1

As the constraints on the number of nodes or connection relationships of members becomes stricter, the feasible region becomes narrower, and it has an impact on computational time. As a result, in the case of $\bar{j} = 3$ or $\bar{n} = 9$, optimal solutions cannot be obatained in realistic time. According to Fig. 4 (b), optimal solution with maximum number of members connected to each node is 7 does not exist. From Tab. 2, it can be confirmed that compliance and connection relationships of members are in a trade-off relationship with each other. However, the amount of increase is unequal. Optimal solutions in Figs. 4 (i) to (o) show that there is no correlation between the number of nodes and the maximum number of members connected to each node.

4. Conclusion

In this paper, a new topology optimization approach with MISOCP that takes into account connection relationships of members is applied to the three-dimentional lattice shell. In addition, the proposed constraint were combined with the constraints on the number of nodes and joint angles used in previous studies and the variation of the objective function values are compared to account for differences in the range of the constraints.

Abstract

This paper proposes an interactive computational approach for designing the layout of timber column-slab structures in a material-saving and structural-performance aware manner. The generated column slab layout meets the serviceability limit state deflection criteria by integrating gradient-based optimization within an agent system approach. This was achieved by extending the ABxM framework with an interactive design framework termed Timber Column Slab (TCS) solver. This solver is underpinned by three data structures: Firstly, an agent system representing a column-slab system for layout exploration. The finite element (FE) model that computes the slab's nodal displacements, which enables rapid serviceability checks at each agent-system update in a real-time loop. With the TCS extension, the agent-based model uses the numerical analysis results to refine the decision of the adaptive agents. The real-time interaction built within the agent-based model is responsible for the live user guidance and design software integration. The proposed methodology has been built with multiple scientific stacks and encapsulated into an open-source framework in a C# environment. The developed method is tested on a wide range of real building floor plans of different scales and typologies, demonstrating how effective it is compared to previous efforts.

Keywords: agent systems, optimisation, interactive design, timber-structures, column-slab system, conceptual-design

1. Introduction

According to the Ellen MacArthur Foundation's guidelines [1] for designing for circularity the early design phase plays a key role in the process and is critical for making maximum changes for environmentally responsive design. While conceptual structural design and rapid analysis tools have been extensively explored for spatial structures, column-slab structures have not, despite being a widely used structural system [2]. Determining irregular support location layouts is particularly challenging as they have a direct influence on the structural material quantities, future adaptability, and architectural appearance [2],[3]. From a material perspective, timber structures pose the biggest challenge in terms of slab stiffness distribution and design due to their anisotropic nature [4]. Currently, few computational tools or techniques aid in designing timber structures in the early-design stage. This study aims to address these knowledge gaps by exploring an interactive optimization technique. The ability of agent systems to make adaptive decisions in changing environments, integrated with serviceability checks at each design iteration, is explored. Ultimately, the proposed method aims to allow architects to make

informed decisions while considering structural constraints for column-slab systems from the early stages of design.

2. State of the art

This research lies at the intersection of design space exploration techniques, conceptual structural design, and architectural design. In the following paragraphs, we will discuss the most relevant studies focusing on the design of column-slab systems, the application of agent systems in structural design, and research on design interaction and guidance.

2.1. Agent systems in architectural design

The advantage of agent-based modelling is having adaptive agents make decisions in a changing environment. Groenewolt et al. [5] successfully applied agent-based modelling (ABM) to the design of segmented shells using a hierarchy of geometric rules to meet specific fabrication and structural requirements. Scheurer [6] simulated irregular column layouts using specific architectural objectives as behaviours to simulate a self-organizing model. Schwinn [7] demonstrates the computational pipeline of a complex segmented timber shell structure using an agent-based approach, optimizing material use and structural stability. Orozco et al. [8] also investigate the application of a multi-agent system in generating design layouts for multi-story timber structures. However, while previous methods achieved rapid interaction and geometric rule-based simulation, the end results are not informed by structural analysis inferences. Groenewolt et al. [5] discuss the interoperability of structural analysis, but this requires pausing the simulation and exporting the results to external software. In contrast, this research presents a method for computing slab deflection checks in real-time.

2.2. Design exploration for column-slab systems

Muresan et al. [3] investigated the design space of modular slab systems with discrete stiffness distribution and irregular column layout through a stochastic approach. Although stochastic approaches present the possibility of generating a large design space, navigating the large datasets they produce becomes challenging, particularly for complex cases. Meng et al.[2] adopt an optimization method to determine optimal support locations in the roof-column structural system. While optimization techniques present a robust approach to identify optimal solutions, they are typically time intensive and depend on accurate and reliable input data, which can be challenging to frame for the early design stages.

3. Method

The following section elaborates on the theoretical basis of an interactive design method that combines gradient-based optimization with ABM. The operation of the ABxM framework [9] is described, which is essential to understanding the agent system design and the proposed TCS extension. Figure 1 illustrates the various components and operations of TCS. By utilizing this method, column-slab layouts can be explored while accommodating various architectural design constraints in real-time. The agent system tracks and adjusts to the slab's changing structural behaviour. The aim of this method is to address the limitations outlined in the previous section by providing designers with an interactive, structurally compliant solver.

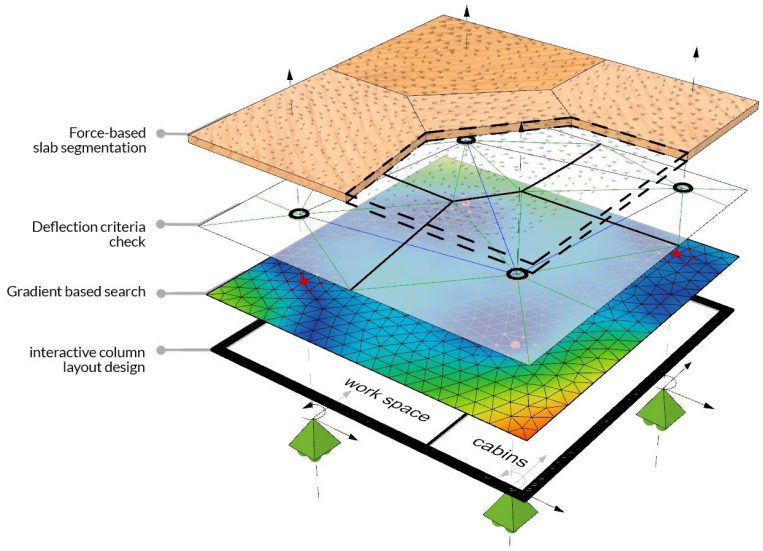

Figure 1. Diagram illustrating various components of the proposed TCS method.

3.1. The ABxM framework

ABM is a simulation technique that includes autonomous decision-making entities called agents. Behaviours that are applied to the agents determine how they interact with the environment and with each other. Schwinn [10] explain techniques to represent building components as agent systems, allowing architects to test and refine their designs in an interactive manner with multiple constrains. The ABxM framework provides an open platform for experimenting with agent-based models in an architectural setting by consolidating previous developments on the topic [5] [10], [11]. It comprises data structures for agents, environments, behaviours, and different data structures for agent systems based on their representation. The cartesian agent system is adopted for the TCS solver.

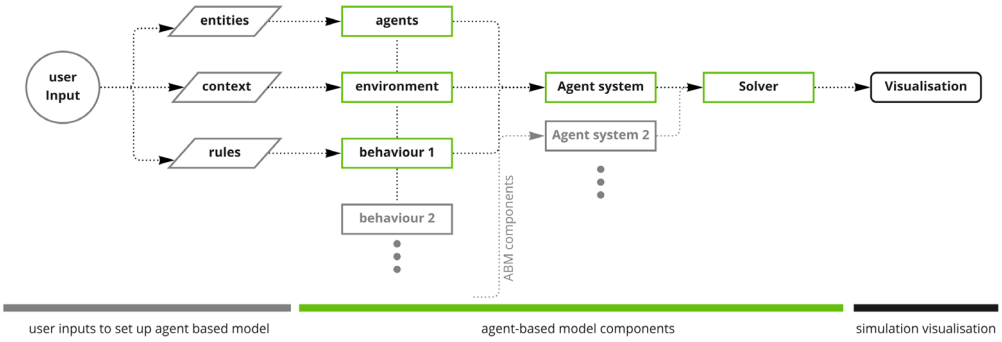

Figure 2. Figure illustrating the workflow of the components of an agent system based on the set up of the ABxM framework [9].

3.2. Agent model definition

For the given context of slab-column systems, the agents represent columns and their environment the slab. The goal of the agents is to converge to a column-layout configuration that minimizes the slab nodal deflection while accounting for designer intent. The primary input from the user is the floorplan layout 2D geometry. This geometry is used to generate the environment mesh. The initial location of the agents is also derived from this input geometry: they are evenly distributed along the exterior boundary of the environment.

The behaviours aim to guide the agents to configurations that minimize the slab nodal displacements. A backend slab displacement solver is a key feature of the TCS extension, which is elaborated in *Section 3.3.*

3.2.1. Serviceability checks

After computing nodal displacement, a static deflection check is carried out to verify if the atypical column arrangement satisfies the deflection standards. The process of determining a measurable serviceable check for irregular slabs and column layouts can be difficult. The first step involves performing a Delaunay triangulation, followed by extracting two types of lengths between the field and the cantilever to express the serviceability criteria, which is the minimum length ratio between them. To derive the serviceability limit checks, the Delaunay triangulation is performed using the irregular column positions. The length of the first edge of the triangulation marks the first length, while each column is measured from its vertex to the floor or the boundary of its respective Voronoi cell. This computation is integrated into the structural analysis package of the TCS solver and is activated at the conclusion of the agent system loop (figure 3).

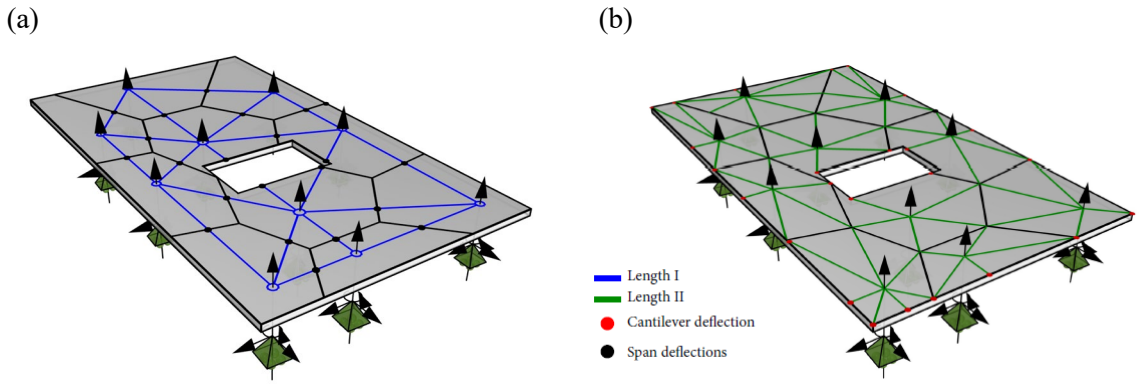

Figure 3. Diagram illustrating serviceability deflection check criteria for floor slabs with cut-outs.

3.2.2. Penalty function for material volume

A penalty feature is introduced to discourage the agent from searching for solutions that will increase the slab material volume. Through the penalty feature, column layout configurations that do not satisfy the SLS deflection criteria are avoided, or if they require higher slab densities. The slab volume is a function f(x) that should be minimised. To navigate away from the positions that cause unfavourable results, a penalty weight "r." is added to the agents when the constraint is not met for certain column configurations. The penalty formulation is explained through the equation below.

$$penality = r * \max(0, f(x) - fmax) \quad (1)$$

Here penalty is the weight that is added to the agent when the constraint is not met and "r" is the penalty weight factor. *f(x)* is the slab material volume function that needs to be minimized *fmax* is the maximum allowed slab volume. max(0, f(x) - f_max) is the maximum of 0 and the difference between the slab volume and the maximum allowed volume. This ensures that the penalty is only applied when the constraint is violated.

3.2.3. Interactivity

There are two types of interaction features, firstly dynamic interaction allows the user to redistribute the column locations while the solver is still converging. By triggering a nodal displacement recalculation, this method immediately updates the positions of the entire network of column agents. Meanwhile, the static interaction feature allows users to save specific design options and revert old iterations. A saved

design option's data structure is preserved in a history class, and the data is serialised into its constituent data structure for instant re-editing.

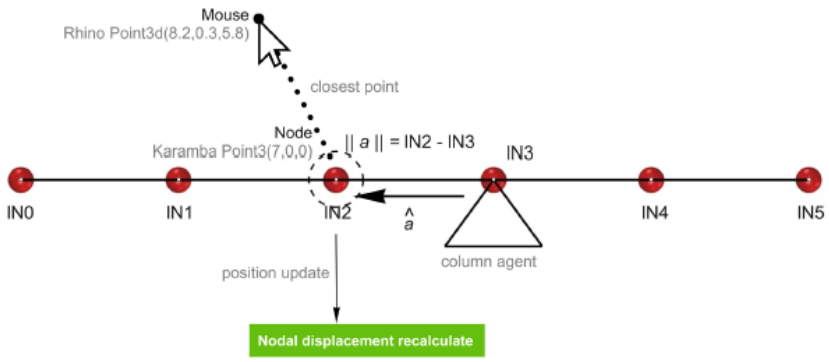

Figure 4. figure illustrating the logic behind the live mouse interaction feature in the context of a beam-column set up.

3.3. Extension to the ABxM framework

The TCS solver utilizes the core data structure of a cartesian system from the ABxM framework, which includes classes defining the agent, agent system, behaviour, and environment attributes. However, TCS extends this inherited structure in three important ways. Firstly, the slab environment is capable of storing not only the geometry data but also the FEA results in each node of the slab. This is achieved by modelling the slab geometry as a finite element model and using a backend FEA package built with the Karamba3D application programming interface [12] to calculate the nodal displacements. The result is a network of nodal positions and displacements of the slab, represented in a dictionary that serves as the environment for agent interaction. Secondly, the agent system includes a behaviour based on gradient-based optimization, which determines the column agent's position coordinates relative to the slab environment and references the neighbouring nodal displacements to compute the agent's updated position vector with the weight of the penalty feature added. Lastly, the TCS recursive solver is a key feature that triggers the environment class to recompute the nodal displacements at the end of each agent system loop until the deflection criteria is met. A broad overview of the data structure is illustrated in figure 5 and figure 6.

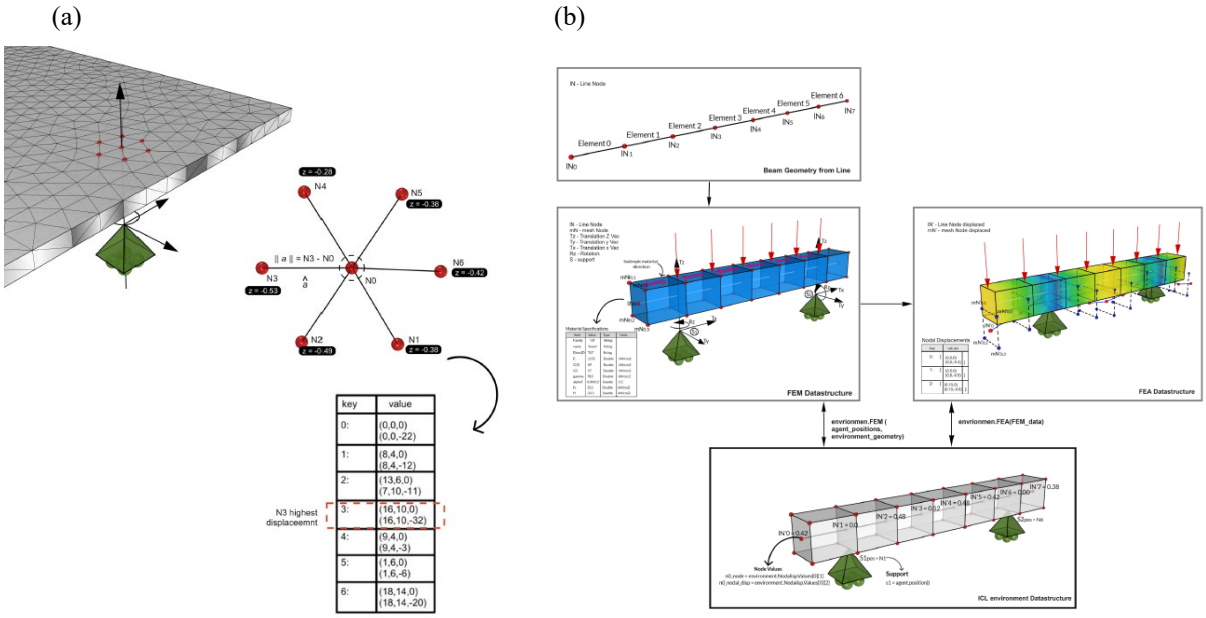

Figure 5. Diagram illustrating the backend communication between the FE analysis to Agent system pipeline of the TCS solver (a) slab-column set up (b) beam-column setup.

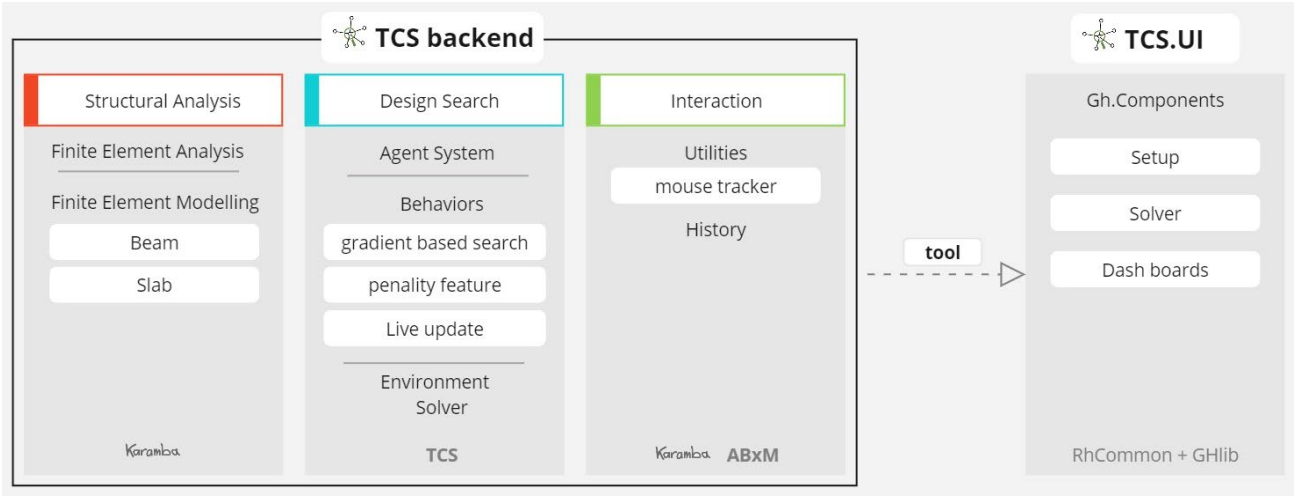

Figure 6. Diagram illustrating the data structure and algorithms of the TCS framework, its dependencies, and user interface.

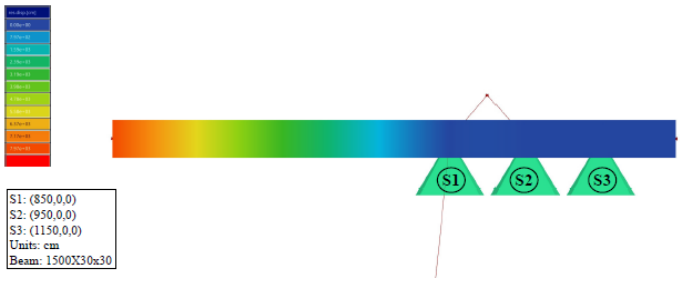
4. Development: examples



In this section, the effectiveness of the TCS solver is evaluated through three design case studies. The first case study involves a simple beam-column problem, followed by solving for a floor slab outline, and finally addressing a floor plan with multiple architectural constraints.

4.1. Beam-column problem

To evaluate the modelling capabilities and applicability of the TCS solver, a beam-column system is chosen as a prototype problem. The system comprises a 12m span beam element subject to both live and gravitational loads, with the aim of determining the positions of the column supports to meet the deflection criteria. The minimum required user input for the simulation is the beam width. Initially, the

column count starts at every 5m, and during simulation, the number of column agents is adjusted based on the deflection check and the penalty feature that aims to limit the material volume of the beam. The ultimate goal is to identify the optimal location for the column supports through simulation. The mouse tracking feature enables real-time movement of column agents, and the user interface (UI) for history tracking and solver prompts is implemented in the Rhino environment.

(a)

(b)

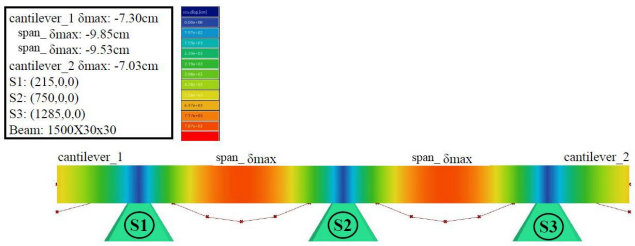


Figure 6. Output of a simple beam-column problem set up (a) start position of column agents on beam (b) result of converged simulation using the TCS solver.

4.2. Solving for floor slab boundary

This section presents a design case study utilizing the TCS solver. The study utilizes the Tamedia Building designed by Shigeru Ban Architects [13] as a real-life building design scenario to test the solver's efficacy. To ensure accurate testing, an actual building design was chosen over a theoretical layout. The solver is first tested to converge the column layout with only a floor layout boundary input. A young's modulus of 1155 KN/cm2 is uniformly applied to all elements. Anisotropic material characteristics are also modelled with the engineered timber grain direction considered along the XY axis. At the beginning of the simulation, the slab is set to a uniform thickness of 35 cm, and the Slab volume penalty results in a thickness reduction. The number of columns is computed based on the slab floor area and the minimum span between columns. The start positions of the column agents, their position at iteration 46, and the final converged solution are illustrated in Figure 6(a).

The live update behaviours tested previously on beam-column problems are then applied to the Tamedia case study. Figure 6(b) demonstrates the three steps of user interaction. Selecting a group of columns and holding down shift + left mouse button aligns the columns in a straight path, and when the column position is updated, the entire network updates. Furthermore, any column can be selected, dragged, or updated, prompting the entire column network to update the nodal displacement values.

4.2. Solving for floor slab with multiple architectural constrains

This section of the paper discusses the testing of a solver for floor plans with multiple cut-outs, which are common in architectural design for introducing atriums, building services, etc. The solver is tested

on the ground floor layout of the Hungarian house of music building designed by Sou Fujimoto architects, which features multiple cut-outs. A finite element (FE) model is computed with void features, which defines the search space of the column agents. For this test, 24 columns are considered, and an orthotropic material definition is used with a Young's modulus of 210 GPa and a tensile strength of 860 MPa.

In the preliminary stages of design, it is often necessary to identify areas with wide spans, and one useful feature is the no-column zone. This allows users to specify regions where columns should not be placed to achieve a wide span. Once these zones are marked, agents are prohibited from occupying nodal positions on the slab within the zone and are included for deflection checks. The FE model's mesh vertices closest to the boundary of the no-column zone marked by the user are highlighted and assigned a Boolean attribute value of "false". The agent system stores this attribute and verifies its status prior to calculating a new position. Figure 7 depicts a screenshot of the simulation at three different stages.

6. Discussion

This paper studied an interactive optimization technique to assist architects in the early design stage by providing guidance on structural and material quantities. The agent-based approach simplifies the computational pipeline by enabling live interaction, analysis, and solver guidance for the user. By incorporating gradient-based optimization as a behavior within the agent system, the search space results are improved compared to a pure geometric rule-based approach. The presented case studies demonstrate that the method generates layouts that fulfill the serviceability limit state deflection criteria for varying floor boundaries, area, and design requirements. The TCS framework and grasshopper plugin consolidate the study's developments and are available as open-source tools.

6.1. Limitations

The study presented in this paper has certain limitations and requires additional development to confirm the validity of results, particularly for large layouts. A significant lag in interaction speed was observed for large floor plan areas or layouts with multiple design constraints. While it is theoretically feasible to add multiple constraints to the current method, this may result in a black-box model with uncertain cause-and-effect relationships and outcomes. Additionally, a performance benchmark is necessary to quantify the tool's limitations and performance areas.

6.2. Outlook

Based on the study and its findings, integrating the workflow with performance algorithms to accelerate computation time, particularly for complex tasks, would be a valuable area to explore. Additionally, processing reuse material information in the (FE) model, which differs from standard factory process materials, has the potential to expand the tool's capabilities. Further research into detailed environmental considerations and modelling behaviour to introduce life-cycle-assessment-based constraints is also recommended.

6.3. Conclusion

The interactive optimization technique adopted in this study has the potential to make agent-based modelling more accessible to designers and simplify the design process by taking into account various technical constraints, such as structural performance and material quantities. The ultimate goal is to improve transparency and make the optimization process more interactive for the conceptual design stage.

Abstract

The folded plate structure is a type of structure that enhances bending stiffness and strength by folding a flat plate. When a flat plate is corrugated, the in-plane stiffness and bending stiffness increase in the corrugation transverse direction, but the in-plane stiffness in the corrugation direction is extremely small because it behaves like a spring. Therefore, when using corrugated shell surfaces to enhance structural performance, it is important to consider the arrangement of the corrugations based on the direction of the forces acting on them. This paper investigates the optimal corrugation directions of corrugated shells using an optimization method. The finite element method with triangular shell elements is used for the structural analysis of corrugated shells. However, instead of directly discretizing the surface of corrugated shell, we approximate it as an anisotropic shell and used its constitutive law in the analysis. The objective of the optimization is to minimize the strain energy under self-weight, and the corrugation direction of each finite element is considered as design variable. The quasi-Newton method is used as the optimization method. We apply this method to two models with different boundary conditions, cylindrical shells and EP shells.

Keywords: cross section optimization, anisotropic plate, corrugated plate, Quasi-Newton method, form-finding analysis

1. Introduction

Thin-walled plates, while having low bending stiffness and bending strength, can be structurally enhanced by utilizing geometric effects. One such effect can be achieved through the folded-plate structure, in which a flat plate is repeatedly folded to add thickness and resist bending moments. Another approach is the shell structure, where forces are channeled in the in-plane directions by providing curvature in two directions to thin-walled plates. This reduces the occurrence of bending moments by distributing the forces throughout the structure. On the other hand, in nature, there are forms that have both of these structural forms in a composite manner. Shells, from which the term "shell structure" is derived, often have a shell surface that is rippled in small increments. CNIT La Defense, built in 1959, is an RC shell structure with a triangular plan and a span of 206 m. The shell surface is given additional stiffness by corrugating. Turin Exhibition Building [1] is a vaulted shell structure designed by Pier Luigi Nervi and built in 1948. The shell surface is precast and has many holes for light, but the overall proportions are corrugated.

In this paper, we define the direction in which the shell surface is corrugated as the "corrugation direction," and the direction perpendicular to it as the "transverse direction", as illustrated in Figure 1. When a flat plate is corrugated, the in-plane stiffness and bending stiffness increase in the corrugation direction, but the in-plane stiffness in the transverse direction is extremely small because it meanders like a spring. On the other hand, shell structures have curvature in two main directions, which mainly provides in-plane resistance to external forces. If corrugated plates are applied to the shell curvature, it may be structurally disadvantageous depending on the direction of the corrugations. When shell surfaces

are corrugated to enhance structural performance, an appropriate arrangement of corrugations should be considered depending on the direction of the forces.

This study investigates the optimal corrugation direction of corrugated shells using optimization methods. The objective function is the strain energy under self-weight, and the corrugation direction of each shell element, which is discretized by the finite element method, is used as the design variable. Mathematical programming is employed as the optimization method.

Previous studies similar to the present paper include Refs. [2], [3]. P. Winslow et al. [2] optimized the intersection angle and orientation of the rods in a two-way grid shell; they analyzed the shell as a continuum shell using the equivalent stiffness of the two-way grid and used heuristics as the optimization method. Y. Matsumura et al. [3] used mathematical programming to optimize the material orientation of shells made of orthotropic anisotropic materials.

T. Michels et al. [4] have generated corrugated cylindrical shells with high resistance to earthquakes by arranging the thrust lines of the arch, which are simultaneously subjected to vertical and horizontal loads, continuously in the girder direction, and have investigated the optimal corrugated shape.

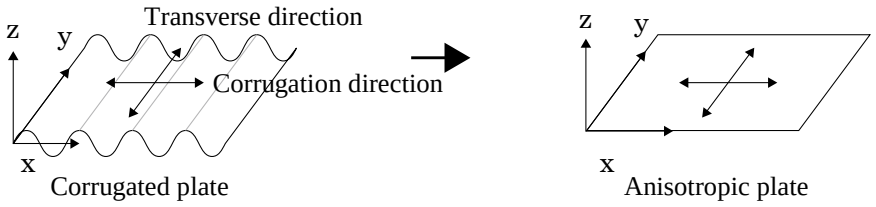

Figure 1. Replacement of corrugated plate with anisotropic flat plate

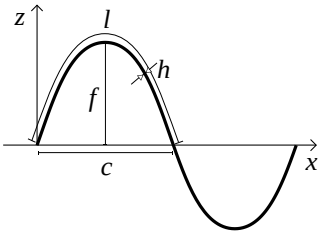
2. Optimization method

2.1. Equivalent stiffness of corrugated plate

The finite element method with triangular shell elements is used for the structural analysis of the corrugated shell. However, instead of discretizing the corrugated shell surface directly, the corrugated plate is approximated as an anisotropic flat plate in this study (Figure 1), and the following constitutive law of an anisotropic flat plate is applied.



$$\begin{Bmatrix} \bar{N}_x \\ \bar{N}_y \\ \bar{N}_{xy} \end{Bmatrix} = \begin{bmatrix} \bar{A}_{11} & \bar{A}_{12} & 0 \\ \bar{A}_{12} & \bar{A}_{22} & 0 \\ 0 & 0 & \bar{A}_{66} \end{bmatrix} \begin{Bmatrix} \bar{\varepsilon}_x \\ \bar{\varepsilon}_y \\ \bar{\varepsilon}_{xy} \end{Bmatrix}, \quad \begin{Bmatrix} \bar{M}_x \\ \bar{M}_y \\ \bar{M}_{xy} \end{Bmatrix} = \begin{bmatrix} \bar{D}_{11} & \bar{D}_{12} & 0 \\ \bar{D}_{12} & \bar{D}_{22} & 0 \\ 0 & 0 & \bar{D}_{66} \end{bmatrix} \begin{Bmatrix} \bar{\kappa}_x \\ \bar{\kappa}_y \\ \bar{\kappa}_{xy} \end{Bmatrix} \quad (1), (2)$$

where $\bar{\varepsilon}_x$, $\bar{\varepsilon}_y$ and $\bar{\varepsilon}_{xy}$ are the in-plane strains in the mid-plane of the anisotropic plate, and $\bar{\kappa}_x$, $\bar{\kappa}_y$ and $\bar{\kappa}_{xy}$ are the curvatures. $\bar{N}_x$, $\bar{N}_y$, and $\bar{N}_{xy}$ are membrane force components, and $\bar{M}_x$, $\bar{M}_y$, and $\bar{M}_{xy}$ are moment components. Y.Xia et al. [5] derived the equivalent stiffness of an anisotropic flat plate for corrugated plates under the condition that the strain energy is equivalent. They derived a general-purpose constitutive law without limiting the shape of corrugation, but in this study, the shape of corrugation is sinusoidal as shown in Figure 2. In this case, following their formulation, we obtain the following equation.

$$\bar{A}_{11} = \frac{2ch^2}{h^2 I_1 + 12 I_2} \frac{Eh}{1-\nu^2}, \quad \bar{A}_{12} = \nu \bar{A}_{11}, \quad \bar{A}_{22} = \nu^2 \bar{A}_{11} + \frac{l}{c} Eh, \quad \bar{A}_{66} = \frac{c}{l} \frac{Eh}{2(1+\nu)}$$

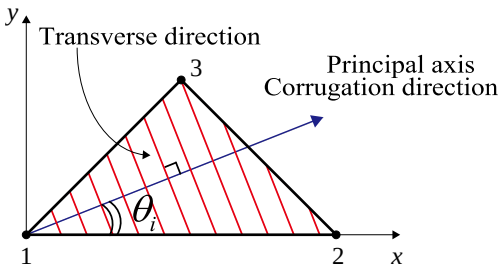
$$\bar{D}_{11}=\frac{c}{l}\frac{Eh^3}{12(1-\nu^2)},\quad \bar{D}_{12}=\nu\bar{D}_{11},\quad \bar{D}_{22}=\frac{1}{2c}\left(I_2\frac{Eh}{(1-\nu^2)}+I_1\frac{Eh^3}{12(1-\nu^2)}\right),\quad \bar{D}_{66}=\frac{l}{c}\frac{Eh^3}{24(1+\nu)} \tag{3}$$

where E is Young's modulus, ν is Poisson's ratio, and $I_1=\int_s\left(\frac{dx}{ds}\right)ds$, $I_2=\int_s z^2 ds$. s is the coordinate along the corrugation curve.

$$z=f\sin\frac{\pi x}{c}$$

c : Half period of corrugation
f : Hight of corrugation
l : Lengh of corrugation
h : Plate thickness

Figure 2. Geometry of corrugated plate



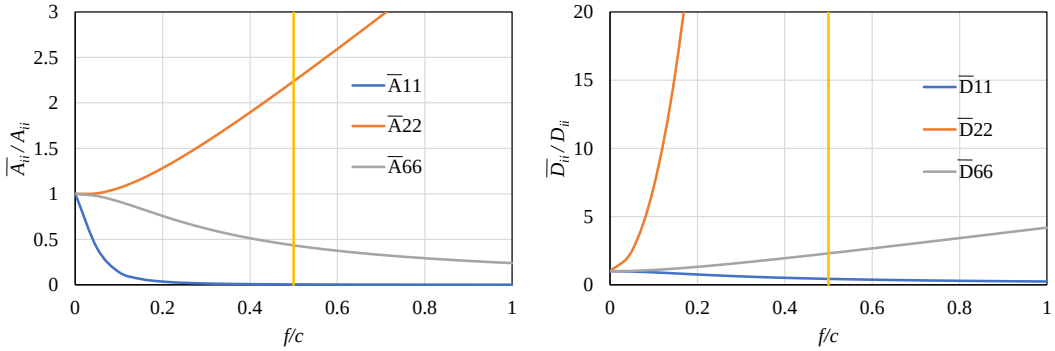


Figure 4. Triangular shell element

(a) In-plane stiffness (b) Out-of-plane stiffness

Figure 3. Equivalent stiffness

The in-plane stiffness of the equivalent stiffness in Eq. (3) is shown in Figure 3(a). The corrugation is represented by the plate thickness h=0.1 m, the half period of the corrugation c=0.5 m, Poisson's ratio ν=0.17, and the stiffness variation is expressed with the corrugation height f as a parameter. The horizontal axis is the ratio of the corrugation half period to the corrugation height, and the vertical axis is the ratio to the stiffness of the isotropic flat plate. Similarly, the out-of-plane stiffness is shown in Figure 3(b).

Figure 3(a) shows that $\bar{A}_{11}$ (in the transverse direction) decreases significantly with increasing corrugation height, while $\bar{A}_{22}$ (in the corrugation direction) increases. $\bar{A}_{66}$ decreases slowly. Figure 3(b) shows that $\bar{D}_{11}$ (in the transverse direction) decreases slowly as the corrugation height increases, while $\bar{D}_{22}$ (in the corrugation direction) increases sharply. $\bar{D}_{66}$ increases slowly. The corrugation height in this paper is f=0.25m, which is indicated by straight yellow lines in Figure 3.

Next, the treatment of the above constitutive law in the finite element method is described. Let θ_i denote the angle between the local x-coordinate of element i of the triangular shell element and the principal axis (transverse direction) of the corrugated plate (see Figure 4).

Since the constitutive law of the element involves a coordinate transformation in the angle θ_i, it can be expressed as follows.

$$\mathbf{D} = \mathbf{H}^T \mathbf{D}_0 \mathbf{H} \tag{4}$$

where

$$\mathbf{H} = \begin{bmatrix} \cos^2\theta_i & \sin^2\theta_i & \sin\theta_i\cos\theta_i \\ \sin^2\theta_i & \cos^2\theta_i & -\sin\theta_i\cos\theta_i \\ -2\sin\theta_i\cos\theta_i & 2\sin\theta_i\cos\theta_i & \cos^2\theta_i - \sin^2\theta_i \end{bmatrix} \tag{5}$$

and $\mathbf{D}_0$ is the stress-strain matrix of Eq. (1) or Eq. (2).

2.2. Formulation of optimization problem

The objective function is the strain energy of the shell under the self-weight.

$$U(\boldsymbol{\theta}) = \frac{1}{2}\sum_{i=1}^{M} \mathbf{d}_i{}^T \mathbf{k}_i(\theta_i)\mathbf{d}_i \tag{6}$$

where $\boldsymbol{\theta} = [\theta_1, ...\theta_M]^T$ is the principal axis angles of all elements, $\mathbf{d}_i$ is the displacement vector of the nodes comprising element *i*, and $\mathbf{k}_i(\theta_i)$ is the element stiffness matrix. *M* represents the number of elements. Eq. (6) is an unconstrained nonlinear programming problem, and the quasi-Newton method is used as the optimization technique. By partial differentiation of the above equation by θ_i, we obtain the following optimality condition.

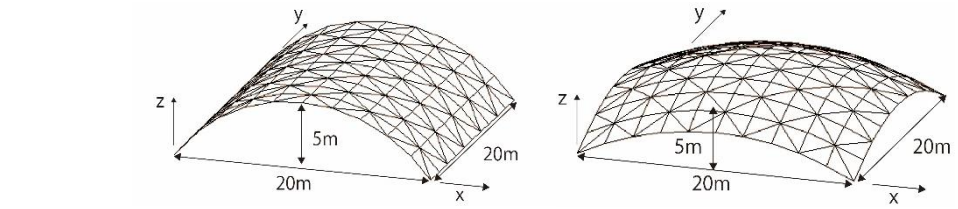
$$\frac{\partial U(\boldsymbol{\theta})}{\partial \theta_i} = -\frac{1}{2}\mathbf{d}_i{}^T \frac{\partial \mathbf{k}_i}{\partial \theta_i}\mathbf{d}_i = 0, \quad (i = 1, \cdots, M) \tag{7}$$

The quasi-Newton method is used to find $\boldsymbol{\theta}$ satisfying the above equation. The element stiffness matrix $\mathbf{k}_i$ can be expressed as

$$\mathbf{k}_i = \int_S \mathbf{B}^T \mathbf{D}\mathbf{B} dS \tag{8}$$

where $\mathbf{B}$ is the strain-node displacement matrix and *S* is the element area. Therefore, $\partial\mathbf{k}_i / \partial\theta_i$ can be expressed as

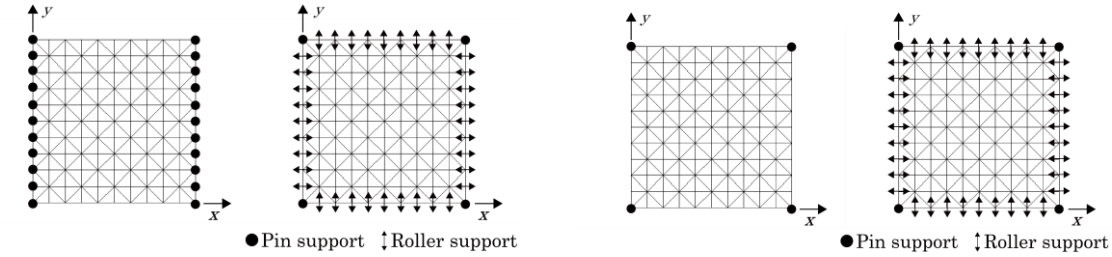
$$\frac{\partial \mathbf{k}_i}{\partial \theta_i} = \int_S \mathbf{B}^T \frac{\partial \mathbf{D}}{\partial \theta_i}\mathbf{B} dS, \quad \frac{\partial \mathbf{D}}{\partial \theta_i} = \frac{\partial \mathbf{H}^T}{\partial \theta_i}\mathbf{D}_0\mathbf{H} + \mathbf{H}^T\mathbf{D}_0\frac{\partial \mathbf{H}}{\partial \theta_i}$$



$$\frac{\partial \mathbf{H}}{\partial \theta_i} = \begin{bmatrix} -2\sin\theta_i\cos\theta_i & 2\sin\theta_i\cos\theta_i & \cos^2\theta_i - \sin^2\theta_i \\ 2\sin\theta_i\cos\theta_i & -2\sin\theta_i\cos\theta_i & -\cos^2\theta_i + \sin^2\theta_i \\ -2(\cos^2\theta_i - \sin^2\theta_i) & 2(\cos^2\theta_i - \sin^2\theta_i) & -4\sin\theta_i\cos\theta_i \end{bmatrix}$$

3. Numerical example

3.1. Analysis models



There are multiple analysis models, each with the geometry of a cylindrical shell or an EP shell, respectively. Both geometries have dimensions of 20 meters in span in the x-direction, 20 meters in span in the y-direction, and a 5-meter rise (as shown in Figure 5). The dimensions of the corrugated plate are defined as corrugation half period *c*=0.5 m, corrugation height *f*=0.25 m (corrugation length *l*=0.731 m), and plate thickness *t*=0.1 m. Since RC is assumed as the material, Young's modulus is $E = 2.1\times10^4$ N/mm^2, Poisson's ratio ν = 0.17, and unit volume weight ρ= 24 kN/m^3. The load is self-weight and thus a distributed load of $\omega = \rho hl / c$ unit area is given by equivalent nodal forces. For each type of shell,

there are two support conditions: 2-edge pin support and roller support for cylindrical shells, and 4-point pin support and roller support for EP shells, as illustrated in Figure 6. Therefore, a total of four models are optimized.

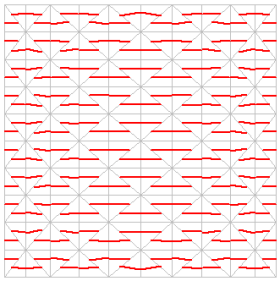
3.2. Optimization results

3.2.1. Results of 2-edge pinned cylindrical shell



The initial solution and the optimal solution for the 2-edge pinned cylindrical shell are shown in Figure 8 and Figure 9, respectively. The red lines in Figure (a) represent the corrugation transverse direction of each element, as in Figure 7. The transverse direction in the initial solution was given in the *y*-direction, but in the optimal solution it is changed by 90 degree, toward the supported boundary.

Figure (b) is a membrane force diagram, where the magnitude of the membrane force in the principal stress direction is represented by the length of the line. The maximum value is also entered in the figure. Comparing Figure 8(b) and Figure 9(b), there is no change in the membrane force distribution. Figure (c) shows a bending moment diagram in the same way. The initial solution in Figure 8(c) shows that the bending moment for each element occurs in two directions, while the bending moment for the optimal solution in Figure 9(c) occurs mainly in one direction and in the same direction as the corrugation pattern in Figure 9(a). Note that these membrane forces and bending moments are the resultant stresses when the corrugated plate is considered an anisotropic flat plate.

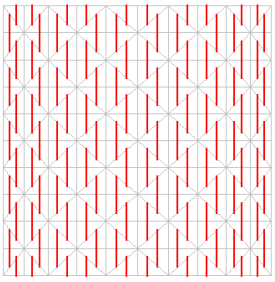


Figure (d) is a deformation diagram, showing the deformation due to the self-weight magnified 100 times. The deformation of the optimal solution is small compared to the initial solution.

Figure 16. Relation between corrugation orientation angle and principal stress angle (EP shell, 4-point pin)

(a) Membrane force (b) Bending moment

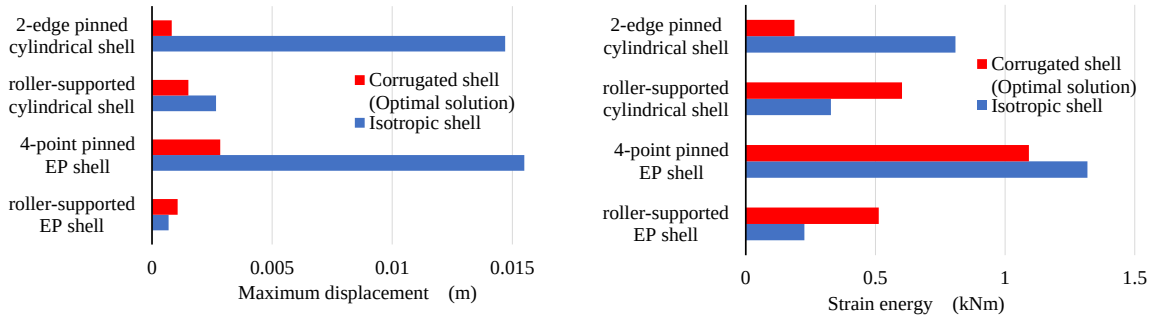
Figure 19. Relation between corrugation orientation angle and principal stress angle (EP shell, roller)

Figure 10(a) plots the orientation angle of the corrugation $\theta_i + \frac{\pi}{2}$ (the transverse direction) for each element on the horizontal axis and the angle of the principal membrane force on the vertical axis for the optimal solution. The figure shows that the orientation angle of the corrugation and the angle of the membrane force are almost identical. Figure 10(b) similarly plots the orientation angle of the corrugation versus the angle of the principal bending moment. In this case, too, the two are almost identical.

3.2.2. Results of roller-supported cylindrical shell

The results of the roller-supported EP shell are shown in Figures 11 and 12. The corrugation transverse direction in the initial solution of Figure 11(a) was given in the *y*-direction, but in the optimal solution of Figure 12(a) it is oriented towards the outer boundary and irregularly oriented near the center, In the initial solution of Figure 11(b), the membrane force for each element occurs in two directions, but in the optimal solution of Figure 12(b), it occurs in one direction. In Figure 11(c), the bending moment occurs mainly in the *y*-direction, while in the optimal solution of Figure 12(c), the bending moment occurs in a direction similar to the membrane force in Figure 12(b). Near the center of the shell, the bending moment is small. Figure 13 shows that the orientation angles of the corrugation tend to coincide with the angles of the principal stresses.

3.2.3. Results of 4-point pinned EP shell



The results of the 4-point pinned EP shell are shown in Figures 14 and 15. Figure 14(a) shows that the corrugation pattern is oriented toward the support points and irregularly oriented near the center. In the initial solution of Figure 14(b), the membrane force for each element occurs in two directions, but in the optimal solution of Figure 15(b), it occurs in one direction. In Figure 14(c), the bending moment occurs mainly in the *y*-direction, while in the optimal solution of Figure 15(c), the bending moment occurs in a direction similar to the membrane force in Figure 15(b). Near the center of the shell, the bending moment is small. Figure 16 shows that the orientation angles of the corrugation tend to coincide with the angles of the principal stresses.

3.2.4. Results of roller-supported cylindrical shell

The results of the roller-supported EP shell are shown in Figures 17 and 18. The corrugation pattern of the optimal solution is oriented toward the boundary and irregularly oriented near the center. The results are very similar to those of the roller-supported cylindrical shell. Figure 19 still shows that the orientation angles of the corrugation tend to coincide with the angles of the principal stresses.

3.3. Comparison with isotropic shells

In order to observe the mechanical effects of corrugated shell surfaces, we compared the mechanical properties of optimal solutions obtained in the previous sections with those of normal shells of uniform thickness. The shells were separately analyzed by replacing the constitutive laws in equations (1) and (2) with the constitutive laws of isotropic flat plates. A comparison of the maximum displacement under self-weight is shown in Figure 20(a), and a comparison of strain energy is shown in Figure 20(b). The red bars represent corrugated shells, and the blue bars represent isotropic shells. The figures show that the values for corrugated shells are generally smaller than those for isotropic shells, but in the two cases of roller support, the strain energy of the corrugated shell is larger. This is due to the greater weight of the corrugated plate shell than the isotropic shell. For shells with free edges, the effect of corrugation is significant because they are more susceptible to bending and the membrane force flow is limited. On the other hand, shells with fully supported boundaries have a large shell effect, so the effect of corrugation is eliminated.

(a) Maxmum displacement (b) Strain energy

Figure 20. Comparison of corrugated and isotropic shells

4. Conclusion

In this paper, we investigate the optimal corrugation directions of corrugated shells. The corrugations on the shell surface are modeled as anisotropic materials, and the corrugation direction of each element is used as a design variable for optimization using the quasi-Newton method. Our results show that:

(1) The proposed optimization method yielded corrugation directions for corrugated shells with low strain energy under self-weight. The optimal solution tended to produce membrane forces and bending moments in only one direction over the entire region of the shell for both models, and the corrugation transverse direction tends to coincide with the direction of the principal stresses.

(2) We compare the mechanical properties of corrugated shells obtained by optimization and normal isotropic shells. The comparison of displacement and strain energy confirms the effect of applying corrugated shells. Depending on the support conditions, the strain energy may be lower for the normal shell due to the increase in self-weight caused by the corrugated surface.

The optimal solutions obtained in this paper may be difficult to realize as an actual structure because the corrugation direction changes abruptly in some places, resulting in almost perpendicular corrugation at adjacent elements. For this reason, we also propose a method to represent a smooth corrugation pattern by using contour lines of polynomial functions [6].

Abstract

The use of aluminium alloys in the construction industry is becoming increasingly popular owing to their favourable mechanical properties such as high strength-to-weight ratio, excellent corrosion resistance, appealing appearance, good recyclability and ease of fabrication. However, a substantial number of studies have shown that high temperature will significantly reduce the strength and elastic modulus of aluminum alloys. Thus, investigations on the structural behaviour of aluminium alloy structures in fire disaster are necessary and significant.This paper presents a review of recent studies on the structural behaviour and performance-based design of aluminium alloy structures exposed to fire. Then, based on cases of some practical aluminum alloy large-span projects in China, such as Pixian Gymnasium, Zhangshu Sports Center, Expo Cultural Park Exhibition Greenhouse and other projects, the performance-based design and passive fire protection methods of large-span aluminum alloy structures are studied. The main contents are as follows: First, the fire smoke analysis model provided in NFPA92B and NFPA 204 is used to calculate the air temperature at different heights above the central axis of the flame. Then the fire dynamics simulation software FDS is used to simulate and analyze the fire development and smoke spread in the building. Through numerical simulation, the deformation and temperature field distribution of members of aluminum alloy structure under fire are obtained. The results show that FDS technology can accurately predict the non-uniform distribution of smoke temperature field in large space buildings. This study will enrich the fire resistance theory of large space aluminum alloy structures and provide reference for fire risk assessment of such large space buildings.

Keywords: performance-based fire resistance, large-space aluminum alloy structure, fire dynamic simulation, smoke temperature field

1.Introduction

Due to the increasingly large scale and complex structure of modern space buildings, the fire resistance performance of different structure will produce different mechanical performances and failure modes under various fire source locations, fire scale, structural parameters, and load conditions. In addition, the development and application of new material and technology has made the requirements for building fire protection increasingly personalized, and fire safety research of spatial structure have encountered many new challenges[1-2]. Traditional fire safety analysis methods cannot meet the design requirements of this new type of building, and performance-based design is the best way to solve the problem[3-4].

The performance-based fire resistance design method is to simulate and calculate the overall performance of the structure under real fire temperature rise, and determine the best fire protection

design scheme to achieve minimum fire economic losses and personal safety.Firstly, it is necessary to determine the overall safety goals, including performance-based goals and performance-based standards. Then reasonable fire scenario is defined. By selecting appropriate calculation formulas and method, a simulation model that conforms to the fire characteristics of the building is established to analyze the possible fire source location ,the spread and diffusion of fire smoke, the working conditions of fire-fighting facilities, personnel evacuation and escape behavior. Performance based fire resistance analysis is complex and uncertain, posing high requirements for designers.

Since 2000, China has established a "Fire Safety Engineering Working Group", which is responsible for collecting and analyzing relevant foreign data, proposing a development plan for China's fire safety engineering standards, organizing the formulation of performance-based design standards, promoting research in fire science, establishing performance-based evaluation methods, and establishing relevant database. In 2004, Tianjin Fire Science and Technology Research Institute of MEM, Sichuan Fire Science and Technology Research Institute and the State Key Laboratory of Fire Science of the University of Science and Technology of China jointly completed the Technical Guidelines for performance-based fire protection design of buildings, which is the first complete performance-based fire protection guidelines in China and has established a relatively complete performance-based fire protection design method and system.

With rapid economic development in the past 20 years, China has gradually established a method system that meets the domestic engineering needs: establishing fire safety analysis models and evaluation methods suitable for high-rise buildings, atrium buildings, and densely populated large space buildings [5-6]; A quantitative analysis model suitable for engineering application were established by combining field, area, and network. The reliability of the mathematical model was verified by combining simulation results with physical experiments; Study on personnel evacuation path planning and design was conducted to obtain status data such as spatial location information, complex perception ability, cognitive ability of personnel as well as evacuation facilities and fire environment [7-9]; The dynamic analysis model of personnel evacuation was established by using situational experiment and isometric graph methods, and the simulation software was completed on this basis; In addition, preliminary studies have been conducted on deterministic criteria, including fire ignition, fire development, limiting fire spread, life safety criteria, and safety factors.

At present, a large number of fire protection design cases of large-span space structures based on fire safety engineering methods have been accumulated, including the checking calculation of fire resistance bearing capacity of roof structures and components, thermal coupling simulation analysis and fire protection design, but most of them were concentrated on steel structures, and the fire resistance design methods of aluminum alloy structures were less involved. Aluminum alloy structures are favored by architects because of their low density, corrosion resistance and strong metal texture. A single-layer aluminum alloy reticulated shell has been increasingly used as a roof supporting structure in public buildings. Yet, the performance-based analysis of aluminum alloy structures is still relatively isolated from the respective fields of fire science and structural engineering, and the high-temperature stress of aluminum alloy structures is still in the initial research stage. The effects of smoke and temperature under fire are not yet uniform. The risk level changes of aluminum alloy structures and issues such as the route and time of personnel escape have not been considered and evaluated in the same environment. Therefore, the overall safety problem of aluminum alloy structures under fire cannot be well solved, the systematic characteristics of building fires cannot be revealed, and the interrelationships between various fire actions and influencing factors cannot be reflected as a whole. Moreover, the actual engineering situation is very different, and the models and methods related to fire development and spread, smoke flow, personnel safety evacuation and structural fire resistance analysis still require a lot of in-depth research.

Based on typical well-known domestic aluminum alloy large-span structural engineering cases, the mechanical properties and overall structural stability of aluminum alloy large-span roofs under fire was

analyzed. The performance-based fire protection design method was proposed and safety performance evaluation under fire was conducted. The project cases in this paper provide reference for the construction of large and complex buildings and engineering application of new technology and materials.

2. Case Study on Fire Resistance of Long Span Aluminum Alloy Reticulated Shell Structures

2.1. Pixian Gymnasium

2.1.1. Project Overview

Pixian Gymnasium is located in Pixian County, Chengdu City, Sichuan Province. It consists of a comprehensive gymnasium and an indoor swimming pool, with the roof of the two gymnasiums connected into one. An irregular hyperbolic aluminum alloy single layer reticulated shell with a span of 65.5 m was adopted.

2.1.2. Basic parameters

According to the European Code for Fire Protection Design of Aluminum Alloys, 170 ℃ was selected as the criterion for determining the failure temperature of aluminum alloys. The air temperature rise formula for large space buildings provided in the Technical Code for Fire Protection of Steel Structures of Buildings (CECS 200:2006) was selected as the air temperature rise curve. The fire smoke analysis models provided in NFPA 92B and NFPA 204 were used to calculate the airflow temperatures at different heights above the central axis of the flame, and compared with the critical failure temperature of aluminum alloy structures to determine the range of protection for aluminum alloy structures.

Fire source 1 is located on the ground of the competition hall area (at an elevation of 0 m), with a fire scale of 8.0 MW； Fire source 2 is located on the ground of the swimming pool site (at an elevation of 0 m), with a fire scale of 2.5 MW; Fast t^2 fire model was used for fire growth curve. The temperature of the airflow at different heights is shown in Table 1 and Table 2.

Table 1. Analysis of air flow temperature on axis of fire source one (8.0MW).

Height	Smoke temperature riseΔT（℃）	Average temperature of smoke T_m（℃）	Temperature of Smoke plume T_c（℃）	Temperature considering a safety factor of 1.2（℃）
11.0m	62.9	88.9	171.6	205.9
12.0m	57.7	83.7	152.0	182.4
13.0m	53.2	79.2	136.2	163.4
14.0m	49.4	75.4	123.4	148.1
15.0m	46.1	72.1	112.8	135.4

Table 2. Analysis of air flow temperature on axis of fire source two (2.5MW).

Height	Smoke temperature riseΔT（℃）	Average temperature of smoke T_m（℃）	Temperature of Smoke plume T_c（℃）	Temperature considering a safety factor of 1.2（℃）
6.0m	81.7	107.7	210.2	252.2
7.0m	70.0	96.0	168.4	202.1
8.0m	61.3	87.3	140.0	168.0
9.0m	54.5	80.5	119.7	143.6
10.0m	49.0	75.0	104.6	125.5

It can be seen from table 1 that the airflow temperature on the plume axis of the fire source one at a distance of 13m above fire source one is 163.4℃ (considering a safety factor of 1.2), which is lower than the critical temperature determination criterion of 170℃; From table 2, it can be seen that the airflow temperature on the plume axis of the fire source 2 at a distance of 8m above the fire surface is 168℃ (considering a safety factor of 1.2), which is below that of the critical temperature determination criterion of 170℃; Therefore, it is possible to determine the range of fire protection for the aluminum alloy structure of the gymnasium: the aluminum alloy structure within a range of 13m above the ground of the gymnasium competition venue in the case of fire source 1 should be protected; Aluminum alloy structures within 8m above the ground of the swimming pool competition venue in the case of fire source 2 should be protected.

2.1.3. Numerical simulation model

Due to the low melting point of aluminum alloys, temperature has a significant impact on the material and mechanical properties of aluminum alloys. As temperature increases, the material properties of aluminum alloys will undergo significant changes. In the finite element model, it is necessary to consider the changes in material properties at high temperatures. Considering that the highest point of the stand at 15.65m is the closest to the vertical distance of the reticulated shell and there are combustibles here, the fire source is set on the stand at 15.65m height, as shown in Figure 1.

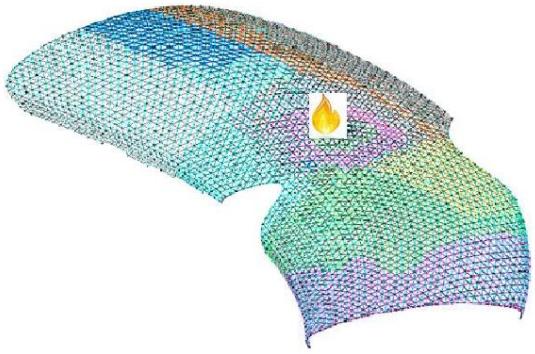

Figure 1. Finite Element Model and Fire Source Location.

2.1.4. Results analysis

Figure 2 shows the temperature field distribution of aluminum alloy structural members. It can be seen that the yield strength of aluminum alloy materials decreases with increasing temperature. When the temperature is around 150 ℃, there will be a significant decline of yield strength, and at 350 ℃, the

downward trend tends to be gentle. When the temperature reaches 500 ℃, aluminum alloy materials have lost their bearing capacity. When the calculation time is 1200s, the maximum temperature at the center of the fire source is 282 ℃. At this time, the yield strength of the rod decreases significantly, and corresponding fire protection measures must be taken.

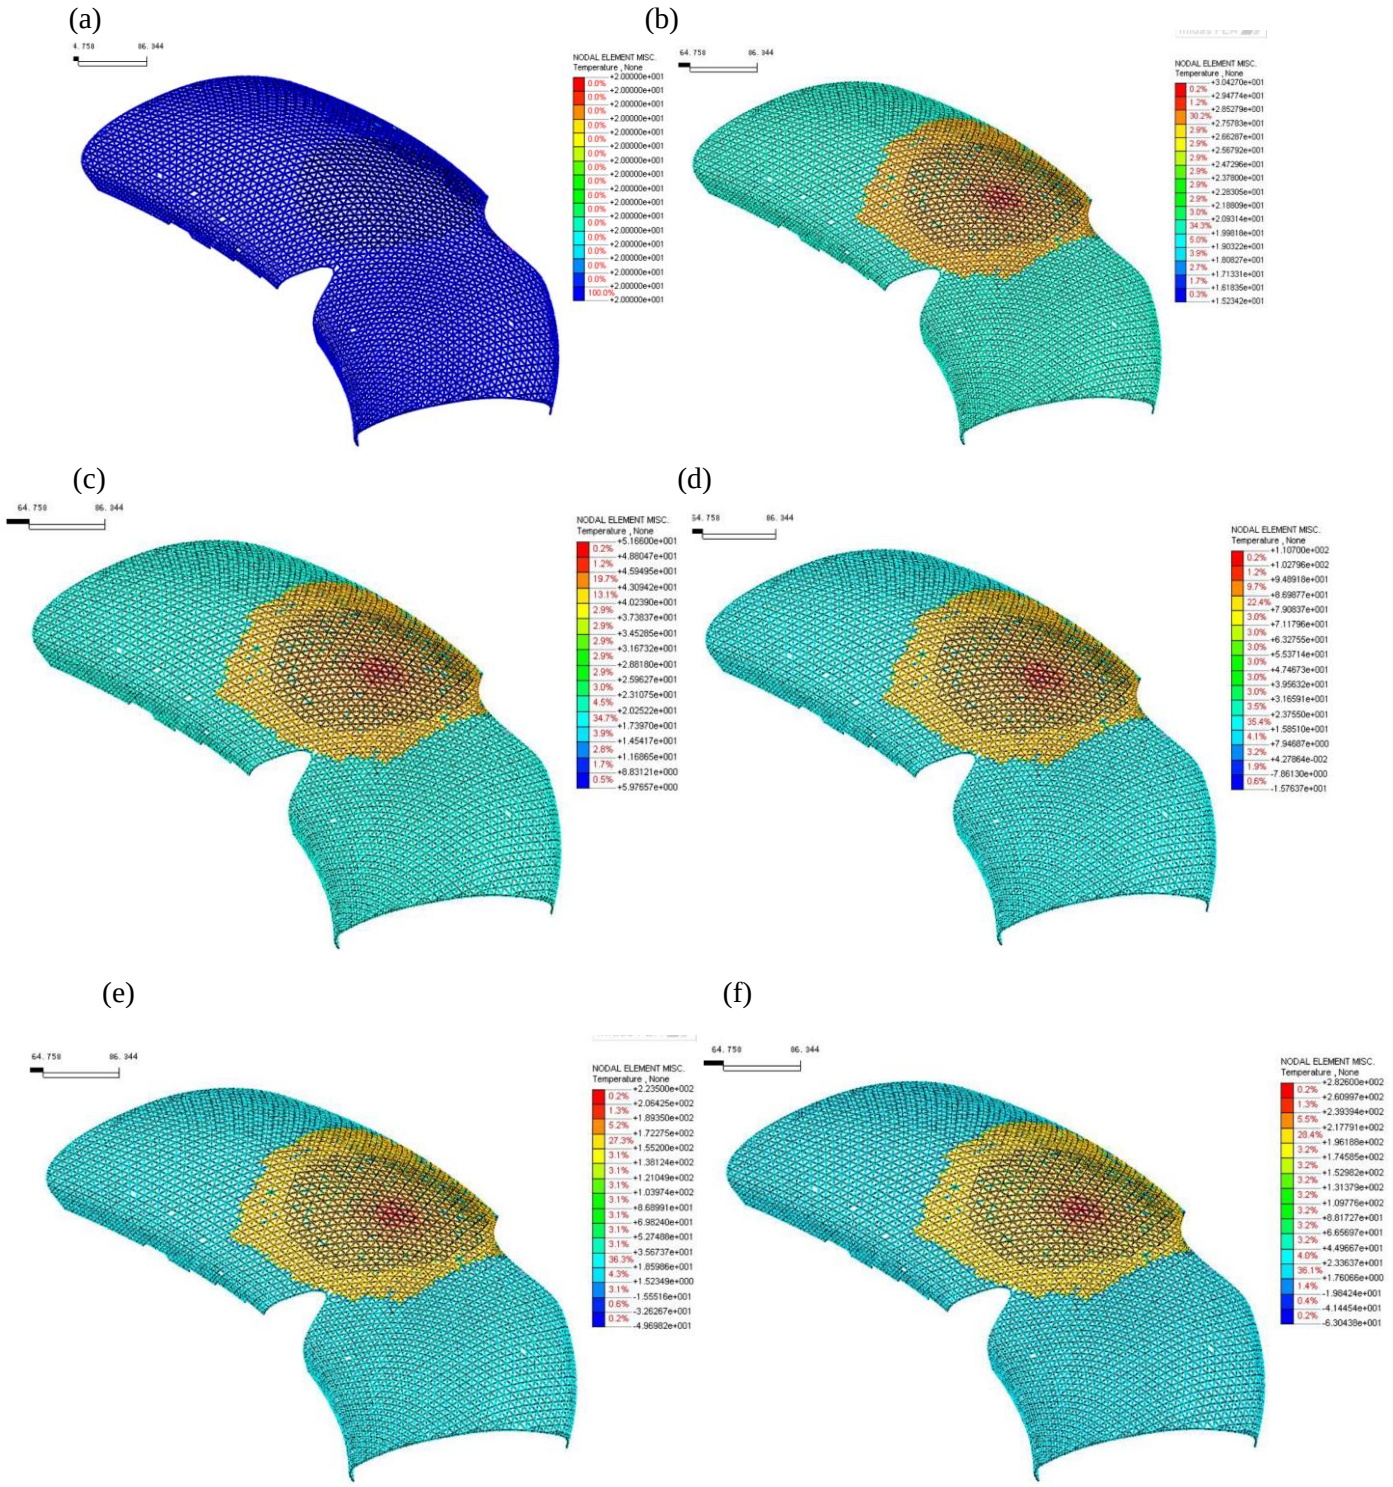

Figure 2. Temperature Field Distribution of Aluminum Alloy Structural Members: (a) 0s (b) 200s(c) 400s (d) 600s(e) 800s (f) 1200s

Figure 3 shows the deformation development of reticulated shell structures under fire. According to the simulation, it can be seen that with the increasing distance from the fire source, the deformation of aluminum alloy structural members gradually decreases, and the deformation above the fire source has exceeded 500mm.This is caused by the material properties of aluminum alloys. As fires continue, aluminum alloys continuously absorb the temperature of hot air through convection and radiation, ultimately leading to a continuous rise in the temperature of the members. The elastic modulus of aluminum alloys is inversely proportional to temperature, and is almost zero at 500 ℃.

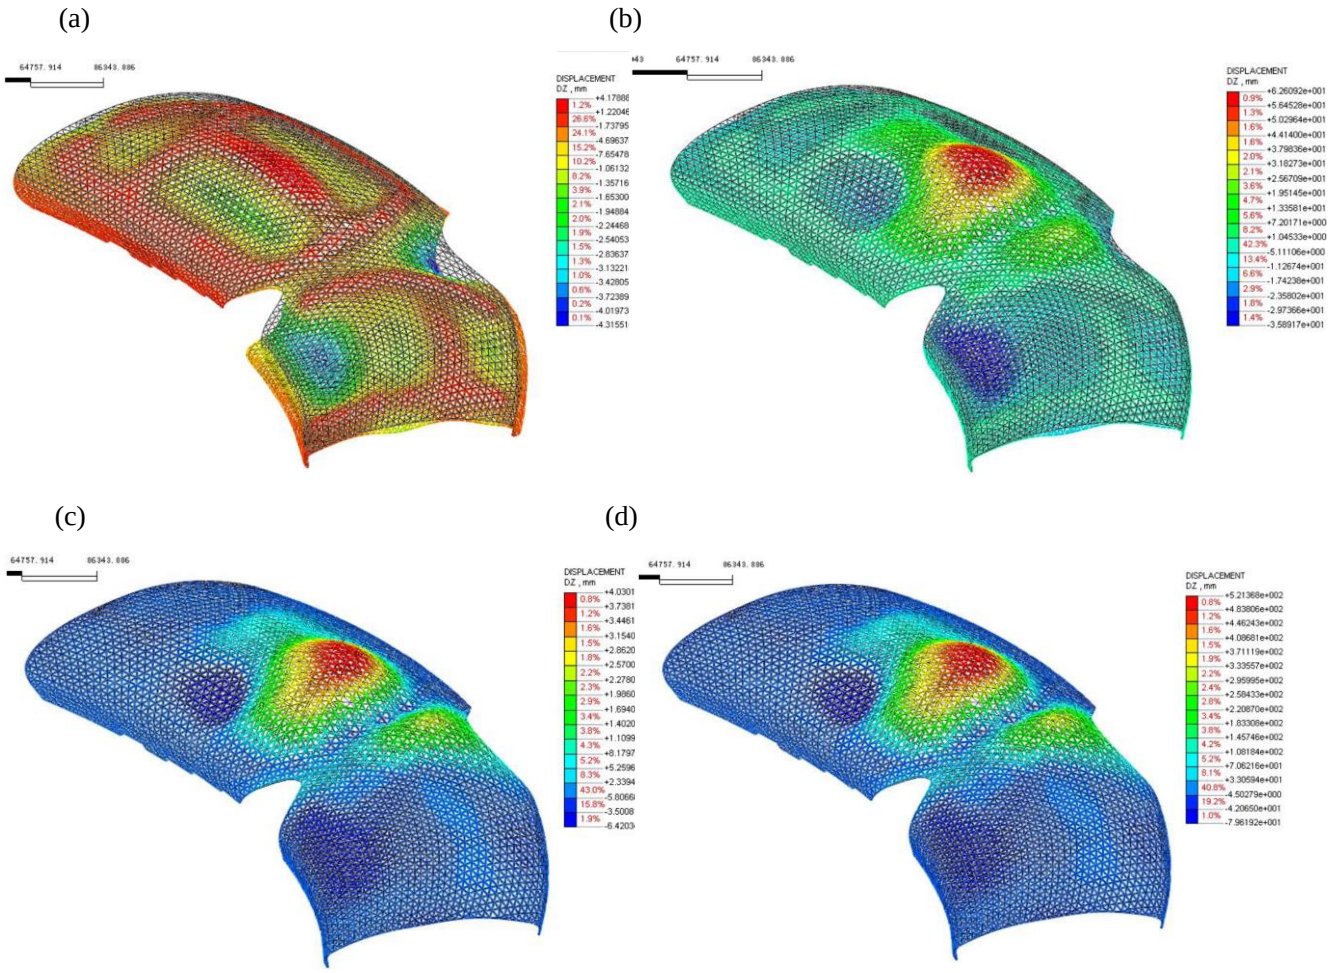

Figure 3. Deformation diagram of reticulated shell structure under fire: (a) 0s (b) 400s (c) 800s (d) 1200s

From the above analysis, it can be seen that under the most unfavorable design fire scenario, aluminum alloy roof structures without fire protection cannot meet the fire resistance bearing capacity requirements, and fire protection measures should be taken for aluminum alloys. Currently, effective water spray systems are commonly used for fire prevention measures of aluminum alloy structures. In addition, the aluminum alloy structure can be separated from the functional area by building a fireproof partition to block the conduction of heat flow under fire. Moreover, there are no fireproof coating products suitable for aluminum alloy on the market. After comprehensive consideration, it is proposed to use a water spray system and masonry fire barriers to protect the aluminum alloy structure in this project.

2.2. Expo Cultural Park Exhibition Greenhouse

2.2.1. Project Overview

Expo Cultural Park Exhibition Greenhouse includes four venues, and outdoor overhead corridors are set at a height of 5.5m between the aboveground buildings P2, P3, and P4. Steel columns are used as vertical load-bearing members. The roof is a string reticulated structure with special-shaped top chord， in which the top chord is made of aluminum alloy structure, the bottom chord is made of coated sealing cable, and the rest of the members of the structure are of steel structure, as shown in Figure 4.

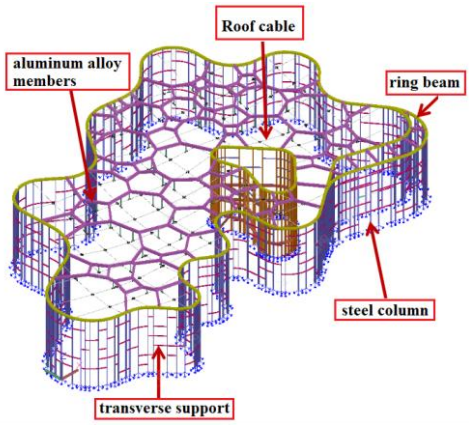

Figure 4. Structural diagram

2.2.2. Fire smoke simulation

The fire smoke model of P2, P3 and P4 venues was established by using Pyrosim software, as is shown in Figure 5. The grid size of the model was 0.5m×0.5m×0.5m, and the ambient temperature was 20°C. The fire simulation software FDS was used for numerical simulation.

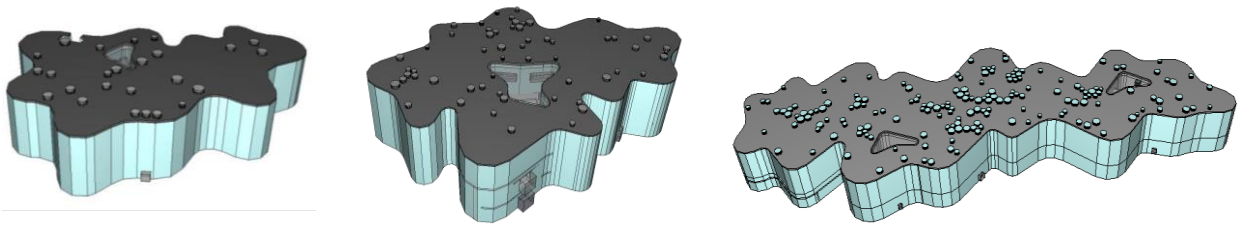

Figure 5. Fire Smoke Model: (a) P2 (b) P3 (c) P4

(a) (b)

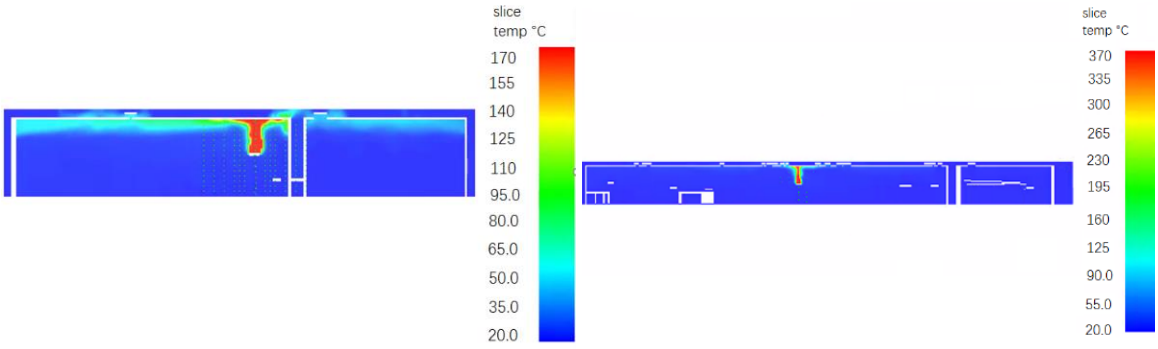

Figure 6. Profile temperature map: (a) Fire Scenario 2 (b) Fire Scenario 8

Figure 6 shows the sectional temperature map under two typical fire scenarios. Fire Scenario 2 (The fire resource is located at the 7.5m elevation of P2, with a fire scale of 11.0MW): Due to the high elevation of the fire source and the impact of fire smoke, the temperature near the aluminum alloy roof directly above the fire source is the highest, up to 170 ℃. The temperature near the aluminum alloy roof in the area far away from the fire source is relatively low, about 40-60 ℃.Fire Scenario 8 (The fire resource is located at the 7.0m elevation of P4, with a fire scale of 11.0MW): The temperature near the aluminum alloy roof directly above the fire source is relatively high, about 370 ℃. The temperature in other areas is relatively low.

2.2.3 Fire resistance bearing capacity analysis

Midas Building software was used to analyze the fire resistance performance of the structure. Based on the fire temperature rise calculation results, temperature action was applied to the components affected by the fire.Load combinations were performed based on the temperature distribution of components, and the stress results of the roof structure under the most unfavorable load combinations for each fire scenario are obtained through calculation, as shown in Figure 7.Fire Scenario 4 ： The fire resource is located at entrance area of P3, with a fire scale of 8.0MW； Fire Scenario 9： The fire resource is located a the 8.9m elevation of P4, with a fire scale of 8.0MW.

(a) (b)

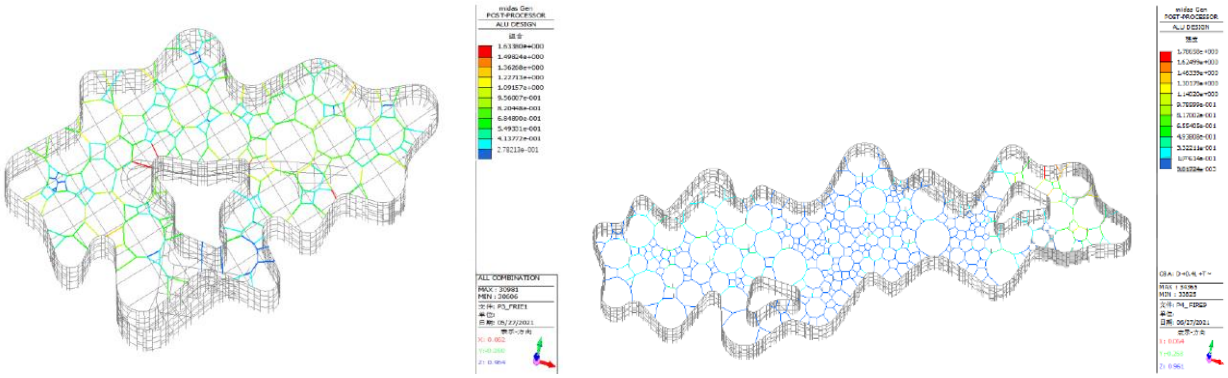

Figure 7. Stress diagram of aluminum alloy components: (a) Fire Scenario 4 (b) Fire Scenario 9

2.3 Zhangshu Sports Center

2.3.1. Project Overview

Zhangshu Sports Center Gymnasium is located in Zhangshu City, with reinforced concrete as its main structure and aluminum alloy single layer reticulated shell structure system as its roof. The size of the roof is an ellipse with a long axis of about 130m and a short axis of nearly 100m. The building elevation at the highest point of the roof is 26.000m. The design fire resistance rating is Grade I.The architectural expression chart is shown in Figure 8.

2.3.2. Fire smoke model

The fire dynamics simulation software FDS was used to simulate the fire development and smoke spread in the building. Since FDS can only build rectangular models , Therefore, the curved parts in this building were handled by using fold lines instead of curved lines. Figure 9 shows the model schematic.

Figure 8. Architectural expression chart

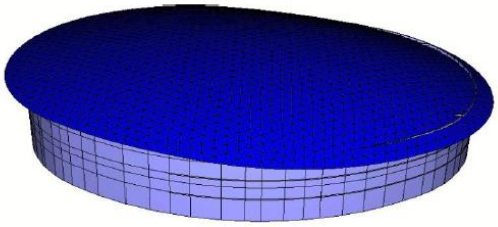

Figure 9. FDS model

The non-uniform grid division method is used to divide the grid: the grid size in the area near the fire source is 0.25m×0.25m×0.25m, and in other areas is 0.5m×0.5m×0.5m. Considering the places with more combustible materials, higher fire hazard and closer to the metal structure of the building, a total of four fire source were selectedas, shown in Figure10 .

(a) (b) (c)

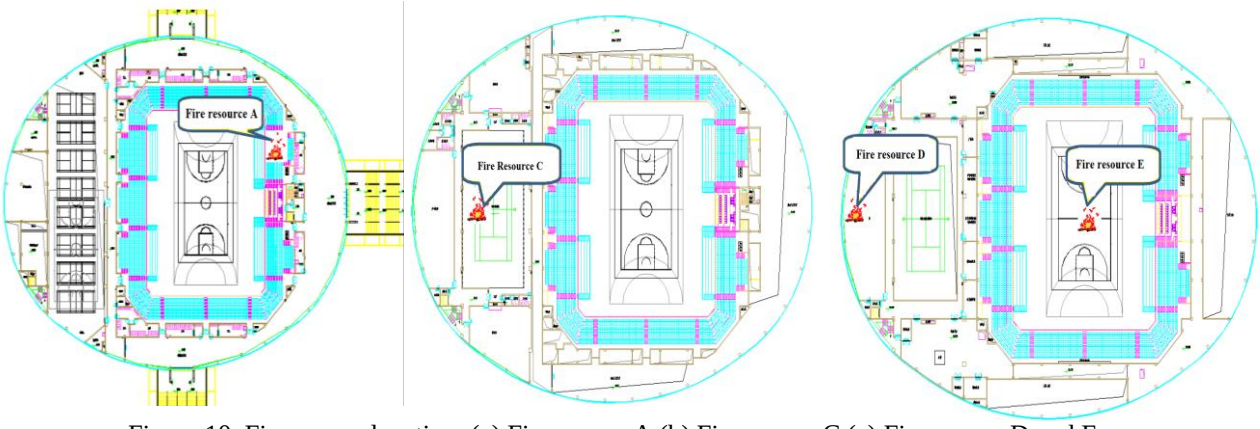

Figure 10. Fire source location: (a) Fire source A (b) Fire source C (c) Fire source D and E

2.3.2. Calculation results and analysis

Fire scenario A :The fire source is located in the stadium auditorium, and the minimum height from the fire source to the roof is 15.1m. The fire growth coefficient is 0.0244kW/s^2. Both the automatic fire extinguishing system and the smoke exhaust system have failed, and the maximum heat release rate of the fire is 2.2 MW. It can be seen from Figure 11 and Figure 12 that after a fire occurs, the fire smoke rises to the ceiling in the form of an axisymmetric smoke plume, which will gather, spread, and descend under the ceiling. Within 30 minutes of the simulation time, the maximum temperature of flue gas at the metal roof structure above the fire source in the fire area is about 68 ℃.

(a) (b) (c)

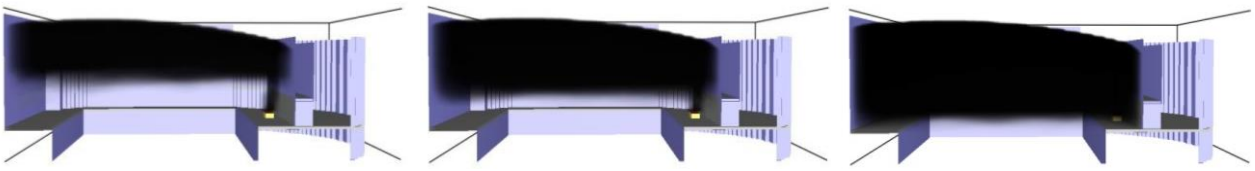

Figure 11. Smoke spread development diagram of fire scenario A:(a) t=600s (b) t=900s (c) t=1800s

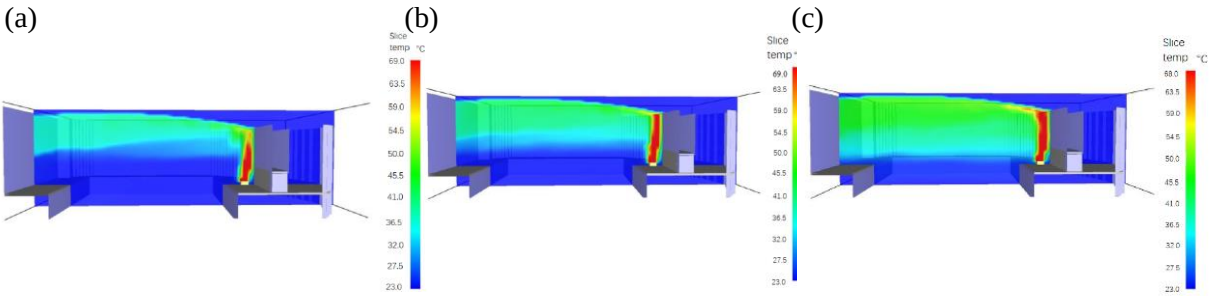

Figure 12.Fire development process and temperature distribution of fire scenario A:(a) t=600s (b) t=900s (c) t=1800s

Fire scenario C :The fire source is located in the gymnasium tennis training hall, and the minimum height from the fire source to the roof is 13.0m. The fire growth coefficient is 0.04689kW/s^2. Both the automatic fire extinguishing system and the smoke exhaust system have failed, and the maximum heat release rate of the fire is 3.5 MW. The simulation analysis results show within 30 minutes of the simulation time, the maximum temperature of flue gas at the metal roof structure above the fire source in the fire area is about 108 ℃.

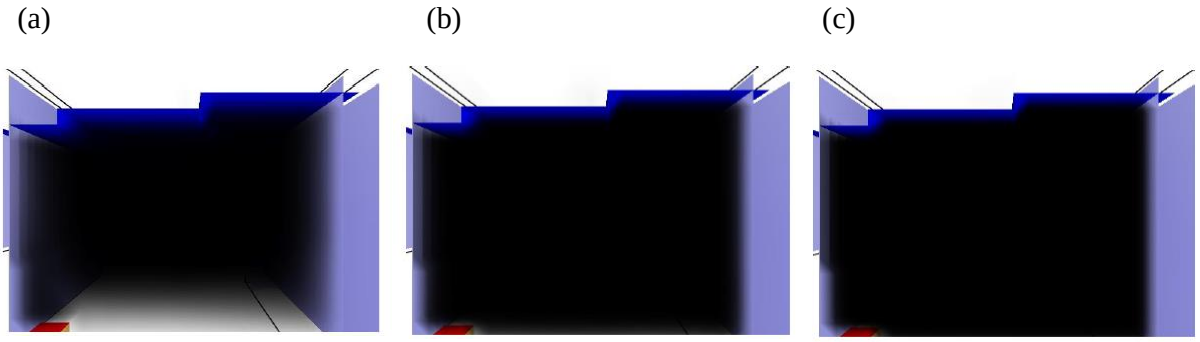

Figure 13. Smoke spread development diagram of fire scenario C:(a) t=400s (b) t=900s (c) t=1800

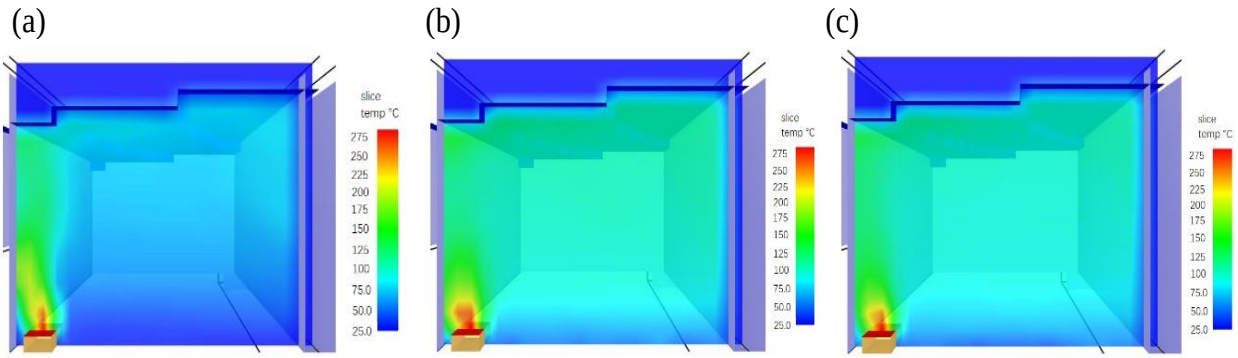

Figure 14.Temperature distribution of fire scenario C:(a) t=400s (b) t=900s (c) t=1800s

Fire scenario D :The fire source is located in the gym on the third floor of the gymnasium, and the minimum height from the fire source to the roof is 5.6m. The fire growth coefficient is 0.04689kW/s^2. Both the automatic fire extinguishing system and the smoke exhaust system have failed, and the maximum heat release rate of the fire is 3.5 MW. The simulation analysis results show within 30 minutes of the simulation time, the maximum temperature of flue gas at the metal roof structure above the fire source in the fire area is about 260 ℃.

(a) (b) (c)

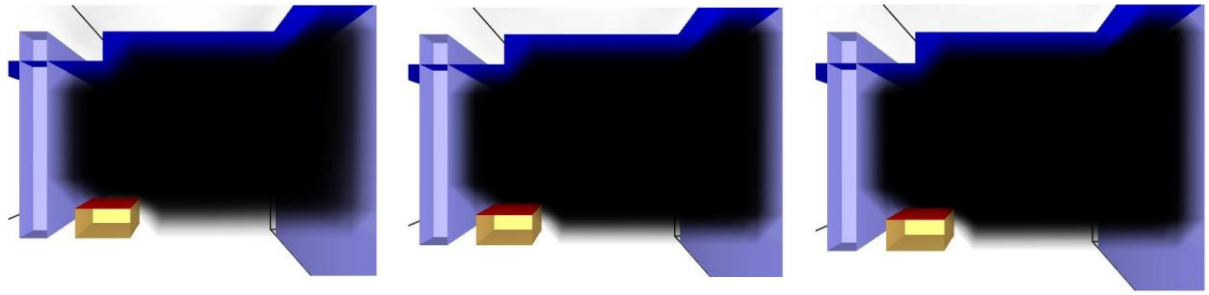

Figure 15. Smoke spread development diagram of fire scenario D:(a) t=400s (b) t=900s (c) t=1800

(a) (b) (c)

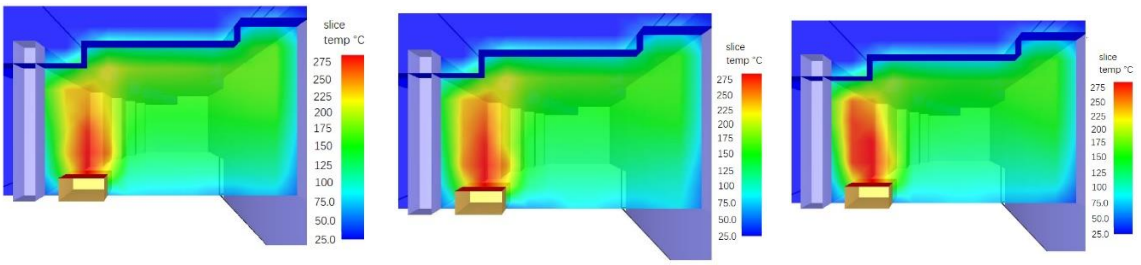

Figure 16.Temperature distribution of fire scenario D:(a) t=400s (b) t=900s (c) t=1800s

Fire scenario E : The fire source is located in the center of the competition venue on the first floor of the stadium, and the minimum height from the fire source to the roof is 25.5m. The fire growth coefficient is 0.04689kW/s^2. Both the automatic fire extinguishing system and the smoke exhaust system have failed, and the maximum heat release rate of the fire is 8.0 MW. The simulation analysis results show within 30 minutes of the simulation time, the maximum temperature of flue gas at the metal roof structure above the fire source in the fire area is about 83 ℃.

(a) (b) (c)

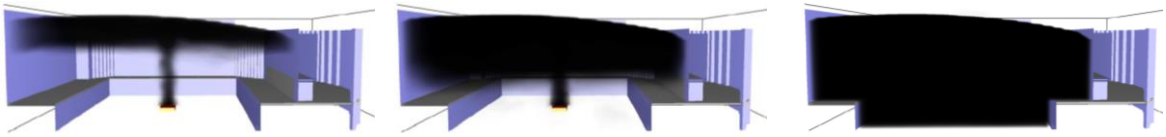

Figure 17. Smoke spread development diagram of fire scenario E:(a) t=300s (b) t=600s (c) t=1800s

(a) (b) (c)

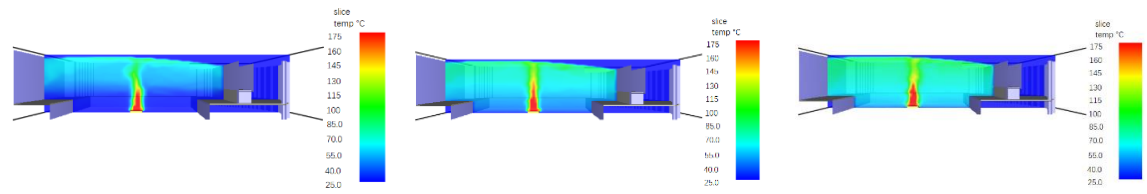

Figure 18.Temperature distribution of fire scenario D:(a) t=400s (b) t=900s (c) t=1800s

Only in the case of fire scenario D, that is, when fire occurs in the gym on the third floor of the gymnasium, the maximum temperature of the smoke layer near the roof exceeds 150 ℃, and the remaining areas are less than 150 ℃. Therefore, the fire protection area of the aluminum alloy roof structure can be determined.

3. Conclusion

The results show that FDS technology can accurately predict the non-uniform distribution of smoke temperature field in large space buildings. At present, China has made significant progress in research on performance-based fire protection design and evaluation, but basic scientific research on fire is still relatively weak and engineering practices are few. There are still many technical difficulties and application skills to be further studied. The fire resistance design cases of aluminum alloy large span structures provided in this paper will enrich the fire resistance theory and provide useful references for practical engineering applications such as fire protection design of complex structures, fire rescue, and fire risk assessment.

Abstract

This paper presents a modification on the height adjustment method (HAM) proposed by Cui and Yan for the shape optimization hyperellipsoid shells. In the modified HAM, all the joints of a shell of concern are always maintained to be located in hyperellipsoid surface during the optimization process. The sensitivity of total strain energy with respect to joint height originally provided by HAM is converted into that with respect to the control parameters of hyperellipsoid shells. The implementation of the modified HAM invovles the construction of hyperellipsoid surface, finite element (FE) analysis and the optimal solution. The sensitivity and FE analysis parts, and its efficiency of the modified HAM is demonstrated by a case study. In addition, the computerized implementation of the shape optimizaiton using the modified HAM with D-SAP is proved to be sucessful.

Keywords: hyperellipsoid shell, shape optimization, height adjustment method, sensitivity, strain energy

1. Introduction

Compared with other common types of shells, hyperellipsoid shells possess a larger number of variations in geometrical configuration by changing its control parameters, being potentially capable of satisfy the needs from various designers. In view of the close relation of shells between structural performance and geometrical configuration, the shape optimization of hyperellipsoid shells needs to be carried out from the physical aspect to satisfy the requirement on structural performance, with full utilization of material.

In nowadays, numerical approaches have been extensively explored to perform shape optimization of curved long-span shells due to their desirable adaptability and robustness. On the basis of finite element method, Espath et al. [1] used the non uniform rational B spline (NURBS) description and automatic differentiation in the shape optimization of shells. Hassani et al. [2] introduced NURBS curve in the shape optimization of general curved surfaces with the solid isotropic microstructure with penalization (SIMP) method. The shape optimization process is to maximize structural efficiency or the degree of stress uniformity [3], as an optimization objective, by finding the relationship between geometrical configuration and internal force distribution of long-span shells, with some design limits (span, the minimum and maximum height, etc.), boundary conditions (support locations) and primary load cases of concern. However, in some cases, it is not easy to achieve expected structural efficiency by changing geometrical configuration of shells only via the adjustment of parameters involved. To overcome this issue, Cui and Yan [4] proposed the free form-based height adjustment method (HAM) to determine the curved surfaces of shells directly without any constraints from shape parameters. In HAM, the structural efficiency of a shell of concern is reflected by the total strain energy of its all joints which can be adjusted by their heights directly. From the physical aspect, the maximum efficiency is believed to be reached when the total strain energy is minimized. The solution flexibility and shape adaptability of HAM makes it more promising for the shape optimization of long-span shells structures.

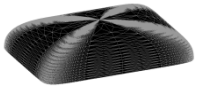
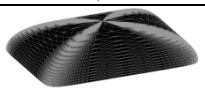
As for free-form shells, discrete structural components consist of their surfaces [5]. In HAM, the spatial correlation mechanism among joints is neglected. However, in the case of the shape optimization of hyperellipsoid shells, HAM is not acceptable for as the variation in stiffness of adjacent joints caused by height change of a joint in these shells is not neglibible. As mentioned by Barr [6], some constraints from other aspects need to be concerned when hyperellipsoid shells are converted into a mathematical model for shape optimization. The main purpose of this paper is to modify HAM to keep all the joints always located in the surface described by a hyperellipsoid equation in the process of shape optimization. In the modified HAM presented herein, the sensitivity of total strain energy with respect to joint height originally proposed by Cui and Yan [4] is converted into that with respect to the control parameters of hyperellipsoid shells. The modified HAM is successfully integrated into an finite element (FE) analytical platform, i.e. D-SAP [7], for both the sensitivity and FE analysis parts, and its efficiency is demonstrated by a subsequent case study.

2. Problem formulation





2.1. Design variables

The surface of hyperellipsoid shells can be mathematically expressed by the following [8]:

$$\left(\left| \frac{x}{r_x} \right|^{\frac{2}{e}} + \left| \frac{y}{r_y} \right|^{\frac{2}{e}} \right)^{\frac{e}{n}} + \left| \frac{z}{r_z} \right|^{\frac{2}{n}} = 1 \tag{1}$$

where r_x, r_y and r_z are the polar radii in the *x*-, *y*- and *z*-axis, respectively; *n* and *e* are the two parameters, controlling the squareness of a concerned shell in the *z*-axis and *x*-*y* plane, respectively.

Table 1. Hyperellipsoids with different control parameters of *n* and *e*

 *n*=0.2, *e*=0.2	 *n*=0.8, *e*=0.2	 *n*=1.0, *e*=0.2	 *n*=2.0, *e*=0.2	 *n*=3.0, *e*=0.2
 *n*=0.2, *e*=0.8	 *n*=0.8, *e*=0.8	 *n*=1.0, *e*=0.8	 *n*=2.0, *e*=0.8	 *n*=3.0, *e*=0.8
 *n*=0.2, *e*=1.0	 *n*=0.8, *e*=1.0	 *n*=1.0, *e*=1.0	 *n*=2.0, *e*=1.0	 *n*=3.0, *e*=1.0

Different combinations of the parameters of *n* and *e*, can yield a variety of geometrical shapes, as shown in Table 1. Table 1 indicates that Eq. (1) can cover nearly all regular polyhedrons and can realize smooth transition of shells between different patterns. It can be also seen that the parameter, *n*, controls mainly the roundness of hyperellipsoid shells while the parameter, *e*, affects the plumpness primarily. During the process of shape optimization using modified HAM (to be discussed later) or HAM, for the sake of simplicity, the *x*- and *y*-coordinates of any joint remain fixed while its height, *z*, is under adjustment. In design practice, the polar radii, r_x, r_y and r_z which are mostly dominated by function requirement are relatively fixed and they are assumed to be constant in the shape optimization process. Thus, only the parameters of *n* and *e* are the design variables in the optimization.

2.2. Optimization objectives

The structural efficiency of a shell of concern can be described by its stiffness and the amount of material used. As strain energy can well reflect both the two aspects via the relationship between stress level and material amount, it is employed as an indicator in the shape optimization problem. Smaller strain energy indicates larger ability to resist external loads and larger deformability. From the physical standpoint, a shell which has the minimum strain energy is believed to be most "shape resisting" efficient [4]. According to the discussion above, the total strain energy of a hyperellipsoid shell of concern $C(\mathbf{Z})$ can be expressed as the function of the heights of all joints invovled, i.e.

$$C(\mathbf{Z}) \rightarrow \text{minimum} \tag{2}$$

where $\mathbf{Z}$ is the vector of heights of all joints.

2.3. Constraints

According to Chinese technical specification for spatial grid structure [9], the deflection of a single-story lattice shell under gravity load should be controlled within $L/400$ (L is span). In the shape optimization of hyperellipsoid shells, this limit could be also used for control stiffness demand where l is taken as the shorter span. Thus, the constraint of the optimization problem is expressed as

$$\begin{cases} \mathbf{S} \subset \mathbf{\Omega}_0 \\ \delta_{\max} \le \delta_0 \end{cases} \tag{3}$$

where $\mathbf{S}$ is the function of joint heights with respect to the parameters of a hyperellipsoid shell of concern; $\mathbf{\Omega}_0$ is allowable design space; $\delta_{\max}$ is the maximum deflection; δ_0 is the code-specified deflection limit, i.e. $L/400$.

3. Optimization algorithm and implementation

3.1. Structural sensitivity matrix

The boundary well-adapted triangular shell elements are used in the shape optimization. For analytical simplicity, the rotational degrees of freedom (DOFs) of the elements are assumed to be not affected by the rotation caused by the variation of heights in adjacent elements [10].

The construction of structural sensitivity matrix depends on that of structural stiffness matrix. According to Tabarrok and Qin [11], the stiffness matrix of the r-th triangular shell element $\mathbf{K}^{sr}$ is expressed as

$$\mathbf{K}^{sr} = \begin{bmatrix} \mathbf{K}^{mr} & 0 & 0 \\ 0 & \mathbf{K}^{br} & 0 \\ 0 & 0 & 0 \end{bmatrix} \tag{4}$$

where $\mathbf{K}^{mr}$ and $\mathbf{K}^{br}$ are the membrane matrix and plate matrix of the r-th triangular shell element, respectively, determined by

$$\mathbf{K}^{mr} = \iint (\mathbf{B}^{mr})^{\mathrm{T}} \mathbf{D}^{mr} \mathbf{B}^{mr} t \mathrm{d}x\mathrm{d}y \tag{5a}$$

$$\mathbf{K}^{br} = \iint (\mathbf{B}^{br})^{\mathrm{T}} \mathbf{D}^{br} \mathbf{B}^{br} t \mathrm{d}x\mathrm{d}y \tag{5b}$$

where $\mathbf{B}^{mr}$ and $\mathbf{B}^{mr}$ are the strain matrices of the membrane part and plate part of the r-th triangular shell element, respectively; $\mathbf{D}^{mr}$ and $\mathbf{D}^{mr}$ are the elasticity matrices of the membrane part and plate part of the r-th triangular shell element, respectively.

The structural stiffness matrix $\mathbf{K}^s$ can be constructed by the summation of all element matrices $\mathbf{K}^{sr}$ over r_{max} with the coordinate transformation. By structural stiffness matrix $\mathbf{K}^s$, the structural sensitivity matrix with respect to the height of the i-th joint $\mathbf{dK}^s{}_i$ can be generated by the following:

$$\mathbf{dK}^s{}_i = \frac{\partial \mathbf{K}^s}{\partial z_i} = \begin{array}{c} \\ 1 \\ 2 \\ \vdots \\ i \\ \vdots \\ i_{\max} \end{array} \begin{array}{c} \begin{array}{cccccc} 1 & 2 & \cdots & i & \cdots & i_{\max} \end{array} \\ \begin{bmatrix} 0 & 0 & \cdots & \mathbf{dK}^s{}_{1i} & \cdots & 0 \\ 0 & 0 & \cdots & \mathbf{dK}^s{}_{2i} & \cdots & 0 \\ \vdots & \vdots & & \vdots & & \vdots \\ \mathbf{dK}^s{}_{i1} & \mathbf{dK}^s{}_{i2} & \cdots & \mathbf{dK}^s{}_{ii} & \cdots & \mathbf{dK}^s{}_{ii_{\max}} \\ \vdots & \vdots & & \vdots & & \vdots \\ 0 & 0 & \cdots & \mathbf{dK}^s{}_{i_{\max}i} & \cdots & 0 \end{bmatrix} \end{array} \tag{6}$$

where i_{max} is the number of joints.

Similary, the structural sensitivity matrix $\mathbf{dK}^s$ is also obtained by the summation of all element matrices $\mathbf{dK}^{sr}$ over r_{max} with the coordinate transformation, determined by

$$\mathbf{dK}^{sr} = \mathbf{dK}^{sr}{}_1 + \mathbf{dK}^{sr}{}_2 + \mathbf{dK}^{sr}{}_3 \tag{7a}$$

$$\mathbf{dK}^{sr}{}_l = \frac{\partial \mathbf{K}^{sr}}{\partial z_l^r} \qquad (l=1, 2, 3) \tag{7b}$$

where $z^r{}_l$ is the height of the r-th element at the l-node (l=1, 2, 3).

3.2. Height adjustment method

As proposed by Cui and Yan [4], HAM is used to optimize the shape of a shell via the adjustment of the heights of its joints in order to minimize their total strain energy. The strain energy of a shell is determined by solving the following static equilibrium equations under gravity loads:

$$\mathbf{K}^s\mathbf{U}=\mathbf{P} \tag{8}$$

where $\mathbf{U}$ is the displacement vector of a shell of concern; $\mathbf{P}$ is equivalent load vector. It is noteworthy that, in the shape optimization using HAM, the dead loads applied on joints may be variable as a result of changing joint heights (or element volume). As service loads are dependent only on projected area, they are constant during entire optimization process.

Differentiating equation (8) for both sides with respect to the height of the i-th joint z_i can yield

$$\frac{\partial \mathbf{K}^s}{\partial z_i}\mathbf{U} + \mathbf{K}^s\frac{\partial \mathbf{U}}{\partial z_i} = \frac{\partial \mathbf{P}}{\partial z_i} \tag{9}$$

If the variation in load vector $\mathbf{P}$ during optimization can be ignored for analytical convenience, equation (9) can be simplified as the following:

$$\frac{\partial \mathbf{K}^s}{\partial z_i}\mathbf{U} + \mathbf{K}^s\frac{\partial \mathbf{U}}{\partial z_i} = 0 \rightarrow \frac{\partial \mathbf{U}}{\partial z_i} = -(\mathbf{K}^s)^{-1}\frac{\partial \mathbf{K}^s}{\partial z_i}\mathbf{U} \tag{10}$$

The total strain energy, C, is determined by

$$C=\frac{1}{2}\mathbf{PU} \tag{11}$$

The sensitivity of C with respect to the i-th joint height z_i, i.e. α_i, can be determined further as follows without the consideration of the variation in load vector during optimization,

$$\alpha_i = \frac{\partial C}{\partial z_i} = \frac{1}{2}\frac{\partial \mathbf{P}^{\mathrm{T}}}{\partial z_i}\mathbf{U} + \frac{1}{2}\mathbf{P}^{\mathrm{T}}\frac{\partial \mathbf{U}}{\partial z_i} = \frac{1}{2}(\mathbf{K}^{\mathrm{s}}\mathbf{U})^{\mathrm{T}}\frac{\partial \mathbf{U}}{\partial z_i} = \frac{1}{2}\mathbf{U}^{\mathrm{T}}(\mathbf{K}^{\mathrm{s}})^{\mathrm{T}}\frac{\partial \mathbf{U}}{\partial z_i} \tag{12}$$

Substituting the partial derivative $\partial\mathbf{U}/\partial z_i$ in equation (10) into equation (12) leads to the following with the use of symmetry of stiffness matrix:

$$\alpha_i = \frac{\partial C}{\partial z_i} = -\frac{1}{2}\mathbf{U}^{\mathrm{T}}(\mathbf{K}^{\mathrm{s}})^{\mathrm{T}}(\mathbf{K}^{\mathrm{s}})^{-1}\frac{\partial \mathbf{K}^{\mathrm{s}}}{\partial z_i}\mathbf{U} = -\frac{1}{2}\mathbf{U}^{\mathrm{T}}\mathbf{K}^{\mathrm{s}}(\mathbf{K}^{\mathrm{s}})^{-1}\frac{\partial \mathbf{K}^{\mathrm{s}}}{\partial z_i}\mathbf{U} = -\frac{1}{2}\mathbf{U}^{\mathrm{T}}\frac{\partial \mathbf{K}^{\mathrm{s}}}{\partial z_i}\mathbf{U} \tag{13}$$

In HAM, the adjustment of the height at the ith-joint Δz_i is calculated by

$$\Delta z_i = -\frac{\partial C}{\partial z_i}\Delta = -\alpha_i\Delta \tag{14}$$

where Δ is an empirical positive parameter. It is suggested to be $1/5\alpha^0{}_{\max}$ by Cui and Yan [4] where $\alpha^0{}_{\max}$ is the maximum sensitivity at the first iteration step of all joints.

With the adjustment of joint heights of equation (16), the total structural strain energy is changed as

$$C(\mathbf{Z}+\Delta\mathbf{Z}) = C(\mathbf{Z}) - \sum_{i=1}^{i_{\max}}\alpha_i^2\Delta \tag{15}$$

With the adjustment above, the height of the ith-joint at the (k+1) iteration step, i.e. z_i^{k+1},

$$z_i^{k+1} = z_i^k - \alpha_i^k\Delta \tag{16}$$

3.3. Modified height adjustment method

To maintain all the joints during the shape optimization process using HAM to be always located on the surface of a hyperellipsoid described by equation 1. With this combination, HAM needs to be modified to reflect the sensitivities of structural strain energy C to the two parameters n and e, i.e. α_{ni} and α_{ei}, by the following two partial derivatives:

$$\alpha_{\mathrm{n}i} = \frac{\partial C}{\partial n_i} = \frac{\partial C}{\partial z_i}\frac{\partial z_i}{\partial n_i} = -\frac{1}{2}\mathbf{U}^{\mathrm{T}}\frac{\partial \mathbf{K}^{\mathrm{s}}}{\partial z_i}\mathbf{U}\frac{\partial z_i}{\partial n_i} \tag{17a}$$

$$\alpha_{\mathrm{e}i} = \frac{\partial C}{\partial e_i} = \frac{\partial C}{\partial z_i}\frac{\partial z_i}{\partial e_i} = -\frac{1}{2}\mathbf{U}^{\mathrm{T}}\frac{\partial \mathbf{K}^{\mathrm{s}}}{\partial z_i}\mathbf{U}\frac{\partial z_i}{\partial e_i} \tag{17b}$$

where

$$\frac{\partial z_i}{\partial n_i} = \frac{-e_i\cdot r_{\mathrm{z}}\cdot\left[\left(\frac{x_i}{r_{\mathrm{x}}}\right)^{2/e_i}+\left(\frac{y_i}{r_{\mathrm{y}}}\right)^{2/e_i}\right]^{e_i/n_i}\cdot\ln\left[\left(\frac{x_i}{r_{\mathrm{x}}}\right)^{2/e_i}+\left(\frac{y_i}{r_{\mathrm{y}}}\right)^{2/e_i}\right]}{2\cdot\left(\frac{z_i}{r_{\mathrm{z}}}\right)^{2/n_i}\cdot\ln\left(\frac{z_i}{r_{\mathrm{z}}}\right)} \tag{18a}$$

$$\frac{\partial z_i}{\partial e_i} = \frac{n_i r_{\mathrm{z}}^{2/n_i}\left[\left(\frac{x_i}{r_{\mathrm{x}}}\right)^{2/e_i}+\left(\frac{y_i}{r_{\mathrm{y}}}\right)^{2/e_i}\right]^{e_i/n_i}\left[\left(\frac{x_i}{r_{\mathrm{x}}}\right)^{2/e_i}\ln\left(\frac{x_i}{r_{\mathrm{x}}}\right)+\left(\frac{y_i}{r_{\mathrm{y}}}\right)^{2/e_i}\ln\left(\frac{y_i}{r_{\mathrm{y}}}\right)\right]\ln\left[\left(\frac{x_i}{r_{\mathrm{x}}}\right)^{2/e_i}+\left(\frac{y_i}{r_{\mathrm{y}}}\right)^{2/e_i}\right]}{z_i^{1/n-1}e_i^{\,2}} \tag{18b}$$

Where x_i and y_i are the x- and y-axis coordinates of the ith-joint, respectively.

With the replacement of α_i in equation (14) with α_{ni} and α_{ei} respectively, the adjustment of the parameters of n and e can be determined similarly by

$$\Delta n_i = -\frac{\partial C}{\partial z_i}\frac{\partial z_i}{\partial n_i}\Delta = -\alpha_{ni}\Delta_n \tag{19a}$$

$$\Delta e_i = -\frac{\partial C}{\partial z_i}\frac{\partial z_i}{\partial e_i}\Delta = -\alpha_{ei}\Delta_e \tag{19b}$$

where the positive parameters of Δ_n and Δ_e can be evaluated as $1/5\alpha_n{}^0{}_{max}$ and $1/5\alpha_e{}^0{}_{max}$, respectively, which $\alpha_n{}^0{}_{max}$ and $\alpha_e{}^0{}_{max}$ are the corresponding maximum sensitivities at the first iteration step of all joints.

After the adjustment at the (k+1) iteration step, the updated two shape control parameters become

$$e_i^{k+1} = e_i^k - \alpha_{ei}{}^k \Delta e_i \tag{20a}$$

$$n_i^{k+1} = n_i^k - \alpha_{ni}{}^k \Delta n_i \tag{20b}$$

The corresponding vectors of $\Delta\mathbf{e}$, $\Delta\mathbf{n}$, $\mathbf{e}$, $\mathbf{n}$, $\boldsymbol{\alpha}_e$ and $\boldsymbol{\alpha}_n$ of all joints can be described by

$$\Delta\mathbf{e} = \{\Delta e_1, \Delta e_2, \Delta e_3, ..., \Delta e_{i\max}\}^T \tag{21a}$$

$$\Delta\mathbf{n} = \{\Delta n_1, \Delta n_2, \Delta n_3, ..., \Delta n_{i\max}\}^T \tag{21b}$$

$$\mathbf{e} = \{e_1, e_2, e_3, ..., e_{i\max}\}^T \tag{21c}$$

$$\mathbf{n} = \{n_1, n_2, n_3, ..., n_{i\max}\}^T \tag{21d}$$

$$\boldsymbol{\alpha}_e = \{\alpha_{e1}, \alpha_{e2}, \alpha_{e3}, ..., \alpha_{e,i\max}\}^T \tag{21e}$$

$$\boldsymbol{\alpha}_n = \{\alpha_{n1}, \alpha_{n2}, \alpha_{n3}, ..., \alpha_{n,i\max}\}^T \tag{21f}$$

If convergence tolerance is satisfied during the optimization process, the averaged values of $\mathbf{e}$ and $\mathbf{n}$ of all joints at the (k+1) iteration step can be taken as final optimal ones, i.e.

$$e^k = \frac{\sum_{i=1}^{i_{max}} e_i^k}{i_{max}} \tag{22a}$$

$$n^k = \frac{\sum_{i=1}^{i_{max}} n_i^k}{i_{max}} \tag{22b}$$

In modified HAM, the total structural strain energy is updated as follows after the adjustment in each iteration step,

$$C(\mathbf{Z} + \Delta\mathbf{Z}) = C(\mathbf{Z}) - \sum_{i=1}^{i_{max}} \alpha_{ni}^2 \Delta_n - \sum_{i=1}^{i_{max}} \alpha_{ei}^2 \Delta_e \tag{23}$$

It is noteworthy that such update is performed one parameter after another, not simultaneously. And, in most cases, the sensitivity of total strain energy varies with the location of a joint of concern, i.e. not uniform, during the height adjustment process.

3.4. Computerized implementation

The shape optimization of a hyperellipsoid shell using the modified HAM invovles three primary steps, i.e. the construction of surface of hyperellipsoid, structural finite element analysis and optimal solution process. In the first step, it is neccessary to determine the coordinates of some key joints for the modeling

of hyperellipsoid surface and then to generate an optimal gird through the grid independence test in ANAYS®. In the second, the coordinates of all joints of a hyperellipsoid shell are transferred to a finite element analysis program, i.e. D-SAP used herein (as described later), for the determination of structural stiffness $\mathbf{K}^s$ and its sensitivity with respect to each joint height $\mathbf{dK}^s_i=\partial\mathbf{K}^s/\partial z_i$ by equation (6). Then, the sensitivity of total strain energy with respect to each joint height α_i is calculated by equation (13) and further to the parameters of n and e of all joints α_{ni} and α_{ei} by equation (17). In the third step, the modified HAM is performed using MATLAB®. The partial derivatives of joint height with respect to the parameters of n and e $\partial z_i/\partial n_i$ and $\partial z_i/\partial e_i$ is determined using equation (18). With these partial derivatives, equation (19) is applied to calculated the adjustment of the parameters of n and e Δn_i and Δe_i of all joints. The shape parameters n_i^{k+1} and e_i^{k+1} are then updated by equation (20) after the (k+1) iteration step. Such iteration is terminated if the following condition is satisfied with a specified tolerance:

$$\alpha_{\mathrm{n}\max}^{k} \text{ and } \alpha_{\mathrm{e}\max}^{k} \to 0 \tag{24}$$

The determination process of the sensitivity of structural stiffness matrix with respect to each joint height $\mathbf{dK}^s_i=\partial\mathbf{K}^s/\partial z_i$ is implemented into the finite element analytical platform D-SAP (Fu et al. 2015). Fig. 1 illustrates the basic framework of the platform using C++ object-oriented language. The information of earthquake wave, constraints and nodal coordinates are stored in the **Load** module, **Constraint** module and **Node3d** module, respectively. The **Analysis** module is used to generate some vectors and matrices, e.g. effective earthquake force vector, **q**, quasi-static load vector, **b**, stiffness matrix, **K**, quasi-static stiffness matrix, **Ḱ**, displacement vector, **u**. The **FullSystem** module yields unbalanced force vectors and the matrices of stiffness, damping and mass for each analytical time step. The **Solver** module is used to solve the generalized quasi-static equation, $\mathbf{\acute{K}\Delta u=\Delta b}$, to obtain $\Delta\mathbf{u}$ and other related response quantities. The updated response vectors are used to update stiffness matrices and restoring force vectors by the **FullSystem** module. The **Record** module and **Load** module are used to output analytical results and to define load cases for analysis, respectively. $\mathbf{K}_e$ and $\mathbf{K}_{sec}$ are the element stiffness matrix and section stiffness matrix, respectively; $\mathbf{f}_e$ and $\mathbf{f}_{sec}$ are the element restoring force vector and section restoring force vector, respectively; E is the Young's modulus of material.

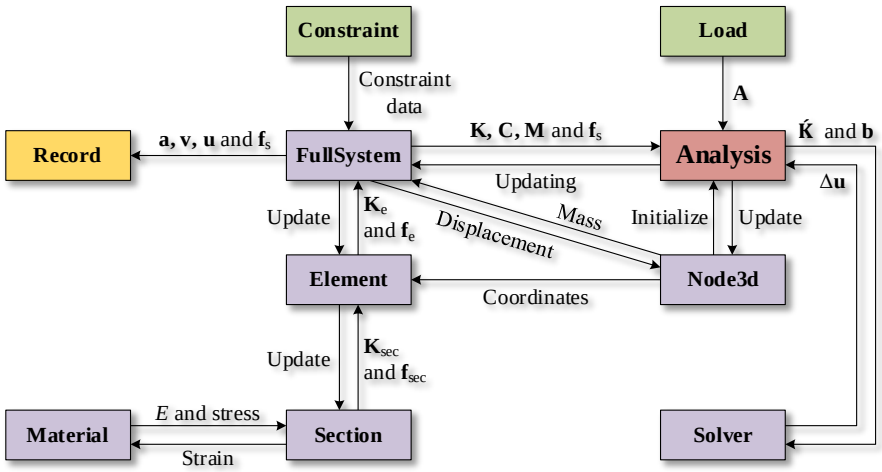


Figure 1. D-SAP analaytical platform [7].

The implemenation involves two parts. The first part is to integrate the triangular shell element into D-SAP and to store the element stiffness matrix and structural stiffness matrix. The second is to generate the sensitivity matrix $\mathbf{dK}^s_i$ with the interaction with the modified HAM program in MATLAB®. As a large number of elements are involved, as discussed in the case study, in the generation of structural

stiffness matrix and sensitivity matrix, narrow-band storage technique is used when they are transferred from D-SAP to MATLAB® for the minimization of storage space.

4. Case study

4.1. Basic information

A case hyperellipsoid steel shell shown in figure. 2(a) has the polar radii of r_x=105.963 m, r_y=71.663 m and r_z=42.335 m which are set as constants in the shape optimization. The parameters of n and e for the shell before the optimization are n=e=0.909. The total surface area of the shell before optimization is 33915.871 m^2. The modulus of elasticity of 206 GPa, Poisson's ratio of 0.30 and material density of 2.55 kg/m^3 are used. For the sake of stiffness determination, the thickness of the shell is assumed to be constant at t=300 mm throughout the optimization process, having the dead load of g=2.355 kN/m^2. The construction and maintenance live load is taken as q=0.7 kN/m^2. The gravity load applied the shell is calculated by G=g+0.5q. The peripheral joints of the shell are pin-connected with the rigid supports which are fixed on the foundation. The deflection limit of L/400 (shorter span herein), i.e. 0.36 m, is used as the constraint in the optimization.

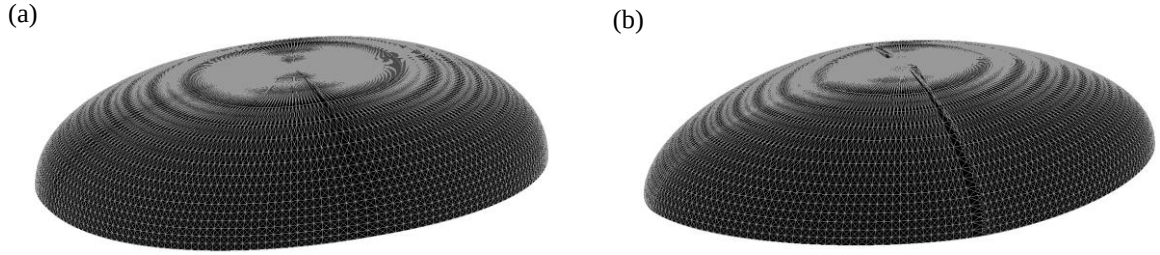

Figure 2. A hyperellipsoid shell: (a) before optimization, (b) after optimization.

4.2. Grid independence test

As the discretization process with finite elements is involved, a grid indepence test needs to be carried out before the shape optimization. Figure 3 shows the variation of the top displacement of the shell with the increase of grid numbers. As the number of elements increases, the top displacement increases but at a slowing rate and converges at 0.0561 m, exhibiting an optimal number around 4×10^4. In the case of the triangular shell elements used herein, the final grid has 40,568 elements.

4.3. Shape optimization

Figure 4 shows the relative variation of total strain energy $\gamma=(C^k-C^{k-1})/C^k$ of the shell in the optimization. As iteration proceeds, γ decreases at a slowing rate and converge at 21.2% in the 78th iteration step, with the parameters of n=1.020 and e=1.140. An increase of 12.2% in n and an increase of 25.4% in e are obtained. Equation (25) shows the mathematical expressions of the shell before and after the shape optimization, i.e.

$$\left(\frac{x}{105.9625}\right)^{2.2}+\left(\frac{y}{71.6625}\right)^{2.2}+\left(\frac{z}{45.2025}\right)^{2.2}=1 \tag{25a}$$

$$\left(\left|\frac{x}{105.9625}\right|^{1.961}+\left|\frac{y}{71.6625}\right|^{1.961}\right)^{0.895}+\left|\frac{z}{45.2025}\right|^{1.754}=1 \tag{26b}$$

Figure 2(b) illustrate the configuration of the shell after the optimization, from which it can be seen that the curvature of the optimized shell becomes smaller than the initial shell. From the aspect of structural design, the optimized shell is structurally more efficient and stable. However, it must be pointed out that,

in the shape optimization concerned herein, the constraint from architectural design is not included.The optimized shell may not be desirable from the functionality standpoing. If more constraints are addressed, the modified HAM needs to be developed further.

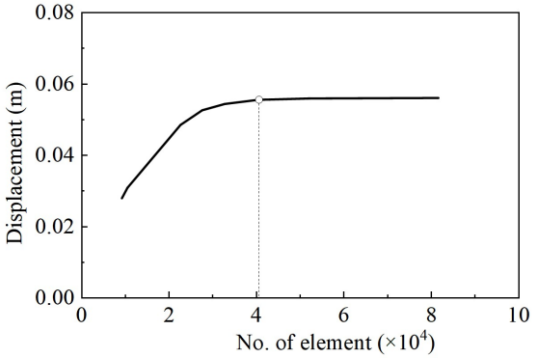

Figure 3. Grid independence test result.

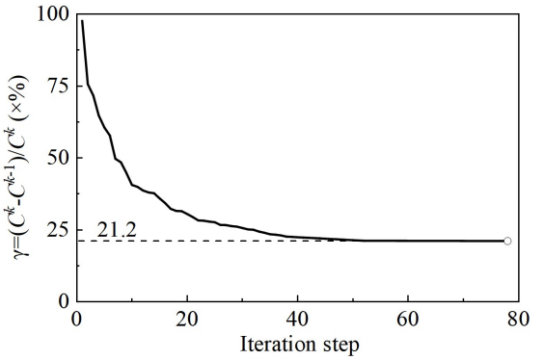

Figure 4. Convergence of total strain energy.

5. Conclusion

In this paper, HAM proposed by Cui and Yan (2006) is modified to perform the shape optimization for hyperellipsoid shells, the following observations can be reached:

(1) The modified HAM can maintain all the joints of a shell of concern during the shape optimization, where the sensitivity of total strain energy to joint height is converted into that to the two control parameters of hyperellipsoid shells. As the mathematicla expression of hyperellipsoid shells can cover nearly all regular polyhedrons and describe the transition of shells between different patterns, the modified HAM developed herein can be applied for more general purposes.

(2) The computerized implementation of the shape optimizaiton using the modified HAM invovlves three steps, i.e. the construction of hyperellipsoid surface in ANAYS®, finite element analysis using D-SAP and the optimal solution with the modified HAM in MATLAB®. Three different platforms interact well with each other. To minimize the storage space in MATLAB®, the narrow-band storage technique is applied for the transfer of structural stiffness matrix and sensitivity matrix from D-SAP.

(3) As indicated by the case study, using the modified HAM can achieve more structural efficiency. A substantial efficiency is achieved by the shape optimization, showing a decrease of 78.8% in total strain energy. The corresponding two control parameters of n and e are increased up to 12.2% and 25.4%, respectively after the optimization. It is noteworhty that a grid independence test needs to be conducted prior to the shape optimization.

(4) The design constraint included in this paper only account for stiffness demand via a code-specified deflection limit of L/400. By this constraint, the structural efficiency of the case shell is increased substantially. It must be acknowledged that the constraint from architectural design also needs to be seriously addressed. The optimized case shell may not be desirable from the functionality aspect. The modified HAM needs to be developed further when more constraints are included.

Abstract

The Slimline floor system is a light prefab floor construction that can be combined with all main supporting structures, allows large spans, functions as a structural disc and delivers very good performance in terms of acoustics and fire. This paper summarizes the state of the art concerning the use of this type of structure and shows an example of modelling on ABAQUS.

Keywords: autarkic, office boat, energy, eco-friendly

1. Introduction

A striking design or specific wishes of clients sometimes require constructive solutions that go beyond the traditionally applied construction techniques alone. As a structural engineer, it is nice to be able to rely on a proven and widely applied structural floor system that makes it possible to meet the most exceptional questions. The Slimline floor system offers a light prefab floor construction that can be combined with all main supporting structures, allows large spans, functions as a structural disc and delivers very good performance in terms of acoustics and fire. A slimline floor makes it possible to realize floor elements with a span up to 16 meters. With this floor it is possible to combine the installations with the structure of the slimline floor. The benefits of this floor are less structural height and reduction of the weight of the floor. It is even possible to change the function of parts of the building in the long term, for example from office function to residential or care function. At the end of the life of the building, the residual value is maximum. The Slimline floor elements are demountable and can be used to realize new buildings. This floor was invented and developed by Arno Pronk and Jos Lichtenberg [1] [2]. The application of this floor is up to now very successful within the Netherlands.

2. Buildings realised with the slimeline floor

The Slimline flooring system has been used in a wide range of buildings in high-rise, non-residential and residential buildings. Rijswijk (ZH) is home to the new office of the largest international organisation in the Netherlands, the European Patent Office. The 27-story office building of 85,000 square meters offers space for 1,950 employees in two main structures: New Main, the main building, and New Hinge, a lower part that includes the company restaurant, an atrium with courtyard and hearing rooms. In New Main, the storey floors, including the technical floor with a greater load, were equipped with the Slimline floor system. Flexibility has been one of the spearheads for this 107 meter high, 156 meter long 24.7 meter wide creation of the renowned architectural firms Ateliers Jean Nouvel (Paris) and Dam & Partners Architects (Amsterdam). All installations of the building are integrated into the Slimline floor and ceiling system with hollow installation space, so that spaces can be flexibly filled in. In addition, the Slimline floor system offered the solution to realize more floors and workplaces within the maximum building height and within such a slim design. The new EPO building combines contemporary architecture with a modern, state-of-the-art infrastructure. According to architect Diederik Dam, it is the tallest and thinnest construction in steel and glass in Europe. The main building is constructed of more than 10,000 tons of steel, making the building the largest steel construction in this quality in the Netherlands. A total of 100,000 m2 of glass was used in the building. The building consortium opted for a steel construction because of its relatively low weight, the modular character that allows construction to be built quickly and relatively quietly and the greater flexibility that the material offers in the layout of rooms. The Slimline floor system also contributes to the slim appearance, the low weight of the construction and the permanent adaptability." This building embodies the drive for innovation that benefits European citizens and the competitiveness of the European economy. This work by Jean Nouvel and Diederik Dam is more than just an impressive landmark in the skyline of The Hague and an economic boost for the region [7]. It is also a sign of our appreciation for the long-standing relationship with the Netherlands," said EPO President Benoît Battistelli. "This extraordinary building provides an environmentally friendly and sustainable workplace for our staff here and it is to the credit of all the people who have worked so hard to bring it about. We are convinced that the new office is also a harbinger of a new era, for our employees in the Netherlands and for the users of the European patent system. It is part of our efforts to modernise the EPO so that we can deliver state-of-the-art services with ever higher quality."A lot of interesting buildings have been realized with slime line floors. Below you will find the three most interesting and price winning projects.

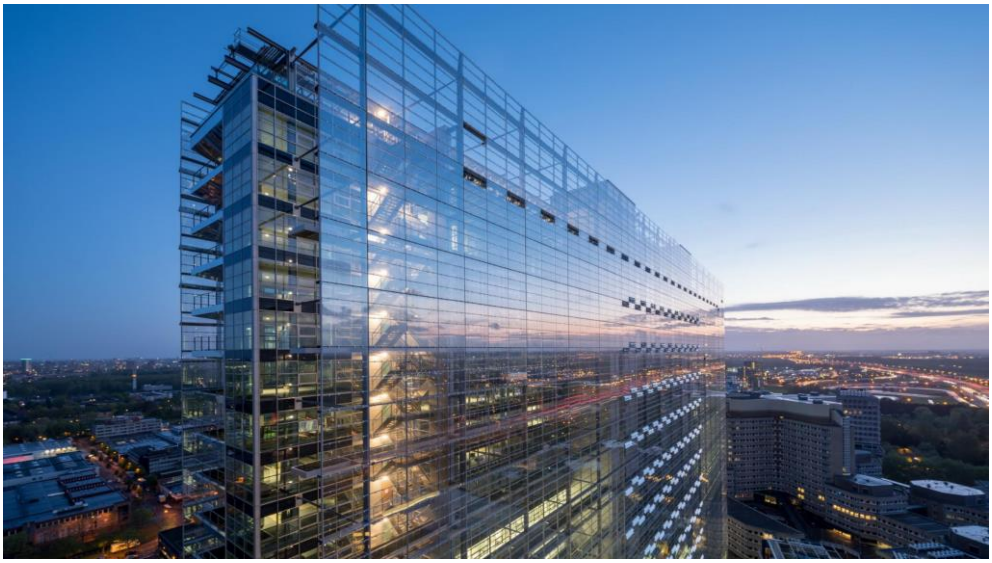

Figure 4. European patent office by Architect Jean Nouvel.

The eye-catcher of the Noord-IJ Oever is the unique Kraanspoor project. Architect Trude Hooykaas designed a 3-storey building with more than 10,000 m² of unique workspace with a beautiful view over the IJ. The aim was to integrate old and new and to maintain the atmosphere of the historic Kraanspoor. The result is a floating, transparent building above the existing structure, so that the former crane track is visible from the inside and there is a maximum view of the surroundings.

Kraanspoor is not only a spectacular, but also a green building. For example, the water from the IJ is used in the summer for cooling and in the winter for heating, ventilation takes place through openings in the floor and there are breeding grounds for wild birds.

Kraanspoor was awarded several prizes, including the National Steel Award 2008, the Glass Award 2008, MIPIM 2008 Green Building Award + Special Jury Award and the Urban Landscape Institute Global Award of Excellence [6].

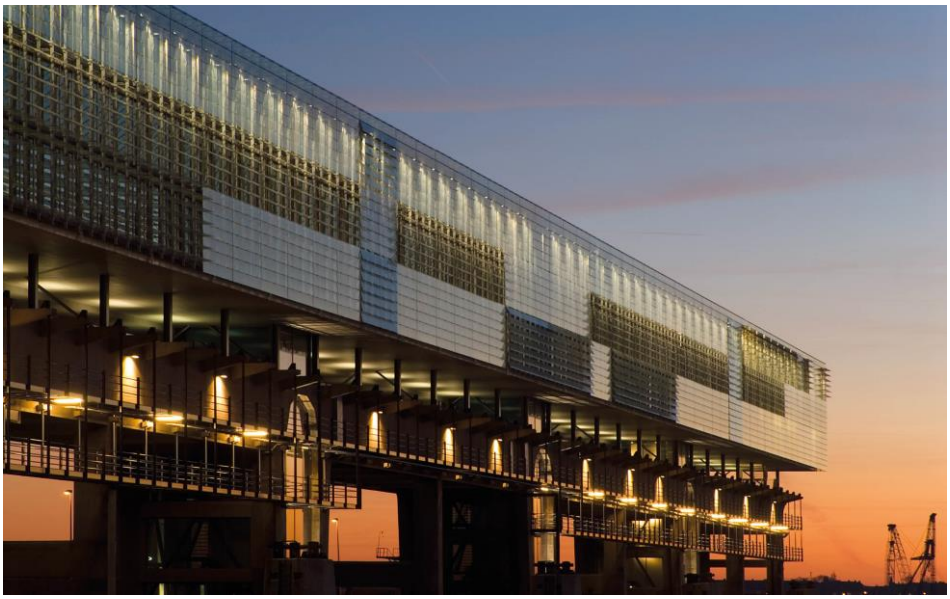

Figure 5. Kraanspoor by OTH Architecten.

The 'residential sculpture' Crystal Court is located at this relatively small location: 36 stacked luxury villas with beautiful wooden facades. In 2010, the project was awarded for the New Construction Award [8].

The houses are stacked in four loosely connected tree structures, in such a way that there is a lot of space in between and the footprint on the ground is kept as small as possible. Despite the compact buildings, many open spaces with views have been created in this way and the complex fits in well with the park-like environment. Due to the high density, 'continuity of the open space' is an important aspect of the design. This creates an interaction between the stacked volumes, the green environment and the open space.

Due to the way of stacking, all are different in typology, design and approach. They all have optimal views, privacy and sunlight. Most have several terraces with a view of the winter garden and the surrounding area.

Due to the high density, 'open space' is an important aspect of the design. This creates an interaction between the stacked volumes, the green environment and the open space.

Due to the way of stacking, all are different in typology, design and approach. They all have optimal views, privacy and sunlight. Most have several terraces with a view of the winter garden and the surrounding area. Both the main entrance and the entrance to the parking garage and the shared facilities

are located in the collective atrium. In the form of a water garden with fish and native plants, the park continues almost seamlessly into the atrium.

3. Construction method

A Slimline floor offers great amount of freedom and great opportunities for large open, freely arranged spaces. Because the installation space is not filled with concrete, the own weight of the total floor package is relatively low, resulting in a weight reduction of 50% compared to traditional systems. In combination with the advantage that installations at Slimline are placed in the floor and therefore not in a suspended ceiling, it is possible to design main supporting structures with lighter foundations.

Building with Slimlinefloors means prefab, dry, fast and a stamp-free construction. In this way, the contractor cold realize the building in a shorter time. This also leads to an integral saving on construction costs. Due to the integration of ceiling, installation space and top floor, Slimline saves between 40 and 50 cm height per floor compared to other systems. This leads to a saving of 15% on the gross floor height. With Slimline, seven floors can therefore be realized at the same building height compared to six with other construction techniques. Slimline also offers excellent properties in terms of acoustics and comfort.

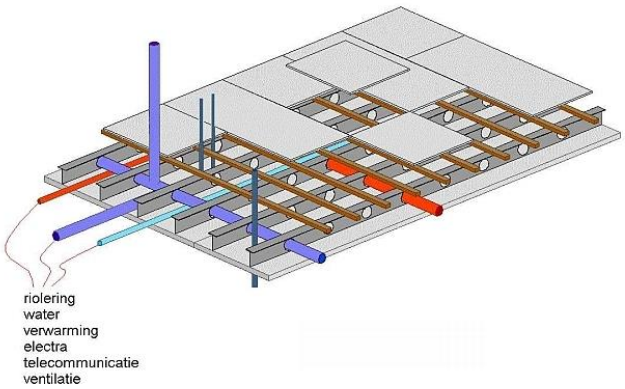

Figure 7. by A. Pronk.

4. Fire safety

The slimline floor has a good fire resistance determined by TNO Brand/Efectis in accordance with NEN6067:1997. With regard to the separating function (WBDBO) of more than 145 minutes for both the criteria of flame density involved in the seal, thermal insulation involved in the temperature and collapse (structural safety), Slimline can be used as a home-separating floor in a residential care or apartment complex. This floor delivers a good performance in terms of fire safety [9].

5. Details

On the steel profiles of the Slimline floor elements, different types of top floors with different possibilities for the accessibility of the installation space can be placed, such as a dovetail cast floor or a computer tile floor. The acoustic decoupling is achieved with a rubber granulate on the beams. Thanks to the two-tier construction with the acoustically decoupled floating screed on 15 mm rubber granulate, sound insulation values of Iluc and Ico > 10dB are achieved in both laboratory tests and practical measurements. Slimline can be used as a home-separating floor in a residential care or apartment complex. The Slimline floor system makes it possible to adjust installations, layouts and even the building function without structural interventions, so that the (rental) yield - and therefore the building value - can continue to be maximized with minimal costs.

Slimline extends the economic life of buildings. Because installations do not collapse and remain permanently accessible in the hollow floor, layouts can easily be determined and changed to measure, different rooms can be easily combined or separated, and the installation technology can easily be maintained or adapted to the latest state of the art and changing user requirements. Slimline makes building faster and easier. Because Slimline uses self-supporting prefab elements, submersible is not necessary. In addition, the installed floor elements are directly walkable, so that the installation of installations and the dismantling can start immediately, without affecting the other work. This makes it possible to slide several construction phases together, resulting in significant savings on construction costs and construction time. In addition, savings are possible on the foundation due to the lower weight and on expensive building components such as facades as a result of the slimmer floor package. In general, this leads to better preparation of the construction process and an increase in the number of building installations. The Slimline floor system enables quick and easy construction with prefabricated floor elements in an outrigger-free and dry process. Building installations are easily and permanently accessible in the hollow floor instead of suspended from the ceiling. The floor elements are interconnected into a constructive disc by welding coupling plates and (in the case of larger spans) tipping strips to be welded into the work. Usually, a (welding) connection is also made with the main supporting structure. Thanks to this stamp-free and completely dry process, up to 1,000 m2 of floor field can be realized per day. With an average total floor package weight of 300-350 kg/m2, it is in many cases possible to carry out the foundation lighter than with traditional floor systems. If desired, it is possible to include prefab climate pipes in the ceiling shell in order to easily realize ceiling cooling or heating. Layouts and facilities can be determined far into the construction process and, with the right facilities, remain adaptable or easy to maintain even after delivery.

6. FEM modeling

Numerical simulation is established using ABAQUS software [3]. The model is a common slimline floor that has the following characteristics. The beams are IPE 300 cellular beams. They are spaced 1.2 m apart and their span is 8.4 m. The steel grade considered is S355. The concrete slab is a 70 mm thick slab with a welded wire mesh made of bars of 16 mm in diameter and spaced 150 mm in both directions. The concrete class is C30. The steel grade of the reinforcement is BS500.

A floor element is composed of 2 beams and a slab element of 2.4m in length. The model considers four floor elements that lay on HEB 700 beams (length = 9.6m) that are supported by four HEB 300 columns (heigh = 3.5 m). In addition to the self-weight of the structural elements, a dead load G of 1.5 kN/m² and a live load Q of 4.5 kN/m² are applied with USL (1.35G+1.5G) and SLS (1.0G+0.3Q) combinations.

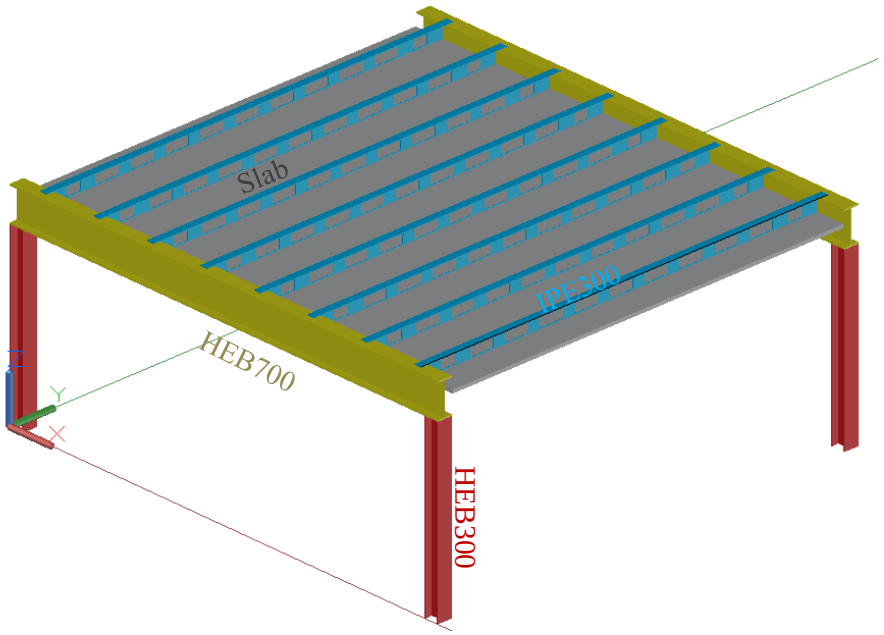

Figure 8. Model of the slimline floor.

The columns, the beams and the slab are modelled in 3D and are meshed with linear brick elements. Steel beams and columns are rigidly connected to each other. The columns are hinged to their supports. The connection between the IPE 300 beams and the concrete slab is not complete. A coefficient of tangential friction of 0.7 is considered between the two. Rebars are 1D elements and are meshed with truss elements. The bars are connected to the slab by the "embedded algorithm". This method allows a group of elements (rebars) to be constrained to the kinetic boundary conditions in "host" elements (slab).

The mechanical properties of steel and concrete are given by Eurocode 2 [4] and 3 [5]. Elastic-perfectly plastic [4] curve is considered for steel. Damage plasticity model [3] is used for concrete. The model considers the degradation of the elastic stiffness induced by plastic straining both in tension and compression.

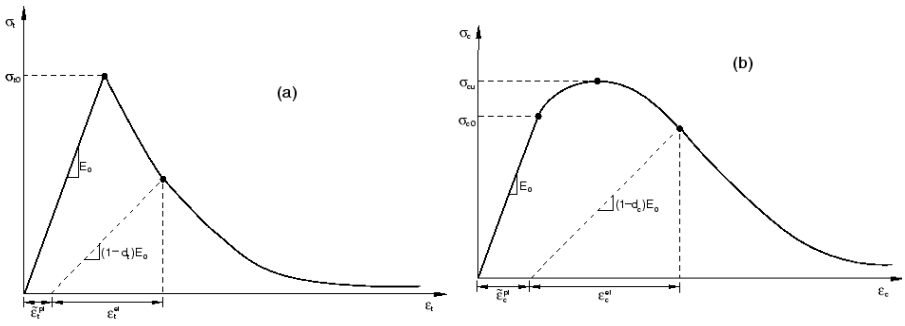

Figure 9. Mechanical model of concrete, tension (a) compression (b) [3].

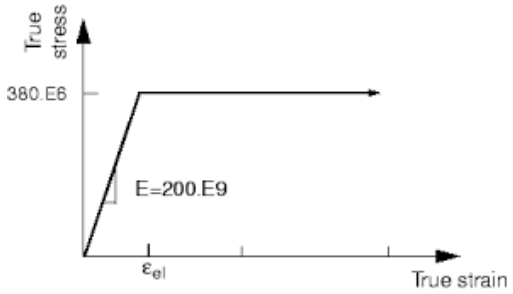

Figure 10. Mechanical model of steel [3].

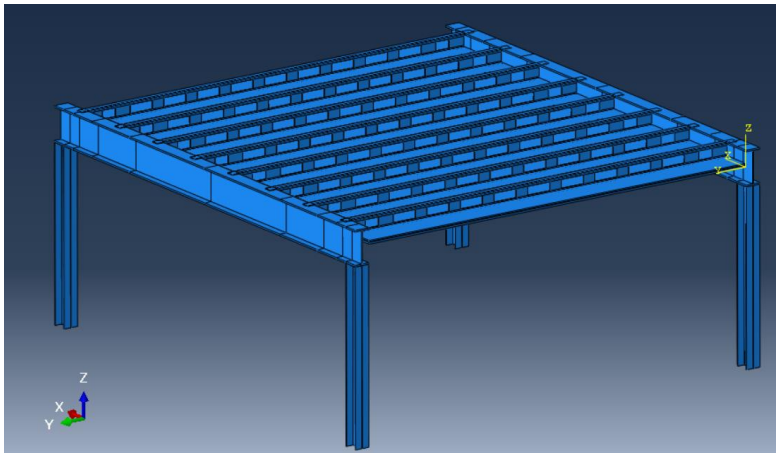

Figure 11. Model of the slimline floor in ABAQUS.

Figure , Fig 13 and Figure 14 show the stresses in the IPE 300 and the slab under the ULS combination. IPE 300 beams are in bending with stresses that do not exceed the strength limits of steel (355 MPa). The material remains in the elastic phase. The slab is subjected to tensile stresses largely taken up by the reinforcement. The stresses in the bars are below the design strength limit of steel (500 MPa / 1.15 = 435 MPa).

Figure 15 shows the vertical displacements when the floor is under the SLS combination. The displacement is limited to 2.26 cm, that is lower to the span of the beam divided by 250.

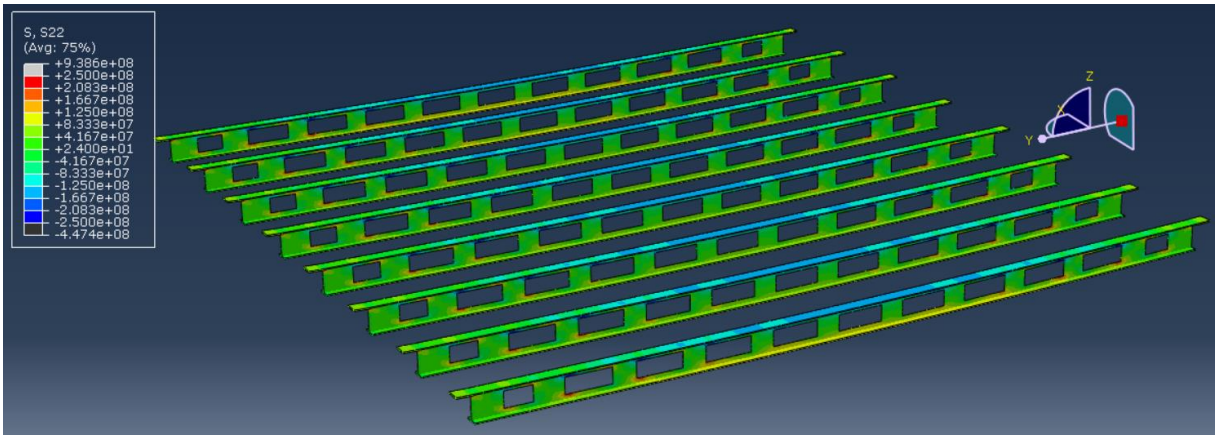

Figure 12. Stresses in y-direction in the beams IPE 300 (ULS combination) in N/m².

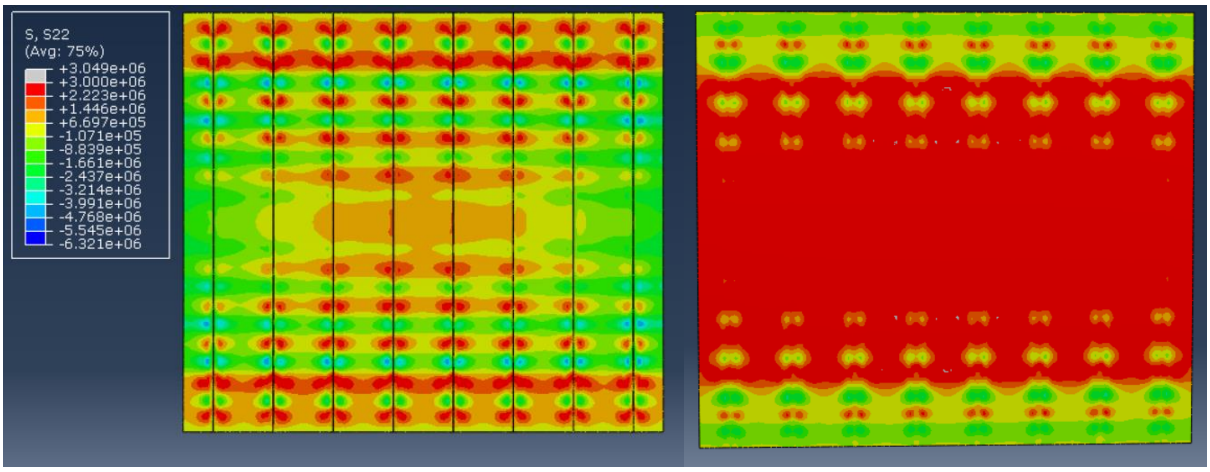

Fig 13. Stresses in y-direction in the slab (top and bottom) (ULS combination) in N/m².

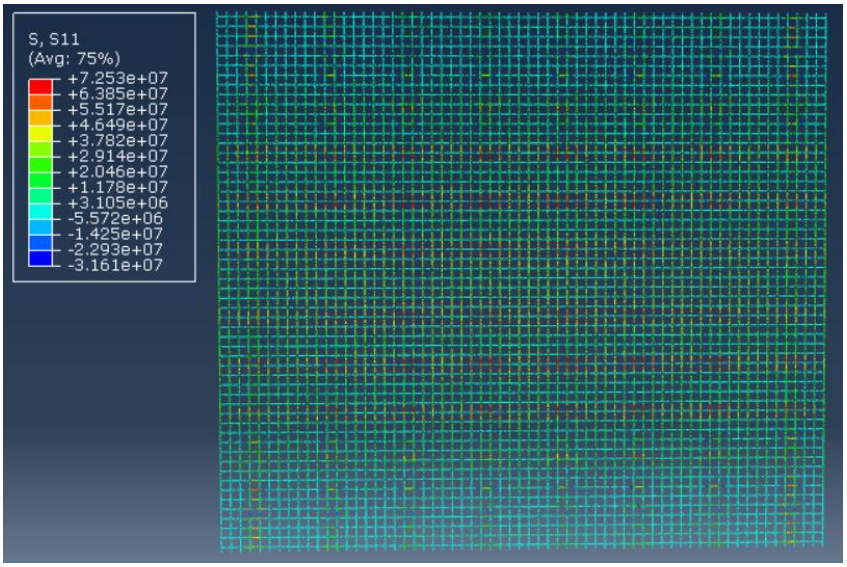

Figure 14. Stresses in the reinforcement (ULS combination) in N/m².

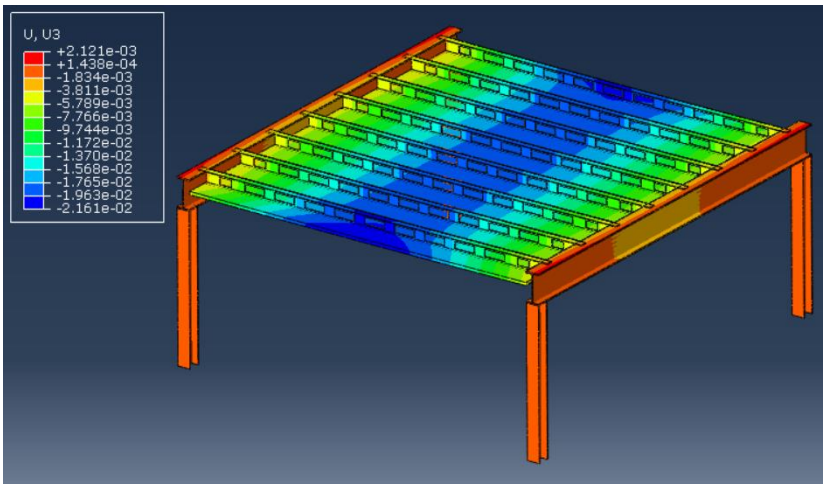

Figure 15. Vertical deflections (SLS combination) in m.

7. Conclusion

Based on this paper this slimline floor is a new innovation that is successful in the Netherlands. The benefits are: large span, better fire resistance, more freedom with installations, integration of the installation within the construction, less height. With this floor you will have more storeys within a building without the slimline floor. Floor modelling is easy and can be done in commercial finite element software's. It would be interesting to promote this type of floor also in other countries.

Abstract

Spherical domes and cylindrical roofs have been used for decades to cover large spaces due to their easy construction. By simply using a rope of a fixed length, the curvature of these structures can be maintained, and the outline can be drawn in 3D space. However, when the rises of these structures were high, large bending moments occurred at their boundaries, causing the domes made of stone or other materials that could not withstand the tension to crack. To prevent this, the plates were modified by thickening them or adding tension rings at the boundaries. This paper examines a method to modify the geometry near the boundary of a spherical shell to produce only beneficial compressive stresses. To simplify the modification of the shape, a shell of revolution was modelled using axisymmetric elements. The change in the normal direction of the upper and lower surfaces near the boundary was expressed as a quadratic function passing through the midpoint of the change value and the change at the boundary. We have also examined what kind of objective function would suit the purpose of this paper, as well as the shell shape and stress intensity distribution. We have also evaluated how much the stress intensity can be reduced by the shell opening angle and the range of change.

Keywords: spherical shell, shape optimization, thickness, stress in latitude and longitude direction, near the boundary, radius of curvature

1. Introduction

Spherical domes and cylindrical roofs have been used to cover large spaces due to their simple construction process, which involves drawing an outline in a 3D space with a rope of a fixed length [1]. However, when the rises of these structures were high, large bending moments occurred at the boundaries of these structures. To address this, some domes have been reconstructed with thicker boundaries or tension rings to strengthen them against any cracks that may occur after construction. Additionally, the shape of these structures has been optimized by hand, taking into account the materials used, such as stone and concrete, which are strong in compression but weak in tension. The optimal shape is one that does not produce tensile stress and has low compressive stress.

By the way, a calculation example revealed that even for a spherical dome, a slight change in its curvature could significantly reduce the bending moment [2]. Since a minor alteration of the shape could lead to a considerable decrease in the degree of stress, we decided to explore the possibility of creating a spherical dome that is easy to build and cost-effective, as fewer types of formworks would need to be prepared if the degree of stress can be dramatically decreased by merely changing the shape towards the boundary of the spherical shell.

Figure 1 shows an example of the boundary of an old shell structure [3]. Through slight modifications near the boundary, this shell has been able to withstand earthquakes and remain in existence. The aim of this study is to find a shape that has a beneficial stress distribution over the entire spherical dome

surface (with no tensile stress and low compressive stress) and to evaluate its degree of benefit by changing the position of the upper and lower surfaces of the spherical dome in a certain area from the boundary.

In this paper, the finite element method and optimization techniques are employed to obtain such geometry. Firstly, an overview of the analytical model is presented, followed by an analysis of the objective function which can be used to attain an advantageous shape. Subsequently, the objective function is utilized to examine the effect of changing the shape of the upper and lower surfaces near the shell boundary to reduce the stress level and its shape.

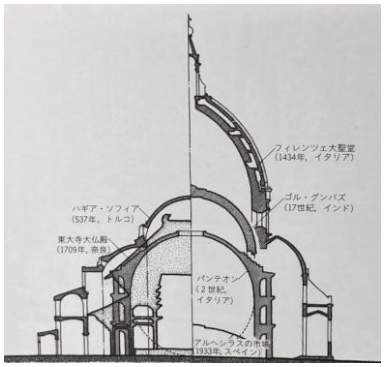

Figure 1. Example of the boundary of an old shell structure [3].

2. Outline of analysis model

The purpose of this study is to investigate how much stress can be reduced by modifying the shape of a spherical dome around its boundary, while keeping most of the dome's shape intact. Figure 2 provides an overview of the numerical analysis model used. To simplify the geometry modification, the rotational spherical shell was modeled with axisymmetric elements.

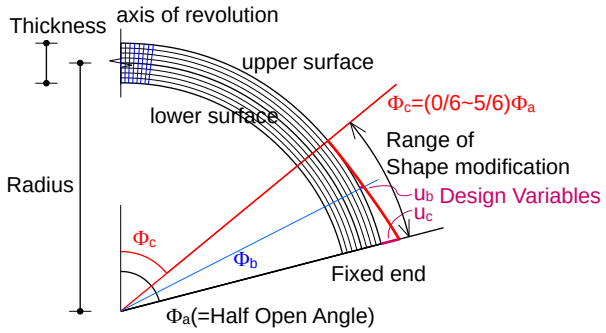

Figure 2. Numerical analysis model

The shape of the modified surface close to the shell boundary, from Φc to Φa in this figure, was expressed as a quadratic function, as shown in Figure 2. This was to avoid having too many design variables which could lead to a local solution. The finite elements were equally divided in the thickness and latitudinal directions to calculate the stress, and the range of shape modification was set to 6 types, from 0/6 to 5/6 of the half-opening angle Φa to the boundary. The quadratic function was obtained from two normal displacements at the Φb (midpoint of Φa and Φc) and Φc points, along with two conditions (normal displacement 0 and slope 0) that ensure a smooth transition to the original shell at Φc.

As a result, there are two design variables when movement is limited to either the upper or lower surface and four when movement is allowed on both. We considered using separate quadratic functions for the upper and lower surfaces to obtain a solution that intersects them, but this was not achieved even without any constraints. This angle, Φc, is referred to as the start angle of shape modification.

3. Examination of objective function

Since a suitable objective function for shape modification was not known, several objective functions were investigated. This chapter then examines the resulting stress distribution. It is noteworthy that all the convergence calculations presented in this chapter were done using the steepest descent method.

3.1. Bending moment minimization

First, we sought to minimize the maximum bending moment. In the prescribed study[1], the appropriate curvature was obtained by bending moment minimization. However, in the analytical model of this study, the boundary became like a pin. In the model with constant plate thickness, we were able to reduce the bending moment value by changing the curvature, thus causing the solution to converge. On the other hand, when we allowed the plate thickness to vary, the objective function became unsuitable. This was because the boundary became thin and pin-like, reducing the bending moment but increasing the stress intensity.

3.2. Minimizing the maximum stress

Next, we minimized the maximum vertical stress intensity in the latitudinal direction. Since the vertical stress varies linearly in the cross-section, we only evaluated the values at the upper and lower surfaces of the shell, which are the edges of the cross-section. From now on, we will refer to the vertical stresses in the latitudinal direction at node *i* on the upper and lower surfaces of the shell as σ_i^{upper} and σ_i^{lower}, respectively, and the maximum and average values as $\sigma_{\text{max}}^{\text{upper}}$, etc., using the subscript max and ave, respectively. The objective function a in this section is as follows.

$$a = \max.(\sigma_{\text{max}}^{\text{upper}}, \sigma_{\text{max}}^{\text{lower}}) \tag{1}$$

The signed value of tensile stress is being minimized as much as possible, with the positive value being reduced to a minimum.

3.2.1. Analysis model and analysis conditions

Table 1 shows an analytical model. Nine models were solved with three different surface patterns (upper surface only, lower surface only, and both surfaces) and three different thickness change start angles Φc, with the shell half-opening angle Φa set at 90°. Equal-distributed loads in the vertical direction were applied, and the amount of movement in one step of the design variable for the steepest descent method was set to *t*/100.

Table 1. Analysis model and conditions

Radius of neutral plane of initial shape (R) [mm]	5000
Initial thickness (t) [mm]	50
Number of divisions in the open angle direction	900
Number of divisions in the direction of plate thickness	10
Boundary condition	Fixed end
External Force	10N/mm² in vertical direction
Surface to be reshaped	moving both surfaces, upper surface only, lower surface only
Half Open Angle (Φa)	90
Shape change start angle(Φc)	75, 81, 85

3.2.2. Change in stress distribution

Figure 3 shows the distribution of vertical stress in the latitudinal direction when the upper and lower surfaces of the shell are changed, with the starting angle of each shape change indicated. Solid lines

represent stress levels on the upper surface, while dotted lines represent those on the lower surface. The tensile stress level is reduced, but not completely eliminated, and in some cases the compressive stress level even increases. This suggests that this is not a suitable objective function for determining the dome shape, which is typically made of compressed material.

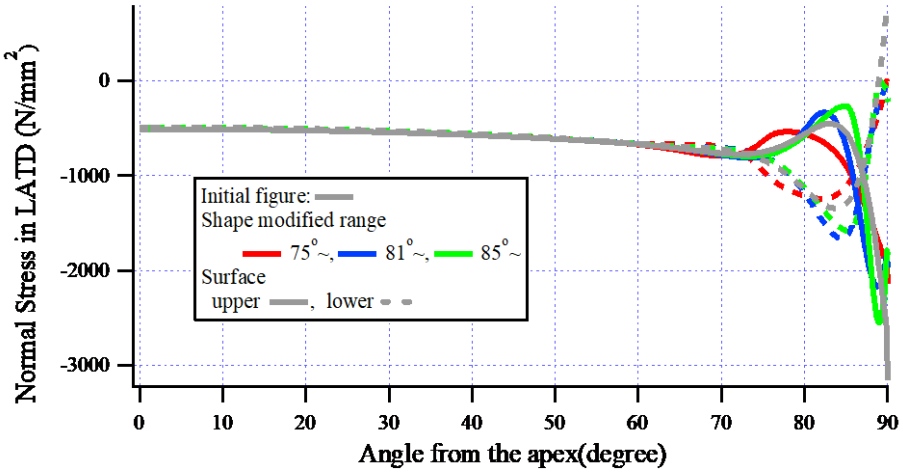

Figure 3. Stress distributions (Minimizing maximum stress)

3.3. Minimizing the sum of the squares of the differences from the mean of the stress levels

As our objective function, we considered the sum of the squares of the differences between the mean vertical stress levels on the upper and lower surfaces of the shell in the latitudinal direction. For the case of changes in the upper and lower surfaces, we used the following equation.

$$a = \sum (\sigma_i^{\text{upper}} - \sigma_{\text{ave.}}^{\text{upper}})^2 + \sum (\sigma_i^{\text{lower}} - \sigma_{\text{ave.}}^{\text{lower}})^2 \tag{2}$$

Note that the analytical model is the same as in the previous section.

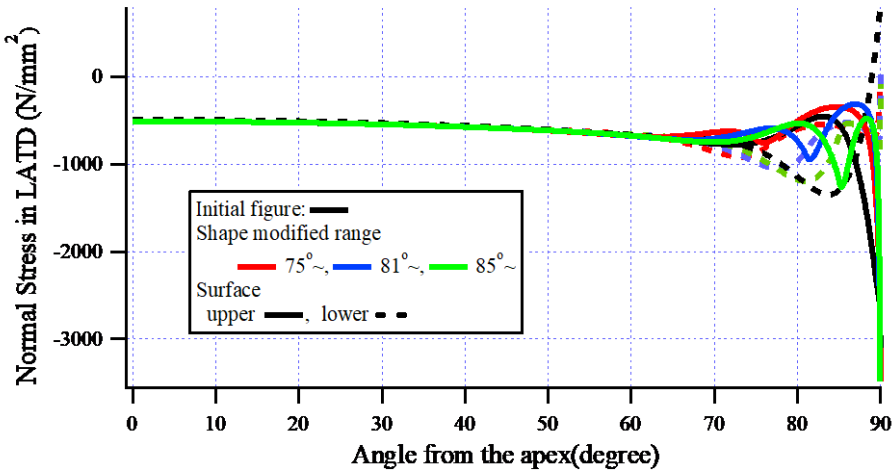

Figure 4. Stress distributions (Minimizing variance)

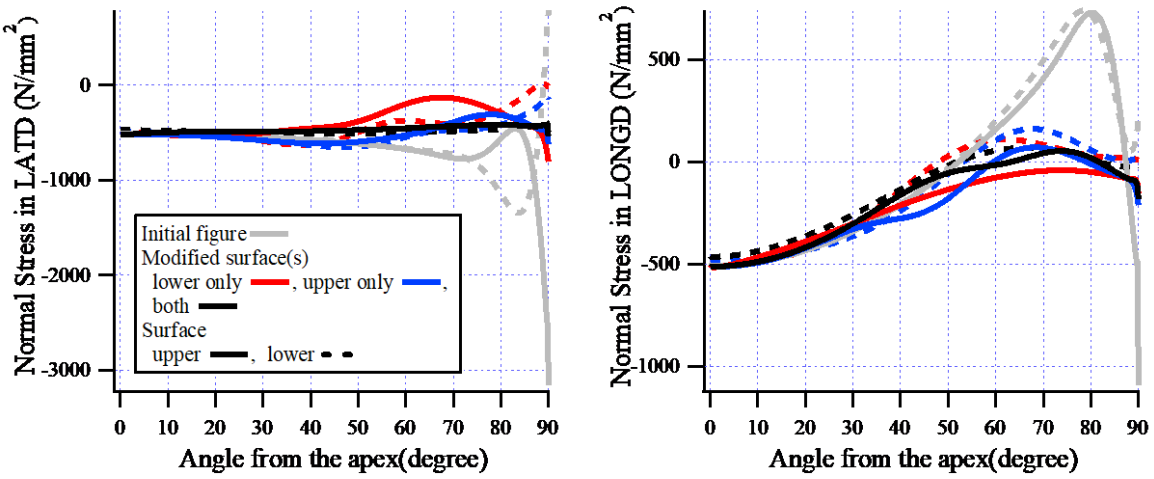
As Figure 4 illustrates, the stress distribution shows that, similarly to what was observed in the previous section, the tensile stress level is decreased but not eliminated, while in some situations, the compressive stress level increases. This suggests that using the maximum stress level as the objective function is not

suitable for producing dome shapes, which are generally made from compressed materials.



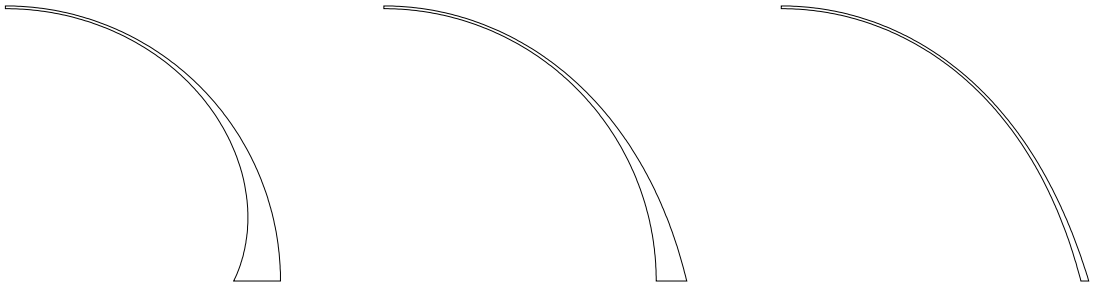
3.4. Minimizing the sum of squares of the difference between the maximum and minimum stress values

In the previous two sections, our aim was to minimize tensile stress and reduce compressive stress as much as possible. However, tensile stress still occurred in both cases. To address this issue, we considered combining the two objective functions and solving the problem as a minimization problem with an objective function of the sum of squares of the differences from the mean of the stress levels and a constraint that the maximum stress level should be less than or equal to zero (i.e., compressive stress level). But, instead, we decided to try a different approach: if the difference between the maximum and minimum stress levels is small, it may lead to a uniform compressive stress level throughout the entire structure. The equation is expressed as follows.

$$a = (\sigma_{\text{max.}}^{\text{upper}} - \sigma_{\text{min.}}^{\text{upper}})^2 + (\sigma_{\text{max.}}^{\text{lower}} - \sigma_{\text{min.}}^{\text{lower}})^2 \tag{3}$$

In the preceding two sections, we only modified the boundary area, resulting in various shape solutions, but it was difficult to determine if they were correct. Therefore, we hypothesized that optimizing the entire shell would result in a suspension surface, and set the shape change start angle Φc to the vertex (0°) in this section.

The distribution of the latitudinal vertical stress intensity at convergence is shown in Figure 5(a). It displays the values for the initial geometry and three geometries change surface patterns. The stress distributions after convergence of each shape change surface pattern show no tensile stress in any case, and particularly for the upper and lower surface changes, the vertical stress values are almost constant over the entire surface of the shell, confirming the effectiveness of the objective function.



(a) in latitudinal direction (b) in longitudinal direction

Figure 5. The difference in stress distribution due to the modified surface

Figure 5(b) illustrates the distribution of the longitudinal stress. Despite the fact that the objective function is composed of latitudinal stresses, normal stresses in LONGD have also decreased.

Figures 6(a)-(c) depict the shapes of the three shape-changing surface patterns at convergence. The shape change surface pattern with the most reduced objective function is the upper and lower surface change, and as can be seen in Figure6 (c), its shape resembles a suspension surface with a bulging

boundary, which is similar to Wilhelm Flügge's isostrength shell [4].

(a) lower surface only (b) upper surface only (c) both of surfaces

Figure 6. Convergent solution (H.O.A.=90º)

3.5. Summary

In this chapter, we considered several objective functions and performed convergence calculations. As a result, we found that the shell shape in the fully compressed state can be obtained by using the sum of squares of the differences between the maximum and minimum values on the upper and lower surfaces of the shell as the objective function.

4. Effect of stress reduction by changing the shape of the shell boundary

In the previous chapter, we investigated the objective functions for obtaining the stress state of an ideal shell. In this chapter, we examine how changing the geometry of the shell boundary can reduce the stress state, which was the original objective. Table 2 presents the analytical model and conditions. As the initial shape, we take a spherical shell with half-open angles of 60°, 75°, and 90°, and we investigate the convergent solutions for six different shape modification ranges. If the shape change start angle is 0°, this means that the whole surface of the shell is changed (as seen in the previous section), whereas if it is 5/6, only 1/6 of the area around the shell boundary is modified.

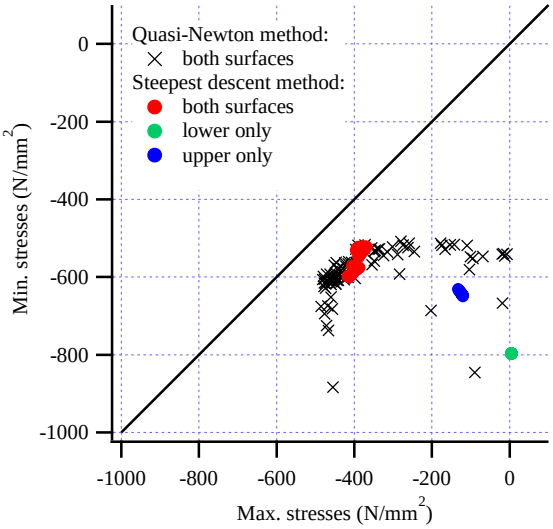
Table 2. Analysis model and conditions

Span (mm)	10000
Radius of neutral plane of initial shape R (mm)	5000
Initial thickness t (mm)	50
Number of divisions in the open angle direction	900
Number of divisions in the direction of plate thickness	10
Boundary condition	Fixed end
External Force	Dead Load
Surface to be reshaped	moving both surfaces
Half Open Angle (Φa)	60, 75, 90º
Modified range	from 0/6, 1/6, … 5/6 of Φa
Number of initial shapes	100
Range of initial irregularities given to design variables	$-0.5t \sim +0.5t$

4.1 Rethinking of optimization methods

In the previous chapter, the optimization method of steepest descent was used to examine the objective functions, but due to the high computational load, the quasi-Newton method was explored in this chapter. As seen in Figure 7, when the number of initial shapes is 50 for the steepest descent method

and 100 for the quasi-Newtonian method, the convergence solutions for the maximum and minimum stress levels are distributed. The initial shapes were created by assigning values for the design variables ub and uc in the range of plus or minus 0.5 times the plate thickness. The linear line crossing the zero point in the graph indicates the equal value of max. stress (horizontal axis) and min. stress (vertical axis). Solutions that are near this line and closer to the zero point are more desirable, and are represented by circles (steepest descent) or X marks (quasi-Newton). The amount of movement of the design variable in the steepest descent method varies from t/10 to t/5120 depending on the convergence calculation times, while the quasi-Newton method involves a linear exploration routine of the solution. Although the steepest descent method has a smaller initial value dependence, the number of convergence calculations is much smaller for the quasi-Newtonian method. Therefore, this chapter discusses the solution with the smallest objective function value among the solutions obtained by the quasi-Newton method, as this is what we aim to achieve.



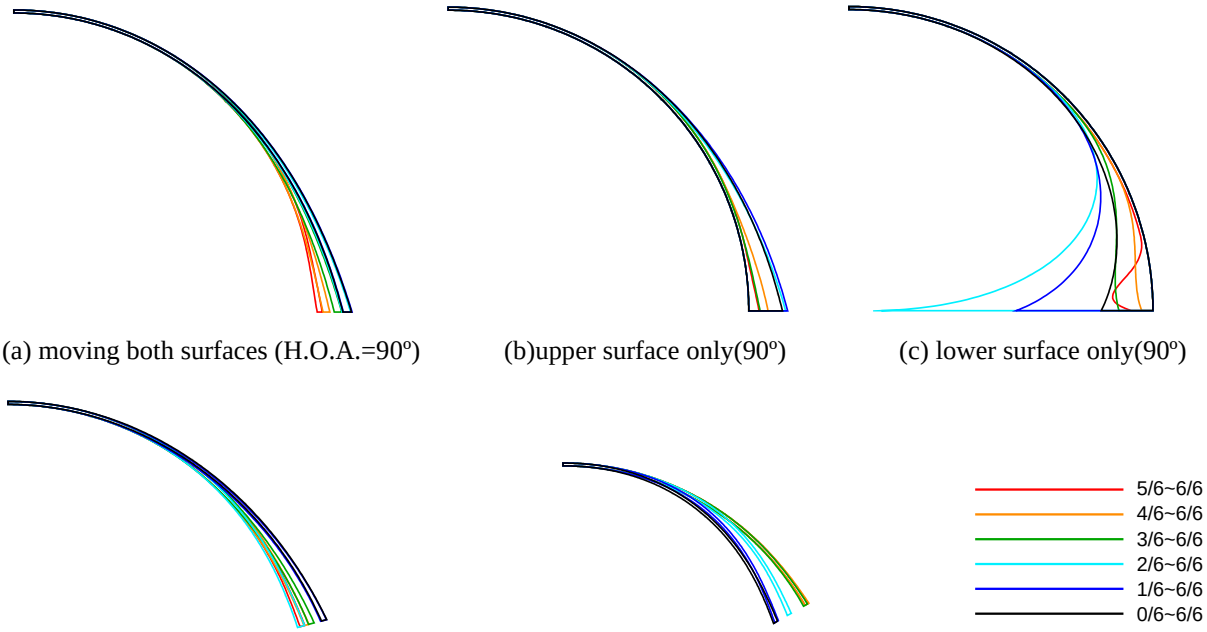


Figure 7. Differences in max/min values due to convergence methods

4.2. differences in optimum shape due to differences in the range of change

4.2.1. Shape change

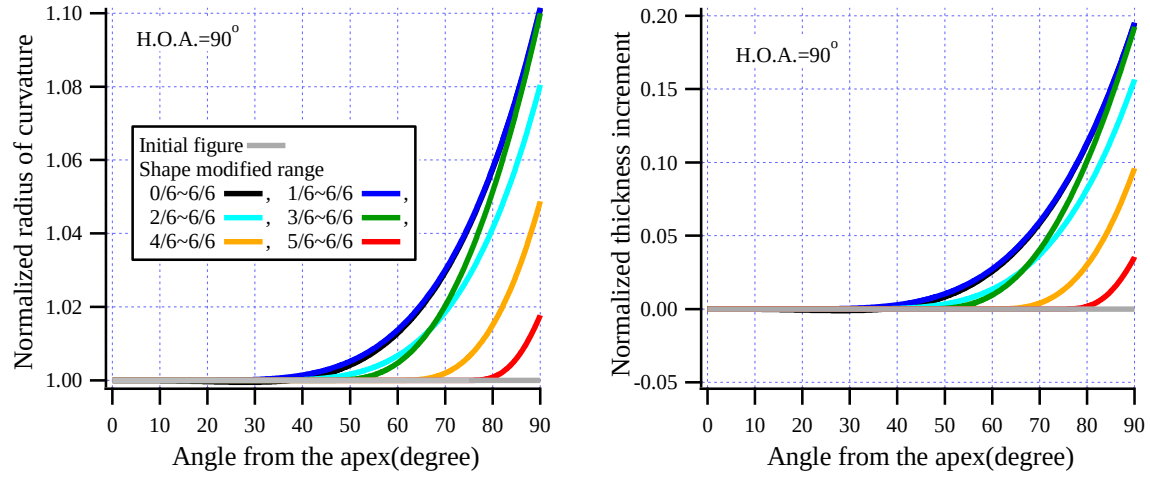
The solutions with the smallest objective function values, obtained from the initial shape with a half-opening angle of 90 degrees, are presented in Figures 8(a)-(c). The six colors in the figure indicate the various degree of shape modification. In (a), where the shape is modified on the upper and lower surfaces, the shape is modified with almost no change in thickness, while the other two solutions, where only one of the surfaces is modified, show a distorted shape. The FEM model used in the calculations was equally divided in the thickness and latitudinal directions, respectively, in order to obtain an element aspect ratio of 1:1. However, as the plate thickness increased during the calculation process, the element aspect ratio became more than 100 times that of the elongated element division, resulting in an incorrect stress intensity distribution. To address this issue, the elements in the thickness direction should be divided in proportion to the thickness. As this paper is focused on the determination of the optimum shape obtained by changing only the boundary, the results of the upper and lower surface changes from the initial shapes with half-opening angles of 60 and 75 degrees are presented in Figures 8 (d) and (e).

(a) moving both surfaces (H.O.A.=90º) (b)upper surface only(90º) (c) lower surface only(90º)

(d) moving both surfaces (H.O.A.=75º) (e) moving both surfaces (60º)

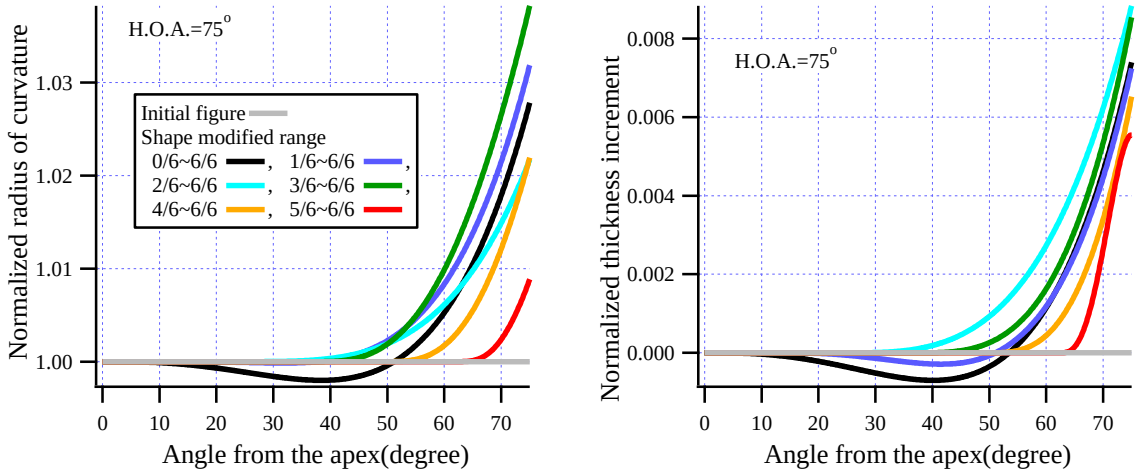
Figure 8. Convergent Shapes

4.2.2. Distribution of radius of curvature and plate thickness



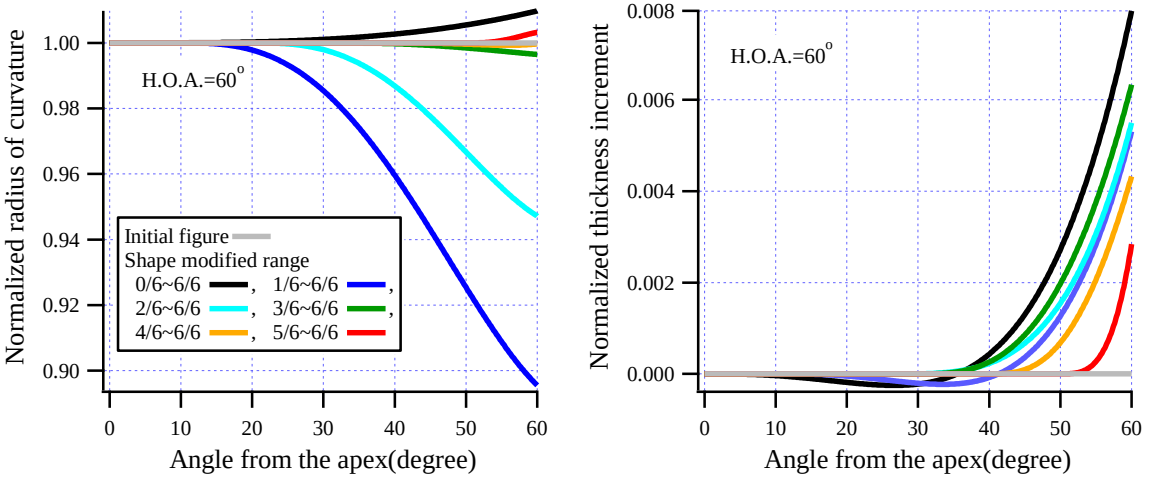
The shapes were roughly shown above. To see the details of the differences in shape change, Figure 9 displays the distribution of the radius of curvature in the latitudinal direction and the incremental thickness of the obtained shape. Since the aim is to observe the ratio of changes, each is normalized by the initial radius of curvature (i.e. the radius R of the spherical shell) and the initial plate thickness.

Outside the shape modification range, the radius of curvature is constant due to the initial shape being a spherical shell, however, at the boundary of the shape modification range, a larger radius of curvature is effective in reducing the stress level. It is also beneficial to adjust the plate thickness toward the boundary in the direction of increasing thickness.



4.2.3. Stress distribution and stress reduction effects

Figure 10 shows the stress degree distributions in the latitudinal and longitudinal directions, where the smallest objective function value of the optimal solution for each modification range was obtained. The stress intensity distribution for the spherical shell is also given in the graph as a gray line. It can be seen that no tensile stress level occurs in the latitudinal direction for all cases, and that the stress in the latitudinal direction is almost constant, particularly for 90° and 75°, but not for 60°. As for the longitudinal direction, the stresses are generally decreased, although some tensile stresses remain in some cases. The initial spherical shell of 60° does not generate tensile stress in LATD, which is why the convergent solution in the 60° case is different from those in other cases.



As shown in Figure 11, the compressive stress level is reduced by approximately 30% when the half-opening angle is 90°, 40% when it is 75°, and 60% when it is 60°. This suggests that even just a small change in shape near the boundary is enough to significantly reduce the stress level.

5. Conclusion

In conclusion, this study suggests that the optimization of a part of the shape rather than the entire shape could reduce the stress level and improve the workability, and the spherical shell was taken as the initial shape because the curvature of a spherical shell is constant and common formwork can be used if as much area as possible is left as a spherical shell.

The following is a summary of the findings obtained within the scope of the study.

(a) For shell structures expected to be under compression, optimizing the geometry can be effectively achieved by taking the difference between the maximum and minimum stress levels on the upper and lower surfaces of the shell and the sum of their squares as the objective function.

(b) This is because the stress level at the top of the shell remains a constant compressive stress level, and the shape can be modified to get closer to this value.

(c) As a result, the entire surface of the shell takes on a suspension-like shape with thicker boundaries, similar to that of an isostatic shell

(d) Furthermore, by making changes only in the vicinity of the boundary, it is possible to reduce the tensile stress level to some degree in the longitudinal direction.

(e) The shape to reduce stress will have a larger radius of curvature near the boundary and a thicker plate.

Although the method in this paper is intended to leave the spherical shell as much as possible and simplify the construction, complex formwork is required at the boundaries where the curvature is varied. Therefore, in order to prioritize workability, we are currently researching a shape in which the curvature of the inner and outer surfaces of the shell is constant for each, and we hope to publish our results in the near future.

Abstract

Structural optimization in its modern definition emerged in the 1960s, and various optimization methods have been proposed to date. Structural optimization plays an important role in modern structural design. It can reduce the consumption of materials while maintaining the structural performance of buildings. Structural optimization can also be considered as a potential means to make architecture more attractive, beyond the change of shape as a by-product of minimizing materials and costs. The author's research group investigated what structural optimization methods were proposed during the decade 2012-2021 and found that topology optimization is important with respect to its impact on architectural design. As an extension of this work, this study focuses on the application of such structural optimization methods to architectural design. In order to evaluate the impact of structural optimization in architectural design as objectively as possible, the content of a major architectural online magazine was investigated. Among the projects, we further investigated whether and how structural optimization methods were applied and provide an analysis and discussion of the results.

Keywords: structural optimization, topology optimization, conceptual design, architecture and engineering, web-scraping, architectural magazines

1. Introduction

In last year's presentation [1], a literature survey was conducted using a systematic mapping approach on academic journals to find out what structural optimization methods have been proposed in the last decade.

The results showed that topology optimization is an optimization method for the layout of components and therefore has a high impact on the appearance of architecture, but the number of such methods is not very large. In addition, the number of real projects was very marginal (Figure 1), even though this was an expected result. This indicates that, due to the survey of literature in academic journals, it was not possible to assess to what extent and how structural optimization methods have an impact on the appearance of architecture in practice. This does not necessarily mean that structural optimization has no effect on the state of architecture.

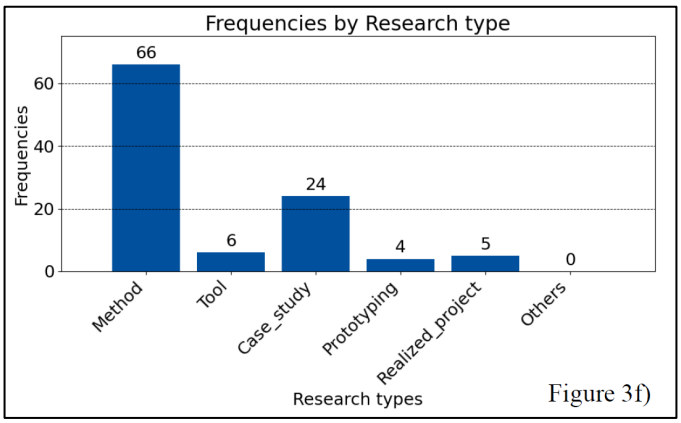

Figure 1. Frequencies by research type [1]

So, what information should be examined to better reveal the actual application of structural optimization? We initially tried to extract projects with structural optimization from architectural awards, but we considered that this would not gather much information. In the end, the authors focused on the architectural media. The information in the media is generally regarded as cobbled together, although it shows the results of editors' selection. However, the authors decided to turn to this option because it contains information that can be analysed in one way, such as attempts worth reporting and information on awards received.

In summary, the following points are sought to be clarified in this report. Research questions:

- What is the number and percentage of projects that allegedly used structural optimization within the last 10 years? In particular, how many of these projects used topological optimization?
- If the above numbers are found to be insufficient, what could be the reasons?
  Are there any unrecognised barriers in performing structural optimization methods, in particular topology optimization?

Limitation of research is as follows. This is the first attempt to use this methodology and relies on datasets from specific websites, as detailed in the Methodology in the next section. Hence, it is expected that different results will be obtained when different data sets are used. This report is therefore not intended to be a complete description of the situation, but rather a preliminary report on the validity of the data analysis methodology. It would also be meaningful to investigate the application of structural optimization in fields other than architecture (e.g. aerospace engineering), but the scope of the present study was to confirm its application in architecture and excluded these fields from the scope of the study.

2. Methodology

2.1. Web scraping

In this study, the main web-based architectural news sites were first selected. News sites often have a search window, but it is rare to be able to search by multiple criteria, such as the year the article was published, whether it contains an optimization statement, etc. Also, some articles contain not only articles on architectural projects, but also articles focusing on architectural education and architects, and articles on peripheral topics such as interior design and product information, etc. The articles also contain articles on other topics, which need to be removed.

In order to do this efficiently, we adopted the web-scraping method, which includes the retrieval of data by a human operator, but in this paper, we refer to a method that automates the process through programming.

2.2. Ethical issues

There are several important points that need special attention when carrying out web scraping. The following section presents the points to note, and the responses taken in this study.

Firstly, it can be accessed significantly faster than a physical human manually going to the information, as the information is accessed by automated methods through programming. However, accessing one site at a high frequency and retrieving information may slow down the response of the site and make it impossible to continue the service. Therefore, it should be noted that this may be regarded as an attack on the site by the site operator. It is recognised that there is no common understanding of how much is considered high frequency, as it depends on the capacity of each site. Here, we have referred to a number of previous cases and other examples, and generally referred to the fact that many sites advise that the site should not be accessed more than once every 1-3 seconds, and in this study, the setting was set to open more than 2 seconds from one access to the next.

Secondly, the usage and access range permitted by the site operators. It is common for major sites to have a "robots.txt" file in the top directory, which states which types of automated visitors are prohibited from accessing which range of directories. This study was conducted with strict adherence to this range. The "Terms of Use" and similar items are located on the website. These often state that unauthorised scrape is prohibited. In this study, sites that explicitly state in the "Terms of Use" base that scrape is prohibited were excluded from the scope of the search.

The last step is the use of the information obtained. Caution should be exercised mainly with regard to personal information such as e-mail addresses. In this study, the scope of information analysis was limited to the range in which the text was written, so that the possibility of personal information being included was reduced. Also, care was taken to ensure that the results obtained were used statistically. However, the resulting projects were analysed because they are in the field of building projects, which cannot be anonymous, and because of the extent to which they are accessible to the public.

2.3. Methods

From the main architectural media, the following two conditions were used to determine which ones were included in the study. One is that there must be no description in the robots.txt file prohibiting automatic access, and the other is that if a 'terms of use' is explicitly stated, it must be judged from its content that it does not prohibit automatic access. Dezeen (hereafter the website) was identified as one of the few websites that fit both criteria.

For the purpose of understanding the current situation, data were taken from web pages published between 2013 and 2022. In order to limit the population of articles, only articles with the tag 'Architecture' were obtained for the website. For the acquisition of information, parsing and analysis, the existing open-source libraries in Python 3, requests and beautifulsoup, were used. The data was acquired in March 2023.

The search key is as follows:

- the tags of the article include “Architecture”.

- whether the body text includes both “structur*” and “optimi*” (with “*” as wild cards).

Systematic approach, inspired by the work of Petersen et. al. [3], is employed to sort out projects identified as they are potentially related to structural optimizations. The including and excluding criteria are as follows:

(Inclusion rules)

- Articles on the website published between the periods 2013-2022 (10 years)
- The description of optimization of the structure of buildings or pedestrian bridges is found in the body text.

- The term “optim*” (with “*” as wild cards, such as optimisation, optimization, optimizing, …) is directly associated with its method.

(Exclusion rules)

- Not a design of new construction (ex. “diagnosis”, “inspection”, or “retrofit”)
- The term “optim*” is not related to structure.
- The term “optim*” is used without referring to particular methods (ex. “optimal shape”, “optimal solution” with no supporting information on methods) in the text.

The selected articles are further investigated according to the items in Table 1. Items excluded in this report are also shown but with striking lines. This is to align with the previous study [1]. In the case of items where a particular item was not readable, an "Unspecified" entry was made to distinguish it from "Others".

Table 1. Investigated items.

1. Category of optimization	Topology, Shape, Size, Unspecified, Others
2. Material	Steel, Timber, Concrete, Composite, Unspecified, Others
~~3. Objective~~	~~Stiffness, Stress, Strain energy, Weight Mass, Cost, Carbon and GHG Emissions, Vibration, Energy, Others~~
~~4. Num. of objectives~~	~~Single Objective Optimization (SOO), Multi-objective optimization (MOO)~~
5. Building type	Multistory, Spatial, Pedestrian bridge, Unspecified, Others
~~6. Type of research~~	~~Methodology, Tool, Case study, Prototyping, Realized project, Others~~
7. Application area	Entire building, Part of building, Building element, Material, Unspecified, Others

3. Result

3.1. Systematic search

The actual procedure of the search is shown in Figure 2. Number shown in the bold letter in the figure shows the remaining articles at each step. The search took place in March 2023. The total number of the articles found in the website was 36683, where the tag “Architecture” was given to 14672 articles (40.0%). The search key presented in the Section 2.3 identified 257 articles as potentially relevant articles. Manual screening was carried out to exclude irrelevant papers according to the rule also presented in the Section 2.3. The 23 relevant articles [5-27] were analyzed according to the predetermined as Table 1. The share of the articles describing on structural optimization was 0.16% against all the articles found under the “Architecture” tag.

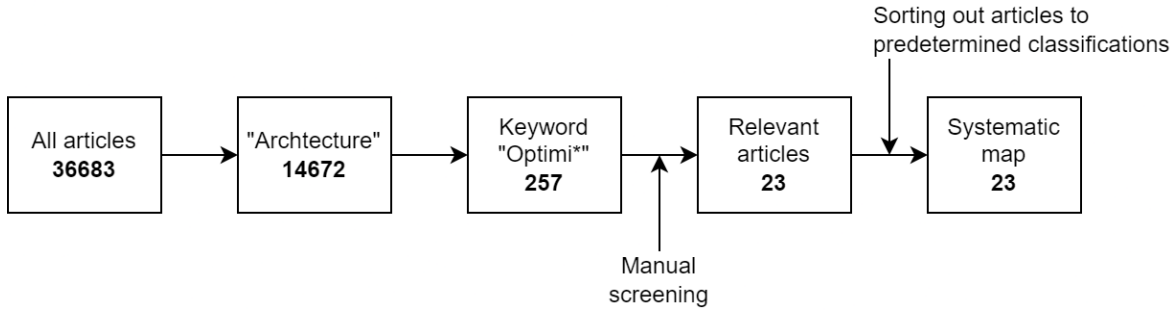

Figure 2. Procedure of systematic search

3.2. Analyses of the result

Results are shown in Figure 3. Figure 3a) shows that the most frequent structural optimization category is shape optimization (n=13) followed by topology optimization (n=5) [12, 16, 17, 21, 23]. There were no articles that showed sizing optimization in an explicit manner. Figure 3b) shows the result according to the building materials. Among the three major materials of steel, timber, concrete, no significant differences in number were observed. The others included carbon fiber, brick, aluminum, and silkworm. Figure 3c) shows the result according to the building typologies. Applications to spatial structures were the most frequent (n=12), followed by multistory type (n=3) and by pedestrian bridge (n=1). Figure 3d) shows the application areas. Application to the entire building was the most frequent (n=12) followed by building element (n=5) and part of the building (n=4).

Then, observations were further made by combining two sets of classifications. All the six combinations are presented in Figure 4. Figure 4a) shows that shape optimization is employed irrelevant of the material. Figure 4b) shows that shape optimization of spatial structure was the largest in number, whereas figure 4c) shows that from the material point of view, timber is used most frequently. Figures 4d) to 4f) shows the results from the application areas' point of view. Figure 4d) shows the shape optimization for entire building is the largest in number, and Figure 4f) shows that spatial structure for entire building is the largest in number.

4. Discussion

According to the results of the previous section, in the last decade, the 23 projects described structural optimization of buildings, of which only five were limited to topology optimization. Although topology optimization shares still non-negligible number of cases among the cases that addressed structural optimization, they are negligibly small cases if the entire population of "Architecture" tag (n=14762) is considered. This section therefore looks at the reasons for this.

According to Bendsøe [4], structural optimization is classified into three types: topology, shape and size. Of these, size is often implemented as a function in structural analysis programmes, and the algorithms that have been widely used in the past are relatively easy to use, so the actual frequency of use is likely to be greater than the number of cases, but the use of these is unlikely to have an impact on the architectural concept However, it is assumed that there is no need to advertise it in the media as it has little impact on the architectural concept and is not necessarily a new approach in terms of structure.

What was observed in large numbers this time was shape optimization. These suggest that with the increasing popularity of parametric design, it is becoming possible to create many variations of form with the same architectural concept in top-runner projects. On the other hand, there are fewer applications of topology optimization. Of particular note was the breakdown of these five projects: three were from university research institutes [12, 16, 23], one was a university student project [16], and one

was a firm with an architecture and engineering department [21]. More detailed research is needed here, but here are some hypotheses.

- Influence of topology optimization on form is too high on behalf of structure to be successfully applied to the architectural projects in collaboration with architects. This may also relate to the decision-making process in architectural design. Applying topology optimization to the entire architectural design, for example, where the architect formulates a concept with respect to form and the engineer assists in realising it, would be difficult due to the high degree of influence on the form of topology optimization. Conversely, the five topology optimization projects found in this study appear to have been examples of design processes where the application of topology optimization was the purpose of the project in the first place, or where the in-house engineer was influencing the architectural concept.
- The geometry obtained by topology optimization is usually optimized for the flow of forces, which makes it more difficult to fabricate members. Although there is software that takes into account fabrication constraints, such as Altair OptiStruct[28] or Autodesk Fusion 360[29], they are mainly placed in the context of additive manufacturing in the mechanical engineering field, and no software was found that takes into account joints, constant cross-sections of elements, etc., as in architecture. These would require programme development by specialists and are still at a stage where they would be difficult to apply in general. Put another way, when it comes to building parts of a certain scale or larger, the hurdle for structural application may be lowered, since the members will be segmented in any case, whether the geometry is special or not.

These are points that were considered suggestive when this study was conducted and cannot be anything concluding. Further research, e.g. interviews with visiting major architectural and structural design firms, would be necessary to prove these points, but are outside the scope of this study.

Limitation of this report includes the following. Dezeen is a web-based general design magazine that includes Architecture with significant rate (40% of the articles are tagged as “Architecture”). That said, it is not meant for the place to address engineering concepts with technical terms. Therefore, there is a chance that the word such as topology optimization has been rephrased to more plain words, that could have made it difficult to keep track of the structural optimization. On the other hand, it was not possible for the authors to find specialized magazines that allowed access to such a huge amount of data without special contracts.

5. Summary

This report supplements the authors’ previous report and an attempt was made to further clarify the status of the application of structural optimization to building projects. Many researchers are currently developing methods for structural optimization, but along with the methods, it is also important in its own right to create a situation where they can be used in real projects (e.g. design methods and software development to facilitate them).

We recognise that structural optimization techniques should be used not only to optimize the quantity of material, but also to enrich architecture. This means that structural optimization has both architectural and structural engineering aspects, and it is important to approach it from both fields.

Abstract

Anticlastic glass surface is an important form for free-form glass facades. The traditional hot bending method can realize arbitrary curvature, but requires a pre-formed mold. Cold bending realizes anticlastic surface by loading at the corners of the plate, which is more adaptive and economic. The instability phenomena of monolithic glass plates in cold bending process are then summarized, and the instability modes of monolithic glass plates are defined clearly. In this paper, detailed FEM models simulating cold bending process of laminated glass plates are established and validated against existing experimental results. The effects of different supporting conditions, laminate compositions, width-thickness ratios are investigated to explore the cold bending properties of laminated glass plates. Bifurcation instability is identified to be the only control condition for both monolithic and laminated glass plates. The instability mechanisms of laminated glass are discussed. A bidirectional compression area in the center of the plate is observed to dominate instability, but the compression area changes from bidirectional to unidirectional for laminated glass with larger width-thickness ratio and PVB thickness-glass thickness ratio.

Keywords: anticlastic cold bending, stability, laminated glass, support condition, laminate composition, width-thickness ratio, free form facades

1. Introduction

The free form glass facades require curved glass elements, and double curved glass, particularly anticlastic glass, which is difficult to produce. The traditional hot bending method can realize desired curvature, but requires a pre-formed mold. Cold bending is an alternative technique for producing anticlastic glass plates. During this process, concentrated forces are applied to one or two corners of the glass plate while the other corners are fixed (Figure 1), the curvature is induced by the elastic deformation of glass under out-of-plane load, making the process more flexible [1-3].

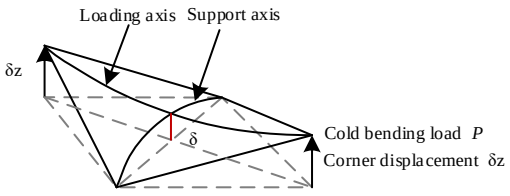

Figure 1. Anticlastic cold bending

In general, the failure of glass plates during cold bending is primarily determined by instability rather than strength. Researches on the stability of anticlastic cold bending mainly focus on discriminating instability phenomena, predicating instability and analyzing influencing factors. Staaks and van [4] discovered that the deformation of glass plate concentrates in one diagonal during cold bending, resulting in asymmetric configuration. This configuration is commonly used by scholars as a symbol of instability, and influencing factors have been studied through testing and Finite Element Method (FEM) analysis. The cold bending force and corner displacement at instability point can be affected by the size of the glass plate, and there is a linear relationship between the cold bending corner displacement at the instability point and the thickness of the glass plate [5-9]. The configuration of cold bending instability can be affected by the types of bearing conditions. Generally, point support has better deformation capacity compared with frame support [5, 6, 9]. Deformation from gravity cannot be ignored when the plates are placed horizontally [5, 7, 9, 10]. Initial defect makes the stability of plate worse [5]. Datsiou defined the asymmetric configuration as the change of deformation mode, and then divided the cold bending instability modes into 3 types: the change of deformation mode, global snap-through instability and cold bending distortion, and attempted to establish a unified failure controlling condition [7, 10]. Actually the global snap-through is a normal curvature change under gravity which is not regarded as instability in this paper. Some tests have demonstrated that laminated glass, especially laminated thin glass, has superior cold forming capacity [6, 11]. The influence of aspect ratios [6] and support conditions [6, 11] have been explored, and a variety of support conditions have been proposed for cold bending laminated glass. However, there's no further analysis focusing on the instability mechanism of laminated glass. Galuppi proposed a bidirectional cylindrical model [12] and enhanced effective torsion thickness method [13] to study the instability of point supported glass elements during cold bending.

In a word, previous research has identified the changes in deformation mode and the cold bending distortion during the cold bending process. Support conditions, initial shape under gravity, initial imperfection, geometric dimensions and lamination may change the instability phenomena of glass plates. However, the controlling condition of cold forming and the instability modes have not been clearly identified for both monolithic and laminated glass plates, and the influences of support conditions, laminate compositions, width-thickness ratios need further analysis.

To address these issues and systematically study the stability of glass plates during anticlastic cold bending, this paper firstly summarizes the instability phenomena observed from literature analysis, and explores the instability modes, then studies the influences of support conditions, laminate compositions and width-thickness ratios on cold bending stability employing the FEM method. The instability mechanisms of laminated glass are discussed based on the results of parameters analysis.

2. Cold bending instability of monolithic glass plate

2.1. Cold bending process

Monolithic glass can be used as the basis for the stability analysis of laminated glass, Figure 7 illustrates the instability phenomena during the cold bending process for monolithic glass plates [7, 10]. For monolithic glass without the influence of gravity (Figure 2a), the deflection at the plate centre changes linearly with the cold bending corner displacement in the early stage of cold bending, with the loading axis and supporting axis bending in opposite directions (Figure 2b), resulting in a symmetric configuration that resembles a saddle surface. However, in the late stage of cold bending, the deflection at the centre of the plate changes nonlinearly with the cold bending corner displacement, and the out-of-plane deformation concentrates on one diagonal while the deformation of the other diagonal is small (Figure 2c), resulting in an asymmetric configuration. Subsequently, the bending direction in the middle of one diagonal reverses, and the curvature at the central area of the plate changes from anticlastic to sinclastic (Figure 2d).

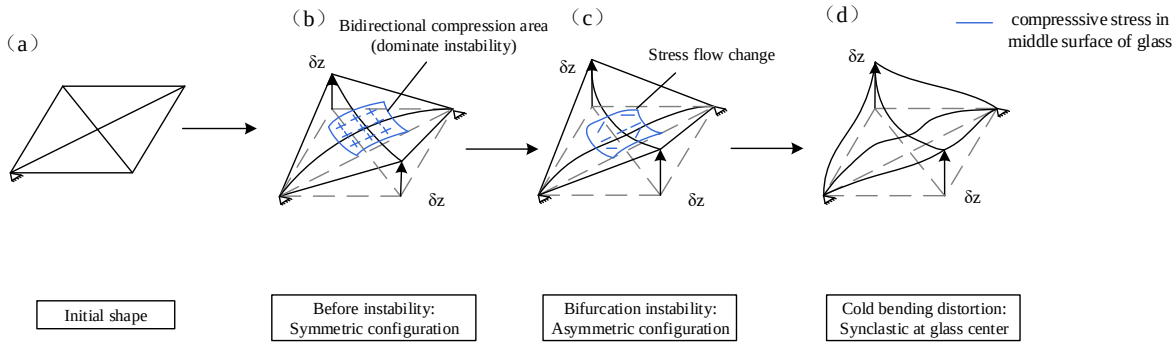

Figure 2. Cold bending process:(a) initial shape, (b) ideal cold bending, (c) bifurcation instability, (d) cold bending distortion.

2.2. Bifurcation instability

During anticlastic cold bending of glass plates, there are tensile stress at the edge of the glass plate and compression stress in both diagonal directions in the middle surface of the glass plate in addition to the bending stress (Figure 3). The collapse of the bi-directional compression area leads to the bifurcation instability, after which the out-of-plane displacement concentrates on one diagonal (Figure 2c).

The point at which the *P-δ* curve changes nonlinearly is known as instability point. Before the instability point, the disturbance force P_0 is applied at the centre of glass plate (Figure 4a), and the disturbance force changes nonlinearly with the deflection at the centre of glass plate (Figure 5b), which indicates the cold-formed plate with negative Gaussian curvature has stable load bearing capacity. Applying disturbance P_0 at the centre of glass plate after the instability point (Figure 4b), the snap through of disturbance force is obvious with the deflection at the centre of glass plate (Figure 5a, b), which means the cold-formed plate is unstable and not suitable for further cold bending. The occurrence of "snap through" confirms the presence of multiple equilibrium paths after the bifurcation point.

(a) (b)

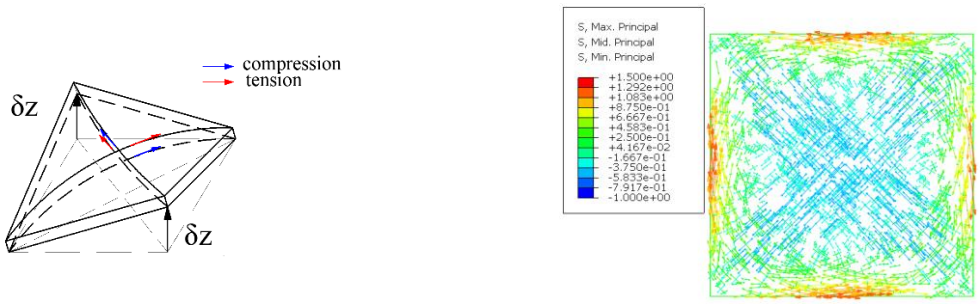

Figure 3. The stress of glass plates before bifurcation instability: (a) the schematic stress on the upper and bottom surfaces of the glass plate, (b) the membrane stress in the middle surface of glass plate.

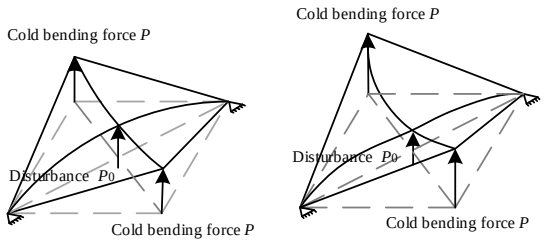

Figure 4. Apply disturbance P_0 before or after the bifurcation instability

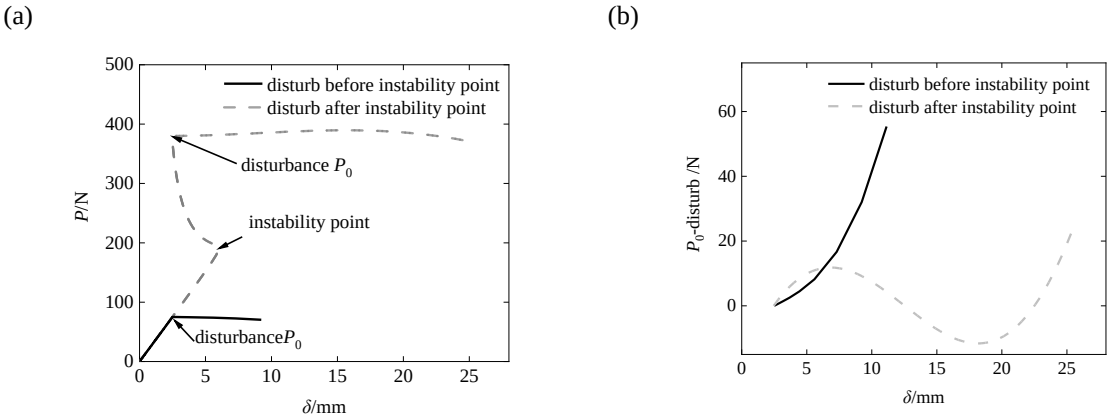

Figure 5. Response to disturbance force before or after instability: (a) P-δ curve (b) P_0-δ curve

2.3. Cold bending distortion

After the bifurcation instability point, the compression stress in the middle surface of glass concentrates on the diagonal with smaller deflection in asymmetric configuration (Figure 2c). As a result, the centre part of this diagonal may buckle, resulting in the changing from anticlastic to synclastic at the centre of plate (Figure 2d). This phenomenon is called cold bending distortion.

Since the cold bending distortion occurs after the bifurcation instability phenomena, monolithic glass takes the bifurcation instability as the controlling condition for cold bending.

3. Finite element model and validation

3.1. Model building

To capture the instability point during the cold forming process, finite element models are developed using ABAQUS software with static Riks step. The material properties of glass and steel are simplified into elastic, and the corresponding parameters are presented inTable 1. The Ogden hyperelastic material model is adopted to model PVB and silicon. Glass and steel are modelled with C3D20R solid elements, while silicon and PVB are modelled with C3D20RH hybrid elements. The size of mesh is set at 12.5×12.5 mm. The glass, silicon, PVB, and steel are divided into two, two, three, and two layers across the thickness, respectively (Figure 6. The finite element models).

Table 1. The property of materials

Material	Elastic modulus/ MPa	Poisson ratio
Glass	70000	0.22
Steel	210000	0.3
Silicon	Related parameters adopted in Ogden hyperelastic model : μ1=0.4145MP, α1=4.8962, D=0.09720.4

The constraints used in this study restrict only the out-of-plane displacements at the corners of glass plate while allowing for in-plane displacements and rotations, as shown in Figure 6. For frame support, 20×40 mm steel frames are bonded to the four sides of the glass plate with 12 mm silicone adhesive. The steel frames are not connected at the corners to enhance deformation capacity during the cold forming process. The silicone-to-glass, silicone-to-steel, and PVB-to-glass connections are assumed to be tie, not considering the debonding. Displacement loading scheme is applied, with loadings applied to the steel frames for frame support, and directly to the glass corners for the roller point support.

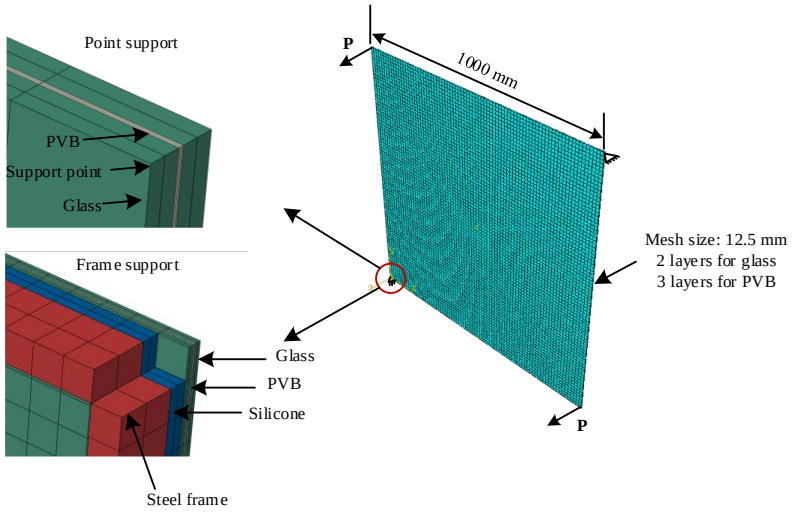

Figure 6. The finite element models

3.2. Model Verification

Caprili's test [11] utilized a linear bonding steel-to-glass connection, which was made up of a tubular stainless steel frame, laminated glass plate (5 mm glass+1.52 mm PVB+5 mm glass) and SIKA MT adhesive (average thickness equal to 6.0 mm). Loads are applied to the corner of stainless steel frame. The finite element models with frame support are modified according to Caprili's test (Figure 7). The relationship between the cold bending load and the corner loading displacement from the test and FEM analysis are illustrated in Figure 8.

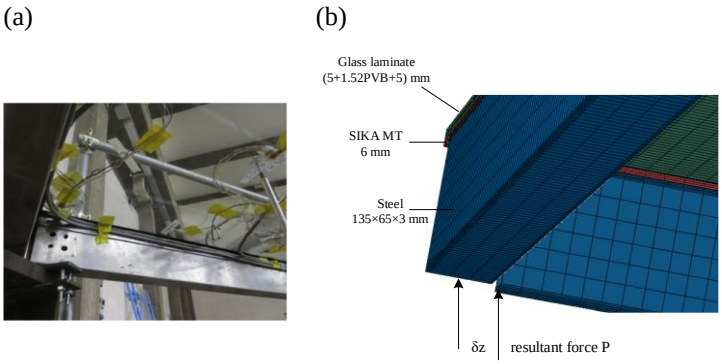

Figure 7. Cold bending laminated glass plate with frame support: (a) Caprili's test[11], (b) Finite element model.

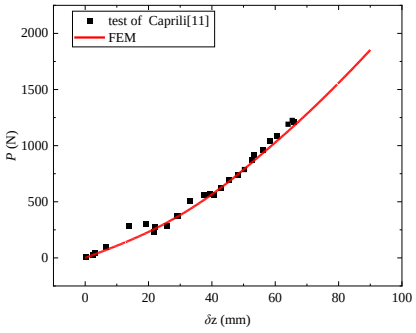

Figure 8. Verification with Caprili's test with frame support

Thierry [6] clamps the laminated glass plate at four points (Figure 9), and the cold bending load is applied by raising one of the four constraints. The deflections at the plate center (δ) and at the middle of glass edge(δ') from the test and FEM analysis are illustrated in Figure 10.

Figure 8 and Figure 10 shows that the deflection and cold bending force from the FEM analyses are in good agreement with the test results, which verifies the effectiveness of the built finite element model.

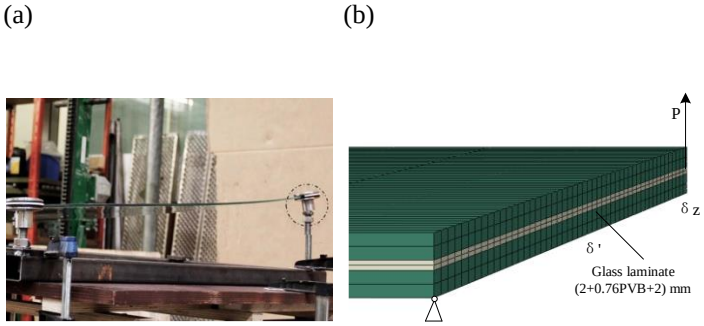

Figure 9. Cold bending laminated thin glass plate with point support : (a) Thierry's test[6], (b) Finite element model.

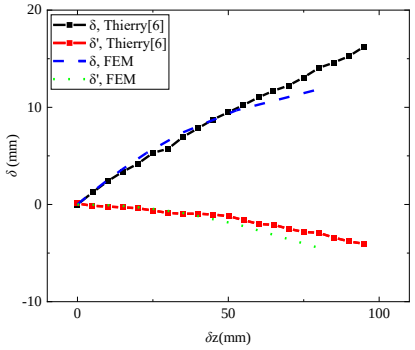

Figure 10. Verification with Thierry's test with point support

4. Parametric analyses

The validated finite element models are used to simulate the cold bending process. When the plate's centre deflection changes nonlinearly, the plate loses its symmetry, indicating that bifurcation instability has occurred.

4.1. The analysis of influencing factors

The influence of support conditions, laminate compositions and width-thickness ratios on cold bending stability is analyzed. The scopes of influencing factors are showed in Table 2.

Hidden frame and point-supported glass curtain walls have better transparency compared to exposed frame glass curtain walls. Moreover, mechanical point supports can avoid perforating the glass surface. Therefore, mechanical point supports and hidden frame supports are considered in cold bending process. Only the degree for out-of-plane displacement is constrained, while other degrees for the in-plane displacements and rotations are free to move for both mechanical point supports and hidden frame supports. The mechanical point support in this constraint conditions is referred to as roller point support. Both monolithic and laminated glass plates are considered with roller point and hidden frame supports (Table 2).

The glass plates used for cold bending are generally not thick, and PVB interlayers are preferred over SGP in cold bending due to their better flexibility. As a result, laminates with 2-10 mm glass and 0.76 mm, 1.52mm or 2.28 mm PVB interlayers are commonly used in cold-forming. 1000×1000 mm square laminated glass plates are used to explore the influence of the relative thickness of glass and PVB in laminates. The influences of laminate compositions are explored by controlling glass thickness, PVB thickness and laminate thickness as constants respectively (Table 2).

Then, the width-glass thickness ratio is taken as the variable, and the glass thickness-PVB thickness ratio is assumed to be constant to exclude the influence of laminate compositions. The widths of glass laminates range from 600 mm to 3000 mm, and the thicknesses of glass range from 2 to 10 mm, so the width-thickness ratios range from 60 to 1500 (Table 2).

Table 2. The influencing factors and the scope

Influencing factors	Support conditions	Glass thickness/ mm	PVB thickness/ mm	Width/ mm
Support conditions	Roller point, Hidden frame	5		1000
		4	1.52	
Laminate compositions	Roller point	5		1000
		3, 3.5, 4, 4.5, 5, 6, 8, 10	1.52	
		2, 2.5, 3, 3.5, 4, 5, 6, 8	0.76	
		5	0.76, 1, 1.2, 1.52, 2.28	
		4	1.52	
		4.2	1.12	
		4.5	0.52	
Width-thickness ratios	Roller point	2	0.76	600, 800, 1000, 1200, 1500, 2000, 3000
		4	1.52	600, 1000, 2000, 3000
		10	3.8	600,1000 ,3000

4.2. The influence of support conditions

Bifurcation instability phenomena are observed for both roller point and hidden frame support conditions and the instability configurations after bifurcation point are showed in Figure 11(a), (b). For monolithic glass, the centre deflection of glass plate before bifurcation instability is found to be similar under both roller point and hidden frame support conditions. However, for laminated glass, the bifurcation point occurs later in the case of roller point support compared to frame support (Figure 11c), but the edge of glass remains linear under frame support which makes it easier for tessellation (Figure 11a, b).

In general, both roller point and hidden frame support conditions can be used as support conditions for cold forming. In the following part of this paper, roller point support is considered for simplification.

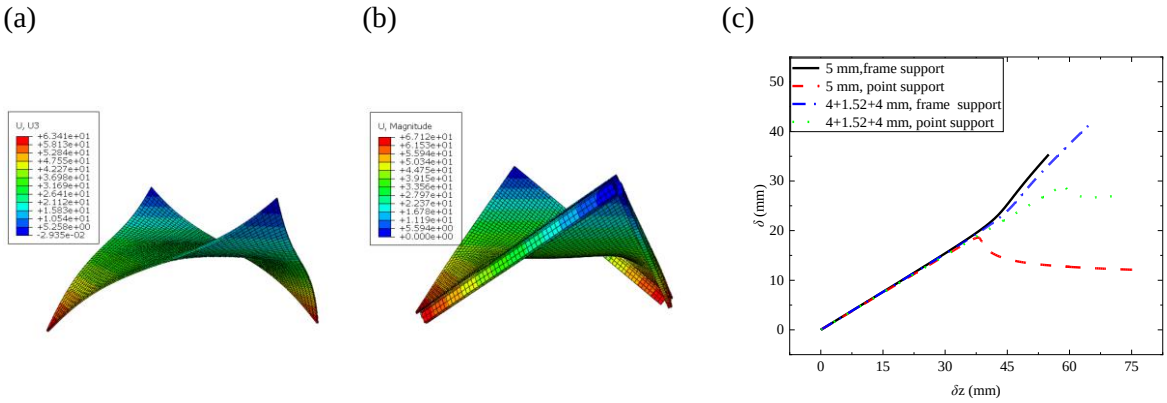

Figure 11 Cold bending under different bearing conditions : (a) instability configuration under roller point support, (b) instability configuration under hidden frame support, (c) δ-δz curve during cold bending process.

4.3. The influence of the laminate composition

The cold bending load and corner displacement at bifurcation instability are recorded as $F_{buckling}$ and $\delta z_{buckling}$, respectively. The relationship of $\delta z_{buckling}$ and t_{glass}/t_{PVB} for different laminate compositions are showed in Figure 12. The $\delta z_{buckling}$ for 5mm monolithic glass plate is also illustrated for comparison. Obviously, laminated glass plates have better deformation capacity compared with monolithic glass plates. Thicker interlayer or thinner glass results in smaller corner displacement at the instability point. (Figure 12).

Bifurcation instabilities always occur during cold bending process for different laminate compositions, which can be detected through the nonlinearity of the deflections at the centre of glass plates. It can also be seen that there are two types of configurations before bifurcation instability (Figure 13). In type 1, laminated glass plates can maintain nearly hyperbolic paraboloid before bifurcation instability, while in type 2, the deflection at the centre of laminated glass plate becomes flat, and the edges of glass plate cannot maintain straight. The configuration before bifurcation instability trends to type 1 with a larger glass thickness-PVB thickness ratio, while the configuration trends to type 2 with a smaller glass thickness-PVB thickness ratio.

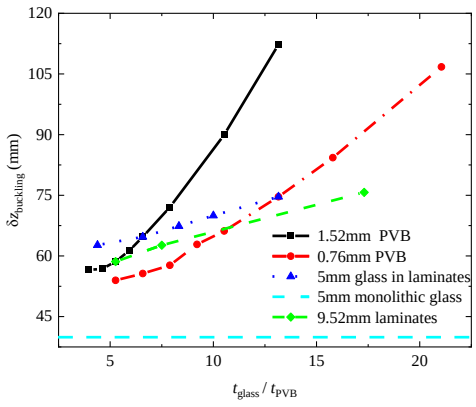

Figure 12. The relationship between $\delta z_{buckling}$ and t_{glass}/t_{PVB}

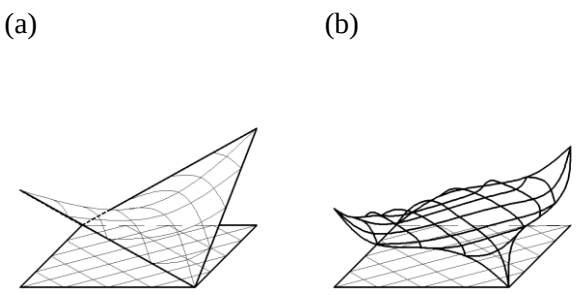

Figure 13. Cold bending configuration before bifurcation instability: (a) Type 1, (b) Type 2.

4.4. The influence of the width-thickness ratio

To eliminate the influence of scale factor, the ratio of $\delta z_{buckling}/t_{glass}$ is used as the dependent variable. Figure 14 presents the relationship between $\delta z_{buckling}/t_{glass}$ and $B/t_{glass.}$ The corner displacements at the bifurcation instability initially increase and then decrease with increasing width-glass thickness ratios. The configurations before bifurcation instability show that, when the width-thickness ratio get larger, the deformation mode tends towards type 2 (Figure 13b) before bifurcation instability.

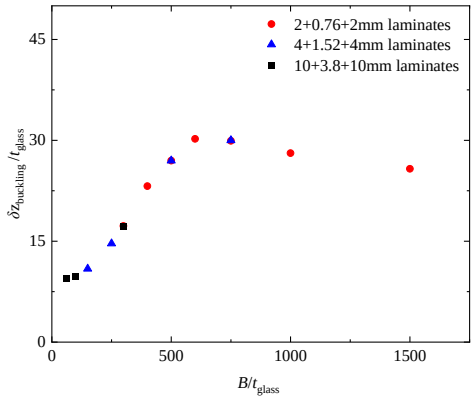

Figure 14. The relationship between $\delta z_{buckling}/t_{glass}$ and B/t_{glass}

4.5. Cold bending instability of laminated glass plate

The parameters analysis indicates that bifurcation instability is the dominant control condition for both monolithic and laminated glass plates. Different from monolithic glass, there are two types of configurations for laminated glass plates before bifurcation instability (Figure 13), which are defined as type 1 and type 2 in section 4.3. This section takes two examples illustrating these two configurations.

For type 1, laminated glass plate with laminate composition of 5mm+0.76mm+5mm and size of 800 mm×800 mm is selected for illustraion. Figure 15 presents the deflection and stress distribution of this example during cold bending process. The stress is the superposition of bending stress and membrane stress. The middle surfaces of both top and bottom glass plates in laminates are compressed in two diagonal directions during cold bending process, but the compressive stress distribution differs along two diagonals due to the influence of monolithic bending. The instability is caused by the collapse of the bi-directional compression area at the centre of plate (Figure 15f). There exists tensile stress in the middle surface of glass in laminates after bifurcation instability (Figure 15g).

For type 2, 1000 mm×1000 mm× (2mm+0.76mm+2mm) laminate is selected for illustraion. Figure 16 presents the deflection and stress distribution of this example during cold bending process. The layerd bending stress and membrane compressive stress are minimal, while the monolithic bending stress is evident compared to the stress distribution in type 1. Therefore, the mid-surface of the glass will always be tensile in one diagonal (Figure 16d). Different from monolithic glass, the cold bending deformation is larger before bifurcation instability because of the disappearance of the bi-directional compression zone in middle surface of the glass, then the edge of plate cannot maintain straight before bifurcation instability. However, the plate is still self-balanced and has stable bearing capacity before bifurcation instability.

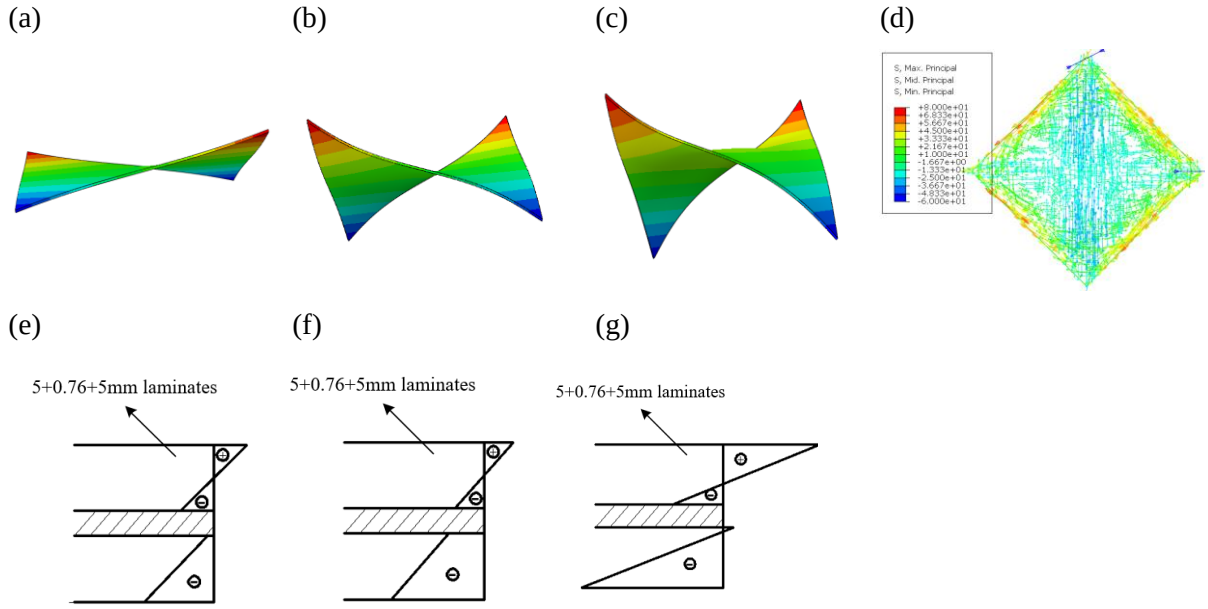

Figure 15. The deflection and stress distribution of (5mm+0.76mm+5mm) × 800 mm×800 mm laminate : (a) the deformation before bifurcation instability, (b) the deformation at bifurcation instability, (c) the deformation after bifurcation instability, (d) bi-directional compression stress at the middle surface of glass in laminate, (e) the stress distribution across the thickness before bifurcation instability, (f) the stress distribution across the thickness at bifurcation instability, (g) the stress distribution across the thickness after bifurcation instability.

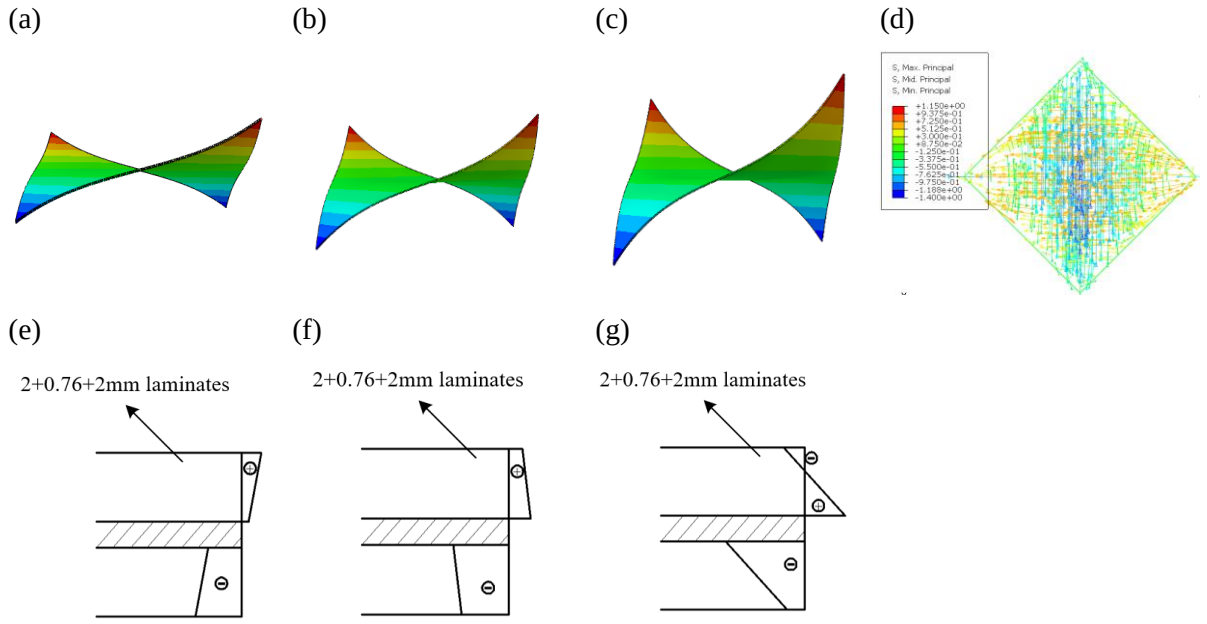

Figure 16. The deflection and stress distribution (2mm+0.76mm+2mm) × 1000 mm×1000 mm laminate: (a) the deformation before bifurcation instability, (b) the deformation at bifurcation instability, (c) the deformation after bifurcation instability, (d) compression and tension stress at the middle surface of glass in laminate.(e) the stress distribution across the thickness before bifurcation instability, (f) the stress distribution across the thickness at bifurcation instability, (g) the stress distribution across the thickness after bifurcation instability.

5. Summary and outlook

In this paper, the instability phenomena are summarized and instability modes are defined for monolith glass plate. The finite element models of laminated glass plates undergoing cold bending are established and verified, and then followed by parametic analyses. Finally, the cold bending instability of laminated glass plates are analyzed. Analysis results are summarized as follows:

(1) Two types of instability modes may occur during the cold bending of monolithic glass plates: bifurcation instability and cold bending distortion. The bifurcation instability is caused by the collapse of bidirectional compression area in the center of the glass plate. Cold bending distortion occurs after the bifurcation instability.

(2) Bifurcation instability is identified to be the only control condition for both monolithic and laminated glass plates.

(3) Laminated glass plate has better stability compared to monolithic glass plate due to the existence of the interlayer, and there are two types of configurations before bifurcation instability in laminated glass plates. The instability is caused by the collapsed of bi-directional compression area for type 1, while unidirectional compression area for type 2.

(4) Both hidden frame and roller point supports are suitable for cold bending. The compositions of laminated glass plates and width-thickness ratios influence the cold bending configurations before bifurcation instability and cold bending corner displacements at the bifurcation instability $\delta z_{buckling}$.

However, there are still some issues need further analysis in this research. Standards for controlling anticlastic cold bending need to be proposed for monolithic and laminated glass plates. A unified standard is possible with the introduction of equivalent torsion stiffness. Moreover, it's necessary to clarify the boundary between the two types of cold bending configurations before bifurcation instability for laminated glass plates.

Abstract

Free-form shells have been increasingly used in architectural applications owing to their aesthetically pleasing appearances and large span-to-weight ratios. Recently, topology optimisation techniques have been extended to shell structures, aiming to achieve innovative designs of free-form shells with improved material efficiency. However, despite its potential, the utilisation of existing topology optimisation techniques in the real-world architectural design of shells remains rare. This paper presents various strategies for optimising free-form shells that may be useful for architectural applications. First, we show that the ribs of shells can be optimised into free-form layouts with improved stiffness. Second, we demonstrate that topology optimisation can be combined with funicular form-finding techniques to generate diverse designs with high structural performance. Third, we illustrate how to combine surface tessellation and periodic constraints to achieve shell designs for cost-effective construction using repeated components. Finally, we present a new method that can optimise free-form shells with Voronoi patterns to facilitate aesthetic expression and functional design for architects. The presented strategies are useful for designing high-performance and innovative free-form shells for architectural applications.

Keywords: form finding, topology optimisation, shells, architectural design

1. Introduction

Shell structures are characterised by thin and curved forms that can span large spaces with minimal material. Due to their ability to utilise materials efficiently and provide aesthetic appeal, shell structures are commonly used in the construction of roofs, domes and other types of architectural structures. Despite their advantages, designing and constructing shell structures can be challenging due to their complex geometry [1]. It is generally difficult to find an optimised form of a shell structure that can sustain specific loads and boundary conditions, while also meeting aesthetical and functional requirements. Thus, there is a demand for innovative approaches that can effectively address these challenges and enable the seamless integration of shell structures in architectural design.

Topology optimisation can generate highly efficient and structurally sound designs that are difficult or impossible to achieve through traditional design methods [2]. This technique can be used to produce a wide range of optimised structures, including civil, mechanical and aerospace structures in engineering and to simulate optimised structures in nature [3]. Topology optimisation typically begins with a given design domain, which is then subjected to a set of loads and boundary constraints. Through a series of iterations, the material distribution is adjusted until the most efficient design is found. Several different methods have been developed for topology optimisation in the past few decades, including the Solid Isotropic Material with Penalisation (SIMP) method [4], the Evolutionary Structural Optimisation (ESO) method [5], the Bi-directional Evolutionary Structural Optimisation (BESO) method [6], the Level-set method (LSM) [7] and the Moving Morphable Component (MMC) method [8]. Among these, the SIMP and BESO methods are particularly popular in designing visually striking and highly efficient buildings and bridges, owing to their simplicity and robustness [9].

Despite the increasing use of topology optimisation by architects, its real-world applications on shells are still limited due to a dearth of guidelines and pioneering precedents. This paper aims to classify different topology optimisation strategies for architectural shell design, as shown in Figure 1, and demonstrate how they can be applied to produce more useful and innovative results to meet architectural design requirements. The remainder of the paper is structured as follows: Section 2 demonstrates the optimisation of free-form ribs for floors and shells. Section 3 illustrates that by combining topology optimisation with funicular form-finding techniques, a variety of designs can be generated with exceptional structural performance. Section 4 illustrates how to combine surface tessellation and periodic constraints to achieve shell designs for cost-effective fabrication. Section 5 introduces a novel algorithm that can optimise free-form shells with Voronoi patterns. Section 6 summarises the key points discussed and identifies potential areas for further study.

2. Optimising free-form ribs for shells

For shells in buildings, *beams* are often used as stiffened ribs to improve stiffness. Traditional techniques typically produce over-designed ribs for shells, resulting in excessive material usage. Recently, computer-aided methods have been created to facilitate the design of rib layouts; nevertheless, they still rely on the conventional experience of ribbed shell designs. To discard the traditional shape restrictions on the ribs and improve their stiffness contribution, we have developed a topology optimisation technique capable of producing free-form and high-performance ribbed shells. Figure 2(a) shows a ribbed shell designed with the proposed optimisation technique [10]. In this example, we optimise and compare the stiffness of our ribbed shell with that of a famous design in architecture. Our result shows a 26.3% increase in terms of structural stiffness with the same amount of material. Additionally, we demonstrate that using a hybrid digital approach to mould fabrication is feasible and sustainable for constructing free-form ribbed shells. The developed technique is also applicable to the design of curved ribbed shells [11], as shown in Figure 2(b).

(a) (b)

3. Optimising free-form shells in funicular forms

In traditional shell design processes, the curvature form of a shell is typically prescribed. A curved shell can be modified by manually adjusting its curvature through trial and error, which is time-consuming and could result in low performance. Here, we show how topology optimisation can be combined with funicular form-finding techniques to generate diverse and efficient shell designs for a real building project. Figure 3(a) shows the floor plan of a building proposed by our industry collaborators, including 11 pillars and 12 walls below the roof. By configuring different support locations on the pillars and walls, distinctly different roof shells in funicular forms can be obtained using the commercial software Kangaroo (Version 2.42) [12]. The left-hand side of Figures 3(b–d) shows three examples of the resulting funicular roofs. Subsequently, topology optimisation can be performed on the three distinctive funicular shells to generate diverse roof designs with exceptional structural performance. The right-hand side of Figures 3(b–d) shows the optimised topology using BESO under gravity [13]. Note that funicular form-finding techniques usually generate shells with different amounts of material under different boundary conditions; thus, the volume constraint in topology optimisation shall be chosen accordingly by the designer, considering the functions, aesthetics and material usage factors. In the cases of Figures 3(b–d), the target volume fractions of topology optimisation are 30%, 63% and 63%, respectively. This case testifies that by simply combining topology and curvature optimisation techniques, diverse shell designs possessing unique curved shapes and optimised topologies can be generated on a single floor plan.

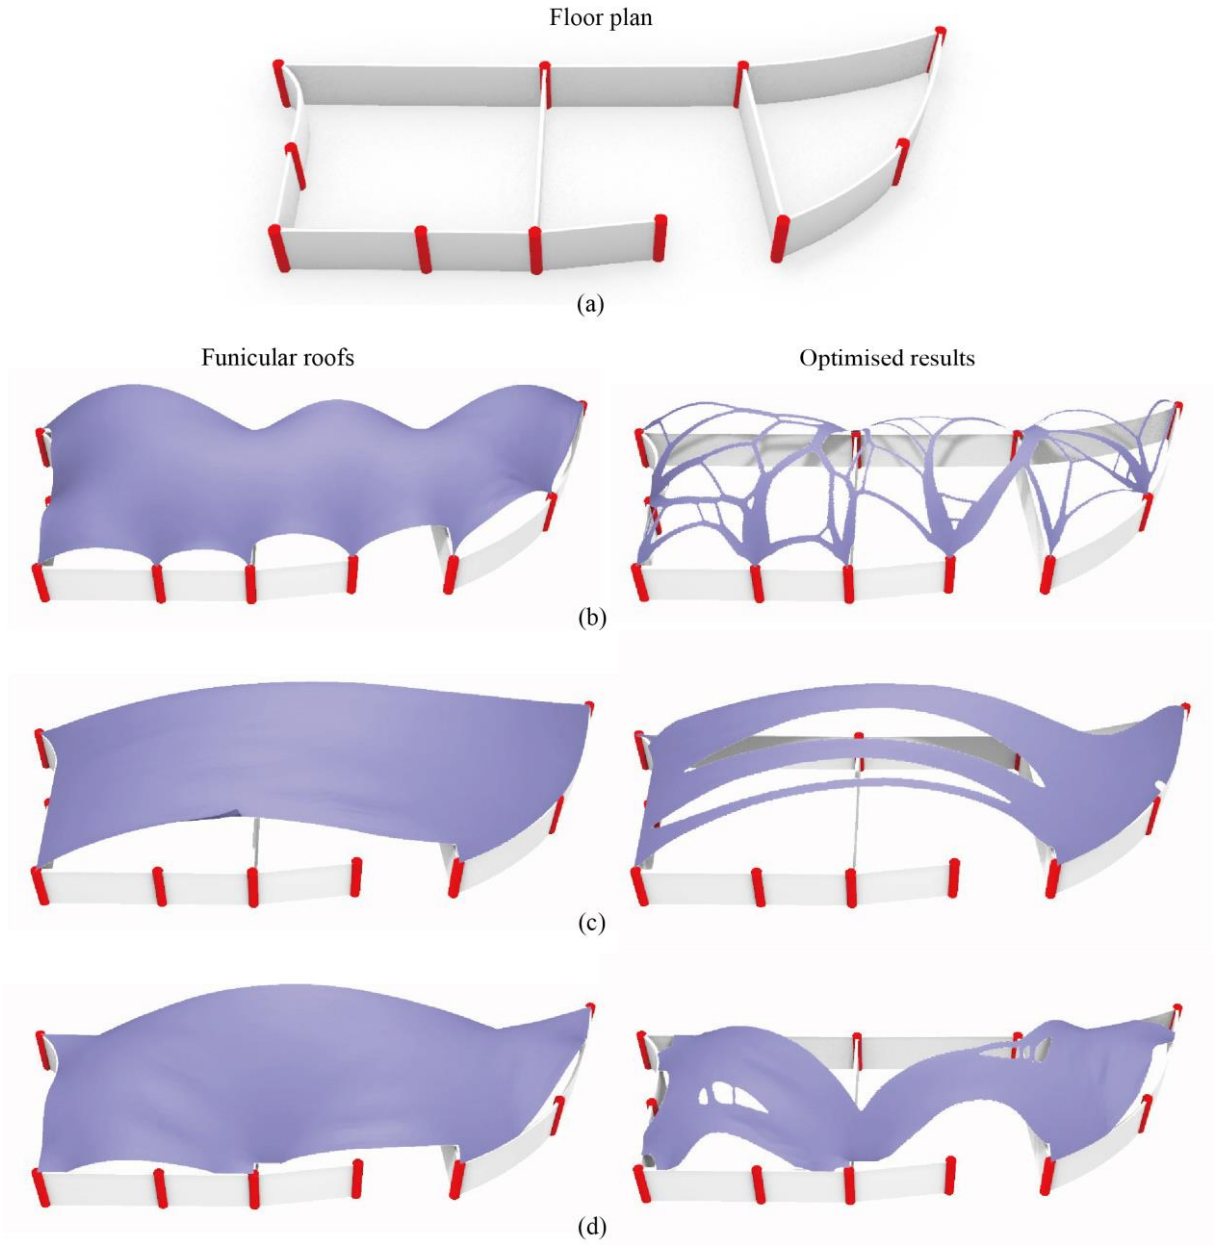

Figure 3. Funicular shells with different support locations and their topology-optimised designs: (a) floor plan, (b) a shell supported purely by columns, (c) a shell supported at the two ends and (d) a shell supported by columns and partially selected walls.

4. Optimising free-form shells with surface tessellation and periodic constraint

The fabrication of shell structures, especially with complex curvatures, is often difficult to perform accurately and within budget in real projects. One of the simple approaches to overcoming this challenge is to tessellate a curved shell with planar panels. Using this method, the general form of the shell can be maintained while the fabrication turns from a 3D problem into a 2D one, which is simpler and less expensive. Furthermore, several techniques have been proposed recently that can reduce the category of panels for shell tessellation [14, 15]. Figure 4 shows a symmetrical curved shell tessellated into multiple planar panels. Note that all the panels at the same axial position have the same shape. In this case, the shell in Figure 4(a) can be fabricated by using only three different categories of planar panels, as shown in Figure 4(b), which can reduce the fabrication costs enormously.

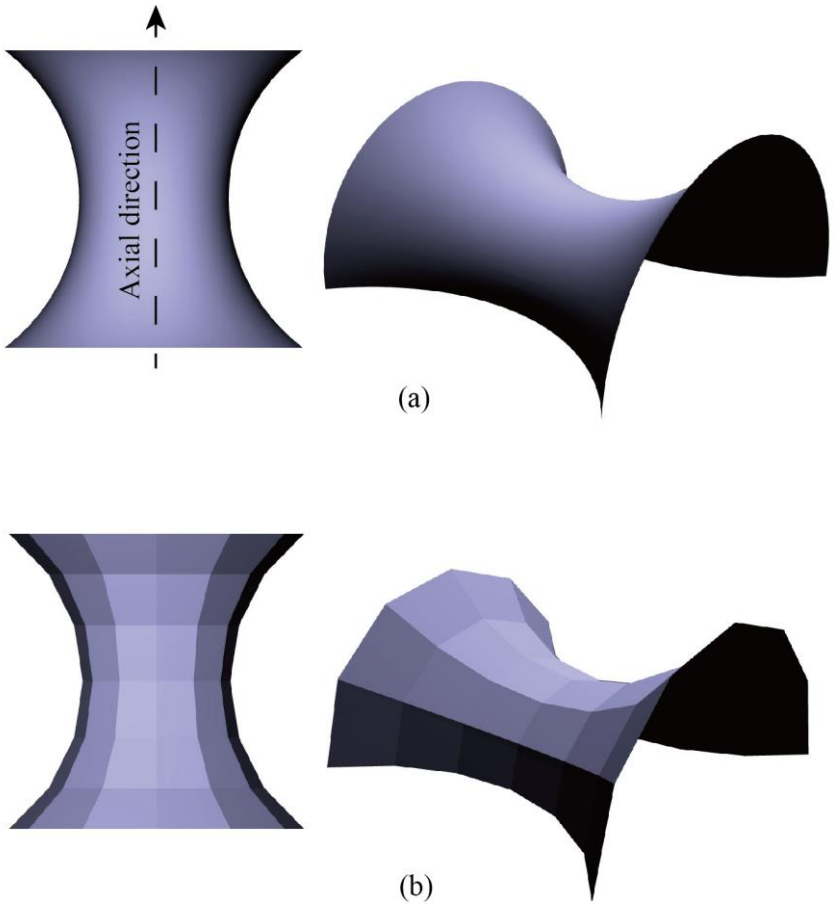

Figure 4. A free-form shell in its (a) curved form and (b) tessellated form.

Nevertheless, since panels within the same category are located at different positions of the shell and thus bear different loads, those panels will have distinctively different internal geometries after topology optimisation. Figure 5(a) shows an optimised design of the shell in Figure 4(b) under gravity using BESO. Non-design solid edges are applied to each panel to improve structural integrity and connectivity. To fabricate the whole shell structure, nine different panel categories are required, which are shown in different colours alongside the structure. Hence, the advantage of using category-reduced tessellation has disappeared. To overcome this setback, periodic constraints can be incorporated into topology optimisation, so that panels in the same category will have the same topology [16]. For example, a simple periodic constraint can be achieved by averaging the sensitivities of panels in the same category during the optimisation process. Figure 5(b) shows the optimised result after applying the period constraint. The panel category number is reduced from nine to three, which has great cost-saving benefits if the shell is to be built using casting. Meanwhile, the compliance is only increased slightly by 13%. Although the combination of category-reduced tessellation and periodic-constrained optimisation sounds trivial, it may significantly reduce the difficulty and costs of fabricating a free-form shell structure and hence would be useful for designers.

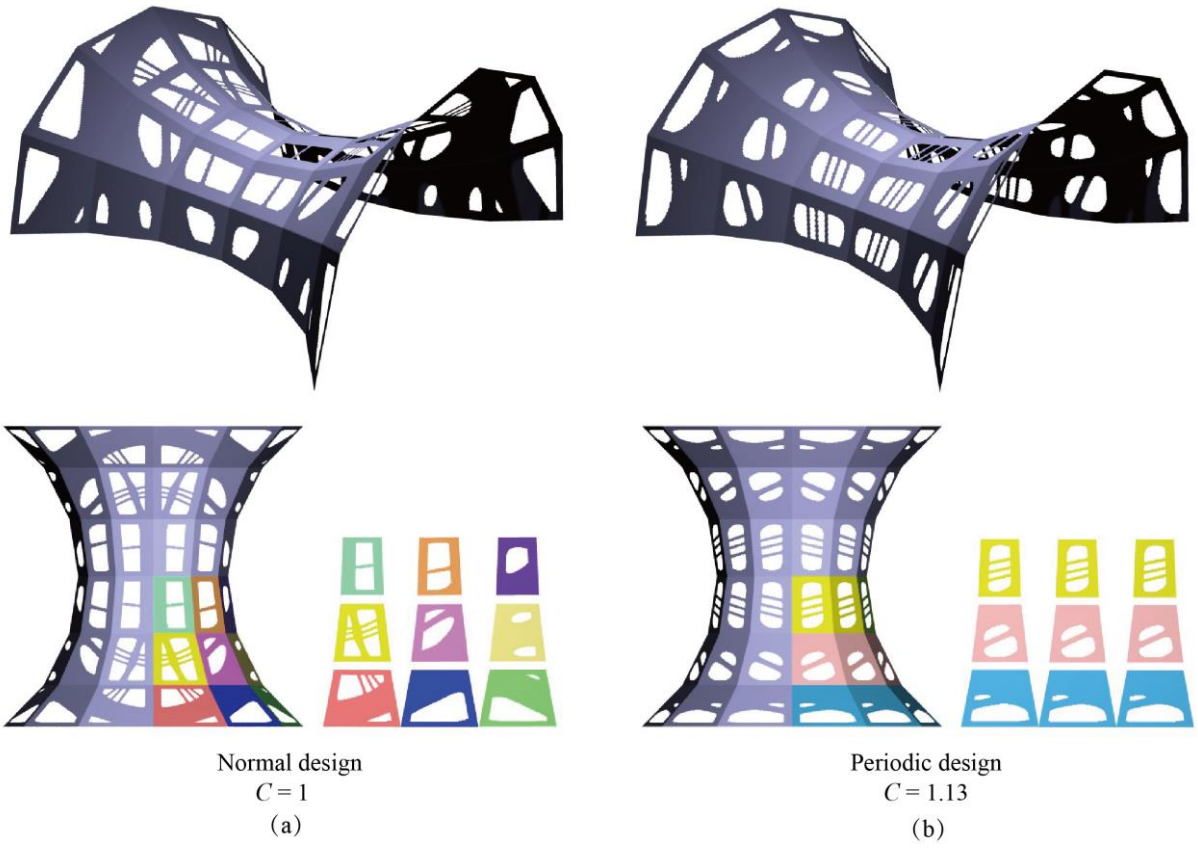

Figure 5. Topology-optimised roof with surface tessellation: (a) without periodic constraint and (b) with periodic constraint.

5. Optimising free-form shells with Voronoi patterns

Although optimising the curvature and topology of shells can maximise their structural performance, the results can be less readily accepted by architects due to their low aesthetic and functional values in architectural practice. In particular, large open spaces in the optimised results usually cannot satisfy buildings' functional requirements, and the unique solutions from traditional topology optimisation often lack artistic expression. To surmount this obstacle, multiple schemes have been proposed in topology optimisation for architecture applications, for instance, diverse and competitive design strategies [17, 18] and local volume constraints [19]. Apart from the existing methods, we advocate that customised design patterns can be integrated with topology-optimised results. Here, we develop a new method to integrate topology-optimised shells with the Voronoi pattern.

The workflow of the proposed method is demonstrated through a shell example as shown in Figure 6. By taking the advantage of symmetry, topology optimisation is performed on a quarter of the shell (i.e., Figure 6(a)) using the SIMP method. Figure 6(b) displays the boundary conditions of the optimisation setting as well as the resulting optimised structure at a 30% volume constraint. Then, by discretising the shell into multiple cells and generating seeds based on the average density of each cell from the optimised result, 3D Voronoi polyhedrons can be developed and projected onto the original shell surface, as indicated in Figures 6(c, d). As can be seen, more seeds are generated in the darker regions of the optimised result; consequently, the Voronoi polyhedrons become denser in those areas to eliminate large cavities. To further improve the organic appearance of the design, randomness can be introduced to the seeds' coordinates. Afterwards, the width of the structural members can be adjusted to precisely control the volume of the final structure. Figures 6(e, f) show the final shell in a quarter and a full model. Spline curves are implemented to smooth the Voronoi pattern. In this case, the solid region

from the optimised results and the non-design domain near the edges are reserved to improve the functionality and aesthetics of the shell. The large open cavities in the topology-optimised design, which is less practical in building applications, are eliminated.

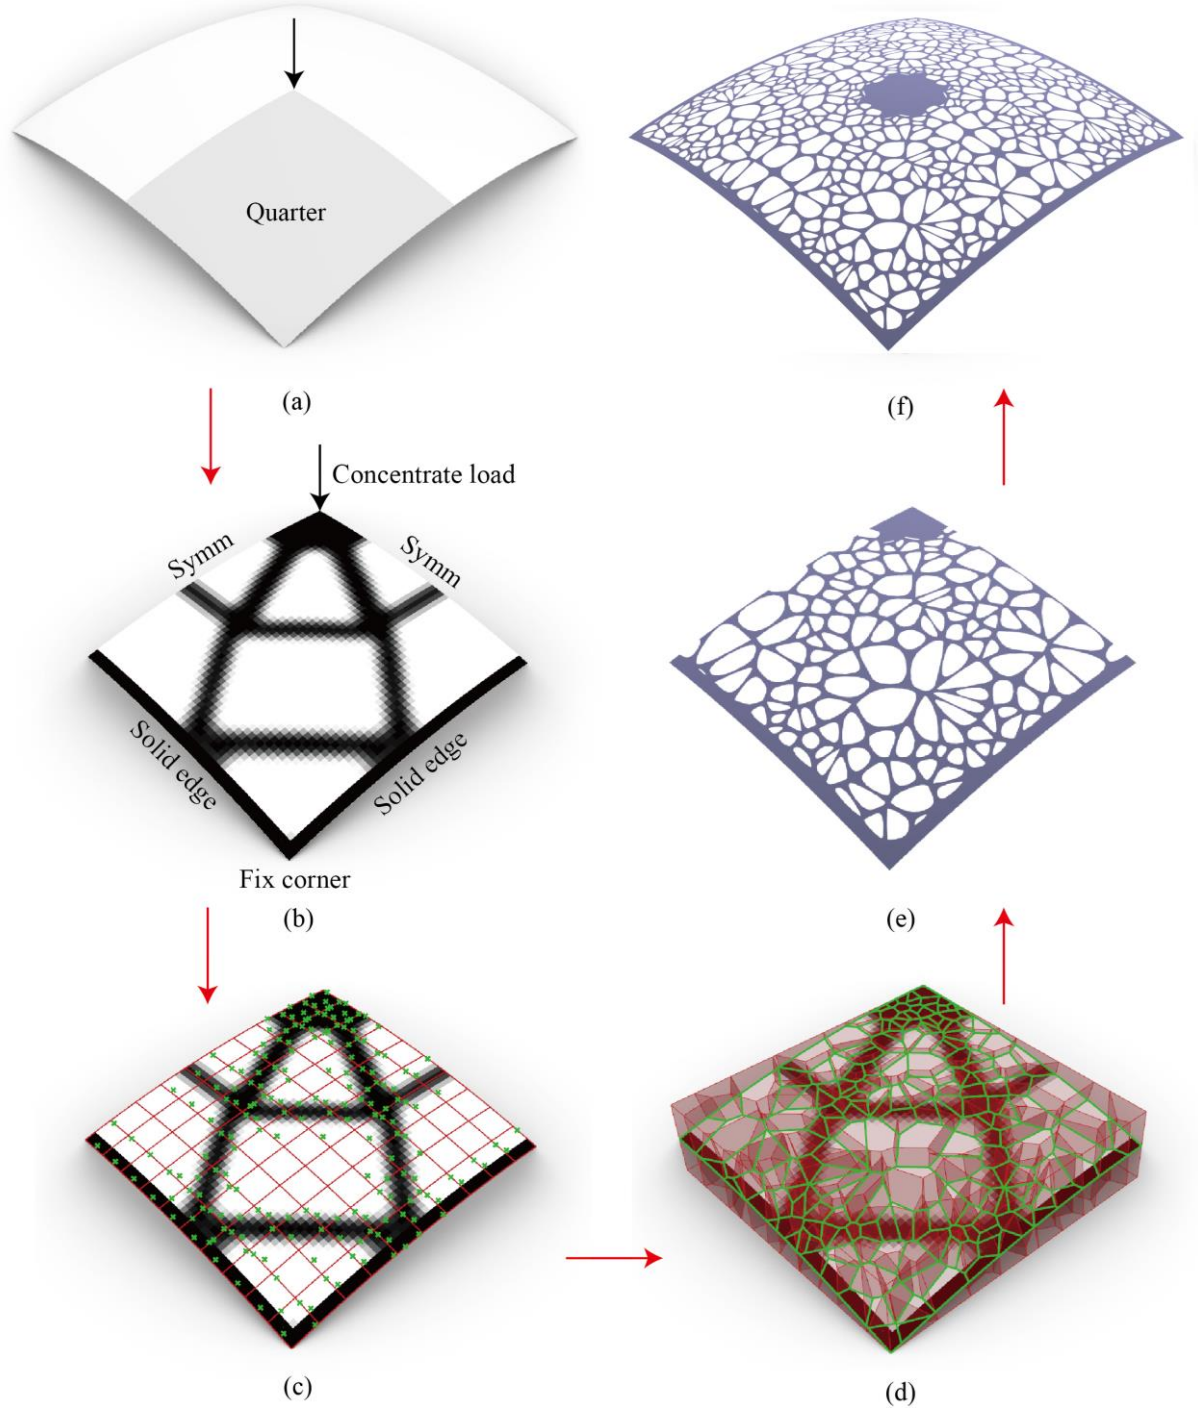

Figure 6. Shell design with topology-optimised Voronoi patterns: (a) initial shell model subjected to a concentrated load; (b) boundary conditions and the topology-optimised result of the quarter shell; (c) discretised shell, with seeds generated in each cell based on the average density; (d) project 3D Voronoi polyhedrons to the original shell; (e) final optimised design of the quarter shell in Voronoi pattern; (f) final shell design.

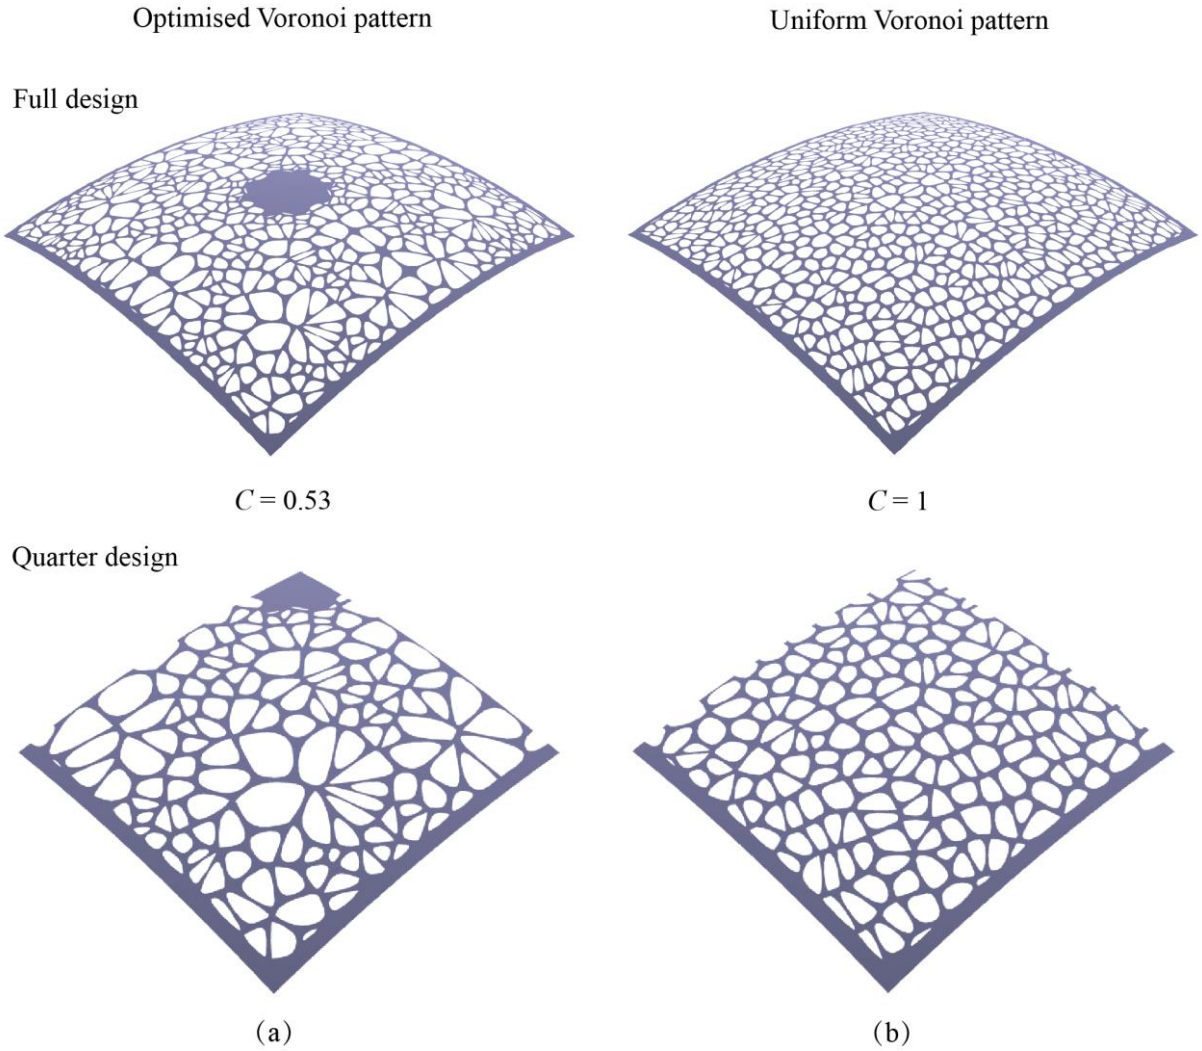

Figure 7. Shell design in Voronoi patterns (a) with topology optimisation and (b) without optimisation. *C* denotes normalised structure compliance.

To demonstrate the improvement of structural performance by generating Voronoi patterns based on topology-optimised results, we present and compare the Voronoi-patterned shell undergone topology optimisation against the one without having it. Figure 7(a) shows the optimised design from Figure 6, which has more materials and smaller cavities allocated to the darker regions of the topology-optimised result. In comparison, a shell with a uniformly distributed Voronoi pattern is generated with the same material volume. The non-design domains of the solid edges are also reserved. By performing finite element analysis on both designs, the normalised structural compliances of the optimised shell and the non-optimised shell are obtained as 0.53 and 1, respectively. Therefore, the structural stiffness of the optimised shell has increased by 88.7% compared to that of the non-optimised shell. In addition to the Voronoi pattern, other customised patterns developed by architects also hold the potential to be combined with topology optimisation to generate aesthetically pleasing and functionally satisfying shells.

6. Concluding remarks

In this paper, we have demonstrated several effective topology optimisation strategies for free-form shells for architectural applications. We reveal that topology optimisation can be used to generate structurally efficient and aesthetically pleasing designs for both the ribs and the surfaces of shells. By

extension, we show that curvature optimisation techniques and tessellation techniques can be combined effectively with topology optimisation to achieve diverse and cost-friendly designs for shells, respectively. Furthermore, we show that customised design patterns, such as the Voronoi pattern, can be integrated with topology optimisation to reflect the aesthetic and functional considerations of architects and engineers in shell design. The strategies presented in this paper are generally applicable to commonly used topology optimisation techniques and are expected to facilitate real-world applications of topology optimisation in architectural shell design projects.

Abstract

Honeycomb core sandwich panels can achieve light weight, sufficient rigidity, and strength and are used in various engineering applications, including aircraft, space craft, and architecture. However, the formability of standard hexagonal honeycomb cores is low because they deform into an anticlastic shape during bending. Therefore, several special honeycomb cores with good curved surface moldability, such as flex and OX cores, have been proposed. Researchers have also proposed techniques for directly producing 3D honeycomb cores. However, these special honeycomb cores have poorer mechanical properties than the standard hexagonal honeycomb cores. In addition, their complex shapes increase manufacturing costs. Herein, we propose a simple and flexible honeycomb core with tetragonal cells. The characteristics of the proposed flexible honeycomb cores are (1) excellent mechanical properties owing to their cylindrical-like cell shape and (2) ease of manufacturing. In this study, the deformation of cells was analyzed using an algorithmic design tool by assuming that each facet deforms only on the edges and diagonals. Our results demonstrate that the tetradecagonal honeycomb cores realize curvature on the panels due to minute strains on the cell walls.

Keywords: honeycomb, structural design, form-finding, optimization, origami, kirigami, Hangai Prize applicant

1. Introduction

Honeycomb core sandwich panels exhibit excellent mechanical properties, including high specific strength and rigidity. This structure has been investigated primarily for applications in the aerospace

industry. In addition, this lightweight structural material works as an engineering solution in architecture, for example, for constructing roofs and doors. However, the formability of a regular hexagonal cell is limited because segments A and B cannot remain parallel when forced into a curved state, as shown in Figure 1(a). Therefore, the curvature of the cores results in anticlastic behavior (Figure 1(b)).

Consequently, flexible honeycomb cores composed of special cells, such as Flex or OX cores, have been developed to form monoclastic or synclastic shapes [1]. However, these cores are more expensive than regular honeycomb cores owing to their more complex manufacturing processes. We previously demonstrated the process of manufacturing from a flat sheet using origami technology [2][5]. Although this method enables the manufacture of an arbitrary cross-sectional core, the stiffness of the core is reduced because the cell walls do not stand perpendicular to the curved surfaces. In this study, we demonstrate that flexible honeycomb cores composed of tetragonal cells exhibit excellent formability and high stiffness. The cores are manufactured using simple crease patterns and origami technology. Furthermore, simulations of the rigid folding model using an algorithm-based design tool illustrated the relationship between the shape parameters and the formability of the honeycomb cores.

The remainder of this paper is organized as follows. The second subsection describes the manufacturing method of tetradecagonal cells using origami technology and the mechanism to follow curved surfaces. The third subsection illustrates the design method of the cell shape using an algorithm-based design tool and details of the simulation when the cell is forced into a curved state. The fourth subsection establishes the relationship between the formability and shape parameters of the cell based on the simulations. Finally, the fifth subsection presents the conclusions and outlook of the study.

2. Tetradecagonal cells honeycomb core

2.1. Crease patterns of flexible honeycomb

In a previous study, we proposed a honeycomb core with a combination of tetragonal and hexagonal cells, as shown in Figure 2(a). This type of cell exhibits synclastic behavior without any reduction in the mechanical properties, as the segments stand perpendicular to the curved surfaces [6]. However, it requires complex manufacturing processes owing to non-orthogonal crease patterns. Therefore, we proposed an improved cell shape for easy production, as shown in Figure 2(b). This newly proposed honeycomb core has tetradecagonal cells folded from the crease patterns with only parallel or orthogonal crease lines (Figure 2(b)). This method enabled the manufacture of flexible honeycomb cores with excellent formability using simple crease patterns.

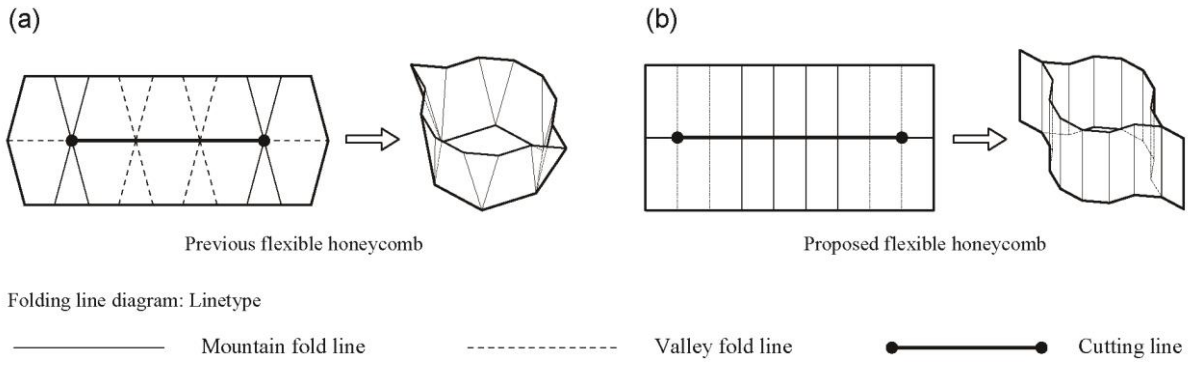

Figure 2. Crease pattern from the flexible honeycomb:
(a) Previous model, (b) Proposed model

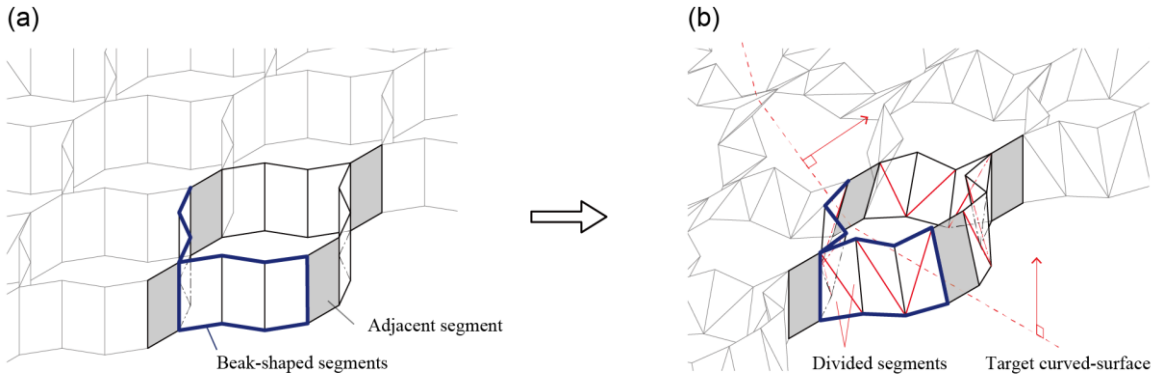

Figure 3. Proposed honeycomb core deformation:
(a) before deformation, (b) after deformation into curved-surface.

2.2. Mechanism to follow curved-surfaces in tetradecagonal honeycomb core

The tetradecagonal cells used in the present study had beak-shaped segments. When the core is forced to curve, the beak-shaped segments are divided into triangular components using diagonal lines [7]. This resulted in opening and closing of the beak-shaped segments opened and closed, causing the contorted segments to form a curved surface (Figure 3).

The cells stood perpendicular to the curved surface and retained their strength.

3. Simulation using of the rigid folding model

In this study, numerical simulations were performed to determine the effects of the geometric parameters of a tetragonal cell on the bending properties of a honeycomb core. Finite element analysis (FEA) is generally required to analyze the deformation of a cell when a honeycomb core panel is subjected to bending [8]. However, the FEA of a cell structure, such as a honeycomb structure, is time consuming because of the large number of elements.

Therefore, we propose a method to obtain the relationship between the curvature of the panel and the deformation of the cell diagrammatically by applying a rigid folding simulation. Our approach is based on the assumption that cell deformation can be accomplished using the crease line and diagonal folding

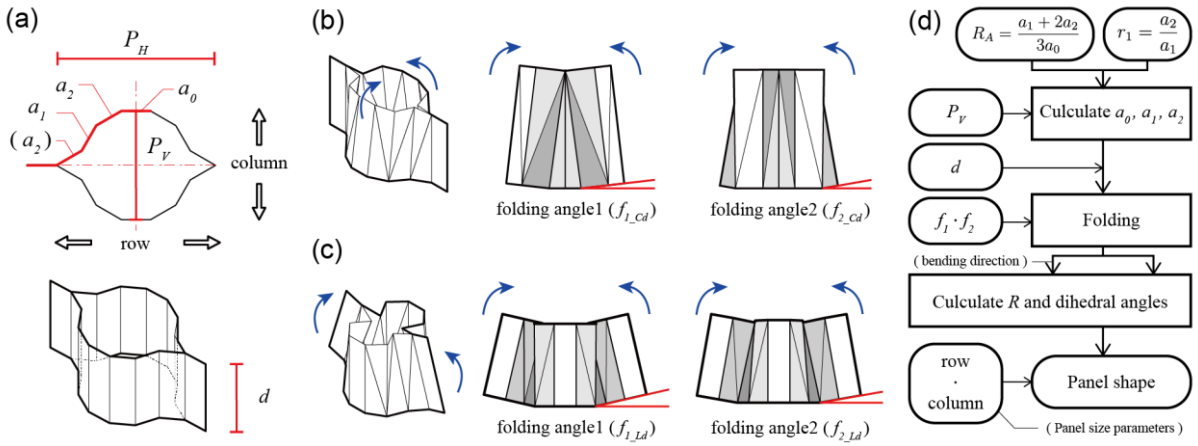

Figure 4. The shape parameters of honeycomb core and the flowchart of the algorithm:

angle of each rectangular segment. We simulated a rigid folding model of tetragonal cells with Rhino 7.0 (Robert McNeel & Associates) and Grasshopper [9], an algorithm-based design tool, to investigate the formability of the cells when bent into a monoclastic surface. Figure 3 illustrates the cell shape and flowchart.

The unit cell deformation was calculated using the following process: First, we define the cross-sectional shape of the unit tetradecagonal cell, as shown in Figure 4. The parameters P_V, R_A, and r_1 are set to model the cell size and shape. The edges of a tetrahedron can be represented by three parameters, a_0, a_1, and a_2, based on the symmetry of the cells (Figure 4(a)). Two parameters, R_A and r_1, representing these relationships, were defined to represent the geometry. When the cell outline coincides with a regular dodecagon, R_A=r_1=1.. In this regard, a_0 represents the edge length of the segment adjacent to the next cell, a_1 is the length of the connection to the beaked-shaped segment, and a_2 is the length of the beaked-shaped segment. R_A corresponds to the ratio of triple a_0 to the sum of a_1 and a_2 and r_1 signifies the ratio of a_1 to a_2.

P_H denotes cell length based on a regular dodecagon. It can be calculated using P_V and a_2 as follows:

$$P_H = P_V + 2\,a_2 \cos\theta \tag{1}$$

Second, the coordinates of the original vertices are determined from P_V, R_A, and r_1 (Figure 5(a)). Using the symmetry of the honeycomb core, P1-P2 and P3-P4 were assumed to be parallel. Third, the coordinates of the three-dimensional vertices were sequentially calculated from the lengths of edges a_0, a_1, a_2 and the thickness d of the core panel (Figure 5(b)). Segments 0 and 7 remained parallel to adjacent

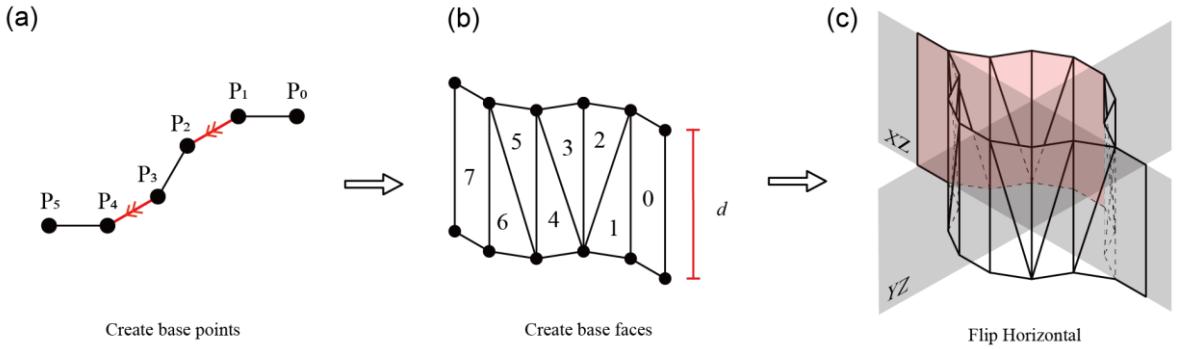

Figure 6. The process of modeling cell:

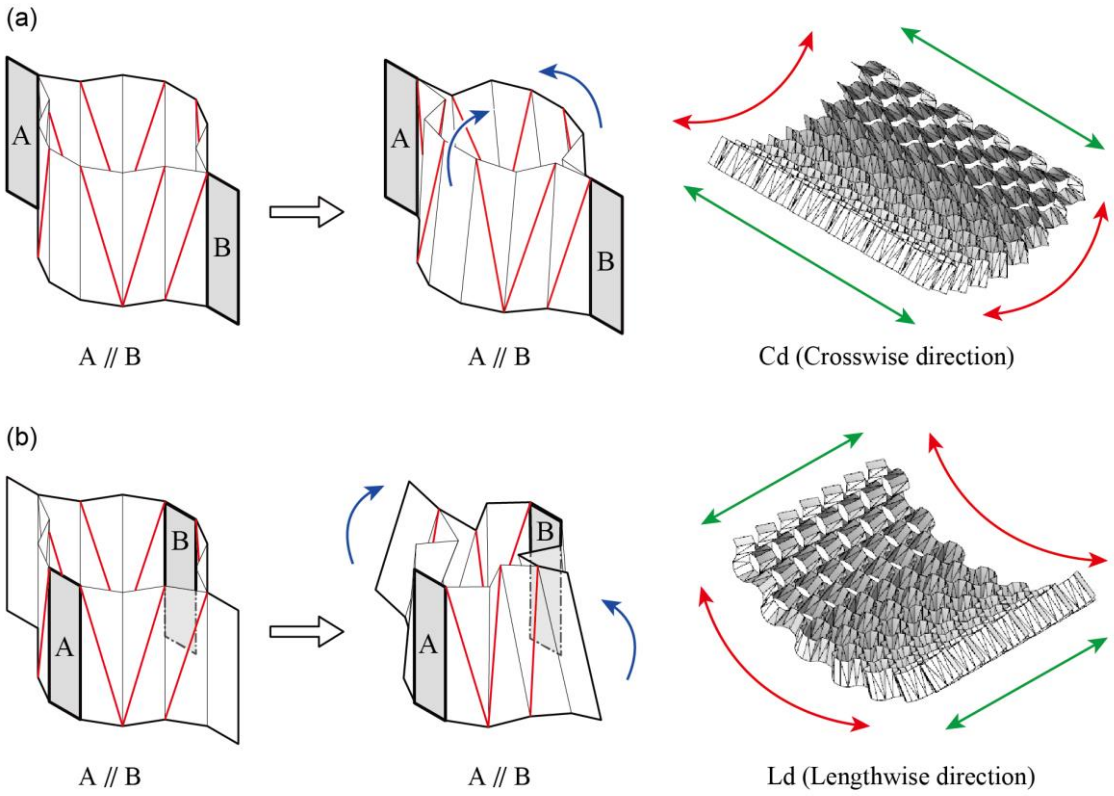

Figure 7. Bending the tetradecagonal honeycomb core:
(a) Crosswise direction, (b) Lengthwise direction.

cells following the bending direction. In addition, the twisting of the cell was attributed to the rigid body deformation as a diagonal fold. Furthermore, the symmetric part of the cell was inverted through its center on the XZ and YZ planes (Figure 5(c)).

In a rigid-fold unit cell with diagonals, if cells A and B are constrained in parallel, the positions of the other vertices can be determined graphically using the values of f_1 and f_2 (Figure 3). Thus, a computational algorithm was developed within the Grasshopper framework to ascertain the shape of the cell and the curvature of the panel. Finally, the cell was bent in the crosswise and lengthwise directions (Cd and Ld) by independent parameters of the folding angle (f_1 and f_2) to a cylindrical panel (Figure 6).

4. Curvature radius and dihedral angle analysis

The radius of curvature, R is the distance from the base of the segment to the adjacent cell to the intersection of the extension lines on the segments (Figure 7).

For simplicity, we assume that the spring constant of each hinge is directly proportional to the length of the fold line, and that the elastic energy stored in the fold line is proportional to the variation in the spring constant and the square of the fold line. Accordingly, we define the generalized energy using the following equation:

$$E = \sum_{i=0}^{4} l_i \cdot \Delta\theta_i^2 \tag{2}$$

We simulated the energy generated within the crease line when the curvature was specified for various models possessing distinct geometrical parameters, and found a combination that could generate a large curvature with less energy and high formability.

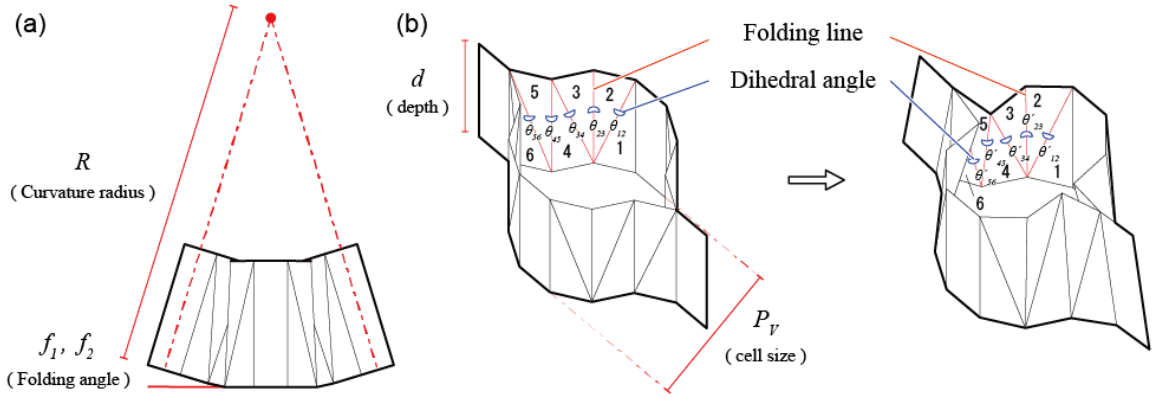

Figure 8. The parameters used to calculate the bending energy:
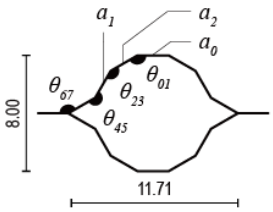
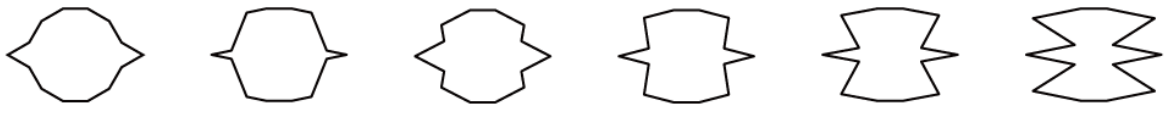
(a) Curvature radius, (b) Folding lines and dihedral angles.



In this simulation, the cell parameters were P_V = 8.0 (mm) and d = 4.0 (mm). The values of *1/R* and *E* with the various combinations of R_A and r_1 were compared. The combinations of R_A and r_1 used in the simulations are listed in Table 1 below.



As f_1 and f_2 are independent variables that determine the curvature of the panel, multiple possible combinations exist for a particular curvature. The calculations utilized the values of f_1 and f_2 that yielded the minimum energy.

The value of f_{1_min} which minimizes *E* at a certain radius of curvature *R*, is calculated first since the deformation with the smallest energy is reasonable. The continuous variation in f_2 at f_{1_min} indicates the correlation between *1/R* and *E*.

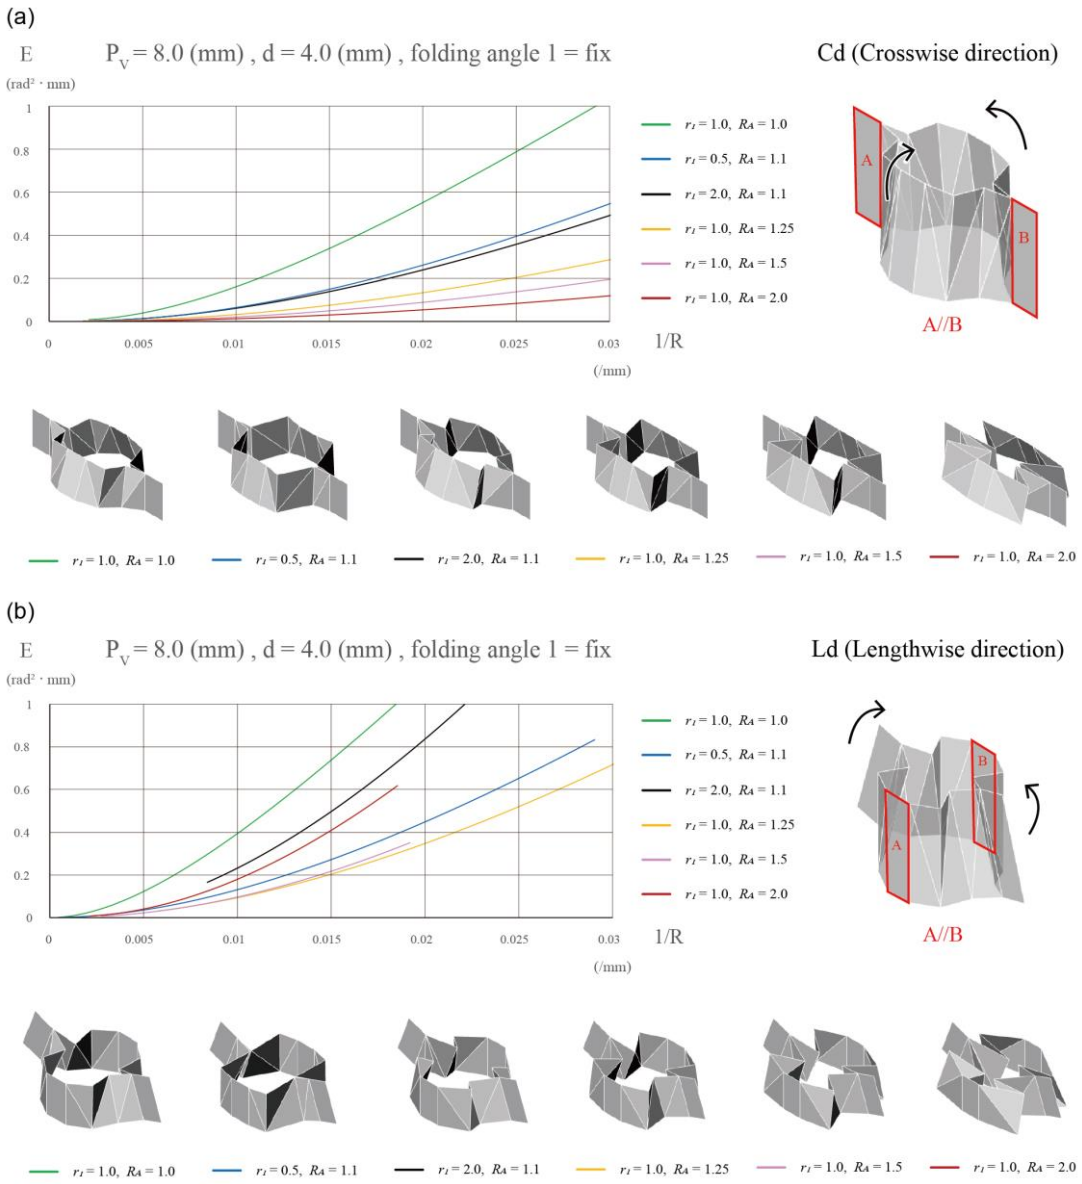

Figure 9. Calculation of *1/R* and *E*: (a) Crosswise direction, (b) Lengthwise direction.

Cd: Increasing R_A significantly improved formability. For r_1, the formability is improved by large values of R_A; however, the difference is nearly 15 times larger than that for the model with a large R_A.

Ld: As with Cd, the formability improved when R_A increased, but decreased when R_A exceeded 1.5.

Although other mechanical properties such as compressive strength should be considered when determining the actual parameters, the proposed method allows for the selection of a cell shape with high formability under the given conditions.

5. Conclusion

This study demonstrates simple manufacturable tetradecagonal cores using origami technology. The core was simulated using Grasshopper, an algorithm-based design tool. This rigid folding simulation

revealed the main formability parameters in each bending direction on cylindrical surfaces. The results demonstrate that increasing the R_A parameter leads to improved formability in the deformation of Cd. However, the formability of the deformation for Ld is improved if R_A is close to a certain value.

These findings indicated the possibility of designing a cell with high formability in each bending direction. In particular, this enabled the optimization of the value of R_A in the deformation of Ld. In addition, the value of r1 represents a trade-off between Cd and Ld, and the cell shape can be optimized depending on the curved surface.

6. Outlook

In this study, we have only described the main cell parameters of formability in unidirectional bending along cylindrical surfaces and have not yet evaluated the formability in bidirectional bending, such as synclastic surfaces. The effect of strain on the segment and variations in stiffness along the folding line are not considered in the simulation. It is anticipated that these effects can be disregarded due to the small deformation. However, we are preparing a further experimental validation with paper-made honeycomb cores. In addition, further verification is required to evaluate the mechanical properties of the structural material upon changes in cell parameters.

Abstract

Recent investigations on foldable structures and particularly foldable tubes, raise the question if they can be advantageous for the construction of bridge-like beams. Transporting a flat packed structure on site and deploying it there, instead of bringing or constructing the structure on site will have a positive impact on the grey energy. Although a straight beam shows a better performance than a folded one with identical cross-section, the energy saved in transportation might justify the effort. In order to be able to answer this complex question, many steps and investigations need to be done. This paper will answer some questions concerning foldable structures and their geometry-related structural performance. During the ongoing research on T-hedral tubes, the authors developed a strategy to generate flat-foldable tubular beams, on which this particular investigation is based. For the paper at hand a set of these beams, with different cross-sections and variable amount of folds will be compared with respect to their structural performance. The study will focus on their geometry without exact detailing of the hinges or the material thickness. With the help of a parametric model a generic solver [1] and a FEM-module [2] the authors developed a method that evaluates the beams based on their weight after optimisation, in final unfolded state as well as in different configurations during unfolding.

Keywords: structural origami, folding, computational design, bridge building

1. Introduction

Recent advancements in the field of technical folding and structural origami have led to numerous innovative approaches for various applications. The development and investigation of new folding systems [3][4], along with experiments on a larger scale, have led to the assumption that large scale folding [5] could become more influential in the building industry.

Although new folding algorithms are often presented with freeform shell geometries, the building industry has often higher interest in simple beams or slabs. Elements that can be unfolded on site are often related to disaster relief. One interesting example in this context is the foldable bridge by Ario et al. [6]. Foldable plates structures of rigid material that can be folded on site, are not yet known to be implemented in the building industry.

During the research on foldable polyhedral tubes of the T-hedral type [7] the authors developed two variations of a flat foldable structure, that have a high potential for a beam-like application, as they can be transported in a small package and unfolded on site to their final configuration. Starting from the feasibility of foldable models with only one degree-of-freedom (1-DoF), the investigation towards realisation requires a validation of different folding concepts concerning their stiffness in relation to

their global geometry. In this paper a folded structure is evaluated through its mass after an optimisation process, that reduces the cross-sections of each element in the structure to be as light as possible. Doing so, we can evaluate the global geometry by its weight after optimisation. If certain boundary conditions as e.g. a fixed span are introduced, an algorithm can search for the lightest geometry, and therefore find the best variant.

As geometric and mechanical constraints allow for different geometric solutions, the authors developed a parametric set-up for their particular systems, in order to find optima within the corresponding solution space. After discussing the chosen geometric constraints, the paper focuses on the evaluation of a series of optimisations, to find the best shape for a 20-meter spanning bridge beam.

2. T-hedral tubes

We aim to design a transformable bridge that exploits the potential offered by polyhedral tubes composed of planar quads (PQ) connected by rotary joints. PQ-meshes in the combinatorics of a square grid with cylindrical topology are generically rigid, but certain geometries allow for a 1-parametric change of the dihedral angles without any deformation of the PQ-panels. This rigid-folding of the whole tubular structure can be controlled by a single actuated rotary joint. Beside this 1-DoF flexion, which can be used for a compact (even flat) folding for transportation, additional properties like a lightweight construction, make these structures suitable to be utilized in kinetic architecture and, in general, transformable design. A close look at the literature [7] on rigid-foldable tubular structures, composed of planar quads where each interior vertex has valence four, reveals that most of the known examples belong to the class of *T-hedral tubes*, which can be generated as follows:

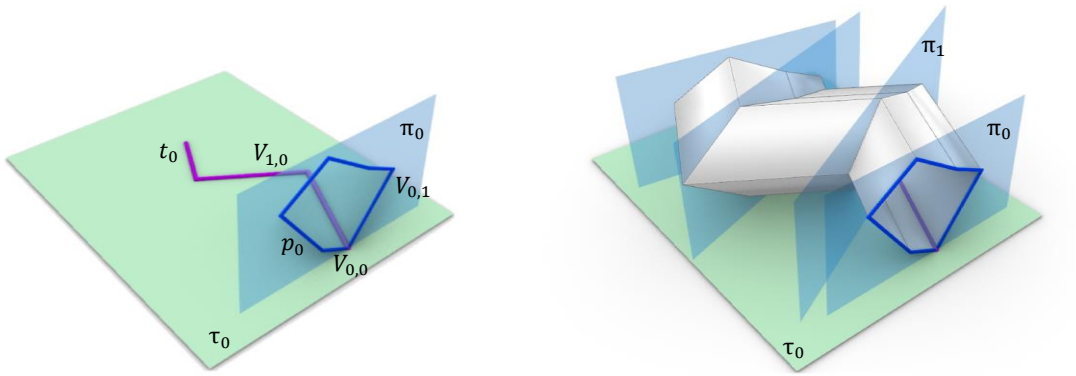

Figure 1. Construction of a T-hedral tube

We start with a planar, closed polygon p_0 located in the plane π_0 and a planar polygon t_0 whose carrier plane is denoted by τ_0 (Figure 1). Moreover, p_0 and t_0 have a common vertex $V_{0,0}$ and the planes π_0 and τ_0 are intersecting orthogonally. The remaining vertices of t_0 and p_0 are denoted by $V_{i,0}$ and $V_{0,j}$, respectively, with $i = 1, \dots, I-1$ and $j = 1, \dots, J-1$. Through each vertex $V_{i,0}$ of t_0 there is a plane π_i orthogonal to the *base plane* τ_0. By a parallel projection of p_{i-1} into the plane π_i along the direction of the polygon edge $V_{i-1,0}V_{i,0}$ of t_0, we obtain the planar polygon $p_i \in \pi_i$. Under this projection the vertices $V_{i-1,j}$ are mapped to $V_{i,j}$. Iteration of this process (for $i = 1, .., I-1$) generates the vertices of the tubular quad-mesh, which has planar trapezoidal faces as the sides $V_{i-1,j-1}V_{i,j-1}$ and $V_{i-1,j}V_{i,j}$ of every quad are parallel. Note that the letter T, stands for trapezoidal, in the nomenclature T-hedral tube. In order that the resulting tube is rigid-foldable the planar closed polygon p_0 has to meet the *loop closure condition* for which we refer to Theorem 3.1 of [7].

It is well-known [8] that T-hedral tubes reach their flexion limits as soon as either a PQ-loop gets completely flat (Figure 2a) or a PQ-strip gets parallel to the base plane (Figure 2c). In the latter case the tube can also transition from one working mode to another. As a consequence, the T-hedral tube can only flex back in such a bifurcation configuration, but the PQ-strip can flip to the opposite side (Figures

2b and 2d). Therefore, this property is also known under the notion of switching [9].

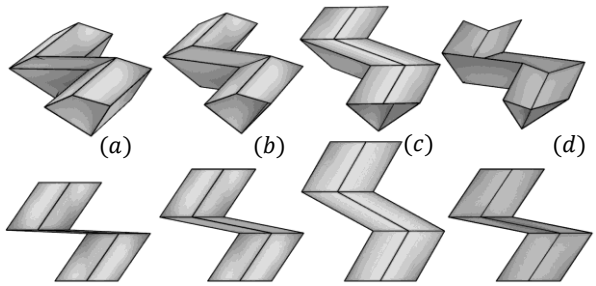

Figure 2. Illustration of the flexion limits (a,c) and working modes (b,d) on basis of a T-hedral tube with deltoidal cross-section in perspective (top) and top views (bottom)

2.1. Specifications for the bridge design

To keep the bridge design as simple as possible, we restrict to T-hedral tubes with a quadrilateral cross-section (Figure 3). It can easily be seen that in this case the above-mentioned loop closure condition is only fulfilled if and only if p_0 is

1. a parallelogram,
2. a deltoid with a symmetry line orthogonal to the base plane τ_0,
3. an anti-parallelogram with a symmetry line parallel to the base plane τ_0.

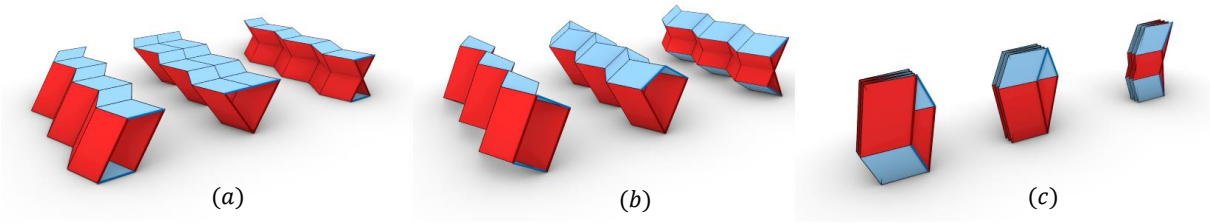

Figure 3. T-hedral tubes with all types of possible quadrilateral cross-sections; parallelogram (left), deltoid (center) and anti-parallelogram (right). (a) unfolded up to the flexion limit, (b) half-folded and (c) flat-folded

In fact, we only deal with cross-sections of cases 1 and 2, because case 3 results in self-intersections for tubular shell models. In addition, we require a repetitive structure of the tubes to ease and cheapen their manufacturing, which yields to the assumption that t_0 is a regular zig-zag. In order to meet our last request of flat-foldability, the planes π_i have to be angle bisectors of t_0 according to [9]. As a consequence, all planes π_i are parallel to the plane π_0 implying T-hedral tubes of the so-called *translational type* (as these tubes are generated by a pure translation from p_0 along t_0).

One can also compose T-hedral tubes by connecting them at PQ-strips in a way that the resulting structure is still rigid-foldable. One can distinguish the following two types of this face-sharing coupling of T-hedral tubes of the translational type [7]. One can put two such tubes together in a way that the corresponding base planes are

- **parallel/identical:** This so-called *aligned-coupling* can easily be constructed by merging two closed polygons p_0^+ and p_0^-, which both fulfil the loop closure condition and share (parts of) a common edge, to a single polygon p_0.
- **not parallel/identical:** This so-called *zipper-coupling* can be achieved by starting with the face-sharing PQ-strip, which has to be a discrete cylinder for the translational type, and chose two base planes in a way that their line of intersection is orthogonal to the cylinder rulings. Note that during the rigid-folding of the zipper tubes the angle enclosed by the base planes changes as illustrated in Figure 7.

Based on these fundamental properties of T-hedral tubes and their couplings, we proceed to explain the

ideas behind the proposed two bridge designs.

2.2. Proposed two bridge designs

Our goal is to achieve a flat bridge deck in the final unfolded state of the structure, which requires to be a flexion limit of at least one involved tube; i.e. the base plane of this tube has to be horizontal. However, as previously mentioned, this is also a bifurcation configuration and it is necessary to prevent the bridge from flexing back (under load). Our focus is on finding purely geometric solutions for blocking the bridge in the final unfolded state.

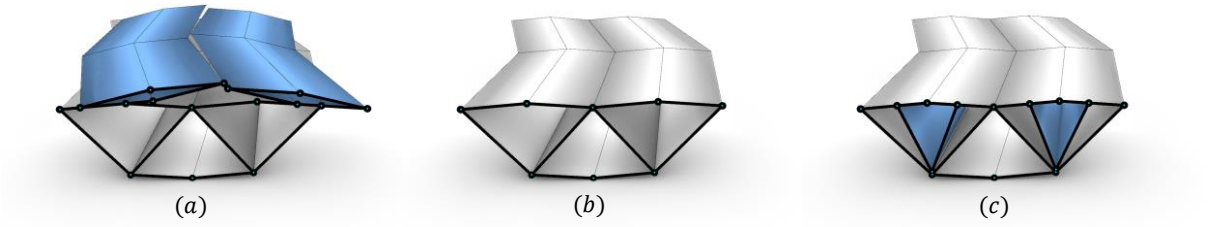

Figure 4. A zig-zag unit of the core structure (b), the zipper-tube solution (a) and the nested deltoid solution (c) close to their final unfolded state

Both presented solutions have the same core structure, which consists of three aligned-coupled deltoidal tubes (see Figure 4b). Note that such an arrangement was also used by Schenk and Guest [10] to construct self-locking metamaterial.

- **Nested deltoid solution**: In this case the bifurcation is prevented by two inner deltoidal tubes, which are aligned-coupled to the outer deltoidal tubes even along two PQ-strips, which is possible due to symmetry (see Figure 4c).
- **Zipper-tube solution**: We zipper-couple two rhombic tubes to the left and right deltoidal tubes of the core structure in a way that in the final unfolded state the rhombic tubes are flat and cover (even extend) the bridge deck (see Figure 4a).

Finally, it should be noted that a flat-foldable bridge structure constructed from zipper-coupled tubes was also presented in Figure 6 of [11]. But neither its deck is flat nor the blocking of the bridge in its finale state was discussed. The latter can for example be achieved by fixing the cross-sections at the bridge end-points to two plates as done in [12]. Moreover, a flat covering of zipper-tubular structures can be obtained by using the concept of smooth sheet attachments [13].

3. Potential application as a bridge

As described above, the T-hedral tubes offer interesting behaviour and potential for the building industry as they can be prefabricated in a controlled environment, transported and unfolded into their final spatial configuration on site. For this investigation the two different approaches were analysed for their performance under load, self-weight and their behaviour during the unfolding process, using the FEM-Tool Karamba3D [2] in combination with Galapagos [1] in the Rhino/Grasshopper environment. The authors decided to reduce complexity in this early investigation, and neglected therefore known problems and questions in relation to hinge detailing, material thickness, actuation or materiality.

3.1. Structural analysis of the geometries

If folding on site for a bridge should become a potential application two related questions need to be answered: What is the best geometry for the bridge in its final configuration, and what is the best geometry for the unfolding process. In the presented case, the authors also wanted to investigate if rather a nested or the zipper version of the bridge has a better structural performance.

To compare the two options the authors used the FEM-Solver Karamba3D and its ability to optimize cross-sections with given parameters as e.g. maximum admissible deformation. In the presented case

the deflection limit is set to span/300 in accordance to European building codes. As a result, the mass of the structure is optimized. This serves as a performance indicator for comparing design alternatives. The lighter the result the better the geometry. For reducing computational effort, the structures were not analysed as shell structures, but as spatial truss assemblies with the truss-members being aligned to the foldlines and placed as cross bracing thereby modelling the in-plane stiffness of the PQ-panels.

For an investigation on the geometry modelled via shell finite elements, the approach would have been to assign the same weight to the different bridge geometries by controlling the shell thickness and then compare the maximum deflection of the alternative structures. As the folded geometries have in the folded state several layers in the same plane, meshing becomes difficult and slow, resulting in inaccurate structural calculation results. Especially the zipper tube has a high level of complexity, that will be addressed in future investigations.

To have comparable results the bridge spans were defined to be 20 meters having a fixed deck width of 6 meters. The supports were allowed to freely rotate being movable in the bridge's axial direction at one end-point. As truss material hardwood D30 was chosen. The truss-members to be optimised were chosen from a set of cross-sections ranging from 10 to 50 cm edge lengths in 5 cm steps.

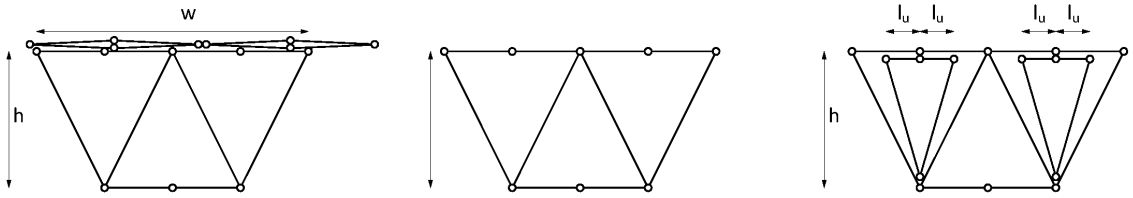

Figure 5. Concept sketch of the variable parameters in section of the zipper tube (left) and the nested solution (right) in its final folded state

The design-alternatives of the bridge had different design parameters that were optimised using Galapagos. As shown in Figure 5, the zipper bridge was variable in the bridge height h, the number of undulations n, the amplitude a of the undulations in x-direction, and the width w of the core structure. The nested bridge was variable in the bridge height h, the number of undulations n, the amplitude a of the undulations in x-direction, and the upper length l_u of the inner deltoid in relation to the total length.

Figure 6. Concept sketch of the two bridge concepts the zipper tube (left) and the nested solution (right) in its final folded state

The structures were optimised for different load cases and in different folding states. The bridges in final state where optimised under self-weight and for a live load of 6kN/m² on the bridge deck. During the (un)folding process the structures were only optimised for self-weight. It was assumed that the bridge would not be folded as a cantilever, but rather as a simply supported beam. This can be achieved with cranes on each side.

3.2. Optimisation results

As the cross-section optimisation in combination with the Galapagos solver necessitates long computation times the maximum amount of undulations was limited to four, and the deviation was limited to the range 0.25 to 7.5 meters, with a step size of 0.25 meters.

Under live load both solutions converge to the maximum allowed height of the system that was limited to two meters, having a maximum number of 4 undulations, using the minimum allowed deviation of 0.25 meters. The ten best results of both geometries have heights in the upper bound of the height domain and feature the maximum number of undulations. The high number of undulations is linked to the reduction of buckling lengths of the truss members, that result in better structural performance. The nested bridge is 1.4 tons heavier, and therefore less performative under live load as compared to the zipper geometry (cf. Table 1 and Figure 8).

Table 1. The best results of the two systems under live load

live load : 6 kN / m2	NESTED BRIDGE

Under self-weight the total mass difference between the best results of the nested and zipper variant remains constant. Similar to the calculation with live load the mass difference amounts to 1.4 tons. Both systems tend towards the lower end of the possible predefined height range. The number of undulations switches from 4 to 2, but the amplitude is kept at the absolute minimum allowed (cf. Table 2).

According to the intended eraction method of unfolding of the structure on site, one investigation was focusing on the optimisation with regards to the series of folding states. As different configurations feature different speeds of folding and unfolding, the folding ratio is defined to be between 0 and 1, where 1 corresponds to the fully unfolded state, and 0 to the fully folded package that has a total

thickness of 1.5 meters. This number constitutes an estimation, since material thickness and hinge detailing will probably not allow for smaller package sizes.

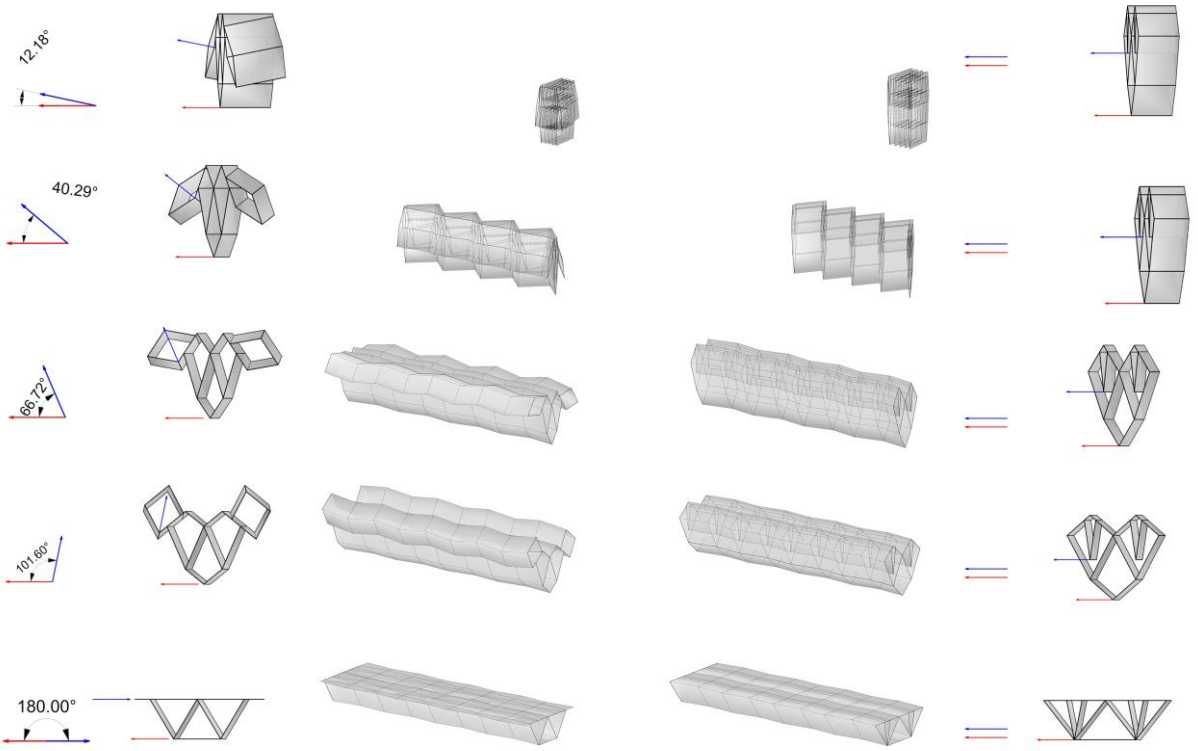

Figure 7. The unfolding sequence from top to bottom of the zipper bridge (left) and the nested bridge (right) with the correspondent angles of the deltoid's base planes. From top to bottom the configurations correspond to the folding ratios 0, 0.25, 0.5, 0.75 and 1.

The folding sequence was split into 4 steps: 0.75, 0.50, 0.25 and 0, respectively. As the entire system is rigidly foldable, the position of each planar quad is exactly defined. Each step has been optimised as a single state, with the endpoints being simply supported.

The results show (cf. Tables 3 and 4), that for the motion states the structural height converges towards the lowest third of the allowable range, whereas for the three best results the optimised height takes on the minimum height possible. The number of undulations is in almost all cases two, its amplitude being 0.25 for most variants. The total mass of both structures is similar and ranges from 7350 kg to 8650 kg. The extreme undulation in the smallest possible folded state leads to an increase in weight for both structures. While the nested bridge has a similar weight in all states, the zipper bridge features a weight increase of 1/3 compared to the case of only self-weight applied. As the folded package represents the transportation case, the latter results are not considered to govern the actual design. For transportation and placement on site necessitate additional manipulation tools which depend on the available technical means.

3.2. Additional comparisons

If we compare the individual optimised solutions in all states, it turns out that we can differentiate between two sets of results: All variants optimised under self-weight have varying but comparable outcomes in all considered states (during folding under self-weight). When adding live loads to the structural models the optimized mass doubles or triples. Comparing solutions under live load to the states during unfolding, one sees, that the optimised mass is only in the fully folded, initial state higher.

Tables 5 and 6 show mass and displacement values calculated via Karamba3D before and after the cross-section optimisation.

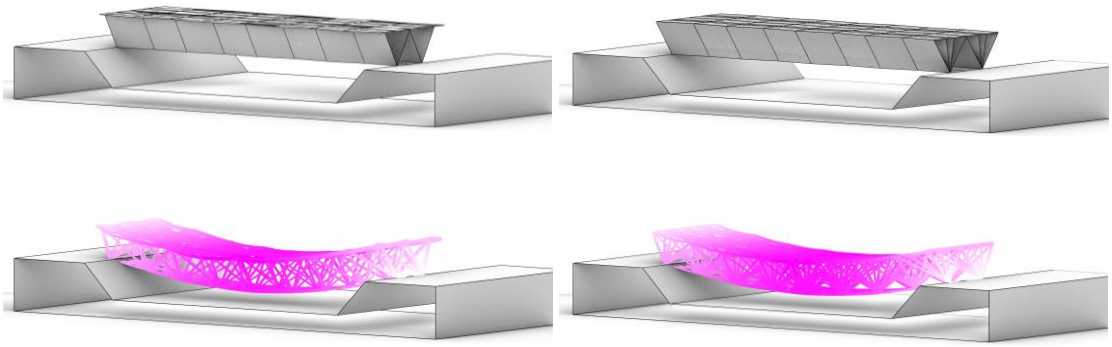

Figure 8. The zipper solution (left) and the nested solution (right) and their deformation under live load

4. Conclusion

The investigation shows that the zipper bridge option has advantages over the nested one in unfolded and final state. Although the zipper tubes are more rigid during the unfolding motion, the nested solution is in some states more efficient. The better performance seems to be linked to the fact that the zipper geometry allows for a slight cantilever of the bridge deck, that reduces the entire surface area and therefore the weight of the core structure.

The investigation shows that the bridge in its smallest possible package state behaves unstable. The reason for this behaviour requires additional investigations, to assess possible solutions to this problem. It can be assumed, that this small transportable package will require special treatment in the course of the erection process.

5. Outlook

This investigation constitutes a starting point for more detailed investigations on bridges based on T-hedral tubes. The presented results are promising and will be followed up by additional research.

In a further study the focus will be on the support conditions during unfolding. Using cantilevering instead of simply supported conditions, one has to control vertical deflections similarly to the analysis presented in [14]. This approach will require multi-objective optimisation to include additional objective functions as e.g. introduced by hinge design, support method, and positioning during unfolding. Another focus is the change from a repetitive pattern of the structural elements to a non-repetitive one that might be adapted for better motion and structural behaviour.

Obviously, future investigations should be refined by using shell elements instead of a simplified beam? model. The simulation problems encountered for the smallest foldable package state suggest a more detailed investigation in relation to the panel thickness, hinge solution, actuation and the temporary support during motion. If these problems can be solved, it is planned to build scaled demonstrators in a consecutive step.

Abstract

Origami models are often idealized by discrete folding of zero-thickness sheets; however, the sheet thickness and the elastic limit of the material cannot be ignored in engineering practice. One solution for realizing thickness is the compliant hinge, which realizes the folding deformation in the elastic range of the material by replacing the crease line with a wide deformation zone where the compliant structure is installed. However, the compliant hinge has several limitations. First, it cannot maintain the center of rotation (CoR) between panels during the folding motion. This makes origami structures with interior vertices not transformable because the crease lines are no longer concurrent. Second, the play caused by the wide deformation zone increases the degree of freedom of the origami structure, leading to instability. To solve these problems, we propose three types of new compliant hinges. We provide two evaluation methods: the play is evaluated using eigenvalue analysis, and the change CoR under unideal load conditions is evaluated using FEM analysis.

1. Introduction

1.1. Background

Origami, a technique of folding sheets that allows for the design of various shapes [1] and stiffnesses [2], can be used to create deployable structures at an architectural scale [1,3]. Origami structures have several advantages, such as the ability to transform from a flat state into a three-dimensional structure through folding, the capability for continuous shape transformation, and the ability to bear loading in the deployed state. These properties are designed based on the concept of rigid origami [1], which treats faces as rigid panels and creases as revolute hinges and allows for continuous transformation without panel deformation. During the design stage of rigid origami, panels are typically treated as ideal zero-thickness sheets. However, in engineering practice, the thickness of panels can cause self-intersection during folding and the elastic limit of panel materials must be considered.

The thickness problem has been typically solved by the geometric arrangement of the revolute hinge and thick panels [1]. However, these approaches require the use of mechanical parts and other materials for hinge structures, which can make fabrication and assembly difficult and potentially cause structural weaknesses such as breaks or delamination in connections between different materials. One solution to these fabrication problems is compliant hinges, i.e., setting the deformation zone and installing proper compliant structures [4,5]. This enables a folding motion within the elastic range of the material.

Compliant hinges can simplify the fabrication process when used in origami structures. However, the following challenges exist to realize a thick origami structure using compliant hinges.

1.2. Challenges

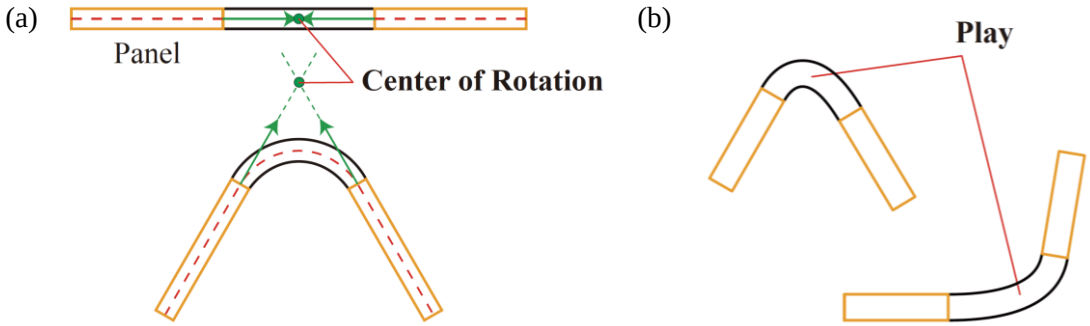

Fig.1 Challenges of compliant hinges. (a) The compliant hinges cannot maintain the center of rotation. (b) The wide hinge zone causes the play.

(a) Center of Rotation (CoR): The folding motion of the compliant hinge is not a perfect revolution about an axis, thus CoR is not maintained. This breaks the kinematics of rigid origami and blocks the deployment of origami structures with interior vertices where multiple crease lines meet.

(b) Play: Flexibility due to the wide deformation zone of the compliant hinge causes play or unwanted motion other than folding. This lowers the rigidity and stability of the origami structure and makes it difficult to control.

1.3. Purpose

In this paper, we aim to design compliant hinges that can maintain the kinematics of an ideal rigid origami. To compensate for both the CoR and play problems of compliant hinges, we propose three new types of compliant folding hinge structures by 1) combining existing compliant hinge designs [4,5], 2) aligning spherical compliant mechanisms, and 3) a hybrid of types 1 and 2. We propose two evaluation methods for compliant hinges from the perspectives of the center of rotation and play. We evaluate 1) the play through the eigenvalue bandgap of hinge structures in Section 5, and 2) the maintenance performance of the CoR under non-ideal loading conditions through finite element analyses in Section 6. The designed hinges are compared and evaluated with each other, and we select the best hinge structure that moves closest to the ideal with the least break to the kinematics of rigid origami.

2. Exiting joint design

2.1. LET hinge

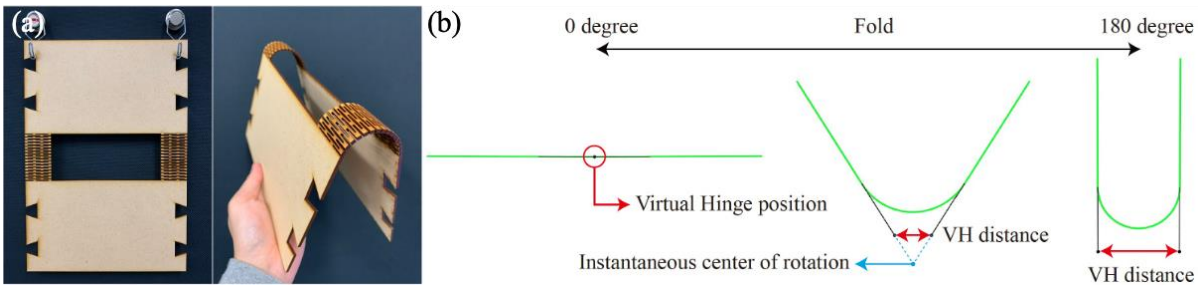

Fig.2 (a) Physical prototype of LET hinge, (b) Geometric model of LET hinge.

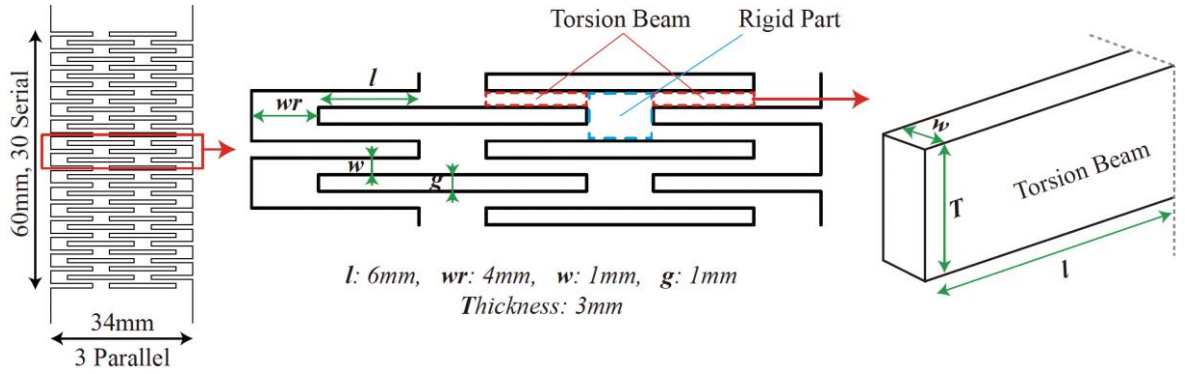

Fig.3 Common settings of LET pattern.

One of the most popular approaches for creating a hinge with patterns is the Laminar Emergent Torsion (LET) joint [4]. The LET joint (Fig.2 (a)) is a compliant hinge structure that allows for folding motion within the elastic range by lowering the stiffness of the corresponding part of the material. The LET pattern can be modeled as the composition of rigid bodies and torsion beams according to the model by Ohshima et al. [6] (Fig.3). With a proper proportion and repeating numbers, the flexible region only bends in parallel to the direction of torsion beams. This design method yields anisotropic stiffness property, making it flexible to folding deformation and rigid to other deformations, thereby partially solving the play problem.

The hinge motion under pure bending moment condition is represented by a circular arc as shown in Fig.2(b). This circular arc of finite curvature causes the loss of the CoR. The *Virtual Hinge (VH) position analysis* introduced by Lang et al. [5] is suitable to evaluate the geometrical maintenance performance of the CoR. The VH position for each panel is the position where the CoR should be for that panel. In the case of zero-thickness origami, the two VH positions coincide throughout the range of motion. However, in the case of the compliant hinge, the VH positions are separated during the folding motion (Fig.2(b)). We use the LET joint as the benchmark model to compare with our proposed joints. We models consist of two hinges that connect the panels. The height of the models is set to 300mm. The width is set to 209mm based on the Tomoe LET hinge, which has the largest horizontal width. All proposed models are made of a 3mm-thick MDF panel. The anisotropic layered composition of MDF is reported to be ideal for torsion beams [6]. The maximum torsion angle is set to 1 degree/mm to ensure that it twists within the elastic range. Under the pure bending condition of the LET hinge, the number of serial connections required for the LET pattern can be calculated as 30 when the folding angle is 180 degrees. The number of parallel connections of the LET pattern is set to 3. We call this LET pattern a "3P30S" LET array for short.

2.2. LEFF (Tomoe) hinge

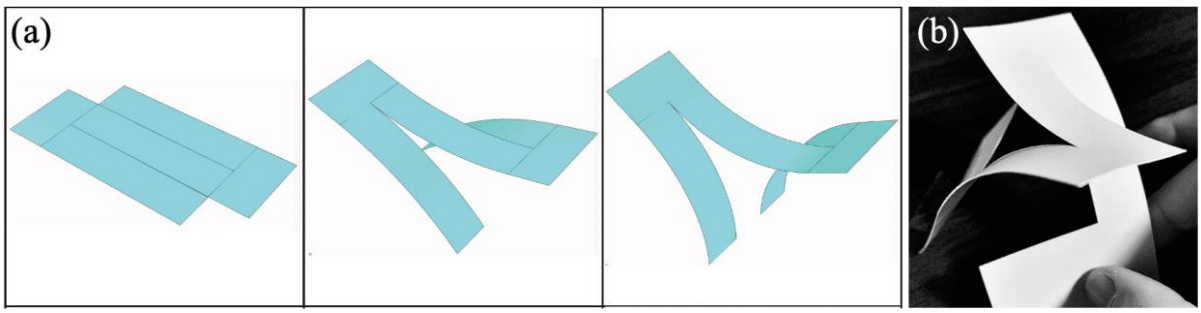

Fig.4 (a) Motion of LEFF joint. (b) example of the play of LEFF joint

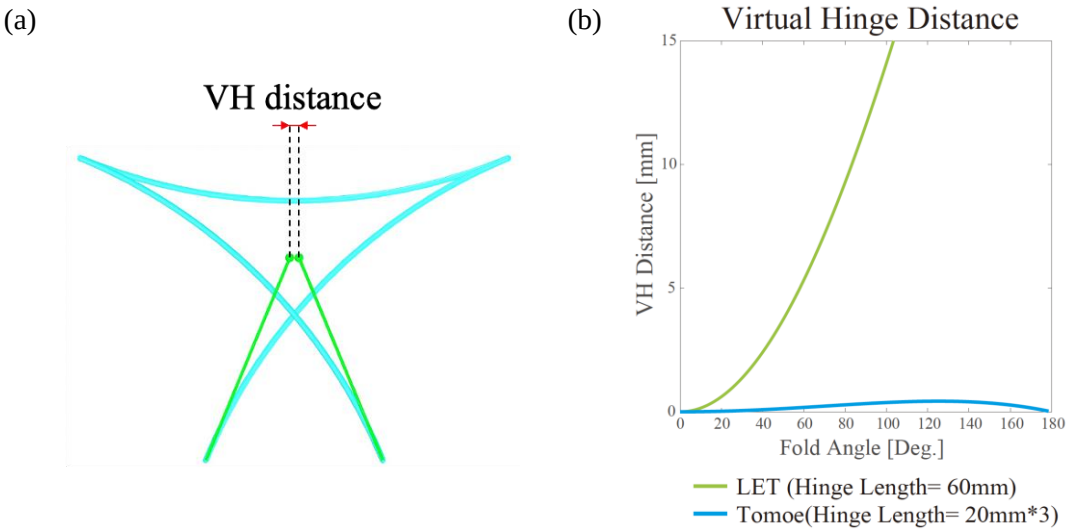

Fig. 5 (a) Geometric model of LEFF joint. (b) VH position analysis of LET and LEFF(Tomoe) joints.

The Laminar Emergent Flexural Fold (LEFF) joint, also known as the Tomoe-type Kirigami structure [5,7], exhibits excellent performance in maintaining the CoR under pure bending moment conditions (Fig.4(a)). Fig.5 (a) shows the geometric model of LEFF. Since the three beams of the LEFF hinge are designed with the same stiffness and length and connected in serial, the LEFF hinge shows symmetrical movements under the pure bending moment condition. The VH position analysis shown in Fig.5(b) compares the VH distances of LET and LEFF hinges, indicating that LEFF geometrically performs better at maintaining the CoR under a pure bending condition.

However, the flexibility of long narrow beams of LEFF slit causes play such as shear and twist, making it challenging to maintain the CoR under non-ideal loading conditions (Fig.4(b)). The reduction of the play is an important challenge for LEFF.

3. Proposed hinges

3.1. Approach 1: Tomoe LET hinge

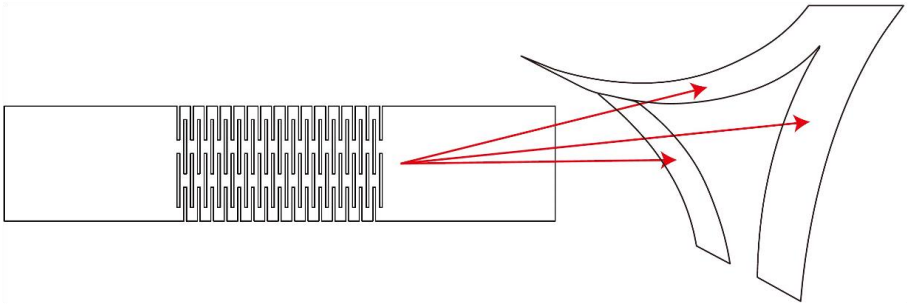

Fig.6 Concept of Tomoe LET Hinge combining LET and LEFF ideas.

The first approach for creating compliant hinges with CoR maintenance and reduced play we propose is the Tomoe LET hinge (Fig.6 (a)). Tomoe LET hinge is a combination of LET (Fig.2) and LEFF (Fig.4). By this combination, we expect that the advantages of LET to reduce the play and the advantages of LEFF of high CoR maintenance under the pure bending condition (Fig.5(a)). To further reduce the play, we join intermediate bodies of adjacent Tomoe LET hinges to unify the motion (Fig.7(b), Fig.8). We call this Joined-Tomoe LET Hinge. The joining technique was also used in the LEFF joint [5] and is expected to reduce the play. To make the folding stiffness similar to that of the LET hinge, we serially connect 3 times “3P10S” LET arrays (Fig.8).

(a) (b)

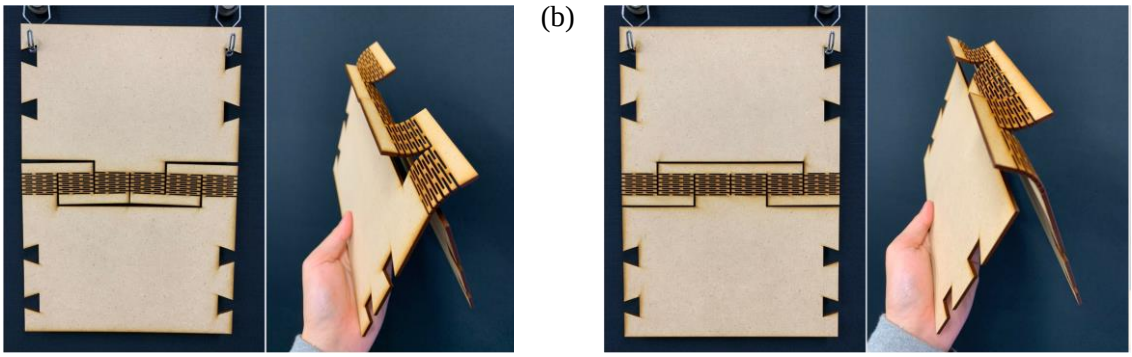

Fig.7 Physical prototypes of (a) Tomoe LET hinge and (b) Joined Tomoe LET hinge

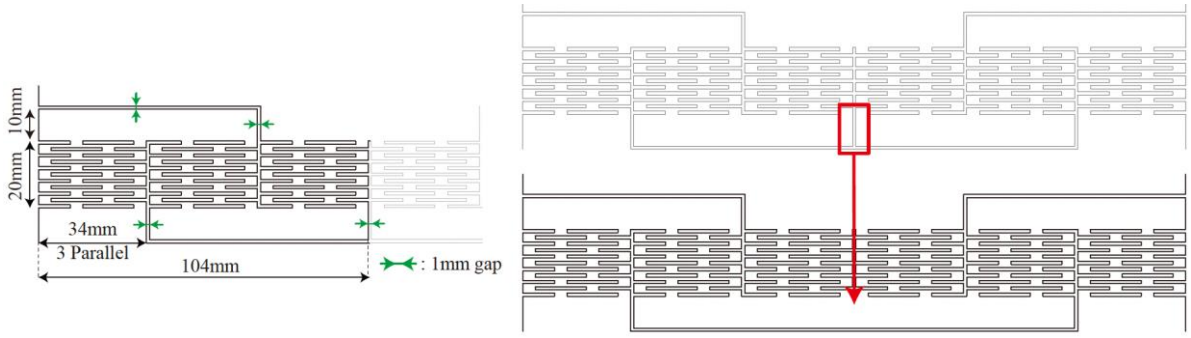

Fig.8 Experiment model settings of Tomoe LET and Joined Tomoe LET hinge (Right bottom).

3.2. Approach 2: Radial LET hinge

(a) (b)

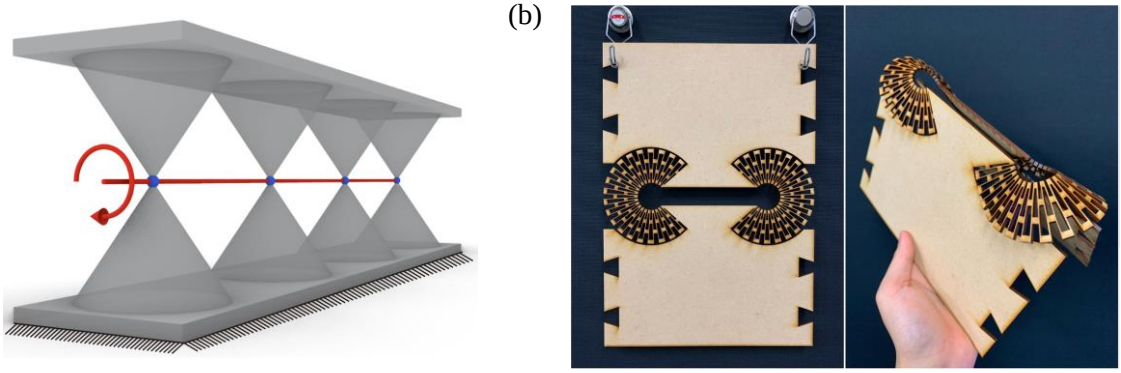

Fig.9 (a) The concept of the 1-DOF structure that consists of multiple spherical joints. (b) The physical prototype of the Radial LET hinge.

The second approach is to design the 1-DOF hinge structure using multiple spherical joints aligned on a straight line. The spherical joint can be designed by radially arranging the LET pattern so that the axis of all torsion beams passes through one point (Fig.9 (b)). Fig.9 (a) shows that placing the center points of spherical joints on a straight line and connected in parallel creates a hinge structure with 1-DOF. This straight line corresponds to the CoR. Using this method, we designed the Radial LET (RLET) hinge by connecting two Radial LETs in parallel.

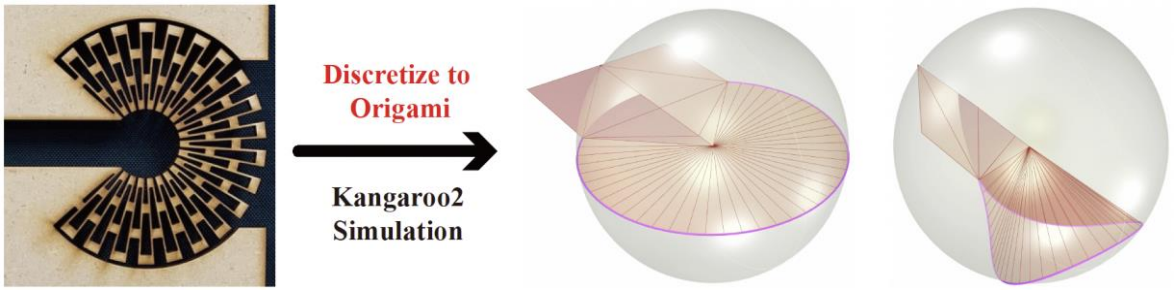

Fig.10 Single-vertex origami model of RLET hinge

Fig.9(b) shows that the curvature of the RLET hinge is not constant along the hinge surface. The curvature is negative (convex) and concentrated in the middle of the curved surface and has a positive value (concave) at its ends. The curvature distribution can be simulated by solving the equilibrium of the discrete shell model [8] as shown in Fig.10, where we consider beam axes as bending-resistant creases that are radially emanating from a single vertex.

For the evaluation model, we tune the number of serial connections of the LET pattern to have the same stiffness as the LET hinge. Based on the abovementioned discrete shell simulation, we chose "*3P40S*" radial (Fig.11(a)), so the average torsion angle of the torsion beams is as close as possible to 1 degree/mm. The average of the absolute values of torsion angles of RLET when folded by 180° was 1.02 degrees/mm. Having positive and negative curvature indicates that some torsion beams are not fully utilized to their capacity and are left unused. Here, we propose the third approach to fully utilize every torsion beam.

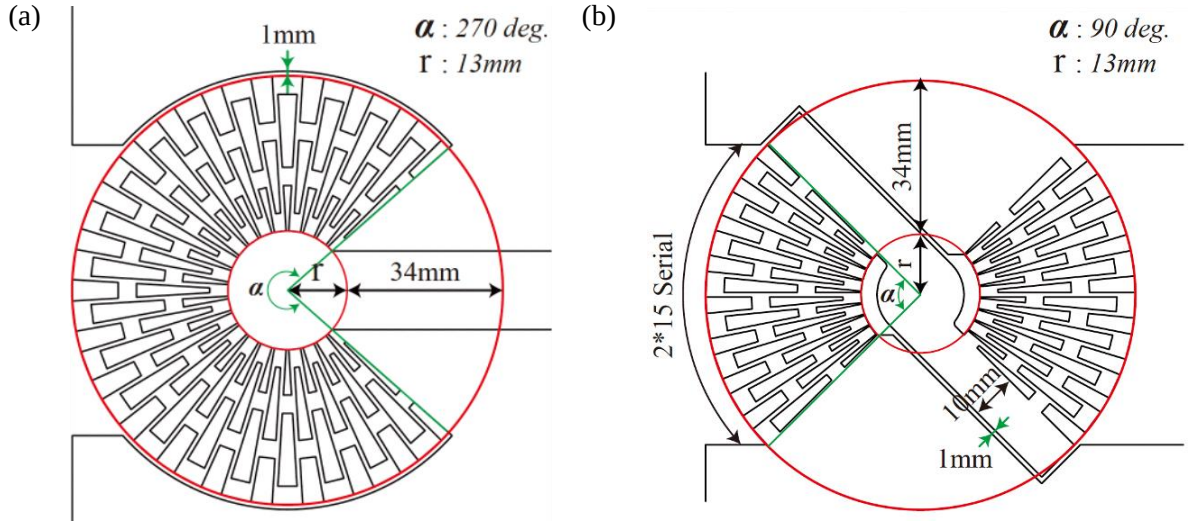

Fig.11 Settings of spherical joint hinge structures. (a) Settings of RLET and (b) S-shape hinge.

3.3. Approach 3: S-shape hinge

As the third approach, we combine the back-and-forth idea in Tomoe LET (Fig.7) with the idea of Radial LET (Fig.9) to propose the S-shape hinge (Fig.12(a)). Like the RLET hinge, the 1-DOF hinge structure is designed by connecting multiple spherical joints in a straight line in parallel (Fig.9(a)). Each spherical joint is composed of two symmetric Radial LETs connected with a rigid body. When we assume that each curved surface of the hinge has constant curvature, we obtain the geometric model in Fig.12(b) and Fig 13(a). From an analysis similar to the VH distance analysis on spherical geometry, we can measure the VH distance on the sphere (Fig. 13(b)).

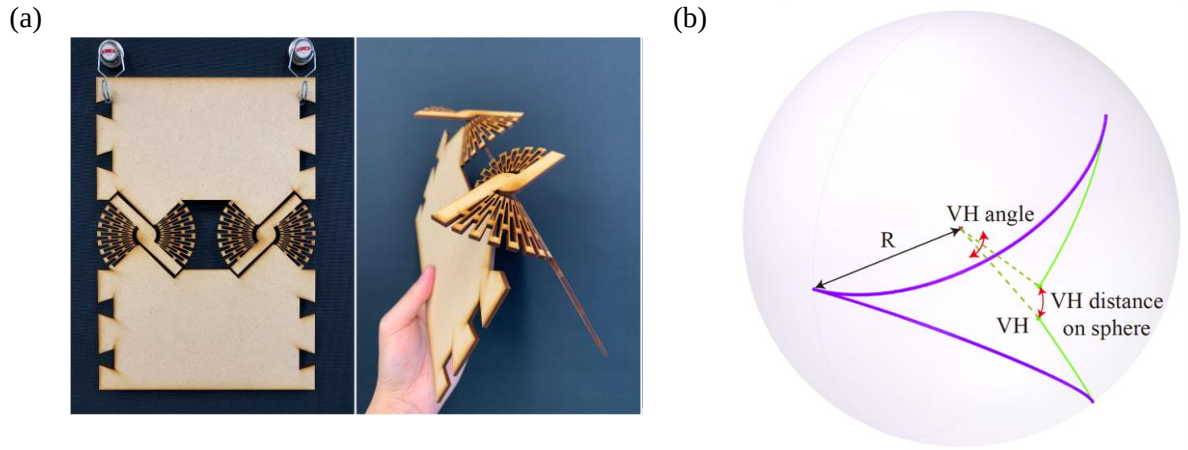

Fig.12 (a) The physical prototype and (b) the geometric model of the S-shape hinge.

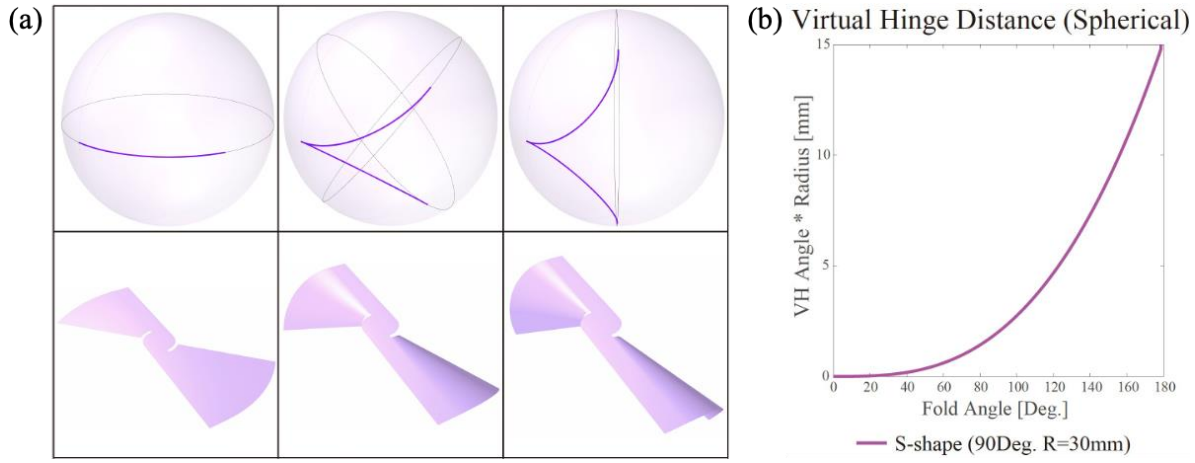

Fig.13 (a) Motion and Geometric model and (b) VH position analysis of S-shape hinge.

By parallel alignments of multiple spherical joints, the VH distance is supposed to disappear by modifying the curvature distribution of the surface. Fig 13(b) shows that the VH distance on a sphere is small ($< 3.86°$) for fold angle between 0° to 90°, indicating that when the joints are aligned in parallel, the curvature is still close to constant and that the curvature concentration problem of the RLET hinge is solved.

Assuming that the surface curvature is constant, the evaluation model is designed by coupling two "*3P15S*" Radial LETs as shown in Fig.11(b).

4. Play analysis

4.1. Eigenvalue bandgap analysis

In an ideal compliant hinge without play, the structure has low stiffness against the folding motion and high stiffness against any other motion. To identify the stiffnesses against different deformation modes, we perform an eigenvalue analysis to extract free vibration modes (eigenmode) and their corresponding frequency (eigenvalue). Each eigenvalue represents natural frequency corresponding to structural deformation modes (Fig.14). Structural deformation modes of compliant hinge structures consist of three out-of-plane modes (Bending Out-of-Plane (Fold), Twist, and Shear) and three in-plane modes

(Bending In-Plane (BIP), Stretch In-Plane (SIP), and Shear In-Plane (ShearIP)) (Fig.14). We evaluate the logarithmic difference between the eigenvalues, called the *eigenvalue bandgap*. Since the natural frequency is proportional to the square root of the stiffness of the structure, a large eigenvalue bandgap from the desired structural deformation mode (Fold-Mode) means that the hinge is stiffer in other modes; in other words, other modes are difficult to appear [9]. Therefore, eigenvalue analysis can evaluate the play of the compliant hinge in infinitesimal deformation.

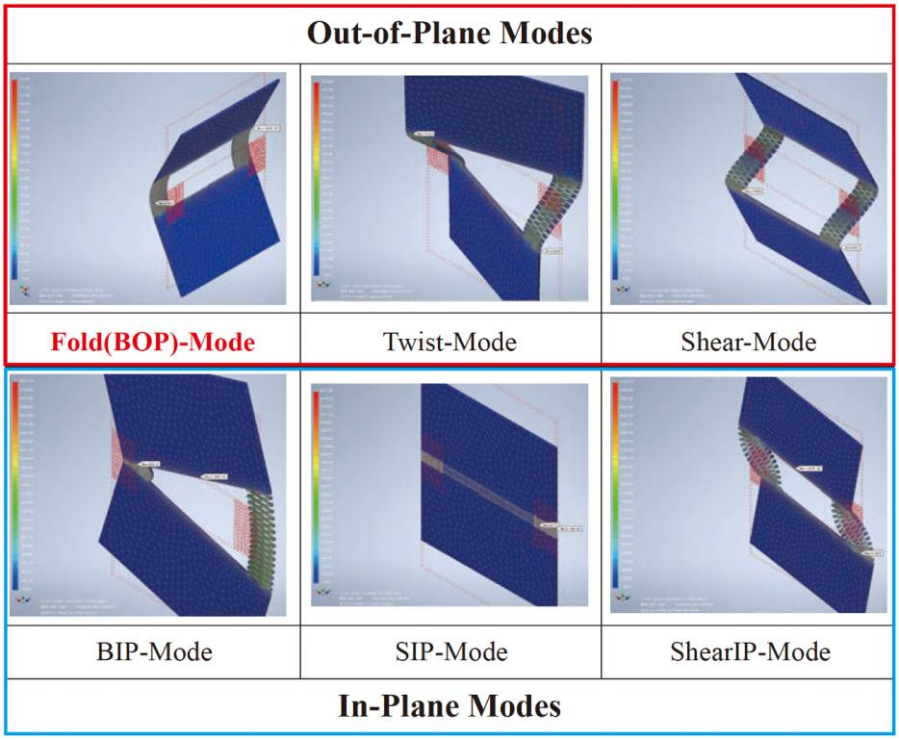

Fig.14 Structural deformation mode of hinge structure

The eigenvalue analysis is conducted without boundary conditions, and rigid body modes (1^{st}-6^{th} mode) are omitted from the analysis as they required zero energy. Table 1 shows the material setting for eigenvalue analysis. The 7^{th} mode and those following represent deformations requiring energy. We expect that the folding mode appear in the 7^{th} mode for the compliant hinge.

Table 1. The material setting for eigenvalue analysis and finite element analysis.

Plywood	Type	Young's Modulus	Poisson Ratio	Density
	Isotropic Material	7700 [N/mm^2]	0.25	5.52e-10 [t/mm^3]

4.2. Evaluation

Table 2 shows the ratio of the natural frequency of the 8^{th} mode and each deformation mode, relative to the 7^{th} mode. All proposed models represent folding mode at the 7^{th} mode. The Joined-TomoeLET hinge has the largest bandgap between the 7^{th} and 8^{th} modes, so it is expected that the play is difficult to occur. In addition, it has the highest stiffness for Twist and ShearIP modes, and the second highest stiffness for shear, SIP, and BIP modes. The S-shape hinge has high stiffness against shear mode but is flexible to in-plane modes, so play can occur easily.

Note that since the eigenvalue analysis is linear, it is limited to infinitesimal deformation. Also, we performed the analysis only at the flat state. Therefore, they may not correctly represent the play for large deformation.

Table 2. Natural frequency ratio from results of eigenvalue analysis

$f_{n(>7)}/f_7$	LET	TomoeLET	J-TomoeLET	RLET	S-shape
8thMode / 7thMode	3.91	3.94	**4.89**	2.94	3.9
Twist	3.91	4.87	**4.89**	2.94	4.57
Shear	5.74	10.11	11.44	7.55	**13.35**
SIP	**14.57**	4.93	8.58	4.95	4.49
BIP	**17.89**	3.94	5.8	4.78	3.9
Shear-IP	11.1	33.41	**33.82**	5.8	16

5. Compositive evaluation

5.1. Finite element analysis

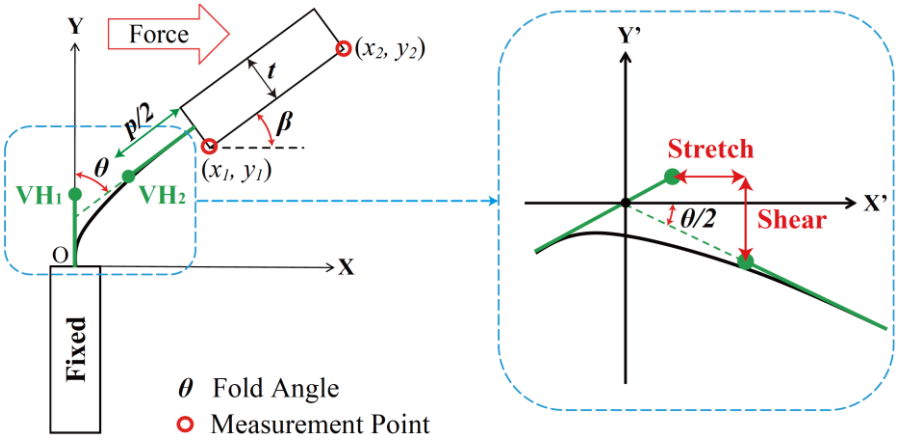

Fig.15 VH analysis under unideal load condition

To simultaneously assesses the CoR maintenance performance and play, finite element analysis is performed under an unideal load condition. The bottom panel is fixed as a boundary condition, and an incremental force of up to 5N is applied to the upper panel in a direction perpendicular to the panel surface as shown in Fig.15. Table 1 shows the material setting for analysis. Unlike the pure bending condition, this loading condition provides non-symmetric deformation due to the play of the mechanism. We decompose the stretch and shear effect by introducing the X'Y'-coordinate system that bisects the folding angle and measures the coordinates of the difference of VH positions, i.e., the VH vector. The X'-direction component of the VH vector represents the combination of the geometric separation of the hinge itself and the play in stretch direction, so we call it the VH-stretch. The Y'-direction component of the VH vector represents the play in the shear direction (Fig.15, right), so we call it the VH-shear.

5.2. Evaluation

Fig.16 (a), (b), and (c) show the plot of the VH-stretch, VH-shear, and VH distance. All proposed models have less play than the LET hinge. Especially, Joined Tomoe LET hinge has the least stretch and shear direction play during the folding motion, and it moved most similarly to rigid origami among the proposed models. The S-shape hinge shows equal to or better CoR maintenance and play performance than the Tomoe LET hinge. As expected through eigenvalue analysis, it showed good performance in the shear direction play.

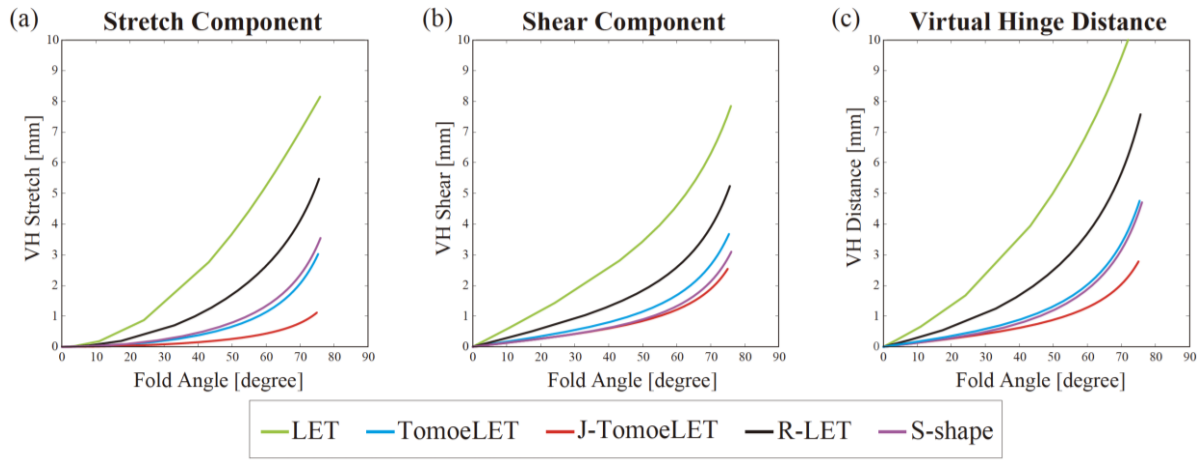

Fig.16 Results of Finite Element Analysis

6. Results

Based on the evaluation results, we conclude that the Joined Tomoe-LET hinge is the compliant hinge that best performs within our design. We consider that this excellence is due to the connection of the intermediate bodies of the two Tomoe LET hinges. This causes the motion of the hinges to be unified and makes it difficult to generate play. Therefore, the geometric maintenance performance of the Tomoe LET hinge is exhibited even under nonideal loading condition. It is expected that as the number of hinges increases, the performance of suppressing play due to unifying will increase. This hinge unifying technique cannot be used in the spherical joint hinge structure of Approaches 2 and 3. This is because points on the hinge move on a spherical surface and there is no motion for the intermediate bodies that are compatible with two neighboring spherical joints. Therefore, if the intermediate bodies are connected, the motion of the spherical joint cannot become realized.

Fig.17 shows the degree-4 vertex (top) and degree-6 vertex (bottom) pattern origami structures utilizing the Joined Tomoe LET hinge. Structures are fabricated by laser cutting machine and black connecting joints are fabricated by the 3D printer. The degree-4 vertex origami structure has one DOF, therefore it cannot deploy unless the CoR of the hinges intersects at the interior vertices. The motion appears to be well-interlocked, indicating that the CoR of the hinge is maintained to some extent. Similarly, the degree-6 vertex origami structure, which has three DOFs, moves well and spherical motion is also possible.

7. Conclusion

We designed four new types of compliant hinges that focus on CoR and Play using three different geometric approaches and evaluated their performance using methods proposed in this thesis. As a result, the Joined-Tomoe LET hinge was found to be the most effective at preserving the kinematics of rigid origami in our experimental condition. Using this compliant hinge, we were able to fabricate and actuate origami structures with internal vertices.

However, additional research is required under specific conditions (large deformation, load bearing, etc.) different from the conditions of this study. We need to evaluate play by performing eigenvalue analysis under large deformation conditions, and compositive evaluations under large deformation conditions of loads such as torsion, etc. that cause three-dimensional deformation are also required. Other hinges might perform better depending on the conditions. In addition, future works include optimizing the trade-off between hinge layout and stiffness to avoid interference with protruding hinge parts.

Experimental study on a type of foldable structure with asymmetrical crease line pattern

Khai Seng CHEW*, Kok Keong CHOONG[a]

[a,*] School of Civil Engineering, Universiti Sains Malaysia
khaisengchew@student.usm.my

Abstract

This paper aims to highlight an experimental study of a light weight foldable structure that geometrically transforms from a flat planar state to a folded one with depth. The study was carried out to measure the folding behaviour of a foldable structure with a primary focus on an asymmetrical crease line pattern. The symmetry breaking pattern is key as it highlights the flexibility of origami pattern designs which can be adopted for foldable structures. The experimental model was made using light weight steel purlins that were boxed up using screws and assembled to form various panels. With a flat surface area footprint of 4m x 4m, the individual light weight panels are connected and arranged to form an asymmetrical pattern with hinges placed between these panels. Prior to the experimental study, a theoretical simulation of the folding process was carried out using Rhinoceros and Grasshopper to understand the transformation of the structure when it is being folded. The paper will also look into the various challenges faced during the fabrication and deployment of the actual model as well as lessons learnt throughout the process. The key points that will be discussed in this paper are the mechanisms of folding, hinges used to allow folding, method of data collection as well as an analysis of the data gathered comparing to the theoretical simulation. The paper will also discuss on the differences and impact of the folding of a physical model with finite thickness as a comparison to the simulation model which was made using surfaces with zero thickness.

Keywords: rigid origami, folded structure, asymmetrical crease line pattern

1. Introduction

Origami is the art of folding a thin sheet of material without cutting, stretching or shrinking the material. By folding a thin sheet of material, it transforms from a two dimensional surface to a three dimensional one with depth. In its folded state, the material would have a higher global stiffness than when it was flat. The additional stiffness and patterns formed from the folding are what draws engineers and architects to incorporate origami into the design of structures.

The folding process of a series of patterns can be simulated by following the mathematics of rigid origami as described by Belcastro and Hull (2002). Rigid origami describes a purely geometric mechanism in which the only flexure occurs along the crease lines. Through the simulation process, we have an understanding of the kinematic behaviour of a crease line pattern that is undergoing the folding process. This simulation provides a basis of comparison to the actual physical model that is being folded but it does not accurately exemplify the actual physical model especially after factoring the fabrication constraints, material thickness and the effect of self-weight.

Several studies have looked into the methods of incorporating thickness into the folding process. One of the studies were carried out by Tachi (2011) who demonstrated a method of hinge line arrangements and trimming by bisecting planes. Pehrson, Magleby, Lang and Howell (2016) also demonstrated the idea of a strained joint method which covers the trimming of the interior vertices. With regards to the

effect of gravity on the simulation of folding, a more recent study by Zhang and Kawaguchi (2021) shows a method of incorporating the effect of gravity as a nodal force using the kinematic frame model.

This paper focuses on the experimental aspect of a foldable structure, with emphasis primarily on the fabrication processes and methods adopted to actuate the folding process. This study was carried out on a 4m x 4m foldable structure that is made using lightweight material. The findings of the experimental study from conception of the asymmetrical pattern, the fabrication of the physical model, the folding process and the interpretation of the data collected after folding are presented in the following sections.

2. Choosing the crease line pattern

The layout of the crease line pattern of an origami will determine the final shape of the material when folded. Figure 1 shows the chosen crease line pattern that was used for the development of the foldable structure in this experimental study along with the assignment of the Mountain and Valley folds. The considerations for the chosen asymmetrical pattern are highlighted in the subsections below.

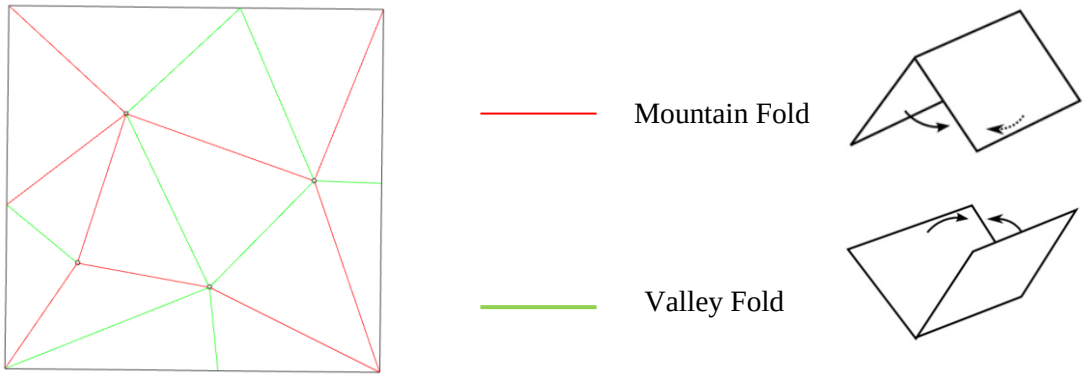

Figure 1. Crease line pattern that was used for the development of the foldable structure

2.1. Triangulation of individual faces

The crease line pattern assignment were intentional to create faces which were only triangular in shape to prevent in plane bending. A preliminary experiment was conducted using quadrilateral panel to test for in plane bending with pre-tension cross bracing and the result shows that the quadrilateral panel was not able to maintain planarity even with the addition of pretensioned bracing. Given the constraints of the folding simulation that follows rigid origami, the in-plane bending of a quadrilateral panel is undesirable and this is removed by triangulating every face forming the foldable structure.

2.2. Assembly and handling constraints

For ease of assembly, a continuous line of valley folds were introduced which effectively divides the model into two segments. The line of continuous valley hinges are necessary as they will be the final connection point between the two major segments as shown in Figure 2. Valley fold hinges can be installed from the top and the assignment of these continuous Valley fold hinges eliminates the need of flipping the fully connected 4m x 4m model around to install the Mountain fold hinges.

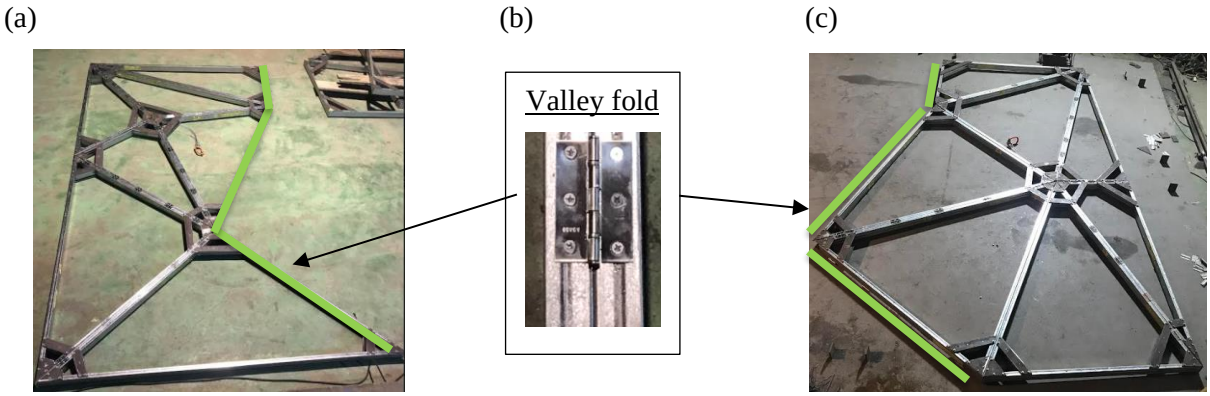

Figure 2. (a) First assembled segment of the foldable structure that comprise of continuous Valley folds (green) (b) Valley folds with hinges on the top side of the member (c) Second assembled segment of the foldable structure with continuous Valley folds (green) along the connecting edge to the first segment

3. Material used for foldable structure

The material that was chosen for this experimental study needed to be lightweight for ease of handling and to minimize the effect of self-weight. The material chosen for the panels were made from two 0.75mm thick steel C section that are combined and locked together using self-tapping screws. The self-tapping screws connect the top and bottom flanges of the C section and are spaced 100mm apart. Figure 3 shows the cross-sectional view of the cross section used.

Table 1. Mechanical properties of the C section used for the experimental study

Thickness of material, *t* (mm)	0.75
Cross-sectional Area, *A* (mm^2)	102.4
Weight, *W* (kg/m)	0.89
Major Second moment of inertia, *Ixx* (mm^4)	77760
Minor Second moment of inertia, I*yy* (mm^4)	10230

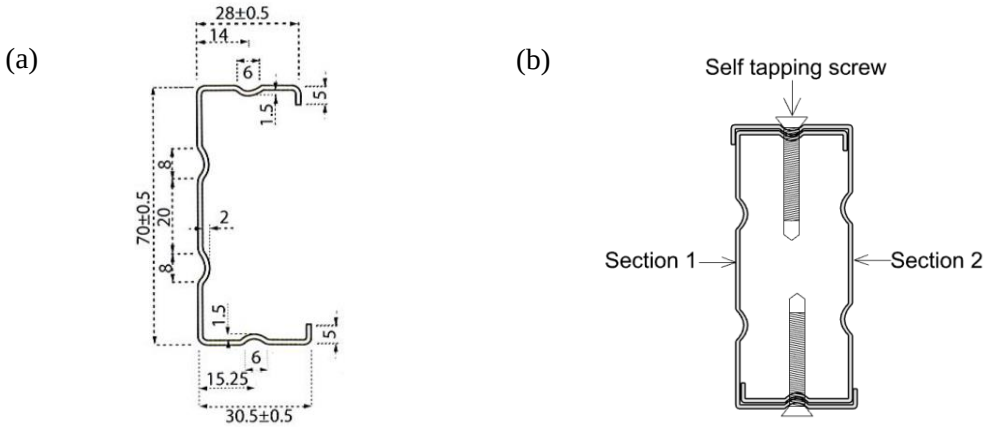

Figure 3. (a) Cross-section and dimensions of the 0.75mm thick steel section and (b) the connection between each member to form a closed box section

4. Fabrication of experimental model

The fabrication of the experimental model was carried out by connecting the combined steel C-section member to form individual triangular panels. These triangular panels were fabricated individually and assembled by connecting to the neighbouring panels along the designated Mountain or Valley fold hinges. The challenges faced during fabrication are highlighted in the subsections below.

4.1. Potential clash at vertices during folding

One of the considerations that needed to be made was on the potential clashing of the member during the folding process, specifically at the vertices. The members converging on the vertex needed to be trimmed back as shown in Figure 4 to allow for the rotation along the crease lines of the foldable structure.

4.2. Replicating a nodal support during the folding process

During the fabrication of the model, it was important to be able to create a node or a concentric point for the purpose of lifting. Additional 6mm triangular plates were connected above the trimmed members with holes drilled through for connection with the 6mm wire rope. These plates will be the points of attachment for the wire ropes that will be used to life the structure and commence the folding process. The setup and methodology of lifting and folding the experimental model is discussed in Section 6 of this paper.

(a) (b) (c)

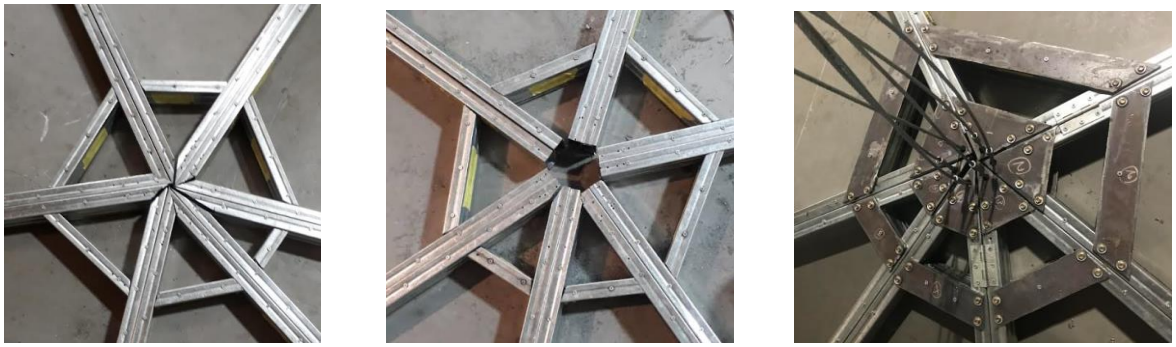

Figure 4. (a) Vertex of the experimental model with panels converging to a point (b) The vertex of the experimental model after trimming to prevent clashing during the folding process (c) The addition of triangular stiffener plates to replicate lifting or support at the nodal point of the vertex

5. Hinges

One of the most important decision that needed to be made was on the type of hinge to be used to enable the physical folding of the experimental model. A door hinge was chosen as the hinge mechanism as it is able to integrate into the fabricated experimental model and allows for the rotation along the crease lines. The hinges are spaced evenly along the length of the member as well as connect one triangular panel to another. The position of these hinges are dependant on whether the folds are designed to be a Valley fold or a Mountain fold. The hinges are located beneath the members for a Mountain folds and above the members for Valley folds. A pullout test was conducted on 4 types of hinges to understand the mechanical behaviour of these hinges when subjected to a lateral loading. Figure 5 shows the various door hinges tested as well as the set up to test the pullout capacity of the hinges.

(a) (b)

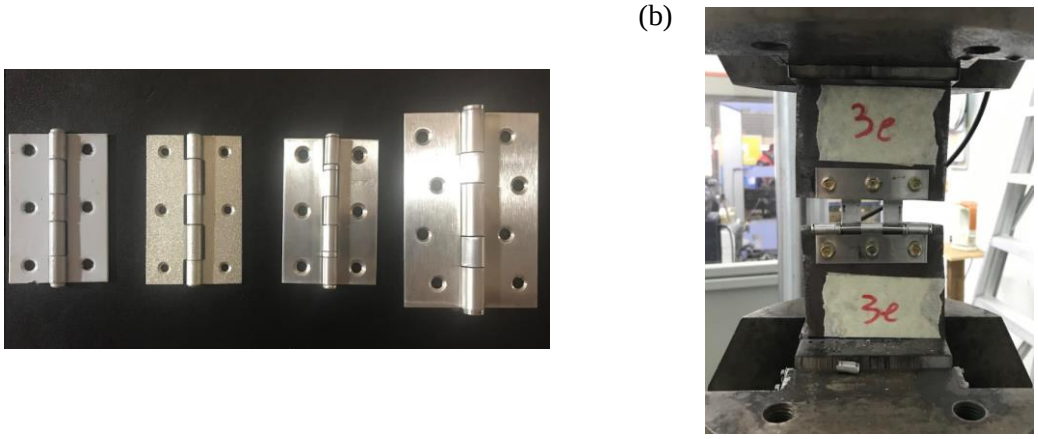

Figure 5. (a) Various door hinges were tested to understand the mechanical behaviour of the hinges under a pulling load. (b) The failure mechanism of the hinges are through the unrolling of the circular curved hook around the hinge bar

Figure 6 shows the comparison of the results from the pull out test on the hinges. The result of the tests shows that the hinges were able to support a horizontal loading perpendicular to the bar of about 7kN which is about 700kg. Although Hinge 2 showed a favourable pull out capacity, the variance in the pull out capacity was high after multiple testing which resulted in Hinge 3 being used in the experimental model.

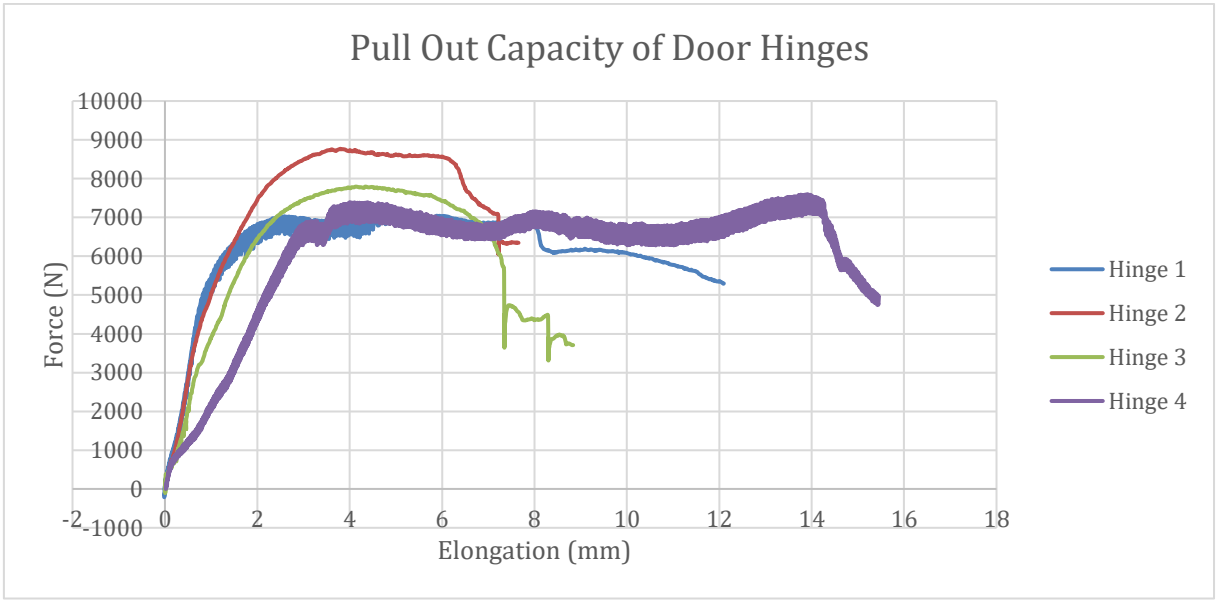

Figure 6. Result of the pull out test measuring the force exerted on the hinges against the elongation of the hinge

6. Folding the physical model

To physically fold the experimental model, an overhead framing system was built with four movable steel beams as shown in Figure 7. A chain block supported by rollers were placed on these steel beams to allow for movement. The moveable steel beams that were supporting the rollers allowed for the lifting points to cover almost all of the area within the steel frame which has a footprint of 5m x 6m, allowing for reusability in carrying out future works on foldable structure that has a different crease pattern.

(a) (b) (c)

Figure 7. (a) A 6m x 5m steel frame that supports the lifting mechanism used to fold the structure which comes with (b) moveable overhead steel beams supported by rollers and (c) moveable lifting hook which traverses along the length of the moveable steel beams

The folding was initiated by the vertical lifting of the experimental model at 3 vertices using chain blocks. These chain blocks were attached to movable beams which allowed for the horizontal movement of the lifting points in both East West and North South direction. The model will be lifted up in sequence to the desired height starting with the vertex that was estimated to be at the highest point in the simulations. The desired height for each of the lifted vertex was decided by the simulated shape and the relative height of these three points were set as the controlled points during the physical folding process. The folding of the physical model is stopped once these three points achieved their desired relative heights.

7. Measurement and gathering data

The important data to gather for the experimental study was the final shape of the folded structure after the folding process which can then be compared against the result of the simulation. Due to the suspended nature of the experimental foldable structure, any direct contact or an external force acting on the model could make the model sway.

To ensure accuracy of measurement and to minimize the impact of potential sway while collecting data on the final geometry of the model, a total station was used with a precision of up to 1mm. The folded nature of the model also made taking measurements tricky, especially due to there being no direct line of sight to the total station. A prism and ranging rods were used to mitigate the issue of direct line of sight to allow for adjustment in the height of the prism as shown in Figure 8.

(a) (b) (c)

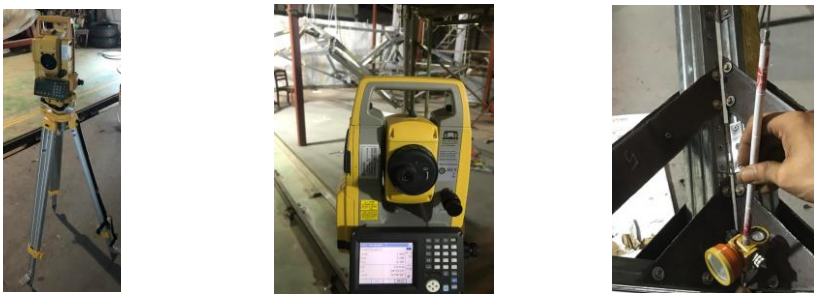

Figure 8. (a) A total station that was used to measure the geometry of the folded structure after folding by (b) establishing the coordinates of each point of interest with the aid of (c) a prism attached to a ranging rod.

8. Comparison of physical model and simulation

The result of the comparison shows that the physical experimental model has folded to a shape that is comparable to the simulation. Figure 9 shows a visualization of the data collected during survey which are represented by the annotated numbers as well as the coloured surfaces. The simulated folding of the experimental model is represented by the solid black lines and when this is put directly next to the collected survey data, the result shows there are difference between the data collected and the simulation, for the surfaces indicated in red to a maximum deviation of 500mm.

(a) (b) (c)

Figure 8. (a) The steel frame of the final folded shape of the experimental model with (b) lightweight surface covering made of foamboard to clearly define the folded surface of the experimental model. (c) The comparison of the simulated model with the actual physical model after folding.

The comparison of the model shows that higher degree of variations were shown in regions further away from the support which attributes the effect of self-weight as one of the factor that led to the variation to the simulated shape.

9. Conclusion

The folding behaviour of an experimental foldable structure with asymmetrical crease lines can be simulated with confidence to a comparable degree. However, the difference between folding a thin sheet of paper to folding a larger scale model brings about various challenges that can be overcome as shown in this paper to create a foldable structure. Through the vertical lifting of vertices which act as the control points, the desired shape of the model can be achieved. The outcome of the comparison between the shape of the simulation model and the folded structure shows a comparable result with higher degrees of variation shown in regions further away from the support which indicate the effect of self-weight on the final folded shape.

Abstract

Curved folded shells made of thin materials find extensive application in architecture, design, and engineering due to their advantageous properties in design, fabrication, and structural performance. While folded shells typically consist of a single sheet of material, this may not always be sufficient to meet the required structural performance for certain applications. One solution is the use of structures composed of multiple layers, forming a hollow cross-section. In the field of technical folding or structural origami, these structures are commonly referred to as origami tubes [1] or multilayer tessellations [2]. This paper presents the authors' development of a (partially) multi-layered curved folding construction that generates one or more folded tubes during the folding process, thereby improving both the static properties and the folding mechanism. The tubes can be generated adjacent to two fold lines, resulting in a multi-layered structure that can have either a constant thickness throughout the folded configuration or explicit individual tubes attached to a specific folded configuration.

Keywords: curved folding, multi-layer folding, folded tubes; thin shells, structural origami

1. Introduction

Technical folding is an approach that enables the creation of three-dimensional spatial geometries using one or several flat sheets of material through folding and/or assembling. Typically, this method produces single-layer shells or tubes. In the construction industry, this approach offers advantages as building elements can be manufactured and assembled in a flat state under controlled conditions, reducing grey energy by minimizing transportation volume. These elements can then be folded on-site into their final form.

To enhance the strength of a shell, the material thickness becomes a crucial factor in addition to its overall geometry. Therefore, it is often beneficial to create shells with a certain thickness, providing them with increased stiffness. Depending on the geometry and fabrication method of the folded configuration, various types of structures can be distinguished, such as folded sandwich panels [3], thick folding [3] [4], and folded tubes [5] [1]. Klett [4] demonstrated that certain tessellations, featuring both straight and curved fold lines, allow for multilayering through coplanar joining, resulting in tube-like openings when in the folded state.

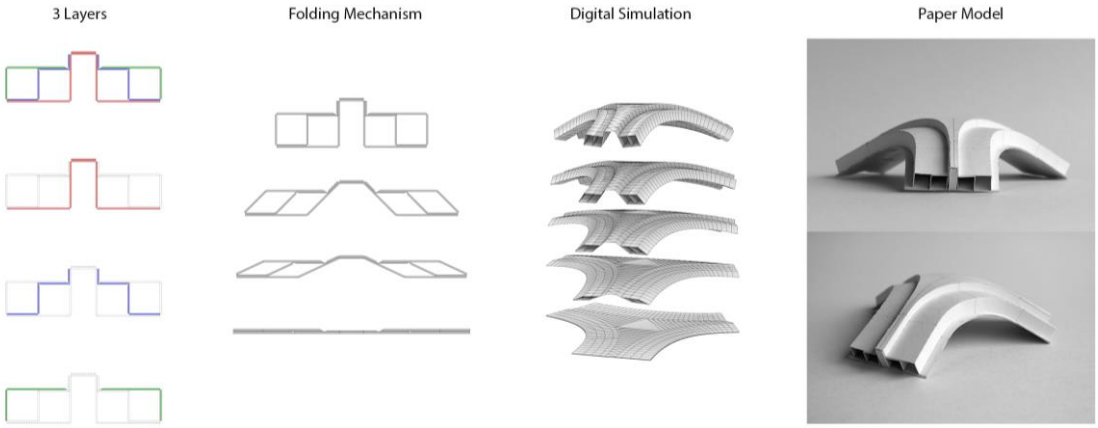

Figure 1. concept, digital and physical model of a multilayered foldable tripod

In this paper, multilayering refers to the incorporation of two or more layers of thin sheet material, where these layers have a coplanar contact area and one or more tubular spacers positioned between the top and bottom layers. Unlike classical sandwich structures where additional sheets are glued to the folded core, the top and bottom layers in this case are integral parts of the entire foldable geometry. The models presented in this study can be assembled in a flat state, making them fully developable. Furthermore, all models can be folded as a single entity in their multilayer configuration.

As depicted in Figure 2, the concept of multilayering can be viewed as a particular form of offset in the cross-section of a foldable component, where the spaced foldable patches remain parallel. Consequently, the multilayered curved folded configurations presented in this paper can also be regarded as foldable shells with an offset, enabling global developability.

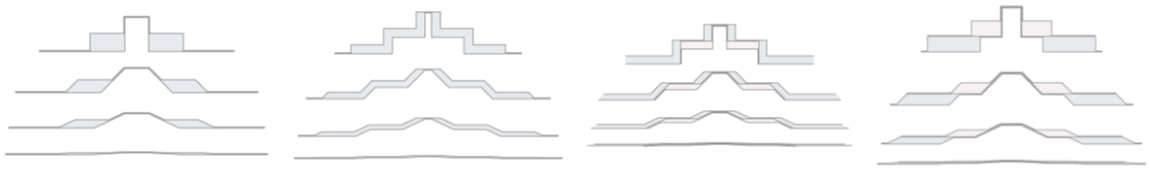

Figure 2. different types of the multilayer concept and its folding behaviour
with two layers (left) and three layers (right).

2. Geometric constraints

Offsetting a curved surface results in a surface with a different surface area compared to the original. However, in the case of multilayering, where globally developable surfaces with identical surface areas are required, additional constraints must be introduced into the process.

A straightforward way to illustrate this approach is through a multilayer shell composed of two identical folded configurations based on a cylindrical surface with parallel rulings, as depicted in Figure 3. By shifting one folded patch along the rulings, a tube emerges between the two patches. The surfaces of these tubes can be viewed as two interconnected offsets that share vertices at the rulings. When these components are joined together, the resulting configuration maintains its properties and can be both developed and rigidly folded.

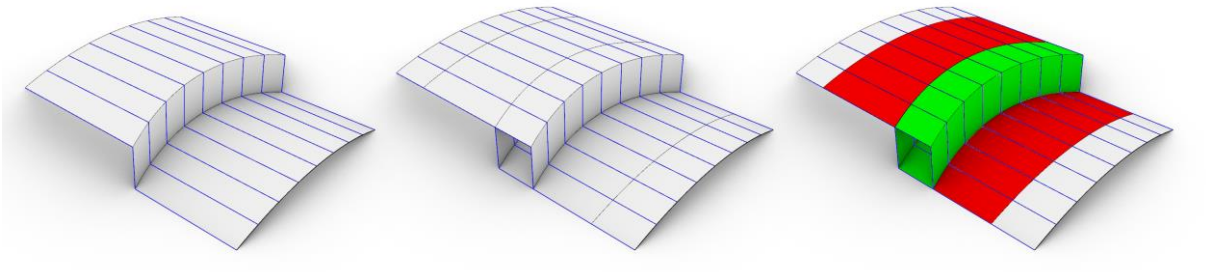

Figure 3. a simple example of a multilayer curved folded shell, with the tube in green and the glued connection surface patches in red

This process gives rise to a new type of curve on the surface, which serves as the fold line for the attached layer and marks the boundary of the surface patch that is glued to the other layer. When considering the entire geometry as a mesh, this curve is described as a manifold mesh edge with three adjacent faces. In the generation of the geometry, this curve becomes crucial as it needs to be defined in both meshes. Since it always represents a fold line but remains unfolded in one layer during motion, we refer to it as a "zero fold" (0-fold) or connection edge.

The distance between two zero folds on one side of the tube must be identical to the distance on the other side. This condition ensures the global developability of the interconnected multilayer structure.

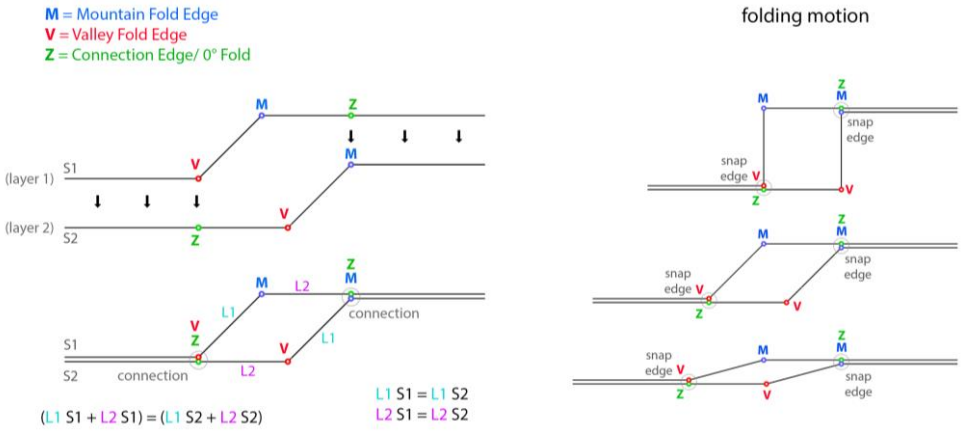

Figure 4. the concept in detail with the zero fold concept and the obligate lengths constrain

We can identify two approaches for generating multilayered shells with folded tubes along fold lines. The first approach involves starting from a folded configuration, as depicted in Figure 3. Alternatively, the tube can be initially generated along a fold line and then extended with surface patches. By combining both approaches, it becomes possible to create complex configurations that incorporate various types of developable surfaces, as well as planar and non-planar spatial curves.

2.1 Tubes in folded configurations

By utilizing a foldable tube as a starting point, there are multiple methods for generating multilayer surfaces. One approach involves extending the rulings of the foldable patches, which results in the creation of a 0-fold and a developable configuration. Two patches can then form different configurations, which can be illustrated as shown in Figure 5. When generated from two distinct sheets, the S- or Z-Types prove to be effective solutions as the tube features only one fold line between the 0-folds. Although other types are possible, they typically require additional fold lines and are not as straightforward to construct using two sheets of material. This paper primarily focuses on the investigation of S- or Z-Types.

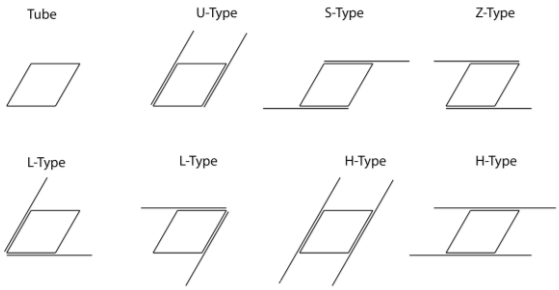

Figure 5. concept sketch of possible construction types, based on a single tube

As depicted in Figure 2, there are numerous possibilities for generating tubes and offsets along or connected to fold lines. Depending on the positioning and arrangement of the tubes, it becomes feasible to create partially or nearly constant offsets within a curved folded shell. When having one tube per fold line in a folded geometry, two layers are sufficient. However, for a constant offset consisting of a series of tubes, a minimum of three layers is required.

Model studies from the paper (Figure 6, left) demonstrate different configurations using various numbers of layers and fold lines between two 0-folds. The findings show that configurations with two layers and multiple fold lines are foldable, although controlling the folding angle precisely to achieve a constant distance between the layers can be challenging. Models from three or more layers allow for geometries whereas larger surface patches can be formed from a series of adjacent tubes that belong to the same fold line. These geometries seem to have 1 Degree of Freedom during folding. A notable example is the folded tripod (Figure 6, right), which serves as a proof of concept with three layers and two adjacent tubes forming the offsets along the fold lines.

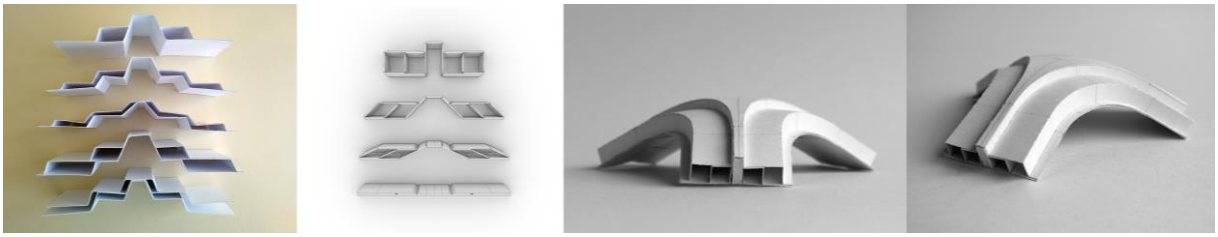

Figure 6. sandwich study (left) and a multilayered curved folded tripod (right)

2.2 Digital design constraints

To successfully achieve control over the numerous constraints involved in multi-layered shells with curved fold lines, it is necessary to adapt or develop new digital approaches and tools. As architects and designers often approximate design surfaces or low-poly meshes using various techniques, the authors of the paper propose a variation of an approach initially introduced by Bhooshan [7]. They combine this approach with the isometry enforcement technique described by Foschi et al. [8]. Starting from a given target geometry, two constrained guessed patches, a 2D development and a 3D guess, are adapted using Mesh relaxation with the help of Rhino3D [9] and Kangaroo [10] to become a foldable structure.

As mentioned earlier, each layer of the folded geometry can be viewed as an individual foldable shell created for the same target geometry but with variations in the positions of the curved fold lines. In order to generate a multilayer configuration, it is necessary to constrain the different layers into a single entity. This can be achieved by ensuring that the 0-folds align with their corresponding mountain or valley folds, and by enforcing the rulings of connected surface patches to be identical on both layers.

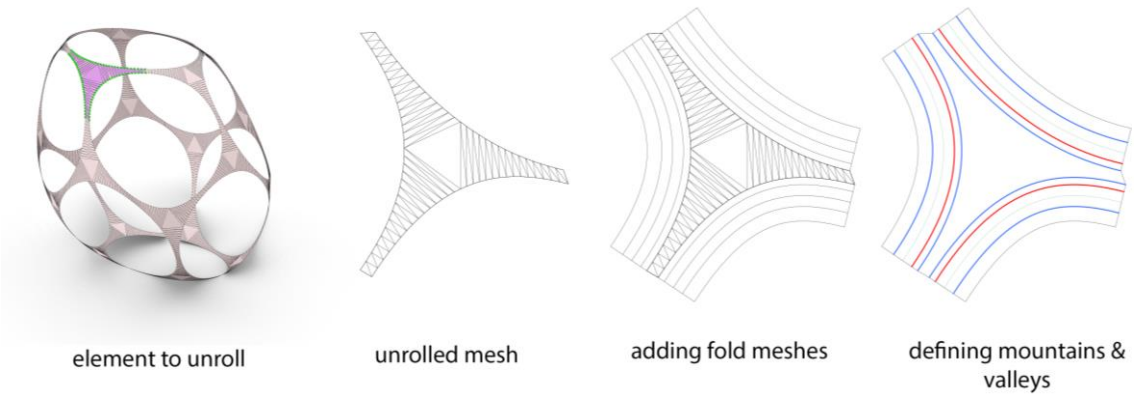

Figure 7. three-layer system applied on a planarized polyhedron

Similar to Bhooshan [7], we begin with a planarized chamfered polyhedron to create a collection of developable patches. These patches consist of planar polygons at the vertices connected by single curved patches. In this specific example, we divide the entire geometry into curved unfoldable meshes, which allow us to obtain 3-armed unfoldable modules in 2D. These are then used to construct the individual folded layers. Following the approach described by Foschi et al. [8], a good initial 2D geometry for the different layers is generated based on this patch. Initially, the outer edges are moved in parallel, and the mesh is extended with surfaces that can be folded in subsequent steps. To facilitate this process, the various fold lines (mountain, valley, and zero folds) must be assigned in 2D prior to guessing the rulings for the surfaces (refer to Figure 7).

The three-armed geometry, also referred to as a tripod [8], can be approximated as a foldable developable geometry through error distribution. At this stage of the process, it is crucial to define the rulings, as they will be enforced to be identical in the touching layers and allowed to change their positions during simulation. The rulings, along with the fold lines, contribute to the formation of a quad-mesh, where each face is required to be planar in both 2D and 3D configurations. Additionally, the surface area of each quad, as well as the entire surface patches, is maintained to be identical. To create tubes within the structure, each layer is assigned different positions for the mountain and valley folds. However, the zero folds are consistently constrained to their corresponding fold lines.

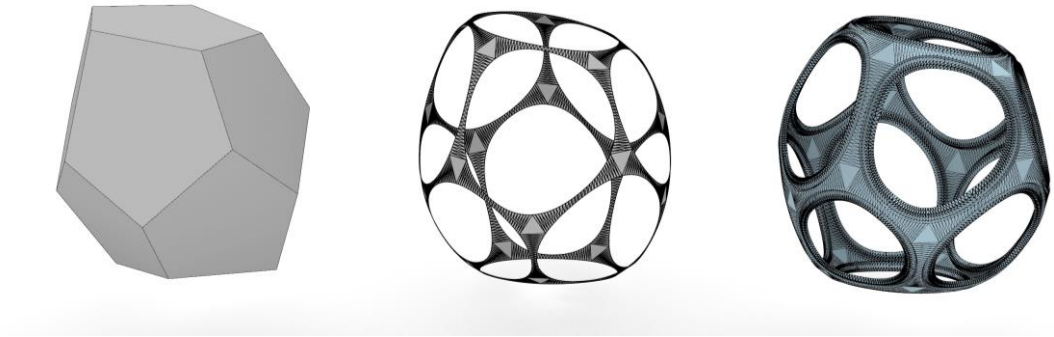

Figure 8. from polyhedron to curved folded multilyer structure with three layers

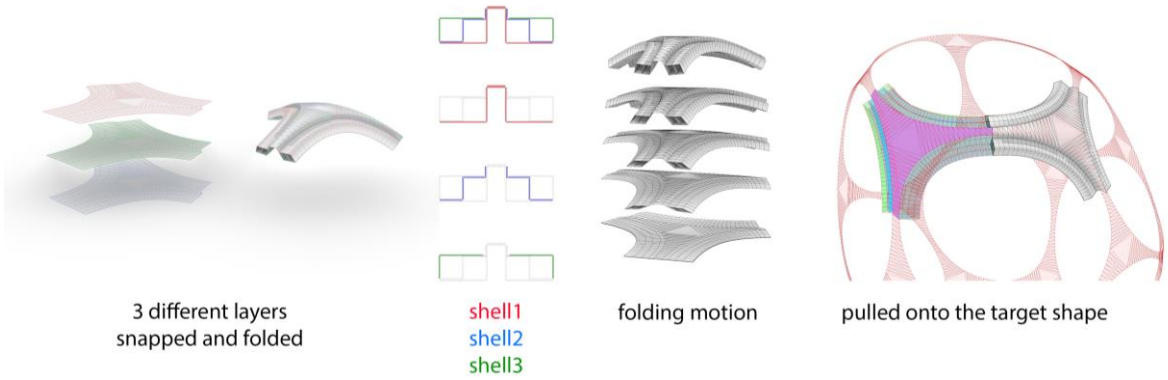

Figure 9. construction and application of the 3-shell construction in digital form

During the simulation, the lengths of corresponding edges and the areas of the planar quads are adjusted to be equalized in both the 3D and 2D states. The fold lines of each tube should be parallel offsets and superimposed in 2D as long as the 3D folding edges are planar curves. The outer boundaries of all layers within each tripod are identical, and the connections between the parts and neighboring tripods are constrained to ensure the formation of a seamless 3D folded geometry composed of multilayer tripods. The folded states of the individual layers can be observed in Figure 9, while the seamless structure and its cross-section are depicted in Figure 10.

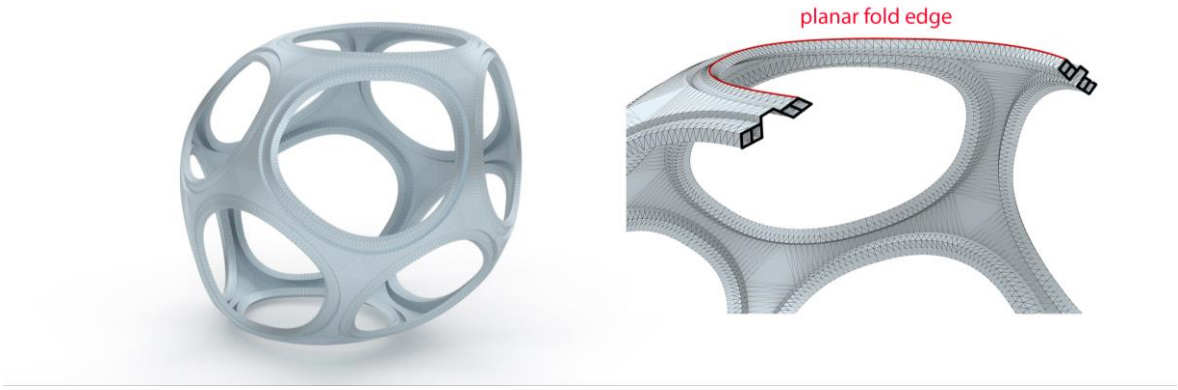

Figure 10. Digital Model of a multilayer curved fold with two adjacent tubes on a planarized polyhedron

2.3 Non-planar curved folds

The motivation for this investigation stemmed from the observation that certain artistic curved folded models utilize not only planar curves but also non-planar spatial curves as fold lines. It was inspired by Tachi's work [11], which demonstrated that such curves must be smooth and can be translated into a curved folding patch by generating consecutive rulings. However, the paper does not specifically address whether these surfaces correspond to cones, cylinders, or tangent developable surfaces, nor does it delve into an in-depth examination of the developed patches.

In this paper, our focus is on an approach that relies on isometry enforcement. By utilizing this technique, we can generate foldable surfaces consisting of planar quads without the need to predefine the surface patches or the parameters of the second patch, as required by the Lotus method [12].

If we apply the strategy described for planarized polyhedra and its resulting planar curves to a non-planar spatial curve, such as a helix curve, the physical models generated will still be foldable. However, the fold lines formed in these models will be planar instead of retaining the non-planar nature of the original curve. To address this, we propose adapting the approach presented by Tachi [11].

The first step involves generating a folded patch along the space curve, which is then unfolded to a 2D representation. In most cases, non-planar curved fold lines result in tangent developable surfaces that limit the extension along the rulings (as depicted in Figure 11, right) in terms of width. To create different 2D patches from the same space curve, the dihedral angle along the fold line can be varied (as shown in Figure 11, left).

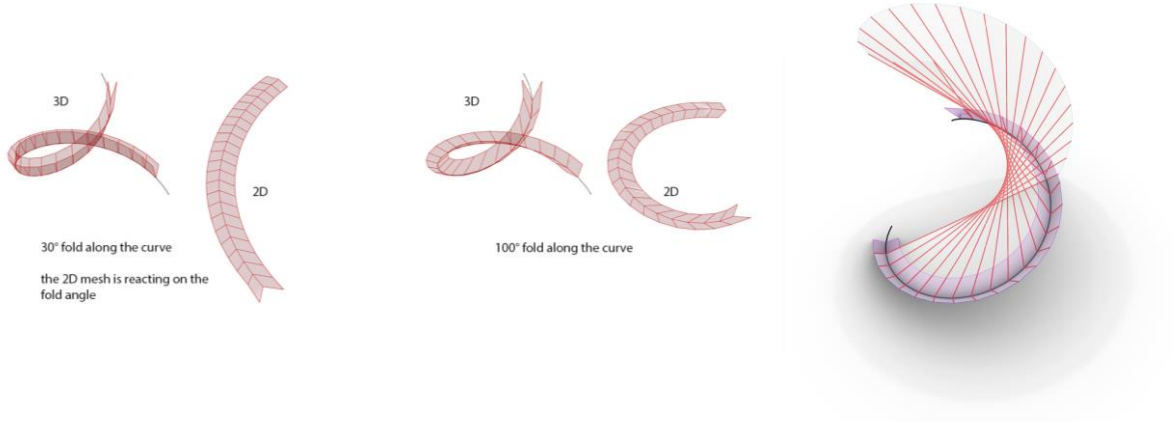

Figure 11. (left) strip out of planar quads folded on a helix curve; (right) extension of the rulings

As Tachi defines the entire tube-profile of the tube to generate it along the space curve, we propose a different approach that can be applied by isometry enforcement. In order to make a foldable tube from this first patch, two things need to be taken into account. The connection between the two strips and the rulings of the two strips.

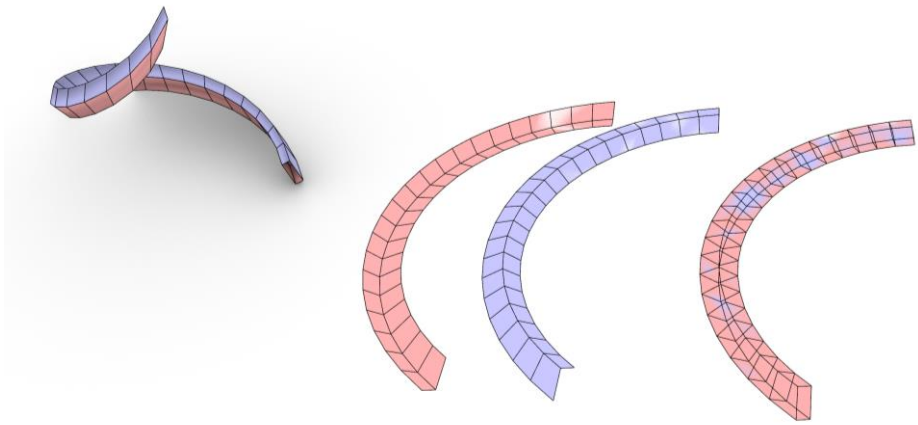

Figure 12. double shell tube along a helix curve in 3D (left) and its developed patches (right)

By considering the fold angle of the second patch as undetermined and utilizing the boundary edges of the first 2D patch as 0-folds to connect the two strips, we can generate a reasonable approximation by directly copying and defining the first patch as the second layer. This approach ensures the proper edge connection along the 0-fold and matching rulings of both patches there.

As the fold line and the rulings of two connected layers cannot be parallel for a non-planar fold line, the rulings and the fold line of the second layer will change position and length. These changes allow for the intersection of the two fold lines in the 2D patch while appearing 'parallel' in the 3D folded structure. As demonstrated by Tachi, the cross section of the resulting tube takes the form of parallelograms.

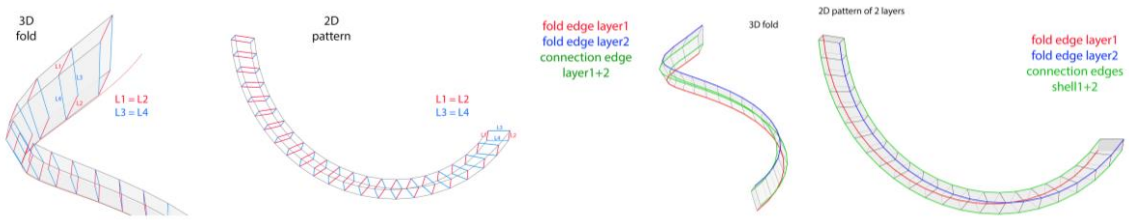

Figure 13. different section parallelograms

In the 2D pattern, the fold lines of a helix fold curve intersect once (Figure 13). In this particular case, the global dihedral angle was set to 120° and varied slightly along the fold line within the constraints of isometry enforcement. However, it has not been conclusively proven whether a consistent variation of the angle along the fold line is always possible. This remains an ongoing area of research.

When applied to other "nice" spatial curves, the authors were able to generate a wide range of foldable tubes. Various tests revealed that the fold lines of a helix intersect once in 2D, while other configurations may allow for multiple intersections in 2D. The authors hypothesize that this behavior is associated with the number of inflection points present in the non-planar space curve.

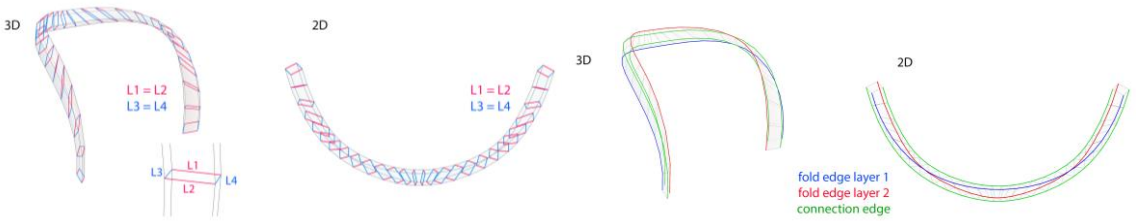

Figure 14. different section parallelograms and interscting foldlines in 2D

While the digital and physical models demonstrate the ability to create a wide range of tubes with varying folding angles, clear limitations have not yet been fully defined. It is evident that excessive changes in curvature along the space curve are not advantageous, as well as relatively wide tubes that may be constrained by resulting curves of regression. A comprehensive investigation into these limitations is currently a subject of ongoing research.

2.3 Tubes and shells from multiple fold lines.

If spatial curves serve as the foundation for a design process, it is essential to accommodate multiple spatial curves within that process. In contrast to Booshan's approach, which uses planar boundary curves of a developable patch as fold lines, the authors propose generating the developable patch between the curves. This patch, along with its rulings, is then utilized to create two connected tubes.

To illustrate this approach, two connected tripods can be employed as a design basis. By rotating one end of the tripod, one curve transitions from planar to non-planar. In Figure 15, a regular tripod with planar curves is discretized using planar quads. By rotating one end of the figure by 17°, the red curve transforms from planar to non-planar. The quads remain planar but undergo a change in the orientation of their rulings.

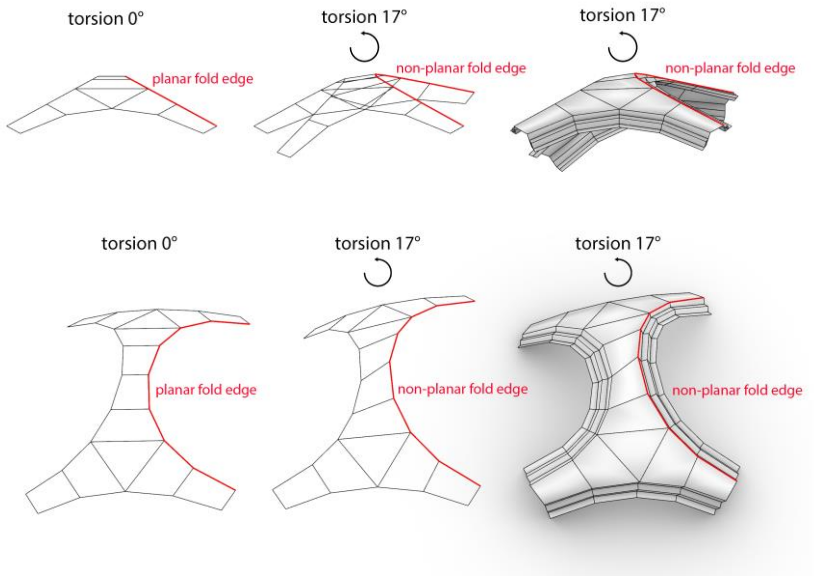

Figure 15. the tripod torsioned and materialized with a multilayer shell

By utilizing this base, a foldable shell with two layers can be generated, resulting in a structure with two tubes along each spatial curve. The original developable patch becomes in this configuration a connected one, that includes both layers with identical rulings and valley folds at the boundary (Figure 16).

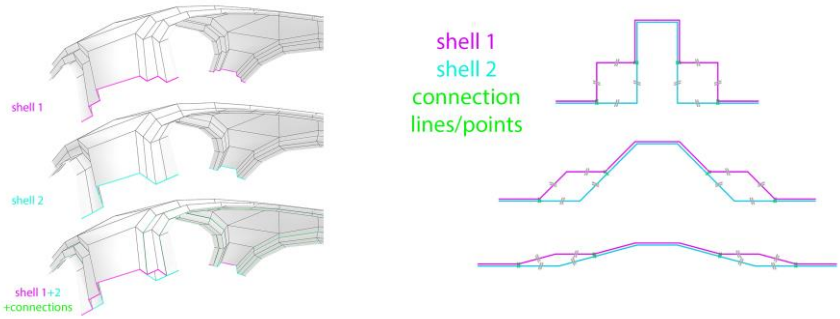

Figure 16. explanation of the layers

As described earlier, the cross-sections of the tubes exhibit unequal parallelograms in the simulation. This implies that the rulings and folded edges of both layers differ only at the tubes or the points where the tubes are formed. However, for the remaining patches, the layers are connected at all points and remain identical throughout and fulfill the multilayer condition.

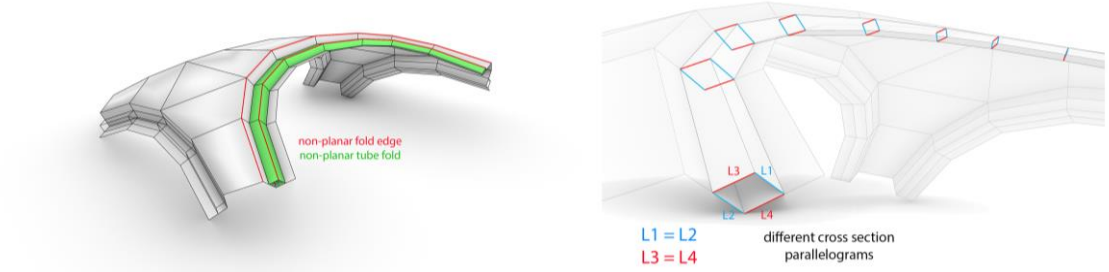

Figure 17. non planar fold edge and equalized tube ruling lengths

The non-planar curve also results in a transformation of the developable surface from a cylinder to a tangential developable one. In certain cases, the surface may exhibit characteristics of two conical surfaces with apexes located on opposite sides of the fold lines. However, defining the precise limits and underlying rules of this transformation is still a topic of ongoing research. By extending the rulings, the overall limits of the system can be readily identified without the need to generate the entire regression curve. The extension can be halted as soon as two non-neighboring faces intersect, allowing for a clear visualization of the limits (see Figure 18).

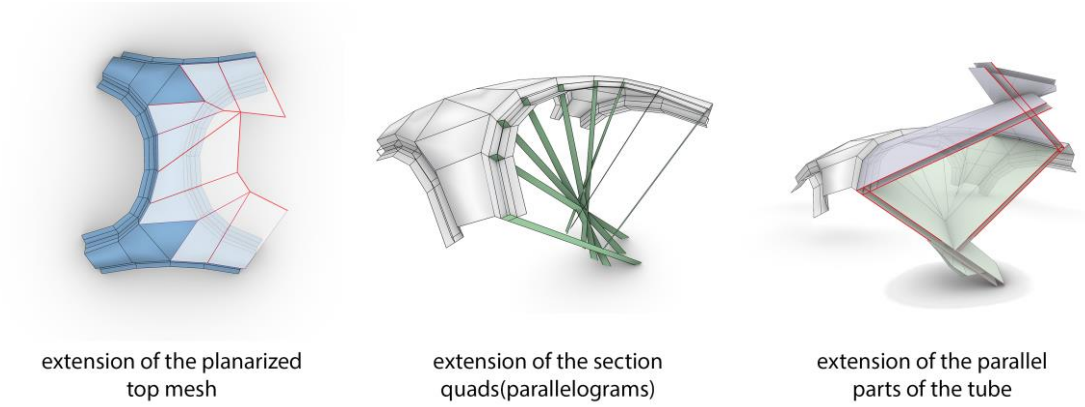

Figure 18. showing some extionsions of different parts of the folded object

2.4 Conclusion

The authors have provided an overview of their novel approach for generating multilayered foldable shells. They introduced the topic and presented two fundamental concepts for developing these new configurations. They discussed the constraints involved in connecting foldable tubes and constructing multilayer configurations. Additionally, they explained the application of isometry enforcement to both planar and non-planar curves, enabling the generation of intricate and complex configurations.

3. Outlook

The implementation of tubes through multilayering in curved folded shells holds great promise for various applications, ranging from architecture and design to fabrication and structural performance.

This paper serves as an initial starting point for a more comprehensive and detailed exploration of these shells. The design potential for spatial geometries is exemplified in Figure 19, showcasing a pavilion-like structure created by one of the authors using a set of spatial curves. Future research will delve further into not only geometric constraints but also manufacturing considerations and structural performance, aiming to advance the understanding and application of these innovative structures.

Abstract

Origami hyperbolic paraboloid (origami hypar) provides an avenue to be multi-stable via bifurcation branches of kinematic paths. However, some symmetry properties make origami hypar possess subtle multi-stability. The extensive application of symmetry properties will simplify the transition among various steady states in multi-stability study. Here, group theory and symmetry breaking are applied to the multi-stability analysis of hexagonal hypar to eliminate singularity in the stiffness matrix near the bifurcations. Results show a single hexagonal hypar has six steady states in total and the tessellation with three hexagonal hypar shows more stable states. Different bifurcation branches will convert to each other only if the structure is fully flattened. Notably, the energy barrier between the two stable states increases with the symmetry order of the branch. The ease of the transition among various steady states is determined by the difference between the potential energies of the initial steady state and the fully flatted state. This strategy will provide a basis for the multi-stability properties of origami hypar and promote the multi-stability study of origami structures with high order symmetry.

1. Introduction

Non-trivial energy landscapes in multi-stable structures contribute to multiple stable equilibrium configurations. The transitions among stable states are often adopted to meet the geometric and functional requirements. Recently, multi-stable structures have received wide attention in bionics [1], metamaterials [2], robotics [3], engineering structures [4] and other fields. Typically, multi-stable structures originate from the combination of bistable units [5]. The overall properties of multi-stable structures depend on the local properties and composition of bistable units. For instance, a specific double-layer Kresling tube can transition between two different stable states without changing the total height [6]. Due to the abundant mechanics [7, 8], more origami structures have been utilized to develop bistable units and become an increasingly important approach to designing multi-stable structures.

Based on classic origami patterns, plenty of multi-stable origami structures have been derived (e.g., Miura-ori [9], Tachi-Miura polyhedron [10], and Kresling tubes [11, 12]). As representative multi-stable origami units, the square twist [13, 14], leaf-like origami [15], and origami hypar [16] are combined to acquire more numbers of stable states and richer programmability of origami structures. Notably, kinematics analysis of multi-stability origami is essential to ensure the folding process smoothly. The popular strategies for kinematic analysis of rigid and non-rigid origami include mechanism analysis and structural analysis. Compared with non-rigid folding, the conditions of rigid folding are much more severe. Consequently, rigid folding possesses a smooth kinematic analysis and can be handled with more computational models [17]. On the other hand, the non-rigid folding exists the deformation of the panel. However, mechanism analysis fails to deal with the deformation of the panel. Hence, analysis of non-rigid origami typically adopts the modified bar-and-hinge model [18], the membrane-and-hinge model [19], and the thin plate element [20].

In terms of the non-rigid and multi-stable origami units, origami hypar has attracted abundant attention, especially the square origami hypar and the circular origami hypar [21]. Two stable states of square origami hypar are macroscopically symmetric. Due to the competing folding, stretching, and bending energy [18], the square origami hypar first flat-unfold and then refold up during the transition between two stable states, going through a significant energy barrier. On the other hand, circular origami hypar possesses different stable states according to different approximate width conditions. For example, it will generate a saddle-like shape under the simplest condition. In addition to the two extreme cases, the multi-stability of polygonal origami hypar remains to be studied in-depth. Therefore, an investigation of the multi-stable properties of the hexagonal origami hypar will be performed.

An efficient and effective approach to identifying all stable states is essential to study multi-stability of the hexagonal origami hypar because experiments have proven it possesses at least two stable states. However, the approach to solving the bistability may be infeasible to handle with the global properties of the hexagonal origami hypar because the tangent stiffness matrix may become ill-conditioned. Kinematic bifurcation analysis of deployable structures can be adopted to simplify the simulation of the global process [22]. Singular value decomposition has been validated to be suitable for determining bifurcations [23]. Additionally, some studies [16, 24] have tackled the method of assuming the bifurcation parameters and the group theoretic approach to simplify multi-stability analysis by bifurcation branches. However, group theory and symmetry property are mostly applied in the design of novel crease patterns, whereas few attempts have been implemented in the field of stability studies.

Here, a new strategy will be proposed to study the multi-stability of hexagonal origami hypar by group theory and its representations. The whole folding process of origami structures will be simplified by the group-theoretic approach. In terms of origami structures with high-order symmetry as the hexagonal origami hypar, the bifurcation branches will be solved by symmetry breaking. Through kinematic analysis of different bifurcation branches, the corresponding stable states will be acquired. The multi-stability in the whole kinematic process is shown by the bifurcation branches and the corresponding stable states. In the following sections, we will study the multi-stability of the hexagonal origami hypar

in different bifurcation branches through the group-theoretic method. In addition, the potential stable states and the effect of geometric parameters will be discussed.

2. Methodology

It is assumed herein that the equivalent bar-and-hinge model will be leveraged to analyze the deformation of the hexagonal origami hypar. Based on group theory, the analysis process is simplified to bifurcation branches. The bifurcation branches can be obtained by symmetry breaking.

2.1. Principle of stationary potential energy

The establishment of the equivalent bar-and-hinge model is based on the potential energy approach. The total potential energy Π consists of strain energy U and external work W. In general, the strain energy U of non-rigid origami is decomposed into facet bending or twisting energy U_b, crease folding energy U_f and bar stretching energy U_s [25]. Thus, the total potential energy can be expressed as

$$\Pi = U - W = U_b + U_f + U_s - W \tag{1}$$

Based on the principle of stationary potential energy, the equilibrium condition can be derived as follows.

$$\mathbf{K}\boldsymbol{\Delta}_\mathbf{d} = \mathbf{F} \tag{2}$$

where $\mathbf{K}$, $\boldsymbol{\Delta}_\mathbf{d}$, and $\mathbf{F}$ denote the tangent stiffness matrix, the generalized displacement vector, and the force vector, respectively. The internal force vector and the tangent stiffness matrix consist of different components. It is essential to assemble them from equivalent nodal loads and elementary stiffness matrices.

The tangent stiffness matrix K includes the folding stiffness of the crease $\mathbf{K}_F$, in-plane stretching and shearing stiffness of the bar $\mathbf{K}_S$, and out-plane bending stiffness of the facet $\mathbf{K}_B$. In equivalent bar-and-hinge models, $\mathbf{K}_F$ is affected by the stiffness of rotational spring elements $\mathbf{K}_{spr}$ and the stiffness of bar elements $\mathbf{K}_{bar}$ is composed of $\mathbf{K}_S$ and $\mathbf{K}_B$. Namely, $\mathbf{K}_F = \mathbf{K}_{spr}$ and $\mathbf{K}_S + \mathbf{K}_B = \mathbf{K}_{bar}$. Hence, the stiffness components can be assembled as follows:

$$\mathbf{K} = = \ d\mathbf{f} \,/\, d\mathbf{u} = \mathbf{K}_F + \mathbf{K}_S + \mathbf{K}_B = \mathbf{K}_{spr} + \mathbf{K}_{bar} \tag{3}$$

To acquire the elementary stiffness matrices, we adopted the hyperplastic model to simulate the constitutive relationship of bar elements [26]. The elementary stiffness matrices have the following expression.

$$\begin{cases} \mathbf{K_F^e} = k_F^e \, d\theta/d\mathbf{u} \otimes d\theta/d\mathbf{u} + M_F \, d^2\theta/d\mathbf{u}^2 \\ \mathbf{K_B^e} = k_B^e \, d\theta/d\mathbf{u} \otimes d\theta/d\mathbf{u} + M_B \, d^2\theta/d\mathbf{u}^2 \\ \mathbf{K_S^e} = k_S^e \left(\mathbf{B}_1^T + \mathbf{B}_2\mathbf{u}\right)\left(\mathbf{B}_1^T + \mathbf{B}_2\mathbf{u}\right)^T + f_s\mathbf{B}_2 \end{cases} \tag{4}$$

2.2. A group-theoretic approach to the global bifurcation analysis

The tangent stiffness matrix near the bifurcations will become ill-conditioned when simulating the kinematic path. Group theory [27] is regarded as an effective method to avoid this problem. The essence of the global bifurcation analysis is to tackle the vector equilibrium equation.

$$\mathbf{f}\left(\mathbf{u}, m\right) = \mathbf{0} \tag{5}$$

where $\mathbf{u}$ belongs to an N-dimensional real vector space and m is a real number. Based on the symmetry-adapted coordinate system, the equation will be simplified by the successful implementation of Newton-Rapson procedure using block-diagonalization, as shown below.

$$\begin{bmatrix} \mathbf{K}_{v^{(1)}} & 0 & \cdots & 0 \\ 0 & \mathbf{K}_{v^{(2)}} & \cdots & 0 \\ \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & \mathbf{K}_{v^{(p)}} \end{bmatrix} \begin{bmatrix} \Delta\mathbf{u}_1 \\ \Delta\mathbf{u}_2 \\ \vdots \\ \Delta\mathbf{u}_n \end{bmatrix} = \begin{bmatrix} -\mathbf{f}_m \\ 0 \\ \vdots \\ 0 \end{bmatrix} \tag{6}$$

Thereafter, the vector equilibrium equation can be decomposed into independent problems associated with specific symmetry subspaces through the decomposition of matrices. Namely, Eq. (5) can be tackled by solving Eq. (7) involved with different subspaces.

$$\mathbf{K}_{v^{(1)}} \Delta\mathbf{u}_1 = -\mathbf{f}_m \tag{7}$$

In symmetric structures, symmetry subgroups are related to different symmetry subspaces. Hence, the bifurcation branches of the original structure will be composed of the bifurcation branches of the corresponding symmetry subgroups [28].

2.3. Symmetry breaking

Symmetry breaking behavior [7] exists in the transformation from the primary path to the bifurcation paths of deployable structures. That is, different bifurcation paths will be captured by reducing the symmetry order of structures.

The C_{nv} symmetry group contains a total of 2*n* independent symmetry operations [16].

$$C_{nv} = \left\{ C_n^j, \sigma_j \mid j = 1, 2, \cdots, n \right\} \tag{8}$$

where the rotation C_n^j represents that the original structure rotates an angle $2\pi j/n$ around the symmetry axis, $j \in [1, n]$, and σ_j donates the *j*th reflection along the vertical symmetry plane.

Without any constraints, the plane pattern of hexagonal origami hypar will be classified as C_{6v} symmetry group. The higher symmetry order of internal mechanism mode, compared with the self-stress state, will lead to kinematically indeterminate structures becoming mobile [29]. Hence, to ensure the foldability of origami hypar, the symmetry order of the self-stress state should be decreased less than that of the initial pattern [7]. The subgroups of C_{6v} group can be computed by

$$C_1, C_2, \ldots, C_6, C_v, C_{2v}, C_{3v} \subset C_{6v} \tag{9}$$

Based on theorems for mountain-valley assignments [30], the plane patterns possess a symmetric distribution of crease along the diagonals. That is, as a symmetry subgroup containing only cyclic rotations, C_6, C_3, C_2, and C_1 will be excluded. Hence, the subgroups with mirror symmetry, namely C_{3v}, C_{2v}, and C_v, will be studied.

When the symmetry order of the mechanism mode fails to meet the full symmetry, the origami structure will undergo a transition to a bifurcation branch with lower-order symmetry. Notably, the symmetry order of the related constraint modes matches the bifurcation branch. Namely, controlling the constraint mode is an effective method to programme the specific symmetry breaking of the structure.

By symmetry breaking, Figure 1A(b), (c), and (d) diagram C_{3v}, C_{2v}, and C_v symmetry origami configurations, respectively. In addition to constraint modes, the mountain-valley properties of the innermost creases are different among different bifurcation branches. The definitions of geometric and material properties are referred to the study of square origami hypar [18]. The geometric parameters include the fold spacing *d*= 8mm, the inner fold spacing *D*= 8mm, the number of the crease layers *n*= 8, and the thickness *t*= 127 μm. The material parameters consist of the elastic modulus *E*= 5GPa and the Poisson's ratio μ = 0.35.

2.4. Capture of stable 3D configurations

To track other stable states, it is urgent to capture a stable 3D configuration as the initial state 1. Because the tangent stiffness matrix near the bifurcations is often ill-conditioned. According to the folding of the square origami hypar [18], Figure 1B(a) shows the distribution of applied forces used to fold the initial pattern. Under this loading mode, the plane C_{3v} pattern will be transformed into an initial 3D configuration, see Figure 1B(b). Notably, this configuration is in a random state and remains existing the ill-conditioned possibility. Hence, the initial 3D configuration should be released from the loading and then transform into one of stable states, as shown in Figure 1B(c). Similarly, the capture of stable 3D configurations should be implemented to be used as an initial state 1 when we track the stable states of structures with different symmetry.

Thereafter, the structure will experience a complex transition from a stable state to a specific state with the imposition of displacement. The variations of configurations and equilibrium load versus displacement curves will be monitored during this process. On this basis, the number of stable states is judged according to the number of minimum in energy versus displacement curves and then validated by physical models. Figure 1C presents the flowchart of the multi-stabile investigation.

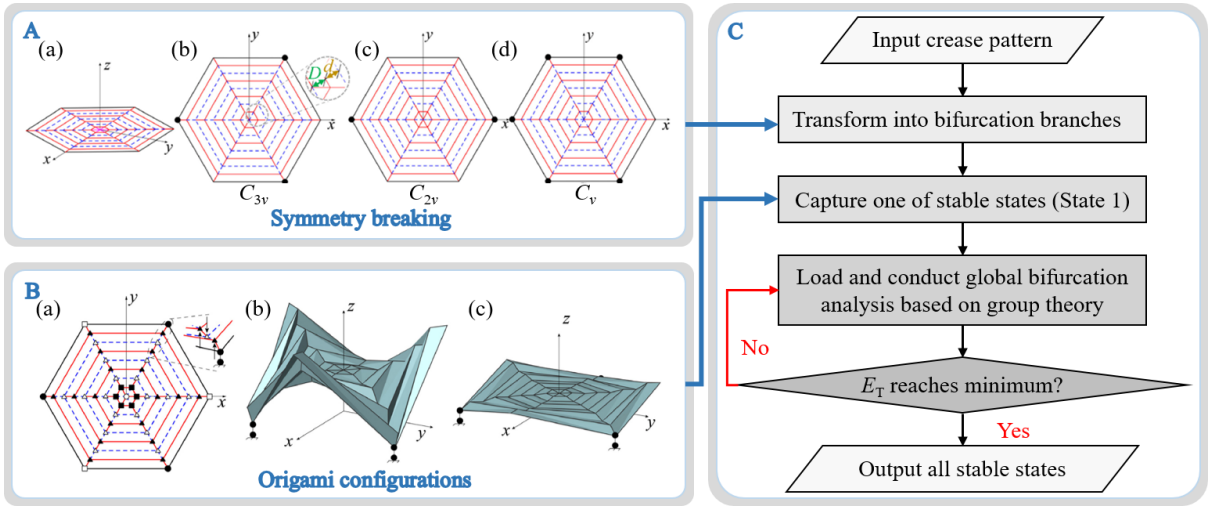

Figure 1 (**A**) Crease patterns of the hexagonal origami hypar: (a) Three-dimensional view of the crease pattern. (b) to (d) Different constraint modes and crease patterns corresponding to C_{3v}, C_{2v}, and C_v symmetry. (**B**) 3D origami configuration with C_{3v} symmetry. 3. Results

3.1. Multi-stability of hexagonal origami hypar

3.1.1. Hexagonal origami hypar with C_{3v} symmetry

According to Section 2.4, state 1 will be tackled as the initial state to find other stable states. In Figure 2(a), three lower vertices on the boundary are constrained, and downward displacements are imposed on the other vertices. In Figure 2(c), the equilibrium load will first increase from zero (state 1) to peak (state P1) and then decrease to zero (state 2) with the imposition of displacement. Subsequently, the equilibrium load experiences a roughly symmetric variation about state 2 as the center point. As for macroscopical configurations, the structure (state 1) will unfold to an approximately fully flat state (state

2). Subsequently, it continues to fold and achieves a new equilibrium (state 3). Notably, state 1 and state 3 are the null points of the equilibrium load-displacement curve as well as the minimum of the total potential energy. Based on the energy principle, it is considered that state 1 and 3 are two different stable states of the hexagonal origami hypar with C_{3v} symmetry.

The total potential energy E_T is composed of the folding energy E_F and the panel deformation energy $E_B + E_S$, which includes the tensile and shear energy E_s and the bending energy E_B. As shown in Figure 2(d), E_F is much larger than $E_B + E_S$. That is why the creases will be folded preferentially. However, $E_B + E_S$ accounts for a non-negligible proportion of E_T, especially when the configuration is close to state 1 and 3. Hence, the panel deformations remain to be taken into consideration during folding. In other words, the folding of hexagonal origami hypar is a non-rigid process.

During the folding process (i.e., the transition from state 1 to state 2), E_T and E_s increase with the folding angle, whereas E_B decreases with the flattening of the panels. On the contrary, the unfolding process (i.e., the transition from state 2 to state 3) undergoes an exactly opposite variation.

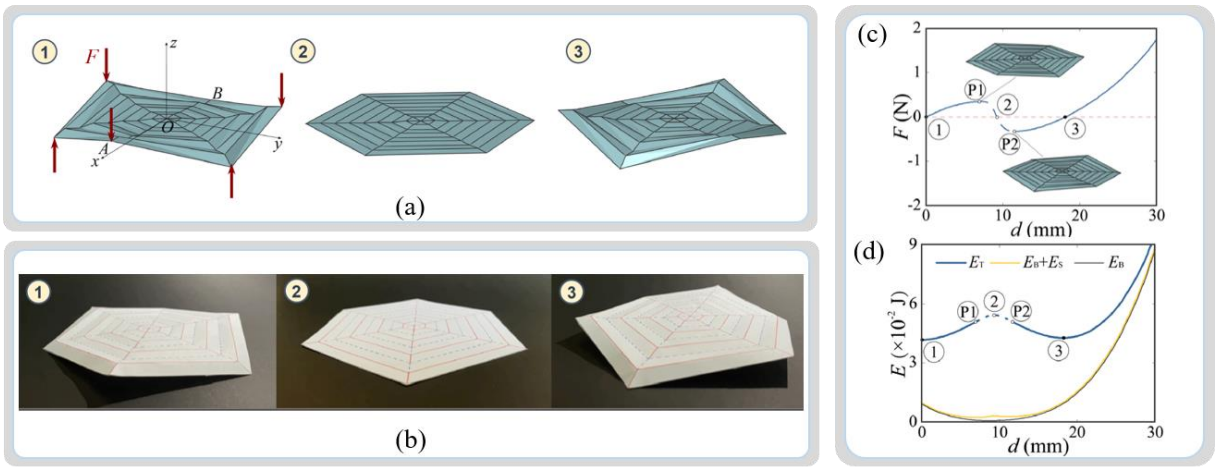

Figure 2 Multi-stability of hexagonal origami hypar with C_{3v} symmetry: (a) Key states. (b) Physical models. (c) Equilibrium load versus displacement curves of single load point. (d) Stored energy versus displacement curves.

3.1.2. Hexagonal origami hypar with C_{2v} symmetry

Notably, constraints and crease patterns in this case are distinguished from Section 3.1.1. Due to the variation of constraint conditions, the unconstrained outermost vertices are imposed downward loads. The loading mode of the remaining nodes is identical with Figure 1B(a).

With the increasement of displacements, the structure first unfolds to approximately fully flat State 2 and then folds to another stable State 3. As shown in Figure 3(d), the bending deformations $E_B + E_S$ dominate the deformations of facets during this transition. Hence, it can be demonstrated the non-rigid property of hexagonal origami hypar with C_{2v} symmetry. Similarly to hexagonal origami hypar with C_{3v} symmetry, the equilibrium load undergoes a symmetric variation about state 2 as center point. In addition, the total potential energy curves achieve two minimums, which indicates the bistability of hexagonal origami hypar with C_{2v} symmetry.

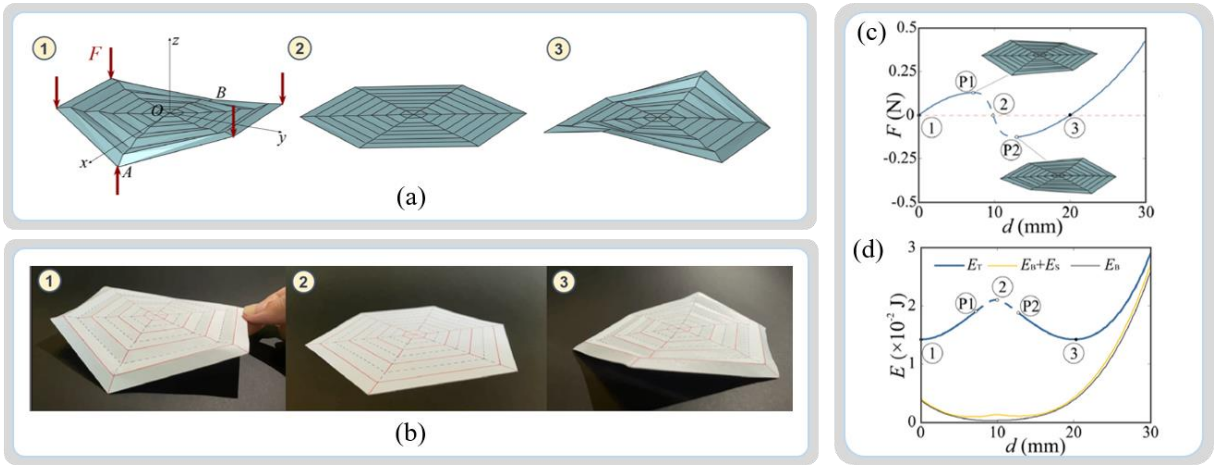

Figure 3 Multi-stability of hexagonal origami hypar with C_{2v} symmetry: (a) Key states. (b) Physical models. (c) Equilibrium load versus displacement curves of single load point. (d) Stored energy versus displacement curves.

3.1.3. Hexagonal origami hypar with C_v symmetry

With the further reduction of symmetry, the lowest symmetry mechanism mode is presented in Figure 1A(d). The stable state 1 is acquired according to the method explained in Section 2.4. Thereafter, the five outermost vertices are constrained and the remaining vertex is imposed a downward displacement, as shown in Figure 4(a).

Compared with Section 3.1.1 and 3.1.2, Figure 4 diagrams similar variations of macroscopical configurations, the equilibrium load, and the total potential energy. In other words, the properties of non-rigid and bistability are invariable regardless of any bifurcation paths.

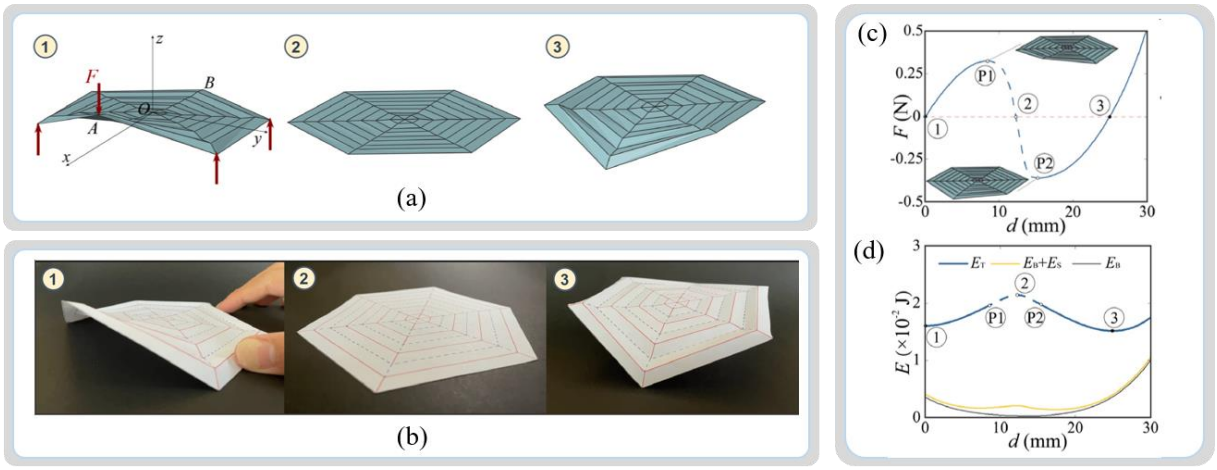

Figure 4 Multi-stability of hexagonal origami hypar with C_v symmetry: (a) Key states. (b) Physical models. (c) Equilibrium load versus displacement curves of single load point. (d) Stored energy versus displacement curves.

3.2. Comparisons of multi-stability among different bifurcation branches

To compare different bifurcation branches, a unified coordinate system is adopted in Figure 5. Points I_a, $P1_a$, $P2_a$, III_a, points I_b, $P1_b$, P2b, III_b, and points I_c, $P1_c$, $P2_c$, III_c correspond to the States 1, P1, P2, and 3 on the bifurcation branches with C_v, C_{2v} and C_{3v} symmetries, respectively. Considering the number of loading points is different among these bifurcation branches, the total equilibrium load is chosen to compare. Owing to the symmetry of loading conditions, the equilibrium loads are identical in terms of any loading points. Hence, the total equilibrium load will be equal to the equilibrium load of a single

loading point multiplied by the number of loading points. For example, the total equilibrium loads of the bifurcation branch with C_{3v} symmetry can be acquired by multiplying the equilibrium load of a single load point by three.

In Figure 5(a), the states of these bifurcation branches at the point X, Y, Z, X', Y', and Z' are different. As for Point II, it is the only intersection of these three bifurcation branches. On the other hand, it is observed in Figure 5(c) that there is no intersection except point II. In other words, point II is the only critical point of these three bifurcation branches. Therefore, the critical point II is considered as the zero potential energy state (i.e., fully flattened state).

The extreme values of the total energy curves reflect the differences of the energy barrier of conversion. Namely, the bigger extreme values are, the more difficult folding transformation will be. Figure 5(d) demonstrates the bifurcation branches with C_{3v} and C_v symmetry possess the biggest and slightest energy barrier against the transition to another stable state, respectively. The energy barrier of the bifurcation branch with C_{2v} symmetry falls in between.

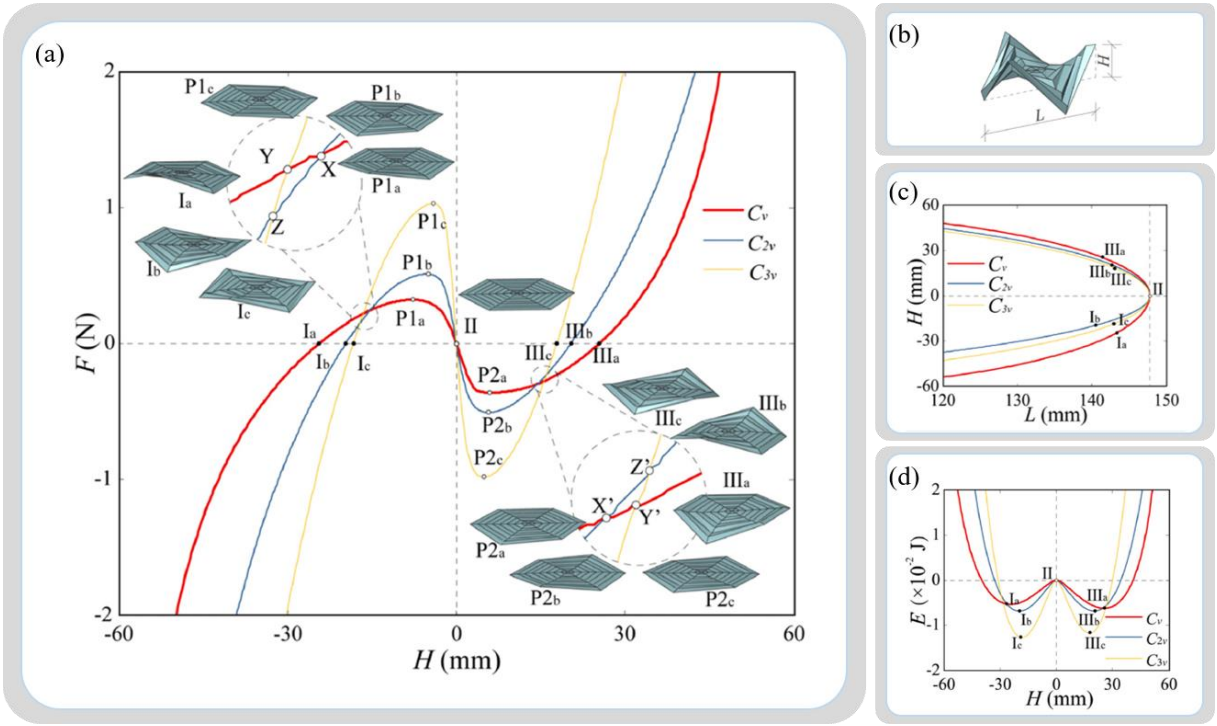

Figure 5 Comparison of various bifurcation branches. (a) Total equilibrium load-displacement curves. (b) Physical meaning of span (L) and height (H). (c) Span versus height curves. (d) Total energy versus height curves.

3.3. Influences of geometric parameters on multi-stability

3.3.1. Influence of material thickness t

The investigation of model T0 in Section 3.1 will be used as a reference to study the multi-stability of model T1 to T4 in Table 1. Figure 6(a), (c), and (e) depict the results of C_{3v}, C_{2v}, and C_v symmetries, respectively. Point $T0_I$, $T0_{II}$, $T0_{III}$ represents state 1, 2 and 3 in model T0, respectively. It is concluded that the bigger material thickness will lead to larger peak values of the equilibrium load during the transitions between two stable states. In Figure 6(b), (d), and (f), the curves of peak equilibrium load are centrosymmetric along the origin point. During the loading transition from state 1 to state 2, the peak equilibrium load is F_L. Similarly, F_R denotes the peak equilibrium load during the recovery transition from state 2 to state 3. The fitting operation demonstrates F_L and F_R are proportional to t^3.

Table 1 Parameters of numerical examples.

Model	T0	T1	T2	T3	T4	F1	F2	F3	F4	F5
L (mm)	64	64	64	64	64	60	60	60	60	60
D (mm)	8	8	8	8	8	12	12	12	12	12
d (mm)	8	8	8	8	8	4	6	8	12	16
t (μm)	127	40	76	200	240	127	127	127	127	127

The stable height H is defined by the height at which the structure reaches a stable state. Figure 6(a), (c), and (e) demonstrate H increases with t. H_I and H_{III} denote the stable height of stable State 1 and stable State 3, respectively. The absolute value of H indicates its structural height. If H increases along the positive z-axis, it is positive. Otherwise, H is negative. Hence, the farther the stable state from H=0 will contribute to the higher stable height. In summary, the bigger material thickness is, the larger peak equilibrium loads and the stable heights will be.

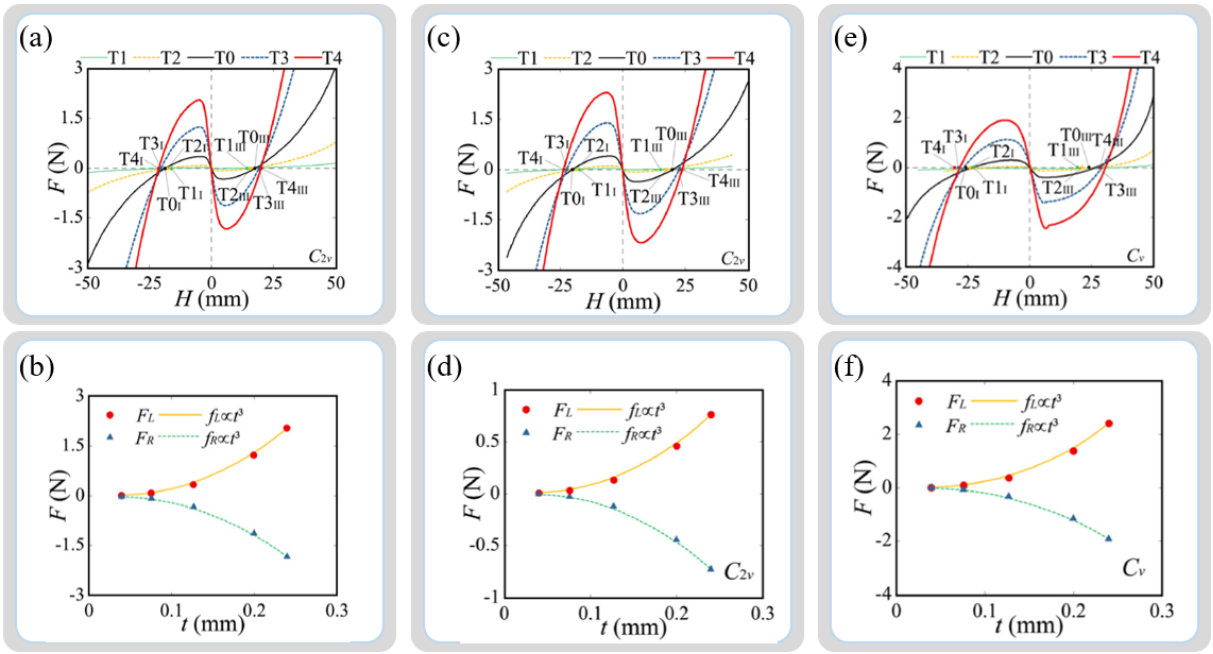

Figure 6 Effects of material thickness. (a), (c), and (e:) Equilibrium load versus height curves of a single load point. (b), (d), and (f): Relationship between the material thickness (t) and the peak equilibrium load (F).

3.3.2. Influence of crease length d

According to the variation of d, creases patterns of model F1 to F5 are presented in Figure 7. Figure 8(a) to (c) illustrate the equilibrium load versus height curves of C_{3v}, C_{2v}, and C_v symmetries, respectively. Point $F1_{P1}$ and $F1_{P2}$ represent State P1 and State P2 in model F1, respectively.

Figure 8 illustrates the peak equilibrium loads increase with d during the transition between stable states with the identical symmetry order. Since L remains constant, the variation of d will directly affect the change of n. Hence, the total length of all creases l is introduced to denote these two variables for simplicity. Figure 8(d) reflects the peak equilibrium loads in both the loading and recovery transitions increase with l. In other words, the longer crease length will lead to a more difficult folding process.

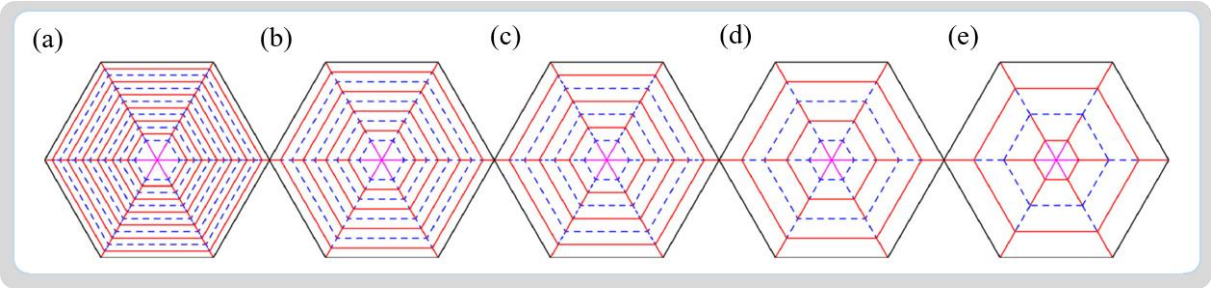

Figure 7 Crease patterns with different *d*.

In conclusion, the increasement of crease lengths will generate more significant energy barriers. The stable height is related to the *d*, *n* and *l* and remains to be further studied. In addition, it is essential for facilitating the design of novel programmable metamaterials to study the effects of different spans *L* and the number of initial polygon sides on the stable states.

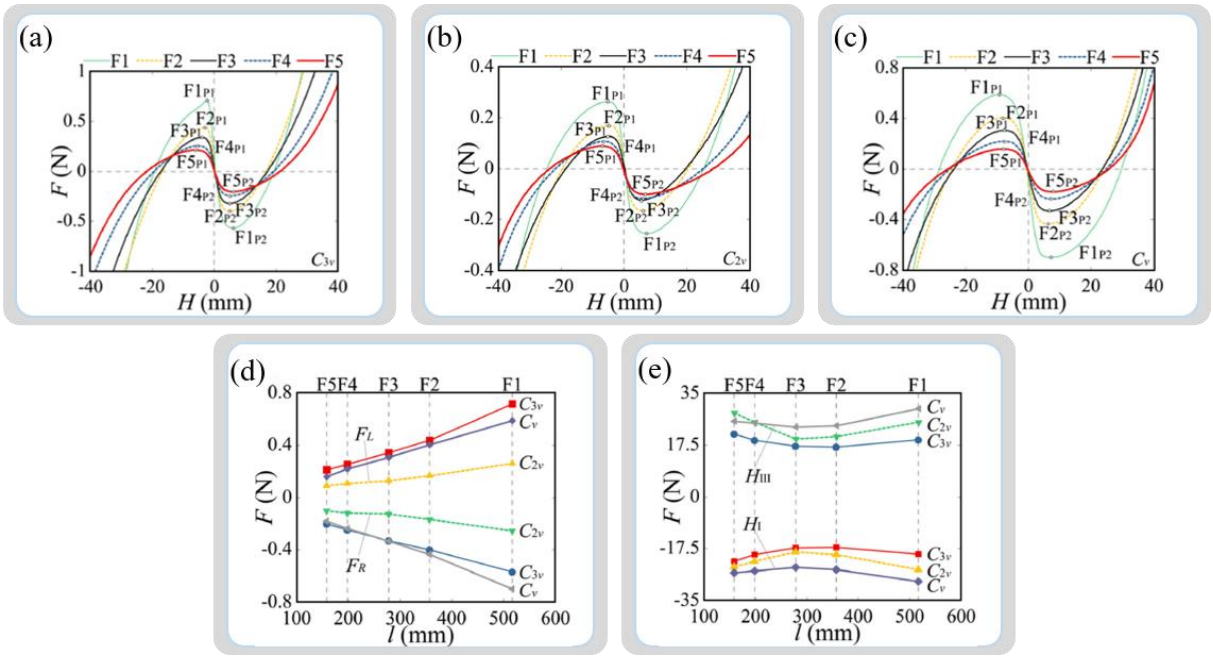

Figure 8 Effect of crease spacing. (a) to (c) Equilibrium load versus height curves of a single load point. (d) Relationship between the creases length *l* and the peak equilibrium loads F_L and F_R. (e) Relationship between the creases length *l* and the stable heights H_{I} and H_{III}.

4. Conclusion

In this work, we have adopted a group-theoretic approach and symmetry breaking for exploring the multi-stability of hexagonal origami hypar. The equivalent bar-and-hinge model was applied to simulate the whole folding and unfolding process. Concurrently, the group-theoretic approach was selected to avoid singularity in the stiffness matrix near the bifurcations. Based on symmetry breaking behaviour, the symmetry subgroups were obtained to trace bifurcation branches. The multi-stability of the structure can be obtained by analyzing the multi-stability of bifurcation branches.

Results illustrate the hexagonal hypar belongs to non-rigid origami due to the existence of non-rigid bending deformation. The bifurcation paths of the hexagonal origami hypar include C_{3v}, C_{2v}, and C_v symmetries. Every bifurcation branches exist bistability. Hence, the hexagonal origami hypar has six independent stable states. Notably, these stable states can be converted to each other only through the

fully flattened state. During the transition, the energy barrier of bifurcation branches with C_{3v}, C_{2v}, and C_v symmetries are in decreasing order. Meanwhile, the larger material thickness *t* or the crease length *l* will result in bigger energy barriers.

Note that the proposed method can convert the multi-stability of origami structures with high-order symmetry to multi-stability investigations in different bifurcation branches. By simplifying the complex folding analysis, this method has the potential to be extended for the multi-stability study of general origami structures.

Abstract

In this study, the mathematical model referred to as the panel-pin model is proposed for analyzing the infinitesimal-deformation mechanism and the large-deformation equilibrium path of a rigid origami composed of rigid faces (panels) and subjected to deformation only at its crease lines. The panel-pin model represents a rigid origami as a structure of rigid panels pin-connected at the vertices and has the following advantages: 1) consistent formulation of compatibility equations for any type of the rigid origami structure; 2) systematic computation of vertex displacements, folding angles, and their derivatives; and 3) ease of accounting for gravity acting on the panels. The infinitesimal mechanism of the panel-pin model is studied according to the standard procedure for mechanisms and linkages, and an equilibrium path is traced as the trajectory of equilibrium points obtained by minimizing the total potential energy of the model with a rotational spring along each crease line. The numerical examples with multiple degrees of freedom of the mechanism show that the multiple equilibrium paths can be obtained by assigning the initial imperfection, and this is also confirmed by the physical model.

Keywords: rigid origami, kinematics, equilibrium, energy minimization, geometrically nonlinear analysis

1. Introduction

Rigid origami is folded and unfolded within strict constraints, with its faces remaining undeformed during the folding process. It has wide range of potential engineering applications; e.g., solar panels on artificial satellites [1], robots [2], and transformable building envelopes [3]. Consequently, the analysis and simulation of folding properties are crucial to effectively exploit the deformation mechanisms of rigid origami, and numerous models and methods have been proposed in this respect [4].

The rotation hinge model [5, 6] in Fig. 1(b) and the truss model [7, 8] in Fig. 1(c) are commonly used for kinematic analysis of rigid origami. In the former model, folding angles are treated as independent variables, and a folding state can be expressed with fewer variables than other models. However, its complicated expression of vertex positions makes it difficult to incorporate displacement boundary conditions and external loads applied to vertices. In contrast, the latter model consists of rigid bars placed along the edges and treats the nodal translations as variables, making it easy to fix nodal displacements and to apply nodal loads. The disadvantage of this model is its complicated configuration for modelling a face with more than three edges; diagonal members must be arranged for the in-plane rigidity, and trigonometric geometric constraints [7] or the three-dimensional member assemblages [8] are necessary for the out-of-plane rigidity. The frame model in Fig. 1(d) has also been developed [9, 10], which consists of frame members hinge-connected at each crease line and rigidly connected at the node on each face. Although a folding path tracing method of this model has been proposed [10], this is not suitable for large models due to the high computational cost associated with a larger number of variables.

In this study, a *panel-pin model* is proposed for providing a simpler manner of ensuring the rigidity of faces compared to the truss model, while requiring fewer variables than the frame model. The

proposed model is highly versatile and can be applied to a wide range of analyses considering gravity, point loads, forced displacements and support conditions. This model offers following advantages;

1) consistent formulation of compatibility equations for describing the deformation mechanism of the model including holes or faces with more than three sides,
2) systematic computation of vertex displacements, folding angles, and their derivatives, and
3) ease of accounting for gravity acting on the panels.

The panel-pin model employs translation and rotation of the centers of gravity of rigid panels as independent variables, which are often used in the classical models of linkages. However, the formulation of the compatibility equations over these variables is different from that for linkages; the panels are pin-connected at the vertices instead of being joined by hinges. The vertex displacements and folding angles are treated as nonlinear functions of the panel displacements. The displacement boundary conditions on the vertices are incorporated as additional compatibility equations. The infinitesimal mechanism of the panel-pin model is determined from the derivatives of the compatibility equations. An equilibrium state under loads is determined by minimizing the total potential energy under the compatibility constraints after adding rotational springs along the crease lines. An equilibrium path is traced by sequentially updating the forced displacements, as proposed in Ref. [10].

2. Panel-pin model

2.1. Compatibility equations and folding angle at a single crease line

Suppose vertices 1 and 2 are the endpoints of the crease line, a unit vector directed from vertices 1 to 2 at the initial state is denoted by $\mathbf{e}^0 \in \mathbb{R}^3$. Note that the superscript 0 indicates the value at the initial state of the vector. In addition, let $\mathbf{n}_i^0$ and $\mathbf{d}_{i,j}^0 \in \mathbb{R}^3$ denote the unit normal vector of panel i and the vector from the barycenter of panel i to vertex j $(i,\ j=1,\ 2)$, respectively, at the initial state. The directions of the unit panel normal vectors are determined to the same side of the origami, and the local panel indices are determined so that panels 1 and 2 satisfies $\left\langle \mathbf{n}_1^0,\ \mathbf{d}_{1,1}^0 \times \mathbf{d}_{1,2}^0 \right\rangle > 0$ and $\left\langle \mathbf{n}_2^0,\ \mathbf{d}_{2,1}^0 \times \mathbf{d}_{2,2}^0 \right\rangle < 0$, respectively, where $\langle \bullet,\ \bullet \rangle$ stands for the inner product of two vectors. $\mathbf{b}_i^0 \in \mathbb{R}^3$ $(i=1,\ 2)$ is also defined such that $\mathbf{b}_i^0 = \mathbf{e}^0 \times \mathbf{n}_i^0$. Note that at the initial state, the crease lines may have non-zero folding angles.

Let $\mathbf{u}_i$ and $\boldsymbol{\theta}_i \in \mathbb{R}^3$ denote the translation and rotation vectors of panel i, respectively, in the global coordinate system $(x_1,\ x_2,\ x_3)$. As shown in Fig. 2(a), $\mathbf{n}_i$, $\mathbf{d}_{i,j}$, and $\mathbf{b}_i \in \mathbb{R}^3$ $(i,\ j=1,\ 2)$ are defined as

$$\mathbf{n}_i = \mathbf{R}(\boldsymbol{\theta}_i)\mathbf{n}_i^0, \quad \mathbf{d}_{i,j} = \mathbf{R}(\boldsymbol{\theta}_i)\mathbf{d}_{i,j}^0, \quad \mathbf{b}_i = \mathbf{R}(\boldsymbol{\theta}_i)\mathbf{b}_i^0 \tag{1}$$

where $\mathbf{R}(\boldsymbol{\theta}_i) \in \mathbb{R}^{3\times 3}$ is the Rodrigues' rotation matrix [11] with respect to $\boldsymbol{\theta}_i$. Using these vectors, the translation vector $\mathbf{v}_j^i \in \mathbb{R}^3$ $(i,\ j=1,\ 2)$ of vertex j can be written in two ways:

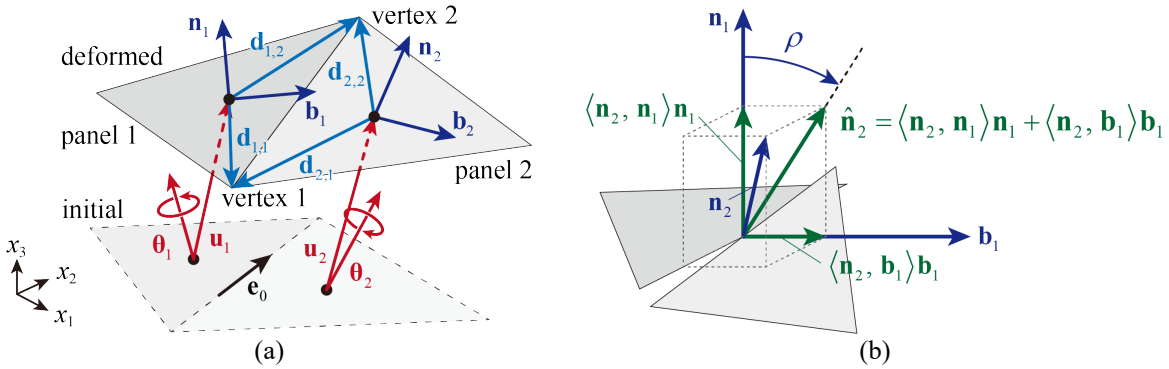

Figure 2. (a) Reference vectors of panels, (b) Reference vectors for calculating the folding angle

$$\mathbf{v}_j^i = \mathbf{u}_i + \mathbf{d}_{i,j} - \mathbf{d}_{i,j}^0 = \mathbf{u}_i + \left(\mathbf{R}(\boldsymbol{\theta}_i) - \mathbf{I}_3\right)\mathbf{d}_{i,j}^0 \quad (i = 1, 2) \tag{2}$$

where $\mathbf{I}_3 \in \mathbb{R}^{3\times 3}$ is the identity matrix. Since $\mathbf{v}_j^1 = \mathbf{v}_j^2$ should be satisfied, the compatibility equation for the displacements of panels 1 and 2 at vertex j $(=1, 2)$ is formulated as follows:

$$\Delta\mathbf{u}_j^{1,2} = \mathbf{u}_1 + \left(\mathbf{R}(\boldsymbol{\theta}_1) - \mathbf{I}_3\right)\mathbf{d}_{1,j}^0 - \mathbf{u}_2 - \left(\mathbf{R}(\boldsymbol{\theta}_2) - \mathbf{I}_3\right)\mathbf{d}_{2,j}^0 = \mathbf{0} \tag{3}$$

Furthermore, folding angle $\rho \in \mathbb{R}$ $(-\pi < \rho \le \pi)$ of the considering crease line is defined as

$$\rho = \operatorname{atan2}\left(\langle \mathbf{n}_2, \mathbf{b}_1 \rangle, \langle \mathbf{n}_2, \mathbf{n}_1 \rangle\right) \tag{4}$$

where $\operatorname{atan2}(y, x)$ is the 2-argument arctangent available in various programming languages. As shown in Fig. 2(b), ρ defined in Eq. (4) is the angle between $\mathbf{n}_1$ and $\hat{\mathbf{n}}_2 = \langle \mathbf{n}_2, \mathbf{n}_1 \rangle \mathbf{n}_1 + \langle \mathbf{n}_2, \mathbf{b}_1 \rangle \mathbf{b}_1$, which is a vector obtained by projecting $\mathbf{n}_2$ onto the plane spanned by $\mathbf{n}_1$ and $\mathbf{b}_1$. When $\Delta\mathbf{u}_1^{1,2} = \Delta\mathbf{u}_2^{1,2} = \mathbf{0}$, $\mathbf{n}_2 = \hat{\mathbf{n}}_2$, $\sin\rho = \langle \mathbf{n}_2, \mathbf{b}_1 \rangle$ and $\cos\rho = \langle \mathbf{n}_2, \mathbf{n}_1 \rangle$. According to Eq. (1), ρ is the function of only $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$, and its derivatives can be systematically calculated using the derivatives of the rotation matrices.

Remark 1 By using $\operatorname{atan2}(y, x)$ function instead of arcsin or arccos function, ρ and its partial derivatives can be compatibly calculated even when $\Delta\mathbf{u}_1^{1,2} \neq \mathbf{0}$ or $\Delta\mathbf{u}_2^{1,2} \neq \mathbf{0}$.

2.2. Compatibility equations for entire rigid origami and displacements of vertices

Let N^{c}, N^{p}, and N^{v} denote the number of crease lines, panels (faces), and vertices of a rigid origami, respectively. The *generalized displacement vector* $\mathbf{X} \in \mathbb{R}^N$ is defined as the assemblage of the components of $\mathbf{u}_i$ and $\boldsymbol{\theta}_i$ for all $i = 1, \ldots, N^{\mathrm{p}}$ where $N = 6N^{\mathrm{p}}$. When adjacent panels i_1 and i_2 $(=1, \ldots, N^{\mathrm{p}})$ are connected at vertex j $(=1, \ldots, N^{\mathrm{v}})$ as shown in Fig. 3, the compatibility equation for the displacements of panels i_1 and i_2 at vertex j is formulated from Eq. (3) as

$$\Delta\mathbf{u}_j^{i_1,i_2}(\mathbf{X}) = \mathbf{u}_{i_1} + \left(\mathbf{R}(\boldsymbol{\theta}_{i_1}) - \mathbf{I}_3\right)\mathbf{d}_{i_1,j}^0 - \mathbf{u}_{i_2} - \left(\mathbf{R}(\boldsymbol{\theta}_{i_2}) - \mathbf{I}_3\right)\mathbf{d}_{i_2,j}^0 = \mathbf{0} \tag{5}$$

Its physical interpretation is indicated in Fig. 3. Since Eq. (5) is formulated at every endpoint of the crease line, there are in total $6N^{\mathrm{c}}$ compatibility conditions for the entire rigid origami. Here, all $\Delta\mathbf{u}_j^{i_1,i_2}(\mathbf{X})$ are assembled into a vector $\Delta\mathbf{U}(\mathbf{X}) \in \mathbb{R}^{6N^{\mathrm{c}}}$, and the compatibility equation for the entire rigid origami is formulated as $\Delta\mathbf{U}(\mathbf{X}) = \mathbf{0}$.

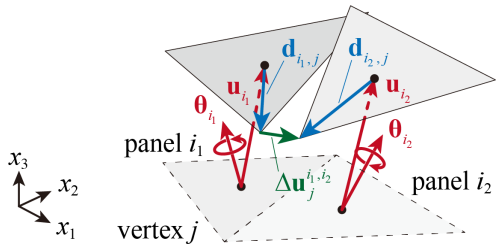

Figure 3. Incompatibility of the displacements of panels i_1 and i_2 at vertex j

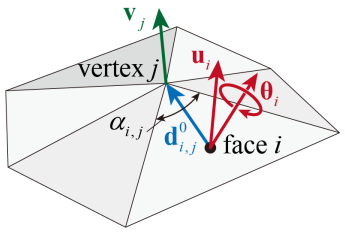

Figure 4. Translational displacement of vertex j

Next, we formulate the translation of a vertex. Although it can be written as in Eq. (2), the different formulation is used to include the case where $\Delta\mathbf{U}(\mathbf{X}) \neq \mathbf{0}$. Let $\mathcal{I}_j$ denote the set of indices of panels around vertex j $(=1,\ldots,N^{\mathrm{v}})$, and $\alpha_{i,j}$ $(i \in \mathcal{I}_j)$ denote the inner angle of panel i at vertex j as shown in Fig. 4. The translation vector $\mathbf{v}_j(\mathbf{X}) \in \mathbb{R}^3$ $(j=1,\ldots,N^{\mathrm{v}})$ of vertex j is calculated as follows:

$$\mathbf{v}_j(\mathbf{X}) = \frac{1}{A_j}\sum_{i\in\mathcal{I}_j}\alpha_{i,j}\left\{\mathbf{u}_i + \left(\mathbf{R}(\boldsymbol{\theta}_i) - \mathbf{I}_3\right)\mathbf{d}_{i,j}^0\right\}, \quad A_j = \sum_{i\in\mathcal{I}_j}\alpha_{i,j} \tag{6}$$

Remark 2 $\mathbf{v}_j(\mathbf{X})$ defined in Eq. (6) is the weighted average of the positions of panel vertices around vertex j, and reasonably estimates the position of vertex j when $\Delta\mathbf{U}(\mathbf{X}) \neq \mathbf{0}$. $\mathbf{v}_j$ and its partial derivatives with respect to the panel displacements can be compatibly calculated even when $\Delta\mathbf{U}(\mathbf{X}) \neq \mathbf{0}$.

Suppose the displacement of vertex j $(=1,\ldots,N^{\mathrm{v}})$ in the x_k-direction $(k=1, 2, 3)$ denoted by $v_j^{(k)}(\mathbf{X})$ is fixed, and let $\mathcal{J}^{\mathrm{f}}$ denote the set of index pairs of the vertices and the fixed directions. When the number of components of $\mathcal{J}^{\mathrm{f}}$ is N^{f}, $v_j^{(k)}(\mathbf{X})$ for all $\{j,k\} \in \mathcal{J}^{\mathrm{f}}$ are assembled into a vector $\Delta\mathbf{V}^{\mathrm{f}}(\mathbf{X}) \in \mathbb{R}^{N^{\mathrm{f}}}$. In addition, we also consider the forced vertex displacements, and let $\mathcal{J}^{\mathrm{d}}$ represent the set of index pairs of the vertices and the directions to which the forced displacements are applied. The non-zero target value of $v_j^{(k)}(\mathbf{X})$ $(\{j,k\} \in \mathcal{J}^{\mathrm{d}};\ j=1,\ldots,N^{\mathrm{v}};\ k=1, 2, 3)$ is denoted by $v_j^{\mathrm{d}(k)} \in \mathbb{R}$, and $v_j^{(k)}(\mathbf{X}) - v_j^{\mathrm{d}(k)}$ for all $\{j,k\} \in \mathcal{J}^{\mathrm{d}}$ are assembled into a vector $\Delta\mathbf{V}^{\mathrm{d}}(\mathbf{X}) \in \mathbb{R}^{N^{\mathrm{d}}}$ where N^{d} is the number of components of $\mathcal{J}^{\mathrm{d}}$. Here, $\Delta\mathbf{U}(\mathbf{X})$, $\Delta\mathbf{V}^{\mathrm{f}}(\mathbf{X})$, and $\Delta\mathbf{V}^{\mathrm{d}}(\mathbf{X})$ are combined into a column vector $\mathbf{C}(\mathbf{X}) = (\Delta\mathbf{U}(\mathbf{X})^{\mathrm{T}}, \Delta\mathbf{V}^{\mathrm{f}}(\mathbf{X})^{\mathrm{T}}, \Delta\mathbf{V}^{\mathrm{d}}(\mathbf{X})^{\mathrm{T}})^{\mathrm{T}} \in \mathbb{R}^M$ which is referred to as the *incompatiblity vector*. The number of components of $\mathbf{C}(\mathbf{X})$ is calculated as $M = 6N^{\mathrm{c}} + N^{\mathrm{f}} + N^{\mathrm{d}}$. Then, the compatibility equations representing the panel connectivity, fixed vertex displacements, and the forced vertex displacements are collectively written in a vector form as

$$\mathbf{C}(\mathbf{X}) = \mathbf{0} \tag{7}$$

3. Infinitesimal mechanism analysis

3.1. First-order infinitesimal mechanism

An infinitesimal mechanism of a panel-pin model is investigated to comprehend the degrees of freedom of the mechanism and the deformation modes in the range of infinitesimal deformation. It is evaluated in the same manner as the basic procedure for other models [2 – 5]. To compatibly incorporate the

degrees of freedom corresponding to the forced displacements, $\Delta\mathbf{V}^{\mathrm{d}}(\mathbf{X})=\mathbf{0}$ is replaced to constrain the relative displacements among the vertices where the forced displacements are assigned. When $N^{\mathrm{d}}=1$, the constraint for the forced displacement is not necessary. When $N^{\mathrm{d}}>1$, a single pair $\{\bar{j},\bar{k}\}$ is selected from $\mathcal{J}^{\mathrm{d}}$, and the constraint between $v_j^{(k)}(\mathbf{X})$ and $v_{\bar{j}}^{(\bar{k})}(\mathbf{X})$ is formulated as

$$\frac{1}{v_j^{\mathrm{d}(k)}}v_j^{(k)}(\mathbf{X})-\frac{1}{v_{\bar{j}}^{\mathrm{d}(\bar{k})}}v_{\bar{j}}^{(\bar{k})}(\mathbf{X})=0\quad(\{j,k\},\{\bar{j},\bar{k}\}\in\mathcal{J}^{\mathrm{d}};\{j,k\}\neq\{\bar{j},\bar{k}\}) \tag{8}$$

There are $N^{\mathrm{d}}-1$ constraints on the relative vertex displacements, and the left-hand sides of Eq (8) for all $\{j,k\}\in\mathcal{J}^{\mathrm{d}}\setminus\{\bar{j},\bar{k}\}$ are assembled into a vector $\Delta\bar{\mathbf{V}}^{\mathrm{d}}(\mathbf{X})\in\mathbb{R}^{N^{\mathrm{d}}-1}$. In the following, the argument $\mathbf{X}$ will be omitted for simple expression. Defining $\bar{\mathbf{C}}=\left(\Delta\mathbf{U}^{\mathrm{T}},\Delta\mathbf{V}^{\mathrm{fT}},\Delta\bar{\mathbf{V}}^{\mathrm{dT}}\right)^{\mathrm{T}}\in\mathbb{R}^{M-1}$, the *first-order infinitesimal mechanism* is represented by a vector $\mathbf{X}'\in\mathbb{R}^{N}$ satisfying

$$\frac{\mathrm{d}\bar{\mathbf{C}}}{\mathrm{d}\mathbf{X}}\mathbf{X}'=\mathbf{0} \tag{9}$$

$\mathrm{d}\bar{\mathbf{C}}/\mathrm{d}\mathbf{X}\in\mathbb{R}^{(M-1)\times N}$ is the *compatibility matrix* whose (i,j) component is $\partial\bar{C}_i/\partial X_j$ where the italic letter such as $\bar{C}_i$ and its subscript represent the component of a vector and its index, respectively. $\mathbf{X}'$ satisfying Eq. (9) is in the null-space of $\mathrm{d}\bar{\mathbf{C}}/\mathrm{d}\mathbf{X}$ whose dimension is $N-\mathrm{rank}(\mathrm{d}\bar{\mathbf{C}}/\mathrm{d}\mathbf{X})$, which is referred to as the number of kinematic indeterminacy, and its bases are referred to as the *infinitesimal mechanism modes*. Note that if the infinitesimal mechanism is investigated by using $\mathrm{d}\mathbf{C}/\mathrm{d}\mathbf{X}$ instead of $\mathrm{d}\bar{\mathbf{C}}/\mathrm{d}\mathbf{X}$, the forced displacements are regarded as the fixed displacements conditions. We can also define a *generalized self-equilibrium force* $\bar{\mathbf{F}}\in\mathbb{R}^{M-1}$ which satisfies

$$\bar{\mathbf{F}}^{\mathrm{T}}\frac{\mathrm{d}\bar{\mathbf{C}}}{\mathrm{d}\mathbf{X}}=\mathbf{0} \tag{10}$$

The self-equilibrium force $\bar{\mathbf{F}}$ satisfying Eq. (10) is in the left null-space of $\mathrm{d}\bar{\mathbf{C}}/\mathrm{d}\mathbf{X}$ whose dimension is $M-1-\mathrm{rank}(\mathrm{d}\bar{\mathbf{C}}/\mathrm{d}\mathbf{X})$, which is referred to as the number of statical indeterminacy.

3.2. Second-order infinitesimal mechanism

For a first-order infinitesimal mechanism $\mathbf{X}'$ satisfying Eq. (9), the *second-order infinitesimal mechanism* is represented by a pair of vectors $(\mathbf{X}',\mathbf{X}'')\in(\mathbb{R}^{N},\mathbb{R}^{N})$ satisfying

$$\frac{\mathrm{d}\bar{\mathbf{C}}}{\mathrm{d}\mathbf{X}}\mathbf{X}''+\left[\frac{\mathrm{d}^2\bar{\mathbf{C}}}{\mathrm{d}\mathbf{X}^2}\mathbf{X}'\right]\mathbf{X}'=\mathbf{0} \tag{11}$$

where $\mathrm{d}^2\bar{\mathbf{C}}/\mathrm{d}\mathbf{X}^2$ is the $(M-1)\times N\times N$ order-3 tensor whose (i,j,k) component is $\partial^2\bar{C}_i/\partial X_j\partial X_k$. The (i,j) component of $[(\mathrm{d}^2\bar{\mathbf{C}}/\mathrm{d}\mathbf{X}^2)\mathbf{X}']\in\mathbb{R}^{(M-1)\times N}$ is $\sum_{k=1}^{N}(\partial^2\bar{C}_i/\partial X_j\partial X_k)X_k'$. The second-order infinitesimal mechanism $(\mathbf{X}',\mathbf{X}'')$ exists if and only if $\mathbf{X}'$ satisfying Eq. (9) satisfies the following equation for any $\bar{\mathbf{F}}$ satisfying Eq. (10) [6]:

$$\bar{\mathbf{F}}^{\mathrm{T}}\left[\frac{\mathrm{d}^2\bar{\mathbf{C}}}{\mathrm{d}\mathbf{X}^2}\mathbf{X}'\right]\mathbf{X}'=\mathbf{X}'^{\mathrm{T}}\left[\bar{\mathbf{F}}^{\mathrm{T}}\frac{\mathrm{d}^2\bar{\mathbf{C}}}{\mathrm{d}\mathbf{X}^2}\right]\mathbf{X}'=0 \tag{12}$$

where the $(i,\ j)$ component of $[\overline{\mathbf{F}}^{\mathrm{T}}(\mathrm{d}^2\overline{\mathbf{C}}/\mathrm{d}\mathbf{X}^2)] \in \mathbb{R}^{N\times N}$ is calculated as $\sum_{k=1}^{M-1}\overline{F}_k(\partial^2\overline{C}_k/\partial X_i\partial X_j)$.

4. Equilibrium path analysis under gravity

4.1. Finding an equilibrium point

An equilibrium state of a panel-pin model is obtained by the energy minimization approach [10]. To stabilize and uniquely determine the equilibrium state, rotational stiffness is assigned to each crease line. The moment around crease line k $(=1,\ldots,N^{\mathrm{c}})$ is calculated as $K_k(\rho_k-\rho_k^0)$ for the constant $K_k\in\mathbb{R}$ where ρ_k^0 is the initial folding angle of crease line *k*. Let w_i and $u_i^{\mathrm{ref}(3)}\in\mathbb{R}$ denote the weight and the reference height of the barycenter of panel *i*, respectively, to determine the potential energy of the gravity in the x_3-direction. When the constant point load $\mathbf{p}_j\in\mathbb{R}^3$ $(j=1,\ldots,N^{\mathrm{v}})$ is applied to vertex j, the total potential energy of the panel-pin model is defined as the function of $\mathbf{X}$ as

$$\Pi(\mathbf{X})=\frac{1}{2}\sum_{k=1}^{N^{\mathrm{e}}}K_k\left(\rho_k(\mathbf{X})-\rho_k^0\right)^2+\sum_{i=1}^{N^{\mathrm{p}}}w_i\left(u_i^{(3)}(\mathbf{X})-u_i^{\mathrm{ref}(3)}\right)-\sum_{i=1}^{N^{\mathrm{v}}}\mathbf{p}_j^{\mathrm{T}}\mathbf{v}_j(\mathbf{X}) \tag{13}$$

where $u_i^{(3)}(\mathbf{X})$ is the component of $\mathbf{u}_i(\mathbf{X})$ corresponding to the x_3-direction.

In this study, the *path parameter* is introduced, and the magnitude of the forced displacements and/or the loads are assumed to be the function of the path parameter $\xi\in\mathbb{R}$ only. Then, an equilibrium state is obtained for a given ξ by solving the following energy minimization problem:

$$\begin{aligned}&\min_{\mathbf{X}}.\quad \Pi(\mathbf{X})\\ &\text{s.t.}\quad\ \mathbf{C}(\mathbf{X})=\mathbf{0}\end{aligned} \tag{14}$$

The pair of the path parameter ξ and the solution $\mathbf{X}$ to Problem (14) is referred to as the *equilibrium point*. Problem (14) is solved by the augmented Lagrangian method (ALM) [12]. The augmented Lagrangian $L(\mathbf{X})$ with the penalty parameter $\gamma\in\mathbb{R}$ and the Lagrange multipliers $\boldsymbol{\lambda}\in\mathbb{R}^M$ is defined as

$$L(\mathbf{X})=\Pi(\mathbf{X})+\mathbf{C}(\mathbf{X})^{\mathrm{T}}\left(\boldsymbol{\lambda}+\frac{\gamma}{2}\mathbf{C}(\mathbf{X})\right) \tag{15}$$

The solution to Problem (14) is obtained by repeatedly solving the following optimization problem:

$$\min_{\mathbf{X}}.\quad L(\mathbf{X}) \tag{16}$$

with constant $\boldsymbol{\lambda}$ while updating the multiplier as $\boldsymbol{\lambda}\leftarrow\boldsymbol{\lambda}+\gamma\mathbf{C}$ until the maximum absolute value among the components of $\mathbf{C}(\mathbf{X})$ becomes smaller than the user-specified tolerance C_{tol}. γ is automatically updated in the process of the ALM based on Ref. [12]. At an equilibrium point $(\mathbf{X},\xi)$, $\mathrm{d}L/\mathrm{d}X_j=0$ holds for all $j=1,\ldots,N$, and the convergence of Problem (16) is evaluated by comparing the maximum value among $\left|\mathrm{d}L/\mathrm{d}X_j\right|$ $(j=1,\ldots,N)$ to the user-specified tolerance E_{tol}.

4.3. Tracing an equilibrium path

An *equilibrium path* is the trajectory of the equilibrium point $(\mathbf{X},\xi)$ and traced by successively solving Problem (14) by the ALM while updating the path parameter as $\xi\leftarrow\xi+\mathrm{d}\xi$ where $\mathrm{d}\xi\in\mathbb{R}$ is the increment of ξ. In this study, the displacement control method is employed; i.e., each forced displacement $v_j^{\mathrm{d}(k)}$ $(\{j,k\}\in\mathcal{J}^{\mathrm{d}})$ is specified at each step of the equilibrium point search as

$$v_j^{\mathrm{d}(k)} = \xi \tilde{v}_j^{\mathrm{d}(k)} \tag{17}$$

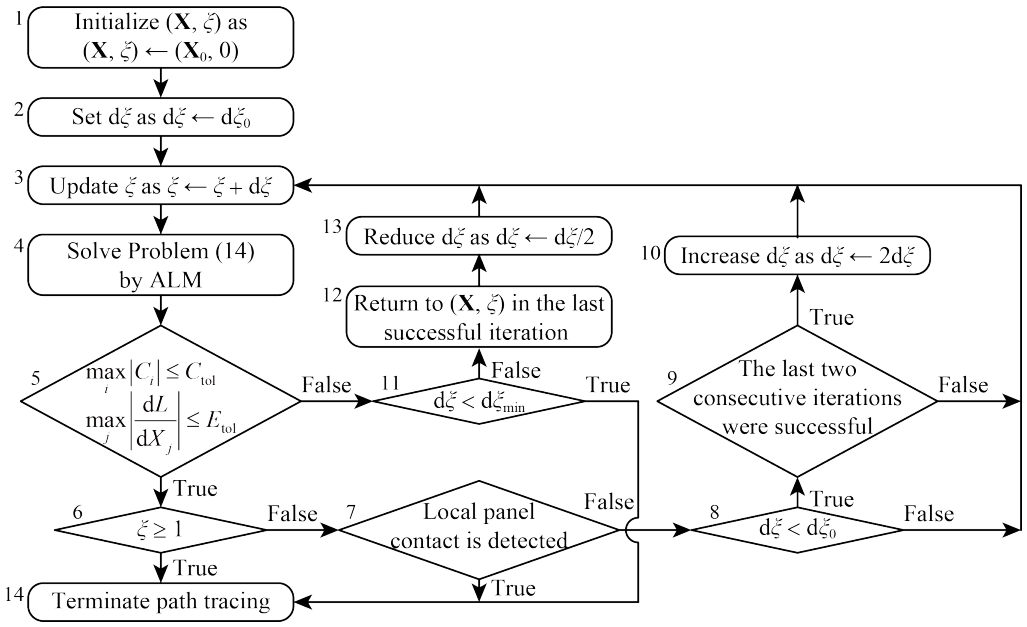

Figure 5. Flowchart of the equilibrium path tracing.

where ξ increases from 0 to 1 at the final step when $v_j^{\mathrm{d}(k)}$ reaches the target forced displacement $\tilde{v}_j^{\mathrm{d}(k)}$. The point loads $\mathbf{p}_j$ on vertices are assumed to be constant throughout the path tracing.

The procedure of the equilibrium path tracing is summarized in Fig. 5. At the initial step of the analysis (Step 1 in Fig. 5), $\mathbf{X}$ is initialized as $\mathbf{X} = \mathbf{X}_0$ where $\mathbf{X}_0$ represents the initial imperfection. Problem (14) is solved so that $\max_i |C_i| \le C_{\mathrm{tol}}$ and $\max_j |\mathrm{d}L/\mathrm{d}X_j| \le E_{\mathrm{tol}}$. However, if these conditions are not satisfied, the step size $\mathrm{d}\xi$ is reduced by half (Step 13). The reduced $\mathrm{d}\xi$ is restored to $2\mathrm{d}\xi$ if the equilibrium points are successfully found in the consecutive iterations (Step 10) to accelerate the analysis. The path tracing terminates when ξ reaches 1, $\mathrm{d}\xi$ decreases less than the specified lower bound $\mathrm{d}\xi_{\min} > 0$, or the local face contact between the panels adjacent to a crease line is detected.

5. Examples

5.1. Settings

The analysis is carried out by using a Python 3.9 program. Problem (16) in Section 4 is solved by using BFGS [13] available in scipy.optimize.minimize for the equilibrium path tracing. The units of length and force are omitted because they do not influence the analysis results.

Figure 6 shows the crease pattern to be analyzed. All the vertices are on the *xy*-plane in the initial shape. As indicated in green, the displacements of the vertices on the shorter boundaries are fixed, and the forced displacements are assigned along the *x*-axis as shown by the purple arrows. The orange arrows represent the loads in positive *y*-direction. The weight per unit area of each panel is 20, and the rotational stiffness per unit length of each crease line is 10. In the equilibrium path tracing, three types of initial imperfections based on sine functions are assigned to the panel translations in *z*-direction as shown in Fig. 7. The parameters are set as $C_{\mathrm{tol}} = E_{\mathrm{tol}} = 10^{-4}$ and $\mathrm{d}\xi_{\min} = 10^{-5}$ for all the following trials.

For an intuitive understanding of the path tracing results, a physical model has also been constructed as shown in Fig. 8. The model is hanged from the curtain rails at the hooks attached at the vertices, and the hooks in front are fixed to the rails. The curtain rail on the right side of the picture can move along

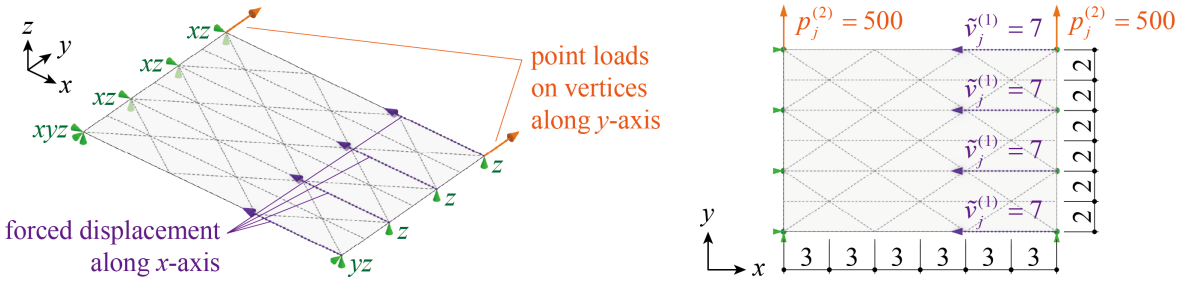

Figure 6. Initial flat shape, panel dimension, and boundary conditions.

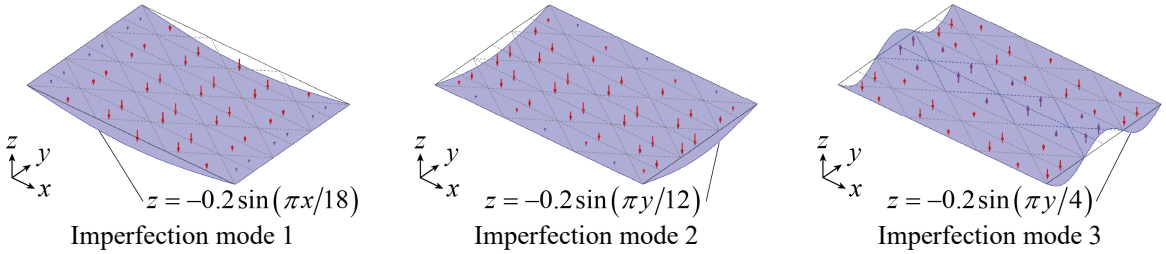

Figure 7. Initial imperfection of face displacements in z-direction based on a sine function.

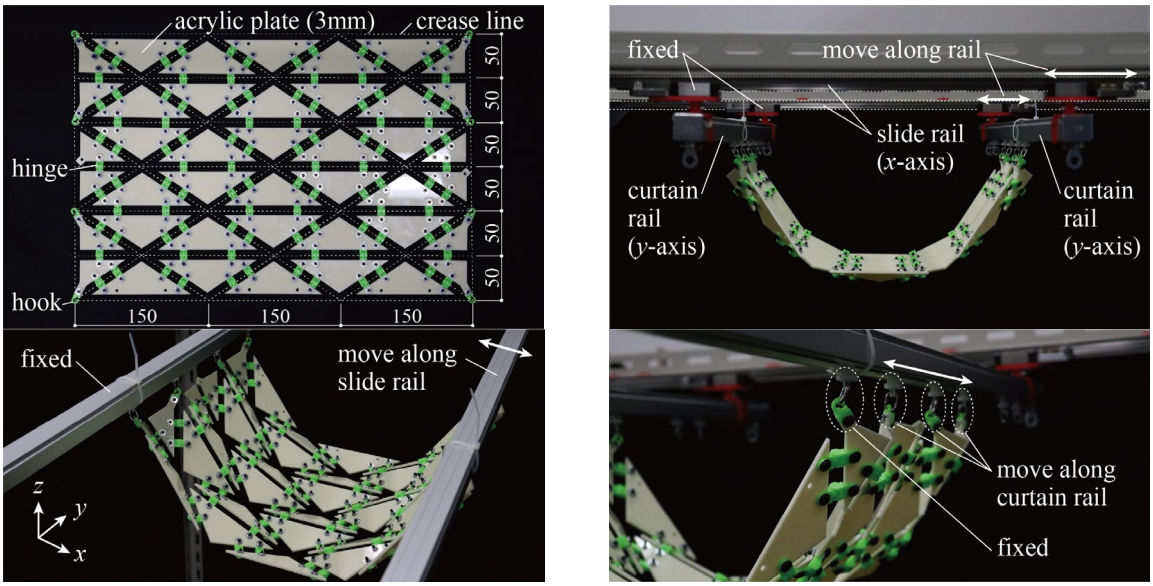

Figure 8. Experimental model.

the slide rails while remaining parallel to the left rail. As we focus on checking the deformation modes and the locking phenomenon of the crease lines, the vertex loads are not introduced in this model. However, friction provides resistance to the displacements in the direction along the curtain rails.

5.2. Infinitesimal mechanism analysis

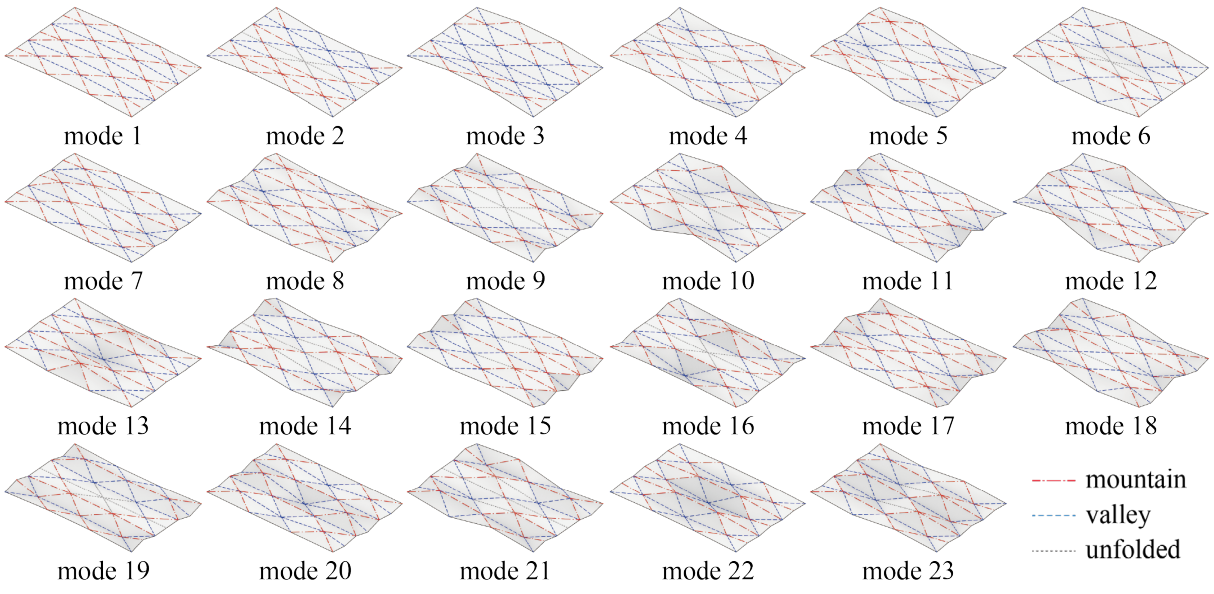
The infinitesimal mechanism analysis introduced in Section 3 is carried out for the initial flat state. The size of compatibility matrix $\mathrm{d}\bar{\mathbf{C}}/\mathrm{d}\mathbf{X}$ is 341×252, and its rank is 229. Therefore, the number of kinematic and statical indeterminacies are 23 and 112, respectively. The orthonormal infinitesimal mechanism modes $\bar{\mathbf{X}}'_1,\ldots,\bar{\mathbf{X}}'_{23} \in \mathbb{R}^{252}$ cannot be uniquely determined only from Eq. (9), and we determine them as shown in Fig. 9 so that the following matrix is diagonalized and its diagonal elements are arranged in ascending order to reflect the bending stiffness of the model:

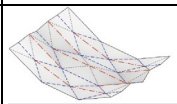
$$\begin{bmatrix} \bar{\mathbf{X}}'^{\mathrm{T}}_1 \\ \vdots \\ \bar{\mathbf{X}}'^{\mathrm{T}}_{23} \end{bmatrix} \begin{bmatrix} \partial\rho_1/\partial X_1 & \cdots & \partial\rho_{54}/\partial X_1 \\ \vdots & \ddots & \vdots \\ \partial\rho_1/\partial X_{252} & \cdots & \partial\rho_{54}/\partial X_{252} \end{bmatrix} \begin{bmatrix} K_1 & & 0 \\ & \ddots & \\ 0 & & K_{54} \end{bmatrix} \begin{bmatrix} \partial\rho_1/\partial X_1 & \cdots & \partial\rho_1/\partial X_{252} \\ \vdots & \ddots & \vdots \\ \partial\rho_{54}/\partial X_1 & \cdots & \partial\rho_{54}/\partial X_{252} \end{bmatrix} \begin{bmatrix} \bar{\mathbf{X}}'_1 & \cdots & \bar{\mathbf{X}}'_{23} \end{bmatrix}$$

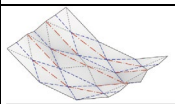
Then, in the first-order infinitesimal mechanism, the stiffness of the crease pattern is lowest in the direction of $\bar{\mathbf{X}}'_1$. Any first-order infinitesimal mechanism $\mathbf{X}' \in \mathbb{R}^{252}$ can be represented by a linear combination of $\bar{\mathbf{X}}'_1,\ldots,\bar{\mathbf{X}}'_{23}$ with the arbitrary real coefficients $a_1,\ldots,a_{23} \in \mathbb{R}$ as

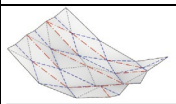
$$\mathbf{X}' = a_1\bar{\mathbf{X}}'_1 + \cdots + a_{23}\bar{\mathbf{X}}'_{23}$$

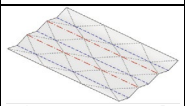
Note that the vertices move only along the *z*-axis in the first-order infinitesimal mechanism, and the displacements in the *x*- and *y*-directions are included in the higher-order infinitesimal mechanism. Eq (12) for the existence of the second-order infinitesimal mechanism turns into 19 independent quadratic equations for $a_1,\ldots,a_{23}$. Therefore, although it is difficult to analytically solve these equations, the degrees of freedom of the mechanism is expected to be 4 at a non-flat state as numerically confirmed in the following subsections. This significant reduction in the number of arbitrary coefficients leads to the bifurcation of the equilibrium path.

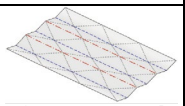


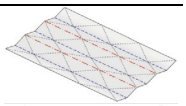


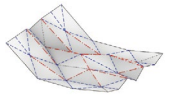


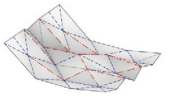


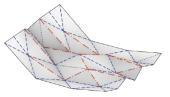


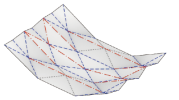


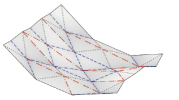


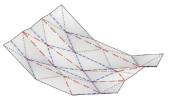


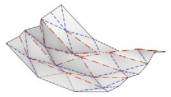


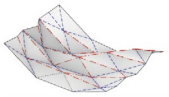


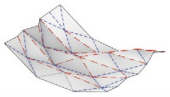


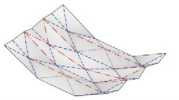


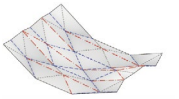


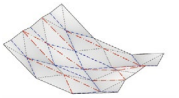


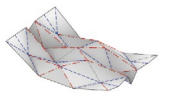


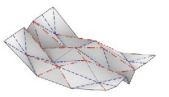


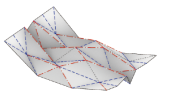


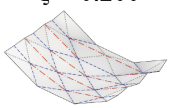


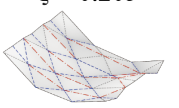












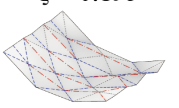


Figure 9. Orthonormal infinitesimal mechanism modes.

5.3. Instability and bifurcation at the flat state

This section demonstrates that the equilibrium path obtained by the method proposed in Section 4 is highly influenced by the size of the initial path parameter increment as well as the initial imperfection. As summarized in Table 1, we have carried out the path tracing without initial imperfection and with the imperfection mode 2 shown in Fig. 7 by changing the step size as $\mathrm{d}\xi_0 = 0.005, 0.010, 0.015$. To investigate the influence of the initial step size, the different step sizes $\mathrm{d}\xi_{\mathrm{ini}} = 0.005, 0.010, 0.015, 0.020$ are used to find the first equilibrium points. Since the deformation mode (assignment of the mountain and valley to the crease lines) hardly changes after $\xi = 0.2$, we show the deformed shape at the step around $\xi = 0.2$ or the final step if the analysis terminate before $\xi = 0.2$ in Table 1 to better illustrate the deformation. As shown in Table 1, different equilibrium paths are obtained by changing the initial step size $\mathrm{d}\xi_{\mathrm{ini}}$, while the regular step size $\mathrm{d}\xi_0$ does not significantly change the equilibrium paths.

Table 1. Deformed shapes around $\xi = 0.2$ or the final step of path tracing with different step sizes.

	Without initial imperfection			Imperfection mode 2

5.4. Path tracing with initial imperfection

In this section, we will show the result of the equilibrium path tracing from the perfectly flat state and the results with the initial imperfections shown in Fig. 7. The deformation modes and the locking phenomenon of the crease lines are also investigated by the physical experimental model.

Figure 10 shows the deformation path with $\mathrm{d}\xi_0 = 0.05$. The paths shown in Fig. 10(a) and (d) are approximately the same. By assigning the different initial imperfection, the different paths can be obtained. The deformed shape may contain the unfolded crease lines, and these crease lines may be locked; e.g., in the equilibrium path shown in Fig. 10(c) where the path tracing has been terminated with small ξ, the diagonal crease lines are locked under the forced displacements in the *x*-direction, and the forced displacements cannot increase due to the locked mechanism.

At every equilibrium point on the paths obtained without initial imperfection and with the imperfection modes 1 and 3, the rank of compatibility matrix is 248, and the number of kinematic indeterminacy is 4, while those are 247 and 5, respectively, at every equilibrium point on the path with imperfection mode 2. The values of coefficients of the first-order infinitesimal mechanism modes investigated in Section

5.2 at an equilibrium point $\mathbf{X}$ are computed by $a_i = \langle \mathbf{X}, \bar{\mathbf{X}}'_i \rangle$ $(i = 1, \ldots, 23)$, and the norm of the residual is computed as $\left\| \mathbf{X} - \sum_{i=1}^{23} a_i \bar{\mathbf{X}}'_i \right\|$. These values are plotted in Fig. 11. It can be seen that the coefficients of mode 1 is significantly larger than those of other modes in every path in Fig. 10, that is reasonable since the bending stiffness of the model is smallest in the direction of mode 1. In addition, since the infinitesimal mechanism modes do not include the vertex displacements in *x*- and *y*- directions, the norm of residual is quite large on every paths, which indicates the higher-order mechanisms. On the other hand, as shown in Fig. 11(c), modes 9, 18, 19, and 20 are not included in the path shown in Fig. 10(c).

The locking phenomenon of the crease lines is also confirmed by the physical experimental model shown in Fig. 12, which approximately reproduces each deformation mode in Fig. 10. In the experimental model, the curtain rail on the right side of the picture cannot move to the negative *x*-direction due to the locked hinges.

6. Conclusions

This paper has presented the panel-pin model, which has been applied to the infinitesimal mechanism and the geometrically nonlinear equilibrium path analysis of the rigid origami with multiple degrees of freedom of mechanism. It has been shown that the multiple equilibrium paths can be obtained by assigning different initial imperfection in the investigated crease pattern.

Abstract

Compared with the conventional braces, origami-based buckling-controlled concentric braces (OBBCCBs) possess distinctive deformation capacity and load transmission path under axial load, like cross sectional twist at brace ends. Due to the specificity of OBBCCBs, the beam-column-brace connections should accommodate additional demands in load carrying capacity and deformation, which can hardly be met by the existing conventional connections. In this study, considering these features, based on the generalized uniform force method, a design method of the beam-column-brace connection is proposed to ensure the connection fails after the brace failure. Numerical study is conducted on the seismic behavior of the brace-connection subassembly under axial compression and reversed cyclic load. The effects of the connections on axial deformation capacity, lateral deformation, failure modes, and energy dissipation capacity of the OBBCCBs are investigated. The results show that the OBBCCBs with the connections can still prevent the global buckling and thus guarantee their energy dissipation capacity in the frame. The study results are expected to serve as a valuable reference for the design and application of the connections between OBBCCBs and frames.

Keywords: origami, concentric braces, connection design

1. Introduction

Conventional concentric braces in frame structures usually suffer from stability caused by globally flexural buckling during earthquake actions, which seriously deteriorates its energy dissipation capacity. To address the issue, origami-based buckling-controlled concentric braces (OBBCCBs) are proposed by Liu et al [1–3]. By applying the curved Miura origami, the OBBCCBs allows non-rigid deformation of the origami pattens to prevent the global buckling under axial compression and exhibit impressive energy dissipation capacity.

In braced frames, the connection plays a significant role in transferring axial force from the brace to the surrounding structure. However, undesirable failure of the connections may occur to the braced frame, limiting the brace to fully dissipate energy. Wu et al. [4] found that the potential out-of-plane rotation degraded the stability of the brace end near the gusset plate in cyclic and hybrid loading tests on the full-scale reinforced concrete (RC) frame with brace. Bai et al. [5] proposed and tested the perfobond strip and welded shear stub gusset connections to ensure the connection reliability by reducing frame action. Tan et al. [6] utilized the unconstrained gusset plates in the braced frame and found that the unconstrained gusset plates significantly reduced the damage to the RC members compared with the conventional gusset plates. Wang et al. [7] conducted subassemblage tests of buckling-restrained braced RC frames with various gusset connections. Results showed that the gusset plate connection type affected the rotation responses of the gusset plate and brace end zone. Thus, for the OBBCCBs, the

beam-column-brace connections must be properly designed so that they can sustain the maximum axial force capacities developed from the braces and exhibit good seismic performance.

In this paper, a design method for the connection of OBBCCB is developed by incorporating the generalized uniform force method [8] and the frame action forces computed from an equivalent strut model [9]. Finite element (FE) models are established by using software ANSYS to evaluate the seismic behavior of the brace-connection subassembly under axial compression and reversed cyclic load. The effects of the designed connections on axial deformation capacity, lateral deformation, failure modes, and energy dissipation capacity of the OBBCCB are investigated.

2. Connection Design

The connection design in this paper is based on a single-story single-bay monolithic precast concrete frame subassemblage with OBBCCB, as shown in Fig. 1. The upper gusset plate, noted as GP-A, is connected to the beam and column. The lower gusset plate, noted as GP-B, is connected to the column. The pinned connections are designed and checked for limit states based on the Chinese specification [10]. Considering the specificity of OBBCCBs, especially the twist of cross sectional at the brace ends, the clearance of the connection are deliberately designed.

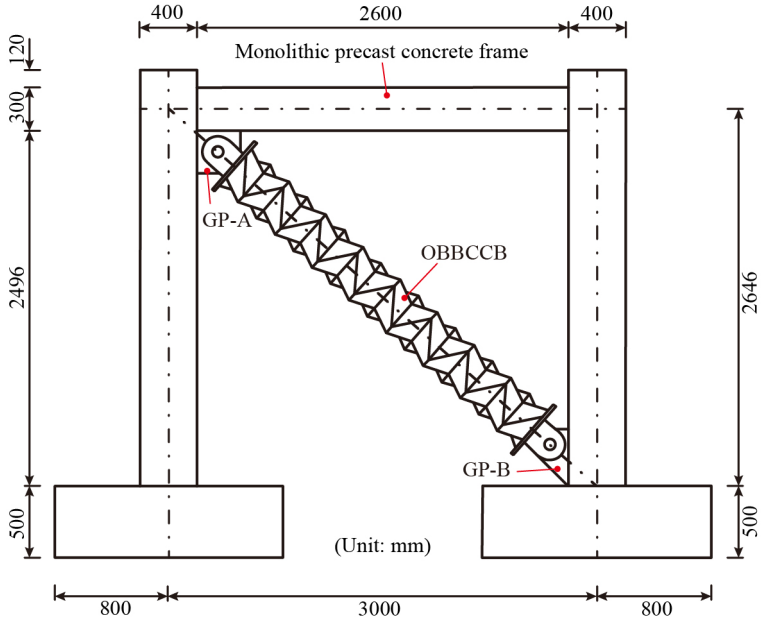

Figure 1. Monolithic precast concrete frame with OBBCCB.

2.1. Brace action

In this study, the generalized uniform force method [8] is adopted for considering the brace action of the gusset plate design. The horizontal and vertical force components at the gusset-to-beam (H_{ub} and V_{ub}) and gusset-to-column (H_{uc} and V_{uc}) interfaces that are caused by brace axial force are shown in Fig. 2 and the forces are calculated following Eq.s (1–4).

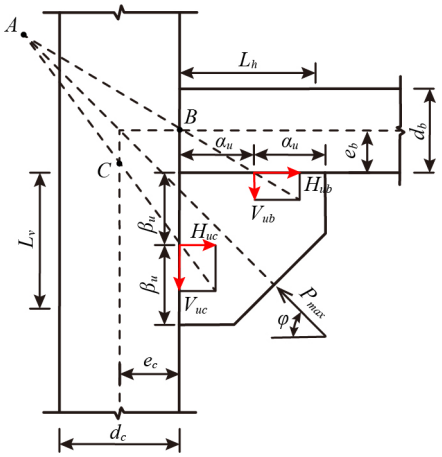

Figure 2. Generalized uniform force method.

$$H_{\mathrm{uc}}=P_{max}\,(e_c \sin\varphi)/(e_b+\beta_u) \tag{1}$$

$$V_{\mathrm{ub}}=P_{max}e_b\,[(e_b+\beta_u)\cos\varphi-e_c \sin\varphi]/[\alpha_u(e_b+\beta_u)] \tag{2}$$

$$H_{\mathrm{ub}}=P_{max}\cos\varphi-H_{\mathrm{uc}} \tag{3}$$

$$V_{\mathrm{uc}}=P_{max}\sin\varphi-V_{\mathrm{ub}} \tag{4}$$

Where α_u and β_u are half of the gusset length (L_h) and height (L_v), respectively; e_b and e_c are half of the beam and column depths, respectively; and φ is the incline angle of brace. The maximum brace axial force, P_{max}, can be obtained from the 1.2 times simulation results under axial load.

2.2. Framing action

To estimate the framing action force, the gusset plate is regarded as an equivalent strut [9] located at points of 0.6 times the gusset length and height from the column and beam flanges, respectively, as shown in Fig. 3. The relationship between the vertical component (V_{FA}) and horizontal component(H_{FA}) of the strut force is defined as follows in Eq.s (5–6):

$$H_{\mathrm{FA}}=\frac{d_bL_hV_{beam}(0.3L-0.18L_h)}{(4I_b/t_g)+d_bL_h(0.3d_b+0.18L_v)} \tag{5}$$

$$V_{\mathrm{FA}}=\frac{d_bL_vV_{beam}(0.3L-0.18L_h)}{(4I_b/t_g)+d_bL_h(0.3d_b+0.18L_v)} \tag{6}$$

Where t_g is the gusset plate thickness; I_b is the moment of inertia of the beam; L is the beam clear span, excluding the gusset region and column depth; V_{beam} is the beam shear when plastic hinge develops.

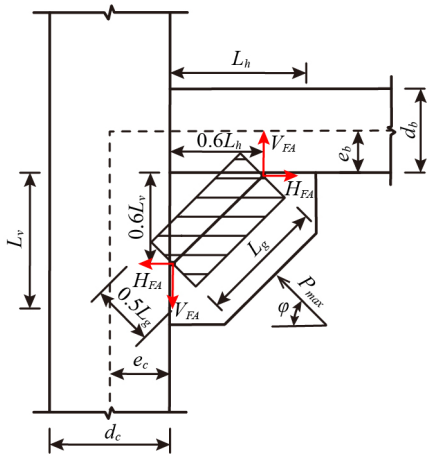

Figure 3. Equivalent strut model.

The combined action can be calculated to obtain the total gusset interface normal (σ) and shear (τ) stress distributions using the method proposed by Lin et al [11]. The maximum stresses on the gusset interfaces are used to calculate the demand-to-capacity ratios (DCRs), which must satisfy the design requirements. Table 1 lists the DCRs for gusset plates in compression (labelled as '-') and tension (labelled as '+') at three failure modes, namely von Mises yielding, tensile rupture, and shear rupture.

Table 1. Design demand-to-capacity ratio checks of design

DCRs	Location	Failure mode	GP-A		GP-B	
			-	+	-	+
$DCR_{m,b}$	Gusset-beam interface	Von Mises yielding	0.203	0.207		
$DCR_{t,b}$		Tensile rupture	0.106	0.101		
$DCR_{s,b}$		Shear rupture	0.290	0.297		
$DCR_{m,c}$	Gusset-column interface	Von Mises yielding	0.291	0.310	0.137	0.156
$DCR_{t,c}$		Tensile rupture	0.095	0.108	0.094	0.107
$DCR_{s,c}$		Shear rupture	0.431	0.457	0.186	0.211

2.3. Pinned design

According to specification [10], the pin connection can be made of the steel with the nominal yield strength of 335 MPa, and the geometric dimensions should meet the Eq.s (7–8). Where a is the minimum distance between the edge of the pin hole and the edge of the plate in the direction of force; b is the distance between the plate edge and the edge of the pin hole. The a, b and other parameters are depicted in Fig. 4.

$$a \geq \frac{4}{3} b_e \tag{7}$$

$$b_e = 2t_g + 16 \leq b \tag{8}$$

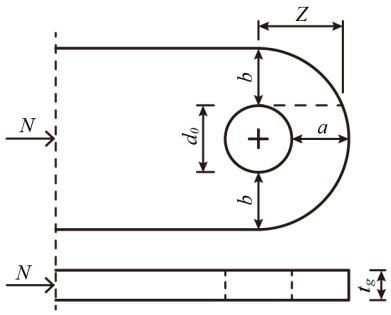

Figure 4. Design methodology of the pinned gusset plate.

Verification of the limit state of the pin connection is performed after determining the geometry. The tensile strength (σ_h) of the net section of the pinned gusset plate hole, the tensile strength (σ_e) of the section of pinned gusset plate end and the shear strength (τ) of the pinned gusset plate are checked by Eq.s (9–11):

$$\sigma_h = \frac{N}{2t_g b_1} \le f,\ b_1 = \min\left(2t_g + 16,\ b - \frac{d_0}{3}\right) \tag{9}$$

$$\sigma_e = \frac{N}{2t_g\left(a - \frac{2d_0}{3}\right)} \le f \tag{10}$$

$$\tau = \frac{N}{2t_g Z} \le f_v,\ Z = \sqrt{(a + d_0/2)^2 - (d_0/2)^2} \tag{11}$$

Where N is the design value of the axial force induced by the brace action, f and f_v are respectively the design value of the tensile strength and the shear strength of the gusset plate. The design values of tensile strength (f) and shear strength (f_v) of the 20 mm thick gusset plate steel are 295 N/mm^2 and 170 N/mm^2, respectively [10]. The dimensions of the pinned design in this study are illustrated in Fig. 5. The results all meet the design requirements mentioned above.

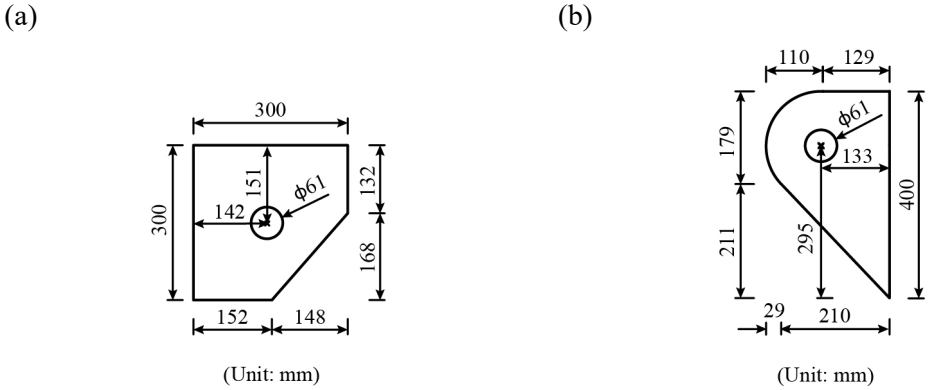

Figure 5. Dimensions of gusset plates: (a) GP-A, and (b) GP-B.

2.4. Clearance details

The OBBCCBs composed of multiple curved Miura origami tubular units longitudinally, possess distinctive deformation capacity and load transmission path under axial load, like cross sectional twist at brace ends. Due to the specificity of OBBCCBs, the beam-column-brace connections should accommodate additional demands in load carrying capacity and deformation. According to the preliminary simulation of the OBBCCB under axial load, the brace ends of OBBCCB may generate

rotational angles under axial force in the range of -3° to 3°. To accommodate the rotation, the clearance configuration is designed as shown in Fig. 6, where S_1 is the clearance between the gusset plate and the ring plate, S_2 is the clearance between the pin hole and the pin, and S_3 is the clearance between the ring plate and the pin cap.

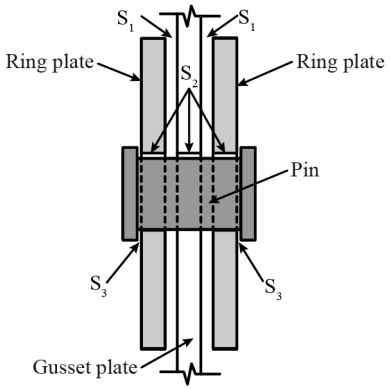

Figure 6. Clearance details.

The brace end rotation process consists of two stages: firstly, the ring plate is rotated by the brace until the ring plate hole is in contact with the pin surface, and then the ring plate is rotated together with the pin until the pin surface is in contact with the gusset plate hole wall. In consideration of the process, S_1, S_2 and S_3 are determined to be 8 mm, 1 mm, 1mm, respectively.

3. Numerical analysis

3.1. Finite element modelling

Nonlinear numerical simulations are conducted using general finite element (FE) package (ANSYS 19.2), aiming at investigating the seismic behavior of the OBBCCBs with designed connection. The finite element model of the brace-connection subassembly is shown in Fig. 7. Typical 4-node shell element SHELL181 is employed to simulate the 8 mm-thick panels of the origami pattern. The 8-node 3-D solid element SOLID45 is employed to simulate the end plates, ring plates, gusset plates and pins. In order to model the pin supports of the brace, MASS21 element is put at the supports, connecting the nodes of the ring plates, gusset plates and pins by constraint equations. The degree of freedom of rotation in the plane of connection is released. Firstly, the axial compression load is executed on the brace-connection subassembly to obtain mechanical properties such as yield displacement (Δ_y) and yield load (F_y); then the cyclic horizontal load is applied to simulate the earthquake action.

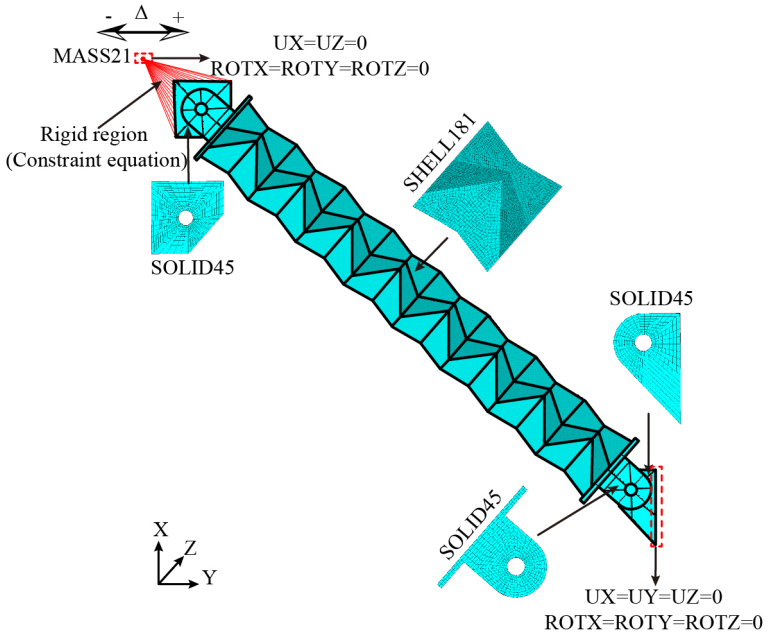

Figure 7. Finite element model.

The axial loading sequence recommended by ANSI/AISC 341-16[12] requires two quantities: D_{by} and D_{bm}. D_{by} is the axial displacement deformation at first yield of the specimen, which is the Δ_y obtained from the compression load simulation. D_{bm} refers to the axial deformation of the specimen at the design story drift (0.02 times the story height). In order to simulate the earthquake action, the horizontal loading protocol can be determined from the axial loading protocol based on the small deformation assumption, as listed in the Table 2.

Table 2. Loading protocol

Load level	Load magnitude	Cycle number
1	$\pm D_{by}$=±26.02	2
2	$\pm 0.5D_{bm}$=±26.67	2
3	$\pm 1.0D_{bm}$=±53.34	2
4	$\pm 1.5D_{bm}$=±80.01	2
5	$\pm 2.0D_{bm}$=±106.68	2

3.2. Results and observations

Fig. 8 shows the hysteretic and skeleton curves of the brace-connection subassembly. The main characteristic parameters (the effective stiffness K_{eff}, the yield load F_y, the yield displacement Δ_y, the ultimate load F_u and the ultimate displacement Δ_u) of the curves are quantified in Table 3 in accordance with FEMA P-795 [13]. The displacement ductility μ is obtained through Eq. (12). The parameters in the positive(labelled as '+') and negative(labelled as '-') directions are calculated respectively.

$$\mu = \frac{\Delta_u}{\Delta_y} \tag{12}$$

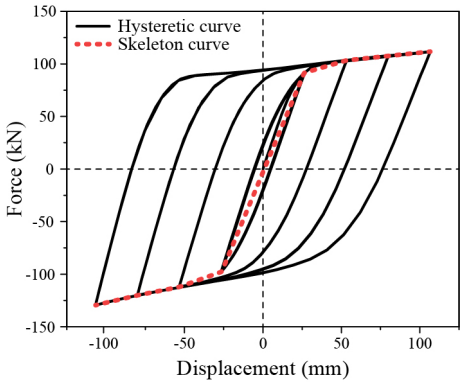

Figure 8. Hysteretic and skeleton curves.

Table 3. Characteristic parameters of skeleton curve

Direction	K_{eff}	F_y	Δ_y	F_u	Δ_u	μ
+	3.48	44.65	32.08	111.63	106.68	3.33
-	3.72	51.79	34.80	-129.47	-106.68	3.07

It can be seen from Fig. 8 that the brace behaves elastically at the early stage, for the curves perform almost linear in both directions. At this stage, the effective stiffness K_{eff} in the negative direction is marginally greater than that in the positive direction. No significant buckling occurrs on the brace-connection subassembly during the horizontal cyclic loading. Equivalent viscous damping ratio ζ_{eq} is obtained as defined in Eq. (13), where E_D is the hysteretic energy and E_{strain} is the equivalent strain energy [14]. The ratio reaches 39.13% at the final level, thus exhibiting stable, reliable and high-level energy dissipation capacity of the specimen.

$$\zeta_{eq} = \frac{E_D}{4\pi E_{strain}} \tag{13}$$

The von Mises stress distributions at the maximum load displacement is shown in Fig 9. It can be seem from the figure that no premature buckling of the gusset plates is found, satisfying the design principle of “strong connection and weak member”. Plasticity distribution is uniform, along the whole length of the OBBCCB. Within each unit, the deformation concentrates at the predetermined creases and plasticity develops there. Beyond a unit, each unit of the brace deforms simultaneously and uniformly and plasticity distributes along the full length of the brace, which prevents the global buckling of the brace.

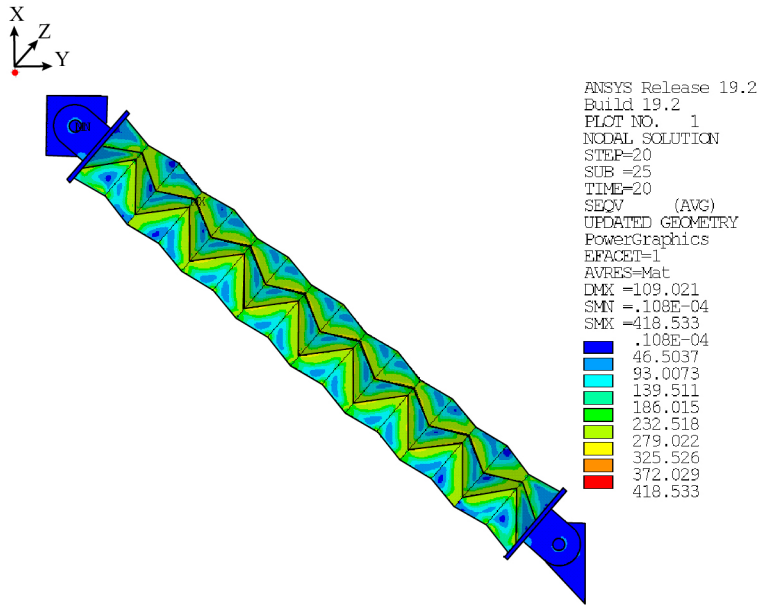

Figure 9. Stress distributions at maximum load displacement.

4. Conclusion

To guarantee that beam-column-brace-connections fail after energy dissipation braces, the connection design is a key issue for energy dissipation braces. The present work provides a design method of the beam-column-brace connection considering the specificity of OBBCCBs. According to the simulation results, the OBBCCB with designed connection exhibits satisfactory seismic performance. In follow-up study, the FE model will be further detailed to consider the actual actions of the concrete beam and column.

Study on the performance of the space structure using CLT folded plate structure

Kaito IKAWA[a,*], Shinta YOSHITOMI[a]

[a,*] Ritsumeikan University
ru0085xk@ed.ritsumei.ac.jp

Abstract

In recent years, the wood materials are used widely in the building field, and various applications of CLT(Cross Laminated Timber) are being considered in Japan. This paper aims to be systematically clarified how each form design parameters of CLT folded parameters affects deformation, and unit stress. A analysis model of a 20m x 20m CLT folded plate catenary arch roof using three form design parameters: mountain height the folded plate, arch rise-span ratio, and the number of arch divisions is constructed. As for this model, the relationship between form design parameters and the maximum and average values of each of the fulcrum reaction forces, vertical displacements, and unit stress of the nodes due to their own weight will be investigated. Increasing the folded plate peak height suppresses thrust and reduces y-directional reaction forces, while the effect of different peak heights on the maximum vertical displacement is small. Because of increasing the rise, the maximum value of vertical displacement and unit stress will be smaller, preventing the concentration of deformation points. In addition, by increasing the number of arch divisions, shape of the model becomes closer to an arch and the joint springs increase, thus reducing the stress level of the CLT.

Keywords: CLT, folded plate roof, parametric design, LSB, FEM analysis

1. Introduction

Nowadays, the use of wood as a sustainable material has been actively promoted in the field of architecture, and among them, CLT (Cross Laminated Timber) has been attracting attention. In research on the structural performance of CLT, there has been much research on its use as a material to resist horizontal forces, such as in earthquake-resistant walls, and as a flooring material, taking advantage of its characteristics as a facing material, but there is relatively little research on its use in other ways. The previous studies that treated CLT as a space structural member of arches were small-scale, with spans as short as 6m [1], and there are not many examples of the application of CLT to roof members larger spans. The folded plate structure is an example of a structural form in which CLT is applied as a space structural member. Its folding frame structure increases rigidity and allows larger spans to fly.

This study analyzes the relationship between form design parameters and structural performance of a 20m span CLT folded plate arch structure and understands the mechanisms that cause this relationship. The goal is to understand the characteristics of CLT as a spatial structural member, thereby expanding the use of CLT and, ultimately, promoting the utilization of wood materials.

2. Study methods

2.1. Evaluation methods for structural performance

A model of a 20m x 20m CLT folded plate catenary arch roof is constructed using mountain height the folded plate, arch rise-span ratio, and the number of arch divisions as form design parameters as shown in Figure.1. The form design parameters are varied as shown in Table 1. For the design parameters of

this model, the relationship between form design parameters and the maximum and average values of each of the fulcrum reaction forces, vertical displacements, and unit stress of the nodes due to their own weight will be investigated.

Structural performance is analyzed by static analysis of Midas iGen. The analysis method is finite element method (FEM), and nodes are generated at the point where the joint springs are inserted. Details of node generation points will be described later in *2.2.2.*

The long-term allowable stress of the CLT, the yield capacity of the joint springs, and the vertical displacement are used as constraints for the results of the analysis. The allowable stress and yield capacity are as shown in Tables 2 and 3, and the constraint of vertical displacement is assumed to be 80 mm (1/250 of the arch span). The fulcrums of the arch are a pin fulcrum, and they are restrained except for rotation around the y-axis.

2.2. Analysis model setup

2.2.1. CLT elements

The overall model shape is created by generating eight mountains of folded plate and extruding them to the division points of the arch. The width of mountains is 2500mm, the mountain height is determined by the form design parameter. The division points to be extruded are generated so that the length of the catenary arch is equally divided, and the folded plate is extruded in the form of fold lines connecting each the division points. The shape of the basic catenary arch is determined from the span between the two fulcrum points and the arch length.

The equation for determining the length of the catenary from the span to rise-span ratio is given below.

For the catenary as shown in the Figure 2, the span is L_x, the deflection is h, the total length of the curve is l, and the rise span ratio $h/L_x = \gamma$,

$$h = f\left(\frac{L_x}{2}\right) - a = \frac{{L_x}^2}{8a} \tag{1}$$

$$l = L_x + \frac{8h^2}{3L_x} \tag{2}$$

Since formula (1),

$$a = \frac{L_x}{8\gamma} \tag{3}$$

Substitute formulas (1) and (3) into formula (2),

$$l = \left(1 + \frac{8}{3}\gamma^2\right) L_x \tag{4}$$

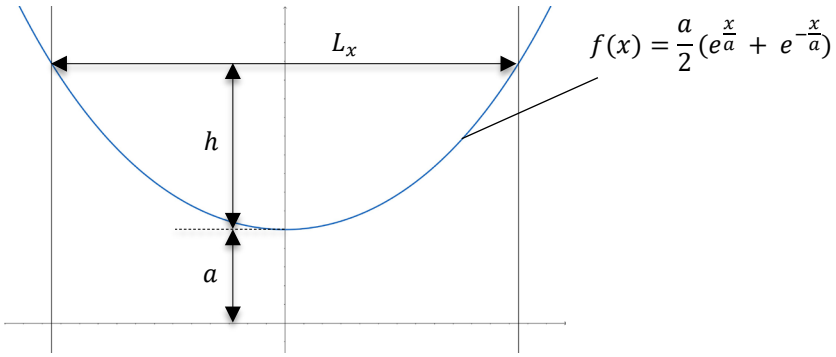

Figure 2. Catenary curve

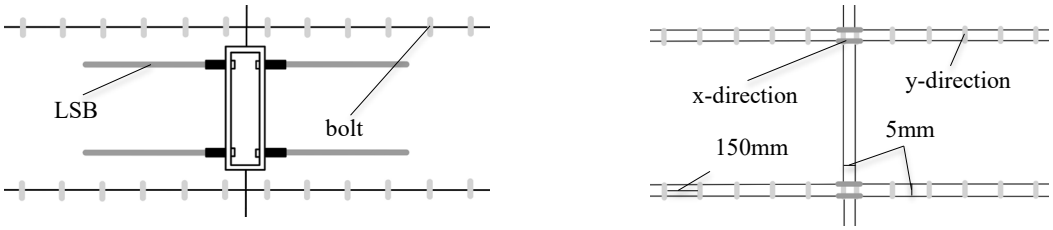
The CLT in this study uses S90-5-5, 150mm thick, with weight of unit volume 5.0 kN/m^3. Table 4. shows the input material properties. In addition, a joint spring is inserted into the CLT and a 5mm gap is left between adjacent plates in the model so that stress is transmitted only by the spring.

Table 4. Properties of CLT (S90-5-5)



direction	E (N/mm^2)	G (N/mm^2)
strong-axis	5400	81.8
weak-axis	1872	40.9
thickness	6000	500

2.2.2. Joint spring elements

Joint springs are inserted in the strong-axis (x-direction) and weak-axis (y-direction). Three types of springs are inserted per joint: compression springs, tension springs, and general springs that include shear and bending stiffness.

The x-directional springs are joined so that the CLT plates are connected at the division points of the arch, and the type of joint is LSB joint. The four types of spring stiffnesses are axial spring D_x, in-plane shear spring D_y, out-of-plane shear spring D_z, and rotational spring R_y. For axial springs, compression is transmitted by the CLT bearing stiffness and tension by the LSB. The spring stiffnesses are determined by calculated values with reference to previous studies.

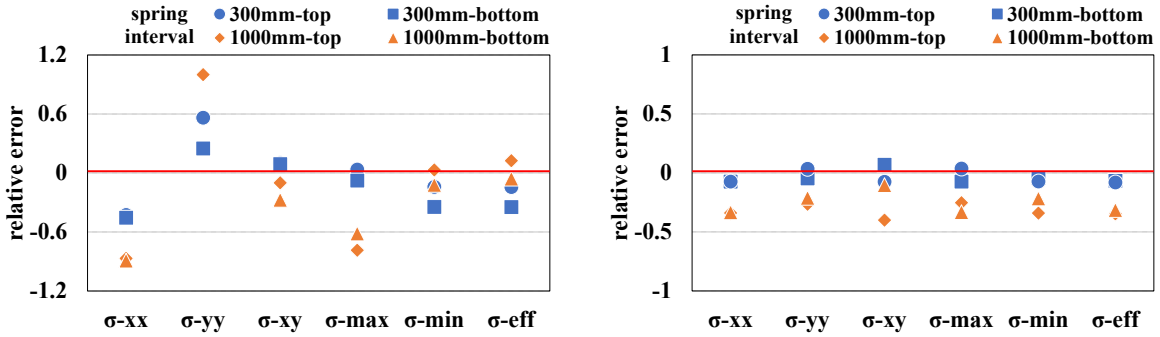
The y-directional springs are joined so that adjacent CLTs are connected at 150mm interval by bolted joints, using the existing building as a reference. There are three types of spring stiffnesses: axial spring D_x, in-plane shear spring D_y, out-of-plane shear spring D_z. The stiffnesses are the values obtained from experiments on the same building. The y-directional axial spring has the same transmission type as the x-directional spring, and at the same time, resistance to bending moment also is ensured. The schematic of the actual joints and the arrangement of the joint springs in the analysis model are shown in Figure 3, and the stiffness each joint springs in Tables 5.

(a) actual joints (b) analysis model

Figure 3. Schematic of the actual joints and the arrangement of the joint springs in the analysis model

Table 5. Stiffness of the joint springs

direction	Dx(kN/mm)		Dy(kN/mm)	Dz(kN/mm)	Ry(kNm/rad)
	Compression	tension			
x	901	105	7.30	14.8	352
y	63.6	4.74	1.73	1.07	-



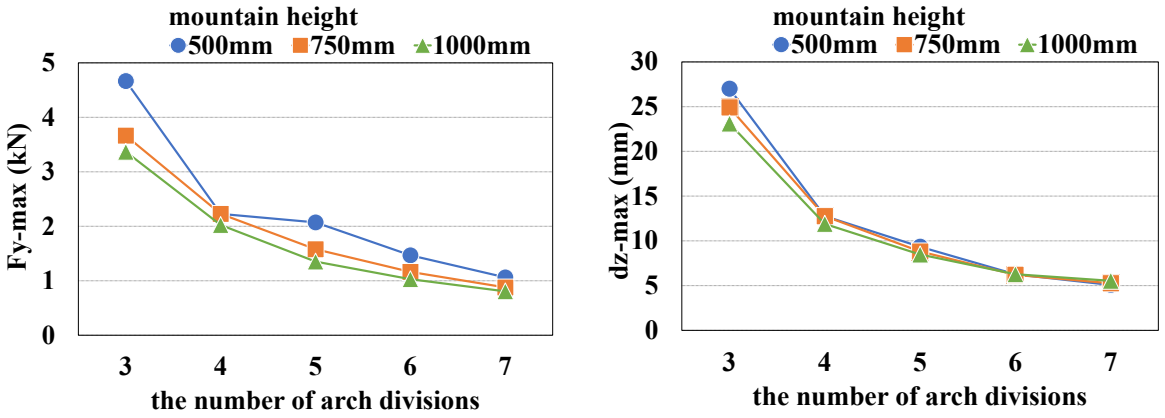
Since the joint springs in the model of this study are arranged at 150mm interval for a 20m roof, the number of elements and nodes is very large. Therefore, to reduce the number of them, it is considered that whether the analytical results are valid for the joint springs interval of 300mm and 1000mm. Only in this section, the length of L_y in the directional perpendicular to the arch is set to 10m. The design parameters are mountain height 750 mm, rise span ratio 1/6, and number of arch segments 6. The error is obtained by dividing the results of unit stress at 300mm and 1000mm interval at the nodes of the end of arch fulcrum and the center of arch top in the analysis model by the result at 150 mm.

3. Analysis results

3.1. Change of y-directional springs interval

Figure 4 shows the graph of unit stresses of CLT elements standardized by the 150mm result when the y-directional spring interval is varied from 150mm, 300mm, and 1000mm. Since the analytical model is a plate element, the results vary between the top and bottom of the plate at the same nodes.

In the end of arch fulcrum as there are no CLTs adjacent to each other and the error is relatively small. The error at the center of the top is the largest, with a maximum value of 3.125 and a minimum value of 0.110. In both cases, the error is larger for the 1000mm interval than for the 300mm interval. This is thought to be due to the fact that the size of each element changes as the y-directional spring interval changes, and the stresses are not equal inside the flat plate, but are biased.

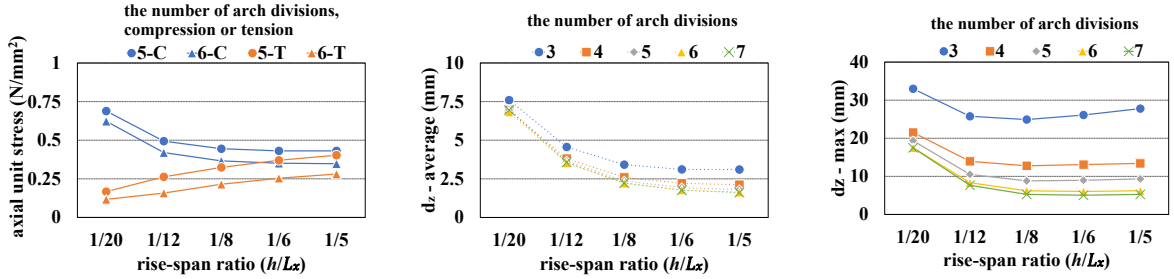


(a) end of arch fulcrum (b) center of top

Figure 4. Relative error of analysis results due to changes spring interval

3.2. Effect of mountain height of folded plate

Figure 5 shows the graph with rise-span ratio of 1/8 as a constant and the number of arch divisions as a variable. It shows how mountain height of folded plates affects from the sequence of lines in the graph. It can be seen from the sequence of lines in the graph that the y-directional reaction force is suppressed since the higher the mountain, the smaller the thrust. Since the sequence of lines of vertical displacement graph are generally same, it can be said that the effect of changing mountain height on vertical displacement is small.



(a) y-directional reaction force (b) vertical displacement

Figure 5. Effect of mountain height

3.3. Effect of rise-span ratio of arch

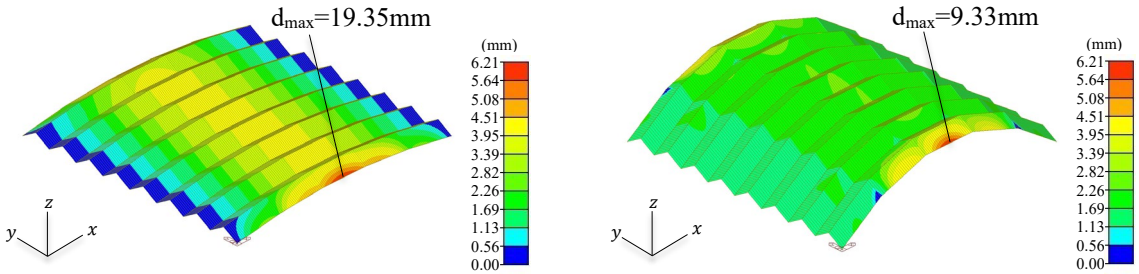


Figure 6 shows the effect of the rise-span ratio on each response when the mountain height is 750 mm. For the maximum value of the strong-axis unit stress, the higher the rise, the smaller the compression and the larger the tension. There is a trade-off between compression and tension, which can be controlled by the rise of the arch.

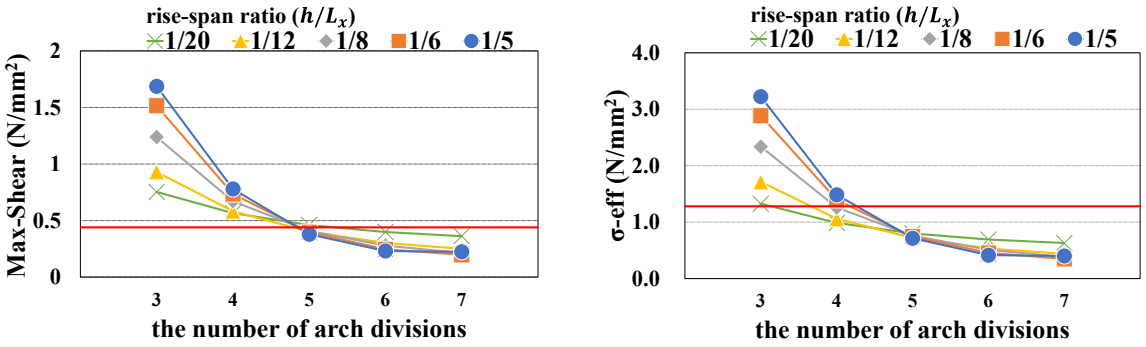
For vertical displacement, the higher the rise, the lower the average value. On the other hand, there is a rise-span ratio that is minimized the maximum value of vertical displacement along the way. The effect of the rise on the maximum vertical displacement becomes smaller when the rise span ratio exceeds 1/8, regardless of the number of arch divisions. Figure 7 shows contours of vertical displacement. Higher rise prevents deformation points from being concentrated in the center of the arch.

(a) strong-axis unit stress (b) d_z-average (c) d_z-maximum

Figure 6. Effect of rise-span ratio



(a) h/L_x= 1/20 (b) h/L_x= 1/5

Figure 7. Contours of vertical displacement

3.4. Effect of the number of arch divisions

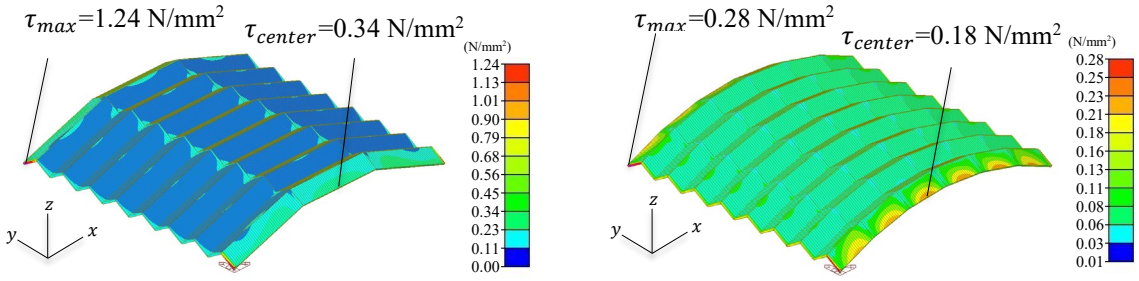


Figure 8 shows the effect of the number of arch divisions on the shear and bending unit stress when mountain height is 750mm. The maximum shear and bending unit stress values both decrease as the number of arch divisions increases. This is thought to be since the model shape approaches a catenary arch as the number of divisions increases and the number of x-directional springs are increase. The diminution of unit stresses increases as the rise increases and converges around 6 or 7 divisions for all rises.

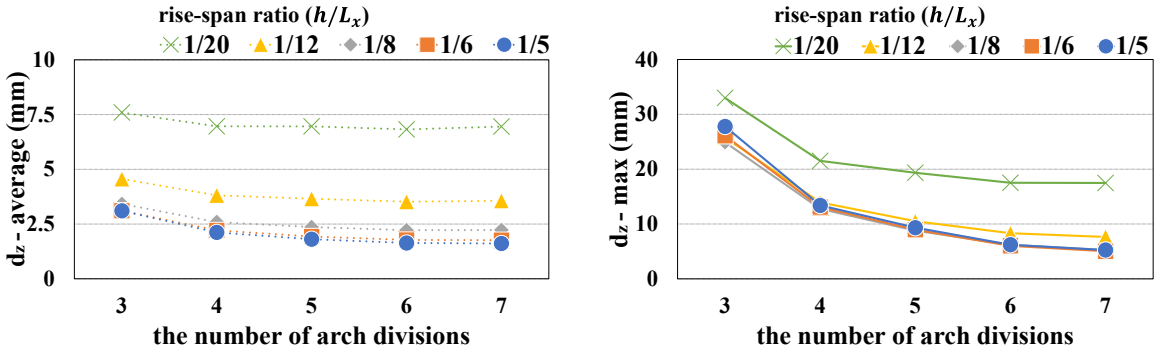
Figure 9 shows contours of vertical displacement. Shear stress is concentrated at the four corners and is particularly pronounced in the case of the number of arch divisions: 3. In the case of the number of arch divisions: 6, the difference between the four corners and the rest of the image becomes smaller, as indicated by the contour tint.

(a) shear unit stress (b) bending unit stress

Figure 8. Effect of the number of arch divisions on unit stress



(a) the number of arch divisions : 3 (b) the number of arch divisions : 6

Figure 9. Contours of shear stress

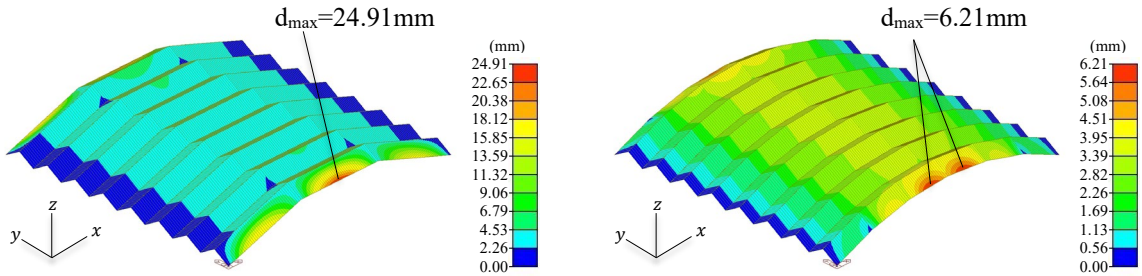


Figure 10 shows the effect of the number of arch divisions on vertical displacement when mountain height is 750mm. The maximum value of vertical displacement decreases as the number of divisions increase, and the amount of decrease also becomes smaller as the number of divisions increases. The average value shows a small change, indicating that the effect of the number of arch divisions is small.

Figure 11 shows contours of vertical displacement. The center of the long side of the CLT in the center of the arch will have the largest deformation, and if the number of divisions is even, two points of maximum vertical displacement will be represented.

(a) d_z-average (b) d_z-maximum

Figure 10. Effect of the number of arch divisions on vertical displacement

(a) the number of arch divisions : 3 (b) the number of arch divisions : 6

Figure 11. Contours of vertical displacement

4. Conclusion

The relationship between form design parameters and structural performance was analyzed for the CLT folded plate arch roof. Increasing the folded-plate peak height suppresses thrust and reduces y-directional reaction forces, while the effect of different peak heights on the maximum vertical displacement is small. By increasing the rise, the maximum value of vertical displacement and unit stress will be smaller, preventing the concentration of deformation points. In addition, by increasing the number of arch divisions, shape of the model becomes closer to an arch and the joint springs increase, thus reducing the stress level of the CLT. Future studies should consider the effects of horizontal forces, number of joints, and cost.

Acknowledgements

The materials necessary for spring modeling were provided by Mrs. Masuda of Tori-sha Co. The authors would like to express our gratitude to them.

Abstract

This project explores the kinetic capacity of a tessellated origami surface by incorporating pneumatic muscles into its structure. Folding surfaces such as origami are intrinsically dynamic and offer a promising approach to creating kinetic systems. They present an opportunity to design dynamic architectural spatial geometries capable of transforming in real-time through kinetic technologies. However, implementing this transformation requires meticulous experimentation and research on the origami system's materialization and actuation mechanism. This research project aims to activate a tessellated folding surface by proposing a novel approach to designing, fabricating, and integrating soft pneumatic actuators that enable complex multi-directional movements without complex mechanical systems. The research includes a computational investigation of the folding mechanism and physical experiments that integrate pneumatic silicone actuators into the origami structure. The focus of this research is to examine its foldability and structural stability. Strategic positioning of soft actuators produced distinct surface geometries by inflating and deflating different groups of actuators. The results reveal that the origami unit module scale and the actuator's position are two primary factors that impact the global deformation of the structure. The findings further highlight the potential of soft robotics to produce more intricate movements than their hard-bodied analogues.

1. Introduction

The traditional approach to architecture has been to design and construct buildings that resist the influence of the changing environment, with a focus on stability and permanence. However, the current discourse in architecture is shifting towards a more sustainable and adaptable approach, which emphasizes the importance of establishing an active relationship between buildings, the environment, and building occupants. This approach recognizes that buildings should be designed to respond and adapt [1] to changing environmental conditions and the evolving needs of their occupants. One of the ways to make buildings adaptive is to include kinetic systems that can facilitate a dynamic relationship between the building and its environment/occupants. Integration of these systems can contribute significantly to the sustainability of the built environment by making it more adaptable and flexible, which can help reduce its energy consumption and minimize its environmental impact.

Dynamic systems require a level of movability of architectural elements and the actuation mechanism that would initiate and control the movement [2]. Most often, they are motor powered or hydraulic, which requires the inclusion of complex mechanical systems. This paper explores the kinetic capacity of origami tessellated surfaces actuated by integrated soft pneumatic muscles. One of the goals is to reduce the need for complex mechanical support.

Origami is a traditional Japanese art that involves folding uncut sheets of paper to produce a smooth

transformation between the flat and folded state by following specific predetermined folding pleats [3]. The folding surfaces of origami provide a kinetic mechanism that is a viable option for generating dynamic structures. Transformability and structural self-support make it a good choice for designing adaptable and deployable structures. The flat-foldability of origami makes it possible to achieve a compact folded state with parallel plate surfaces. This facilitates the deployment and transformation of structures, which is advantageous within an architectural context. Flat-foldable surfaces also retain impermeability during transformation, making them a potentially ideal component for building envelopes [4]. In certain origami patterns, panels are not subject to deformation and therefore qualify as rigid components. To implement kinetic surfaces in architectural applications, the three-dimensional transformation of the surface and its performance must be regulated to achieve the desired design configurations. This requires the application of actuators to provide physical force.

This research project focuses on origami tessellation surfaces with embedded actuating elements (force), that transform between several shapes through equilibrium configurations while preserving their geometric integrity. Producing controllable folding movement in an origami surface, such as the triangular tessellated pattern, can be exceedingly challenging due to the convergence of multiple folds at each vertex. Implementing automated folding motion at the scale of a building using conventional mechanical actuators would require a complex arrangement of sizable linear or rotary actuators. This would, in return, increase the weight of the structure, its energy consumption, and maintenance requirements [5]. This project uses soft pneumatic muscles (capable of movement in all three axes by inflation and deflation) [6] instead of mechanical actuators. A single pneumatic muscle (soft robotic) actuator can produce complex movements, contrary to its mechanical counterpart. In this way, complex movement trajectories of an origami surface can be supported by strategically positioned inflatable components. However, due to their nonlinear behaviour, these systems are challenging to design. The design and prototyping of the soft inflatable muscle have been explored in this research project.

1.1. Tessellated surfaces

The presented project employed a periodic triangular crease pattern, originally developed by Ronald Resch [7]. Resch defined tessellated structures as systems with two fundamental features: modularity and the ability to generate an infinite range of variable dispositions through the alteration of angles between faces [8]. Modularity can be particularly beneficial since it can reduce manufacturing complexity and cost and facilitate constructability [9].

However, Tachi emphasizes that although modular tessellations offer certain benefits, the act of folding periodic origami tessellations becomes increasingly inflexible and rigid as creases increase [10]. This phenomenon is due to the gathering of rigid panels (as they fold) that impede the seamless folding of the tessellations. Consequently, folding tessellations into intricate forms becomes more challenging. Accordingly, he characterized this origami design as periodic origami tessellations that have two degrees of freedom (DOF), namely the "folding-unfolding" motion and the "twisting" motion [10]. Contrary to this, the Resch tessellated structures comprise hinged panels that allow bending and twisting in multiple directions concurrently and can create Gaussian curvature in the form of the saddle or spherical shapes [11], shown in Figure 1, while presenting static equilibrium in both open and closed shapes [12]. Furthermore, the structural stability of folded triangular tessellations is attributed to their rigidity and inertia when erected, resulting in greater stiffness than non-triangular tessellations [13]. This means that it is possible to construct larger structures that sustain flexibility and mobility [14, 15].

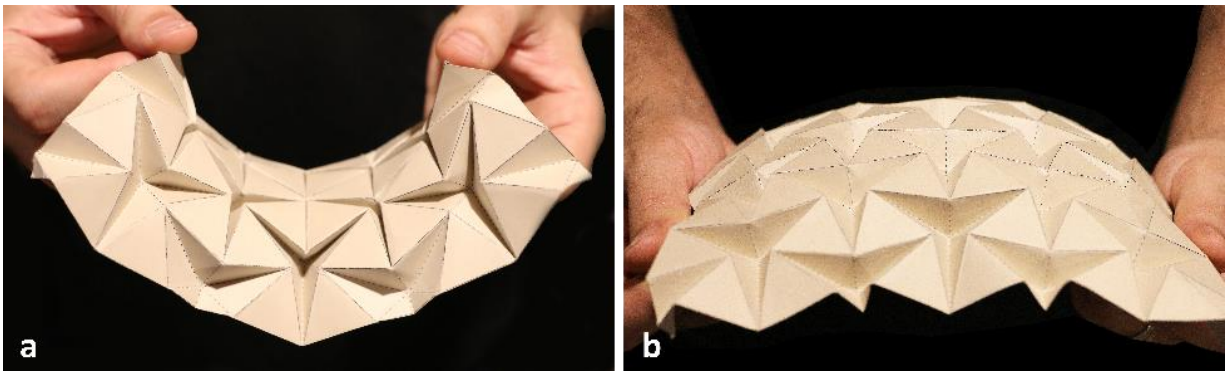

Figure 1. (a) Saddle and (b) spherical form the Gaussian curvature produced by warping tessellated triangular origami.

The foldability of paper origami is determined by the paper's thinness. Replacing paper with a thick, rigid material makes constructing a fully deployable tessellated structure challenging. In order to enhance the foldability of thick panels, Tachi proposed two approaches: relocating the rotational axis to the edges, Figure 2 (a), and trimming the solid of each facet by bisector planes of dihedral angles between adjacent pieces, Figure 2 (b), [16].

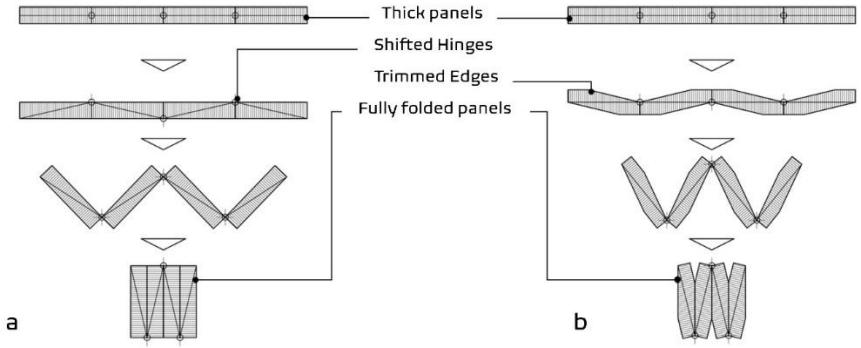

Figure 2. Optimizing foldability of thick panels in origami structures.

Thün et al. used Resch's triangular tessellation model [17] to create the "Resonant Chamber", an expressive acoustic envelope system. This folding structure prototype featured laminated membrane joints as hinges on the edges of the rigid panels [16]. Mechanical linear actuators between adjacent panels are used to animate the surface creating programmable spatial configurations based on sound analysis of the space. To explore the kinematics of a single unit module of the triangular tessellation pattern Mazzucchi developed a digital technique using a bespoke computer simulation [18]. He suggested two different kinds of hinges to make the rigid panels inside each unit cell more foldable. First, he used a system with hinges at the outer margins of the tapered panels, like Tachi [16] and Thün [17], that is similar to projection hinges. Second, he proposed a pin-joint-based hinge. By applying heat-sealing techniques to fabric sheets, Siéfert formed channel patterns that resulted in an anisotropic contraction in the plane and a potential alteration of Gaussian curvature [19]. This versatile single-step method for shaping stiff inflated structures can potentially be applied at a building scale, including deployable space structures and emergency shelters. Attempting to resolve the inflatability of origami structures Melancon et al. created a library of pneumatically actuated foldable origami shapes. The key here is inflatable cavities that, when inflated, preserve the shape of the structure [20].

1.2. Pneumatic actuation

Inspired by the inflatable structures in the early 1950s, the first generation of pneumatic artificial muscles was invented by J.L. McKibben in the late 1950s [21]. Since then, pneumatic muscles have been predominantly utilized in soft robotics to create flexible robots and soft actuators; their flexibility, inflatability, and high elasticity have added new performance capabilities for intricate movements. These inflatable muscles can be more fluidly integrated with moving components and can perform complex movements with a single action, outperforming multiple electromechanical actuators needed for a similar task. Their use simplifies the actuation mechanism, requires fewer mechanical components, and reduces manufacturing cost, assembly time, and operation energy consumption [6]. Due to their lifelike behaviour, soft muscles provide new functionality and improve the fluidity and safety of human and machine interaction [6, 22]. These qualities make them promising candidates for kinetic architecture applications as integrated actuators that generate movement of other elements [5, 23] or as sensor-embedded functional kinetic bodies that facilitate the interactivity of architectural systems [23-25].

The project presented in this paper explores the design, fabrication, and integration of soft inflatable muscles and their capacity to activate an origami-inspired structure. The project's initial phase involves examining the origami surface's folding mechanism, geometric morphology, and kinematic aspects. A computational design platform is utilized to model an origami-inspired folding structure. The spatial deformation of the folding triangular tessellated surface is simulated and systematically studied with the use of a physics engine. The later phase of the project centres on developing a soft pneumatic actuator that exhibits the capacity to generate multi-directional movement. The project also includes the development of a design prototype to test the folding and unfolding effectiveness of the actuator.

2. Methods

2.1. Simulation of surface kinematics

To better understand the geometry and kinematics of the origami tessellation, a surface is divided into unit modules. Simulating the movement of a single unit module enables a simulation of a much larger tessellated surface. The Rhinoceros 3D [26] modelling software was used to model the unit, while Grasshopper was utilized to determine the movement algorithm. Grasshopper's node-based visual programming and data management offer necessary mathematical and geometric functionalities for the development of algorithms.

The folding mechanism of a single unit module of Resch's triangular tessellation was simulated by the Kangaroo plugin – the particle physics engine that runs within the Grasshopper environment. The Kangaroo engine employs the dynamic relaxation method, which involves an iterative approach to compute the forces acting on nodes, followed by a pseudo-dynamic process over time to achieve a state of equilibrium. The nonlinearity of kangaroo simulations [27] renders them suitable for modelling origami structures that exhibit significant deformations. To imitate the folding mechanism, the model requires defining a mesh with its boundary that comprises all creases (valley and mountain), the rest angle of both valley and mountain folds, and the hinge strength.

The panels of the rigid origami surface were modelled as non-bendable mesh facets. Likewise, all the mesh edges, including the creases, were considered rigid beams to prevent elongation. Rigid beams were fabricated by utilizing the Length component. The strength parameter of this component determines the elasticity of the beam. A high numerical value indicates a beam that is rigid and exhibits minimal extension or compression, while a low numerical value indicates characteristics similar to those of a linear spring. All panels and their edges are subjected to compression and tension forces during the folding and unfolding simulation of the surface; therefore, rigid meshes and creases prevent the folding structure from collapsing. In order to simulate the hinges between folds, the rotational creases that link a pair of triangular facets were converted into spring elements using the Hinge component and assigned the strength parameter, which determines the hinges' stiffness. Tuning the strength parameter is crucial

for the simulation because it directly affects the quality of the origami's final deformation. The strength parameter in the Hinge component denotes the actuation force of the soft pneumatic actuators. In addition, a constraint is set using the NoFoldThrough component at all creases to prevent individual triangular faces from travelling through one another. Moreover, the Kangaroo plugin allows the application of virtual forces, such as gravity, translational, and rotational limitations, to the spring model, which helps control the folded pattern's global deformation.

We modelled the origami surface in a fully folded configuration, then started the actuation process by applying unbending forces on the creases locally in several patterns and globally on the entire folded surface. A digital workflow was developed to parametrically replicate inflation actuation through unfolding among the targeted units of the tessellation. The unfolding force is applied in a circular pattern, with the greatest force concentrated at the centre and diminishing outwards. The Kangaroo model simulates the surface deformation and results in a static equilibrium after a few iterations when applying the unfolding force and all predefined constraints. This simulation helps us to better understand the behaviour of the global surface geometry under various inflation-pattern scenarios. Triggered by various inflation rates, the unit module's different folding angles led to different origami surface deformations, as shown in Figure 3.

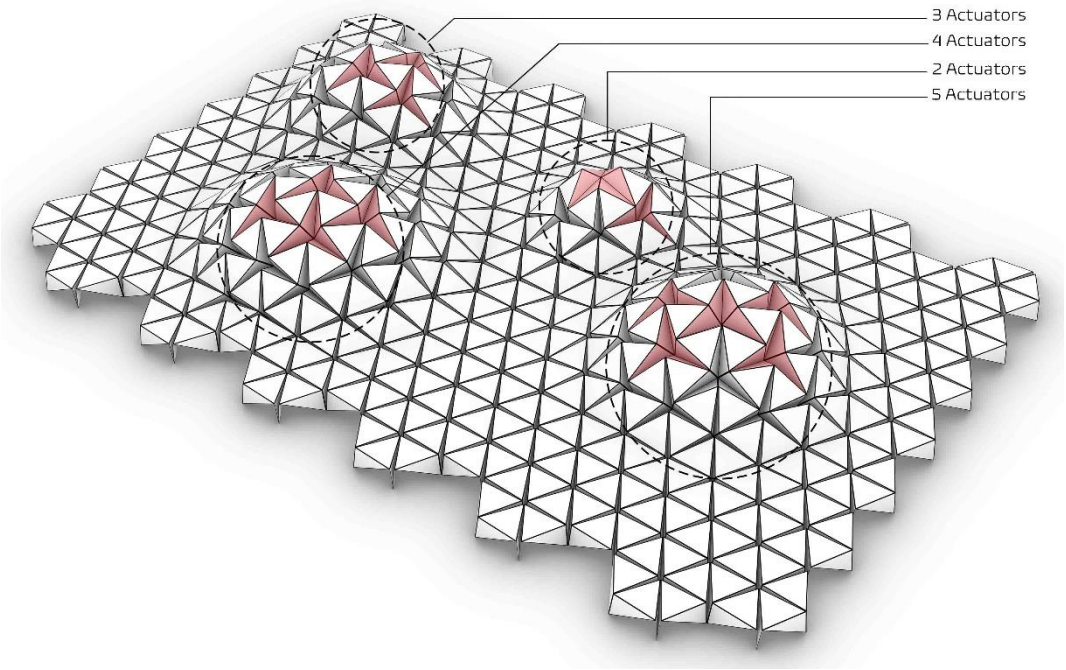

Figure 3. Origami surface deformation shows the surface behaviour caused by specific inflation patterns of actuators.

As mentioned earlier, the Resch origami tessellation is abstracted into an array of unit modules, Figure 4(a). The unit module exhibits a trifold symmetry, Figure 4(b), and includes two distinct vertices, A and B. Vertex A demonstrates a three-fold symmetry due to its six creases, Figure 4(c), while vertex B, also with six creases, displays plane symmetry, Figure 4(d) [13]. After primary analysis of the kinetic mechanism of the unit module of Resch origami, we divided its triangle panels into two kinds, namely, folding and non-folding, where the folding panels create the movement within the unit and the entire folding surface. Accordingly, two effective dihedral angles were recognized for the unit actuation. To move the unit facets from folded to a flat state, dihedral angles α and β, Figure 5(a), need to be increased from 0 to π and from $\pi/2$ to π, respectively. Consequently, if we were to use linear or rotary actuators to fold the unit module, up to nine actuators would be necessary to connect the panels on both sides of each hinge of the unit module, Figure 5(b).

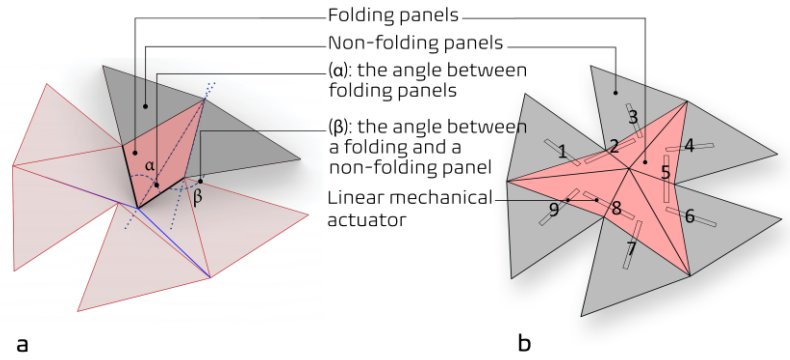

Figure 5. (a): diagram of the folding mechanism for a unit module. (b): Possible placements of linear actuators required for module movement.

2.2. Pneumatic muscle fabrication

The primary objective of this project is to replace linear actuators with a single soft robotic system integrated into a unit module capable of actuating its complex shape. Our proposed actuators are designed to prevent altering the origami pattern and interfering with the folding mechanism by taking into account the position of mountain and valley creases within the geometry of the folded module. Accordingly, two variations of a silicone actuator are created that function differently: (A) pushing and (B) pulling, Figure 6. Actuator A is installed within the foldable panels to push them to unfold when inflated. In contrast, actuator B is attached to the rear of the folding panels to pull them open when inflated.

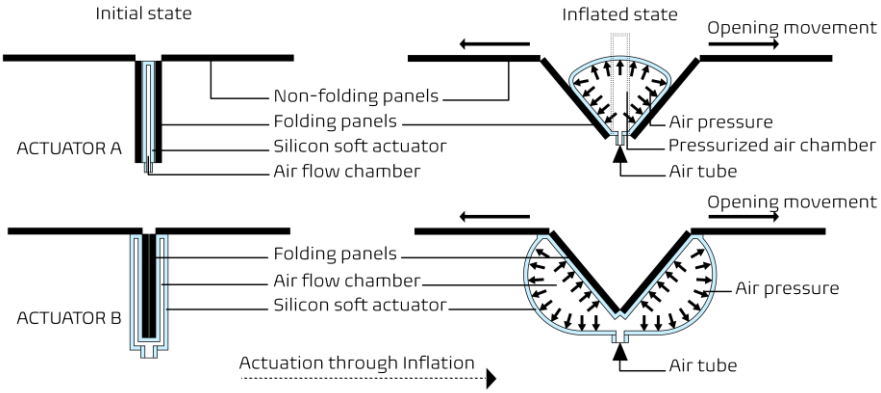

Figure 6. Two proposed actuators: type A functions as pushing, and type B functions as pulling.

Actuator A was designed to fit inside the tessellation folding pattern, Figure 7(A). It consists of three fins corresponding in size and shape to the unit module geometry. Three connected air chambers within the fins provide airflow for actuation. The casting procedure consisted of the main silicone body, made first and then cast with the cap to seal the air chambers. Accordingly, a ten mm wide gap was constructed between the folding panels to accommodate the three-fin silicone actuator with the unit module's folding pattern. Each fin of the soft actuator was attached to the fabric at the bottom of each crease, acting as a hinge between each pair of folding facets. Air was supplied for inflation through a polyurethane tube connected to the actuator from the rear of the unit module.

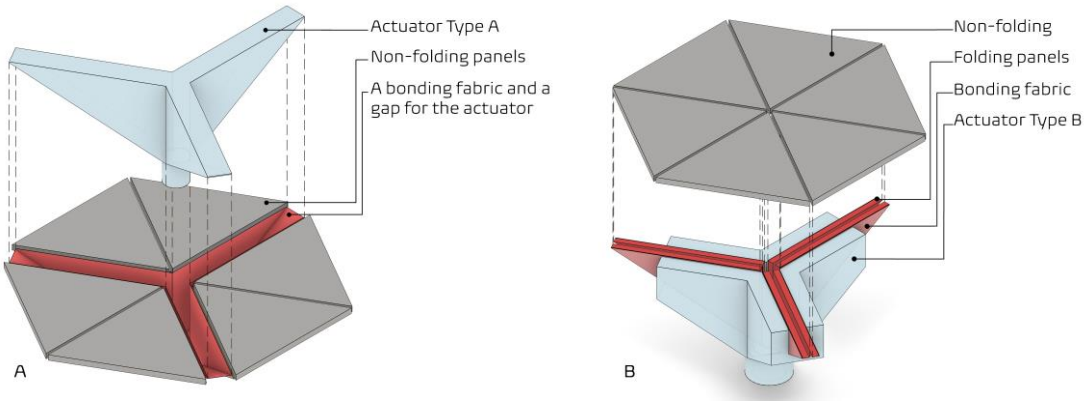

Figure 7. A and B actuators and their placement in a unit module of Resch's origami.

Actuator B was designed to hug the two folded faces of the module from the rare side of the surface., Figure 7(B). Similar to actuator A, its dimensions and shape are based on the origami unit module pattern and size. Unlike type A, however, each fin is divided into two sub-fins with distinct air chambers attached to both sides of the two folded panels. This structure provided larger bonding surfaces for the panels. In order to regulate inflation and attain the intended three-dimensional motion of the six chambers of actuator B, a constraining fabric layer was attached to the back side of the pneumatic actuator. This directed the force of movement toward the module's centre, which concentrated the force required to unfold the panel. The directed and constrained inflation force led to a notable reduction in air pressure requirements, Figure 8.

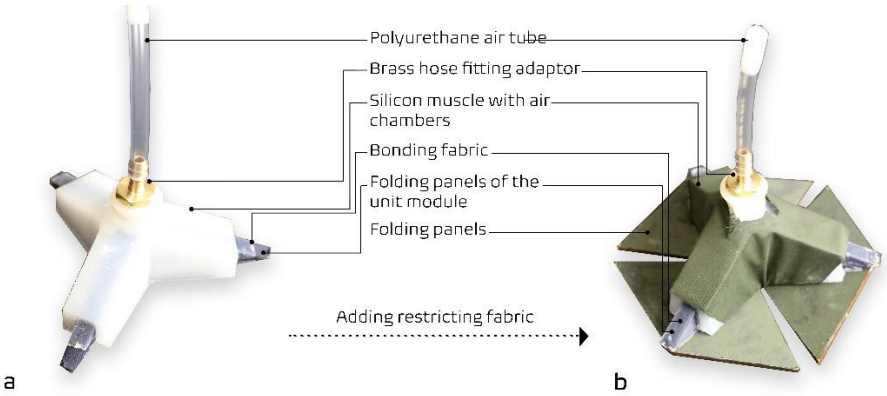

Figure 8. A restricting layer of fabric was attached over the pneumatic actuator.

2.3. Origami surface prototype

Soft actuators are cast using "Dragon SkinTM 10 Slow" silicone. Actuators are integrated into a wooden tessellation surface using the fabric matrix to create strong bonds between the surface and the silicone actuators. The gap layout between the triangular plywood elements is determined by considering the

plywood thickness and the edge hinge system [16, 17]. A prototype of 32 fully-folded unit modules is assembled in a four-by-eight grid, Figure 9(a). Twelve units are equipped with actuator B, Figure 9(b), and strategically grouped over the surface. This layout was used to explore the relationship between the folding mechanism and the local and global deformation of the origami surface. The non-actuated unit modules were kept in a folded position by embedded silicone clamps Figure 9(b). The entire tessellated structure was mounted on a 90 cm x 30 cm wood chassis, with two 30 cm and 60 cm–high walls on its two adjacent sides. The actuators were separated into six pairs, each connected to an independent air supply tube via pneumatic solenoid valves and an air compressor with an integrated air pressure sensor. They were commanded by an Arduino microcontroller with a MOSFET (metal-oxide-semiconductor field-effect transistor) driver module shield, Figure 9(c). Using pulse-width modulation, we programmed solenoid valves to perform six inflation patterns in a loop.

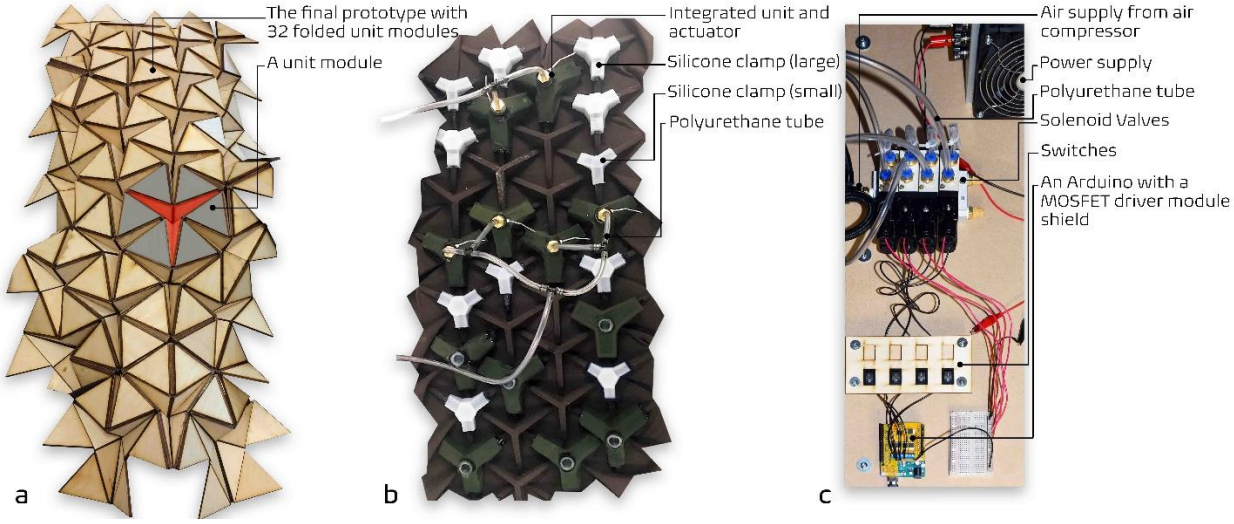

Figure 9. (a) The top surface of the final prototype of Resch's origami surface. (b) The reverse side of the completed prototype displays the locations of the actuators and clamps. (c): the control board containing Arduino and solenoid valves that regulate the air supply to the actuators.

3. Results and discussion

3.1. Simulation

The tessellated surface simulation assumes rigid and planar surface facets, as their bending is considered negligible. Despite the rigidity of the individual triangular facets, the mesh as a whole is regarded as a non-rigid and compliant body due to its ability to fold at the creases. The motion of the surface was generated within specific areas or across the entire model by modifying the angles of the folds, contingent on the distribution of the applied actuation. Regulating the magnitude of the angle constitutes a viable approach for managing the spatial changes of the creased surface. When no external forces or constraints were acting upon the surface, by increasing the angles α and β, the folding angles of both valley and mountain folds remained uniform due to the origami's inherent symmetry. Accordingly, the structure expanded only along X and Y axis at its equilibrium state without forming a spatial deformation. However, after local activation, as the angles of the fold increased, the α (angle between folding panels of each unit) decreased towards the edges of the deformation arch (Figure 10), indicating a greater compressive force at lower units due to their weight. Hence, the resting angle of α depends on the gravity stress on the folding panels, the stiffness of the hinge material, and the mechanical properties of the soft pneumatic actuator.

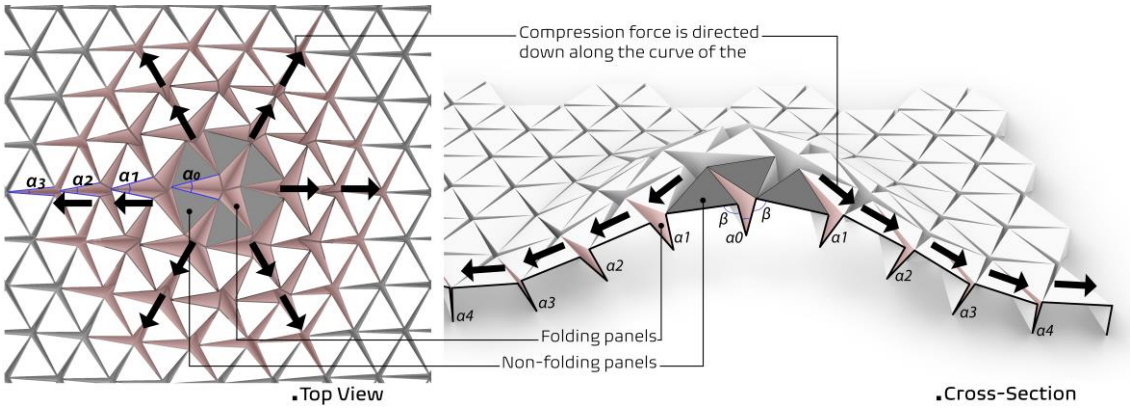

Figure 10. The angle between folding panels (α) was smaller towards the edges of the arch in each deformation.

The kinematics of the origami tessellation was simulated in vertical and horizontal positions using the particle engine of the Kangaroo plugin, Figure 11 and Figure 12. The simulation allowed for an easy change of the unit size within the surface. Scaling down the unit module increased the number of unit modules and, thus, the number of folds and actuators on the surface. More folds led to more varied deformation with more dramatic folding patterns of the origami surface that could be more easily calibrated. However, the increased number of unit modules compromised the structural stability of the surface. On the other hand, scaling up the unit module size reduced the number of unit modules on the surface and decreased the number of folds and actuators. This resulted in less varied deformation of the surface but more structural stability.

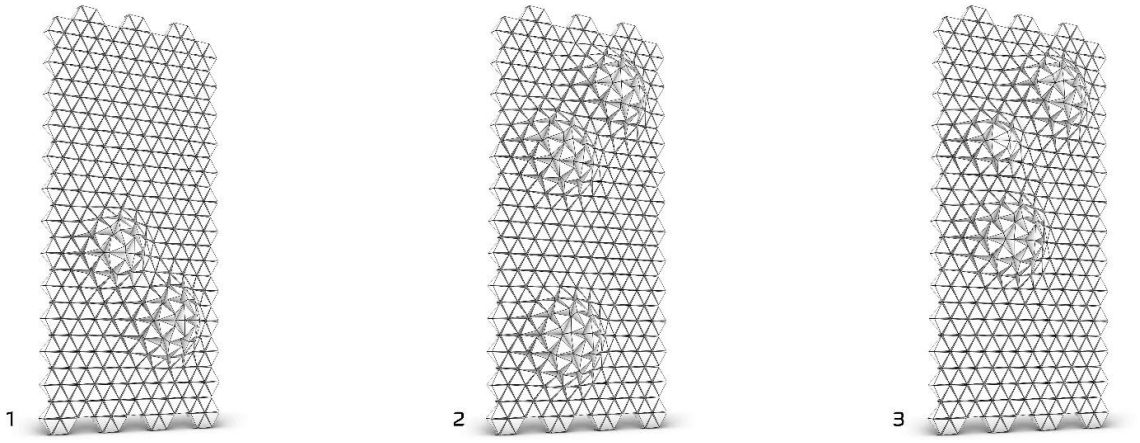

Figure 11. Simulation of various inflation patterns shows the surface's behaviour in the vertical position.

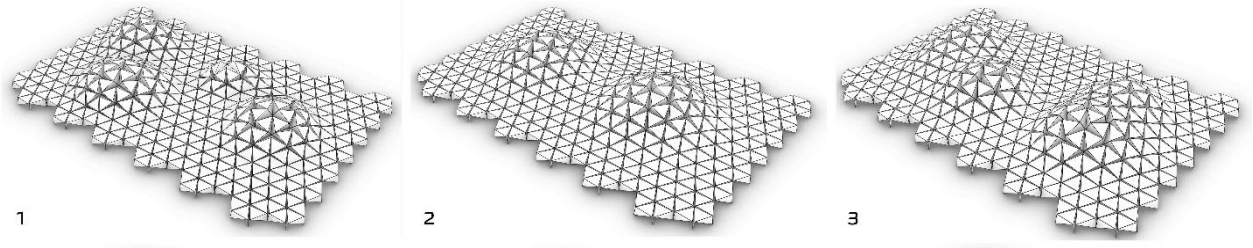

Figure 12. Simulation of various inflation patterns shows the surface's behaviour in the horizontal position.

3.1. Inflatable muscle performance

During the actuator inflation, several things were noted. Actuator A failed to fully open the unit module, as its inflation force was not fully utilized. Increasing the air pressure inflated the actuator in the opposite direction instead of increasing the pushing force. Because of its placement on the upper surface of the origami structure, this actuator would be exposed to possible damage, Figure 13(A). These observations obtained during the fabrication phase led to the design of the type B actuator.

Unlike actuator A, actuator B was fabricated as an integral part of the unit module's folding panels and placed under the surface. During the initial inflation test, the unit opened only partially, indicating that the actuator force must be more precisely directed. Applying a non-flexible fabric on the actuator enabled full inflation force towards the centre of the folding panels; thus, the amplified and directed force of the air unfolded the module, Figure 13(A).

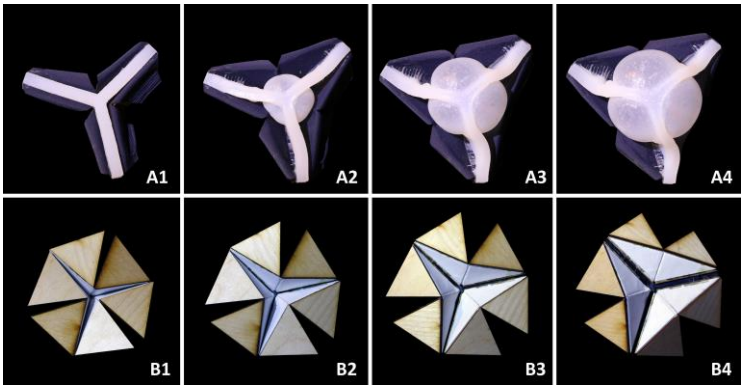

Figure 13. (A): Type A actuator opening sequence. (B): type B actuator opening sequence.

The final origami prototype consisted of 12 integrated actuators, while the rest of the unit modules remained closed with silicone clamps to provide the structural stability of the origami surface. Two sizes of silicone clamps were used on 11 non-actuated modules to help stabilize the origami surface in the folded state. The clamps allowed a minor folding/unfolding of each non-actuated module to enable a smooth global deformation of the entire origami surface. The size of the silicone clamps and their gripping force was critical in calibrating the surface deformation. If too large, clamps reduced the actuation force and caused a slight deformation, while small clamps resulted in structurally compromised and non-stable deformation.

The physical prototype inflation tests were carried out by orienting the prototype horizontally and vertically, Figure 14 and Figure 15. Various inflation patterns created different geometrical configurations, which helped examine the functionality of the actuators under the force of gravity. Although the actuators performed better in the vertical position, the folded units at the upper margin of the origami (where it was attached to the wood chassis) tended to unfold. In contrast, when in the horizontal position, the origami structure tended to remain folded due to the structure's weight. Therefore, actuating the units on the horizontal surface required higher air pressure. Furthermore, the analysis of the origami deformations in both positions determined that achieving a smoother global deformation would demand more actuators uniformly distributed through the surface.

4. Conclusion

This prototype-based study integrates soft robotics with Resch's triangular tessellation to exploit origami's kinetic properties. Compared to the linear actuation of the origami surface presented in the Resonant Chamber project [17], it was concluded that a single silicone actuator could replace up to six linear electromechanical actuators. Considering its folding kinematics, each unit module is divided into two parts: folding panels and non-folding panels. The final design embeds the folding panels in a soft actuator, enabling a one-step fabrication of the new module and actuator. Performing the inflation tests on the final prototype, equipped with 12 embedded actuators, underlined the significant influence of gravity on the surface deformation, its structural stability, and the unfolding function of the actuators. Designing an origami surface must account for its two intrinsic characteristics: flexibility and structural stability. The project strives to maintain both by integrating a soft actuator within a unit module of the origami pattern.

The outcome of this research highlights the possibility of making a tessellated origami structure kinetic by embedding soft robotics systems. Structures like these that include moving elements can be used in diverse architectural applications, such as adaptive facades or deployable shelters. For example, as a prefabricated deployable module, this design can aid in creating shelters for the survivors of natural disasters. The advantage of this folding system is that its prefabricated modules can be shipped to remote sites and assembled without any skilled labour. Once activated by specific air pressure, they would rapidly form a structurally stable shell.

This project is part of an ongoing study of actuating an origami surface. The authors believe further investigation is required to improve the efficiency of the soft pneumatic actuator and evaluate its nonlinear performance more precisely. In addition, given the compliant characteristics of Resch's origami, further structural analysis is necessary to evaluate its stability against different loads, including lateral loads.

Acknowledgements

The second phase of this project was a collaborative group effort for a course on responsive architecture offered at the School of Architecture, Planning, and Landscape at the University of Calgary. The authors

would like to thank Joseph Kaplan, Faraz Aghajafari, and Yanjinlkham Tumurbaatar for contributing to the fabrication of an early prototype.

Abstract

Long-span roofs are usually associated with a complex shape and are typically snow load-sensitive, but in most design codes, there is no specific guides for the design of roof snow load for these kinds of roofs. Therefore, it is of great significance to develop an algorithm or method to aid the design of roof snow load for long-span, complex roof structures. In this paper, the Finite Area Element (FAE) method proposed by Irwin and Gamble was modified to analytically simulate the evolution of roof snow load on a cylindrical roof. The modifications include three aspects: 1) the formula to estimate roof snow transport rate due to snow drifting; 2) the method of evaluating the wind field around the roof; and 3) the estimation of roof snow depletion. Using the modified model, the evolution of roof snow load on a cylindrical roof in Harbin China is simulated and analyzed for the period of 1971 – 2017. Results indicated that the modified model is easy to implement and could be a useful tool to aid the design of roof snow load for long-span, complex roofs.

Keywords: roof snow load, long-span complex roofs, finite area element, snow drifting

1. Introduction

The current load code for building structures in China specifies roof snow load factors for several conventional and simple roof types (shapes), so the roof snow load of these types of roofs could be designed by following the corresponding specifications. However, for roofs with complex shapes, such as that of many transportation hubs, stadiums, and exhibition centers that have been widely constructed in recent years in China, the roof snow load could hardly be designed by following the code since no specific guides are provided. The distribution of snow load on the roofs of such buildings are more complex than those on ordinary buildings. Therefore, it is of great significance to develop an algorithm or method to determine the design roof snow load for these long-span, complex roof structures.

At present, the research methods for studying roof snow load include field measurement [1-4], wind tunnel or water flume test [5-7], and numerical simulation [1,8,9]. In recent years, the Computational Fluid Dynamics (CFD)-based numerical simulation techniques have become a powerful tool in addressing the problem of snowdrift around/on buildings in snowy regions [10], and many applications of this technique could be found in the literature [11-13]. However, an overview of the current numerical models indicates that these models are mainly single event-based, i.e., the simulation result is associated with a single event of specific snowfall intensity, wind speed, and wind direction. Consequently, the simulation result cannot reflect the complex distribution of roof snow owing to the strong uncertainties

in the combination of snowfall intensity, wind speed, and wind direction under natural conditions, so it could not be used directly to assist the design due to the lack of probabilistic implications.

Unlike the CFD-based simulation, analytical simulation such as Finite Area Element (FAE) method [14] incorporate historical meteorological variables in the simulation, so the result is a reflection of the time-history evolution of the roof snow load under actual climate condition and is associated with probabilistic implications, which is necessary for a structural design that is based on probability theory. Although the CFD-based simulation could also be extended to a time-history analysis, its high requirement in computational resources makes it not feasible under the current situation.

The FAE method was proposed by Irwin and Gamble [14] in their study of snow loading on the Toronto Skydome. The fundamental of this method is to carry out detailed computational simulations of snow deposition, erosion, and melting hour-by-hour, the absorption of rainwater and meltwater by snow is considered in the simulation. By carrying out the time-history analysis of roof snow load, the design value of roof snow load is determined through statistical analysis of the most unfavorable snow load in each winter.

In this paper, the FAE method is partially modified to simulate roof snow load on a cylindrical roof in Harbin China. In the modified model, the friction velocity on the roof surface, rather than the wind velocity at a height of 1 m above the roof surface suggested in the original model, is used to calculate the snow drifting rate at each node of the grid. Also, by considering the difficulties in measuring friction velocity in wind tunnel tests, numerical simulation is applied to determine the friction velocity on the roof surface. Additionally, since hourly records of meteorological variables are not available in China, daily records of snow and wind data were used in the simulations. Another major modification to the original FAE method is the method to estimate snow depletion due to melting and sublimation. The remaining part of the paper is organized as follows: details of the modifications to the model are presented in section 2, and the application of the model to simulate the roof snow load on a cylindrical roof is described in section 3. Finally, conclusions are drawn in section 4.

2. Modified FAE model

2.1. Summary of original FAE model

Assumptions and details of the FAE method could be found in Irwin and Gamble [14] and Irwin *et al*. [15], and a review of the steps of the method was given in Gamble *et al*. [16].Basically, to perform a FAE analysis, the roof is first divided into an orthogonal grid of elements, and a mass balance equation is performed on each area element of the grid to derive the snow load within the element. For an area element as shown in Figure 1, snow transport rate at each node of the element, $q_{i,j}$, is first calculated using an empirical equation between the wind speed and the snow transport rate. The two components of the snow transport rate are then estimated to be:

$$\begin{aligned} q_{xi,j} &= q_{i,j} \cdot \cos \alpha_{i,j} \\ q_{yi,j} &= q_{i,j} \cdot \sin \alpha_{i,j} \end{aligned} \tag{1}$$

where $\alpha_{i,j}$ is the angle of the local velocity vector to the grid at node (i, j). The snow transport rate normal to the four boundaries of the element is then calculated using:

$$\begin{aligned} q_1 &= 0.5 \times (q_{x(i,j)} + q_{x(i,j+1)}) \\ q_2 &= 0.5 \times (q_{y(i,j)} + q_{y(i+1,j)}) \\ q_3 &= 0.5 \times (q_{x(i+1,j)} + q_{x(i+1,j+1)}) \\ q_4 &= 0.5 \times (q_{y(i,j+1)} + q_{y(i+1,j+1)}) \end{aligned} \tag{2}$$

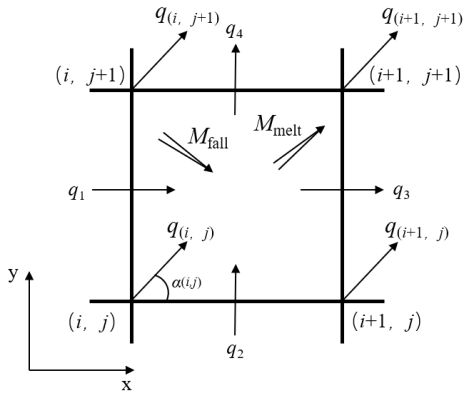

Figure 1. Schematic of snow mass balance for an area element

Finally, the change in snow mass, dm, in the element after a time interval, dt, is computed using:

$$\mathrm{d}\,m = \mathrm{d}\,t \cdot (q_1 l_1 + q_2 l_2 - q_3 l_3 - q_4 l_4) + M_{\text{fall}} - M_{\text{melt}} \tag{3}$$

where l_1 to l_4 are the lengths of the four sides of the element, M_{fall} and M_{melt} is snow mass caused by snowfall and snow melting during dt, respectively.

As a quick reference, the steps of the original FAE model are extracted from Gamble *et al*. [16]. The roof is divided into many area elements by a grid system.

a) The wind velocity distribution near the roof surface (1 m above the roof at full scale) is determined by wind tunnel tests on a model for a series of (typically16) wind directions, velocities are measured at each grid intersection point.

b) Snow drifting rates are then computed using empirical relationships for snow flux versus wind velocity. By computing the mass fluxes into and out of each element, the rate of build-up or depletion of snow mass in the element due to drifting is determined.

c) Time histories of meteorological data are used as input and the computations proceed in a time step manner in typically one hour time increments.

d) The mass balance computations at each time step include the additional mass from snowfall and the depletion due to melting. Hourly values of snowfall are produced from six-hour records of snowfall using a uniform rate of accumulation or weighted by qualitative snow flags if available. Melting calculations are performed by using hourly information on air temperature and cloud cover.

e) The result is a detailed time history of snow mass in each area element and the computed time histories extend over all the winters that are associated with sufficiently detailed meteorological data.

f) The snow mass time histories are analyzed statistically to determine various loading conditions of interest for design, 50-year return period value of the total imbalance in snow load between one half of the roof and the other for example.

2.2. Snow transport rate

In the original FAE method, the formula used to calculate the snow flux at a grid point is:

$$q = c \cdot U^2 \left(U - U_{\text{th}}\right) \tag{4}$$

where U is the wind speed at a height of 1 m above the roof; U_{th} is the threshold wind speed at a height of 1 m above the roof for the snow drift to occur, which is taken as 4 m/s, and c is a constant determined from field test results.

The formula was derived from field test [4], which were typically carried out on a flat, open ground. Since the actual roof geometry is much more complex than flat, open ground, the wind profile along the vertical direction on the roof should also differ a lot from those on the ground, this will result in different shear forces on the surface even when wind speed at 1m height is the same for the two cases. As a result, the snow transported by the wind will differ from each other. Consequently, it's considered in this study that the snow transport rate should be directly related to the shear force on the surface, and the equation given by Pomeroy and Gray [17] is used to obtain the snow flux at the grid nodes:

$$q = \frac{0.68\rho_a}{u_* g} u_{*t}(u_*^2 - u_{*t}^2) \tag{5}$$

$$u_* = \sqrt{\tau_0 / \rho_a} \tag{6}$$

where ρ_a is air density; u_{*t} is the threshold friction velocity which is taken as 0.2m/s in this study; u_* is the friction velocity that is calculated using Eq. (6), τ_0 is shear stress on the surface that could be derived from numerical simulations, and g is the acceleration of gravity that is taken as 9.8 m/s.

It should be noted that the relations given by Eq. (5) is also derived for flat, open ground, and it's assumed that the snow flux has reached a saturate or equilibrium state when developing the equation. Typically, a fetch length of about 200m to 350m [18] is required for the snow drift to reach a steady or saturated state, but for most buildings, the size of the roof is typically less than 200m. In addition, the development of the snow flux on the building roof is usually interrupted by obstacles on the roof such as roof steps. Consequently, a reduction factor, η, should be considered when applying Eq. (5) on building roofs, and the value of η should be case-dependent. The evaluation of η is out of the scope of this study and deserves further investigation. As a simplification, a value of 0.1 for η is considered for the roof considered in this study.

2.3. Utilization of daily wind speed

In the original FAE model, hourly records of meteorological data were required to run the simulation. However, historical meteorological data in China is daily at its highest temporal resolution. Consequently, an algorithm is required to estimate the daily snow transport using daily records of snow and wind data, such that the estimated snow transport should be as accurate as those estimated by hourly information. For this purpose, it's noted that the wind speed in the Chinese code is regarded as 10-min mean wind speed measured at 10-m height above the ground, U_{10}, and that the daily wind data provided by the China Meteorological Administration includes the daily average wind speed, U_{mean}, the daily maximum wind speed, U_{max}, and the daily maximum gust wind speed (3-s mean wind speed), U_{gust} [19-20]. Based on this situation, the 10-min mean wind speed U_{10} is regarded as a random variable in this study, and the two-parameter Weibull distribution was used to fit the probability distribution of U_{10}. According to the probability distribution model of U_{10}, the logarithmic law of wind speed profile that relates U_{10} and u_*, and the snow transport rate given by Eq. (5), the expected value of the daily snow transport, M_{exp}, can be obtained. Given this expected value of daily snow transport, an equivalent wind speed, U_{eqv}, is assumed and estimated, such that the snow transport caused by U_{eqv} for a period of 24 hours is equal to M_{exp}. In this way, the estimation of daily snow transport could be greatly simplified since only a single wind speed (U_{eqv}) is to be considered in the simulation for each day. Details of the probabilistic modeling of U_{10} and the estimation of U_{eqv} can be found in Li *et al.*[21].

2.4. Evaluation methods for snow depletion

In the original FAE model, the melting and sublimation of snow on the roof was estimated by considering an energy-balance-based snowmelt model, which works well but complicates the simulation. In the modified model, it is assumed that snow depletion on the roof is proportional to the reduction in snow depth on the ground:

$$\Delta M_{i,r} = M_{i-1,r} \cdot \left|\Delta h_{i,g}\right| / h_{i-1,g} \tag{7}$$

where $\Delta M_{i,r}$ is the reduction in snow amount on the roof for day i, $M_{i\text{-}1,r}$ is the snow mass on the roof on the previous day (day i-1), $\Delta h_{i,g}$ is the reduction in the ground snow depth on day i (compared to day i-1), and $h_{i\text{-}1,g}$ is the ground snow depth on the previous day.

Considering that the air temperature and solar radiation are the same for the roof snow and ground snow, and that air temperature and solar radiation are the main factors considered in the energy equation of the snowpack, the above-mentioned assumption is justified. Note that another important source of energy coming into the snowpack is the heating from the ground for ground snow and heating from the building for roof snow. Typically, the temperature inside the building is much higher than the temperature under the ground, consequently, the amount of snowmelt on building roofs is typically greater than those on the ground. The assumption adopted in this study would therefore underestimate the loss of roof snow, which is conservative to the structural safety.

2.5. Summary of the modified FAE method

Based on the considerations mentioned above, the steps of the modified FAE model are shown in Figure 4 and summarized as follows:

a) The roof is divided into many area elements by a grid system.

b) CFD simulations are run for a series of wind directions and wind speeds to establish a database for the friction velocity on the roof surface.

c) Starting from the first day of a snow season, snow drifting rates are computed using wind direction, equivalent wind speed, and Eq. (5). By computing the mass fluxes into and out of each element, the rate of build-up or depletion of snow mass in the element due to drifting is determined.

d) Snow depletion due to snow melting or snow sublimation is estimated using Eq. (7).

e) The result is a detailed time history of snow mass in each area element and the computed time histories extend over all the winters that are associated with sufficiently detailed meteorological data.

f) The snow mass time histories are analyzed statistically to determine various loading conditions of interest for design.

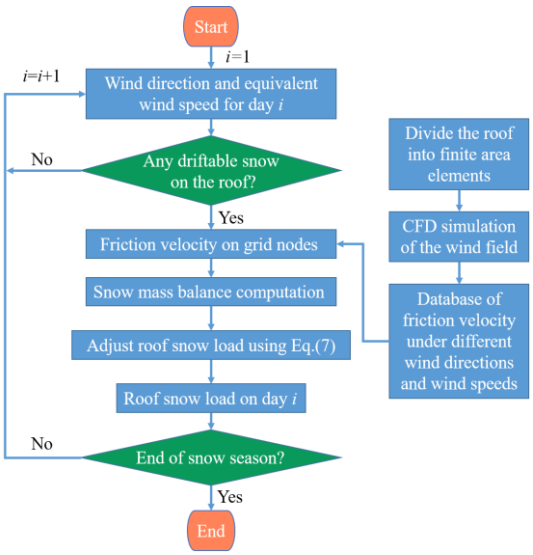

Figure 2. Flowchart of the modified FAE Method

3. FAE simulation of roof snow load for a cylindrical roof

3.1. Simulation of the wind field

As shown in Figure 3, the full-scale model of the cylindrical roof is 30 m in span, 50 m in length, 5 m in height at the eave, and associated with a rise-span ratio of 1/5. The computational domain is 400 m (length) × 300 m (width) × 60 m (height) in size, where the model is located 150 m downstream from the inlet section. The domain is divided by hexahedral mesh grids with a minimum size of 0.1m near the roof surface. An example of the mesh around the model is shown in Figure 4.

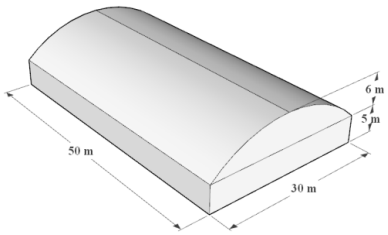

Figure 3. Size of the roof model

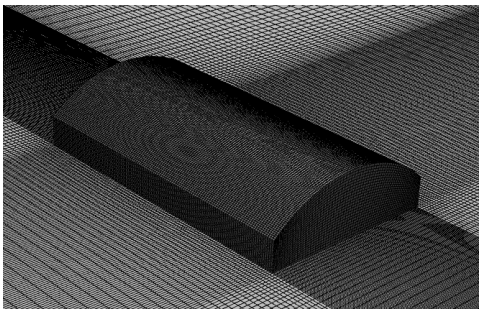

Figure 4. Mesh around the roof model

The boundary types used in the simulation are listed in Table 1, and the parameters of the inflow are given in Table 2. The Realizable *k-ε* model is selected for the turbulence model, and the solution is solved in the QUICK format. The iteration is treated as converged when the root means square residual reaches 1×10^{-5}.

In the simulation, 16 directions are considered as shown in Figure 5. Since the cylindrical roof is a biaxial-symmetric structure, wind fields for only five wind directions (0°, 22.5°, 45°, 67.5°, and 90°) are simulated in this study. The derived dimensionless friction velocity on the roof under different wind directions are presented in Figure 6, where the friction velocity on the roof is normalized using the corresponding friction velocity on the ground at the inlet. It can be seen from Figure 6 that, in general, the friction velocity is highest when the wind direction is taken as 0° and decreases gradually as the wind direction increase to 90°. This implies that more snow would be drifted when the wind is blowing from the radial direction (0°) than when the wind is blowing along the axial direction (90°).

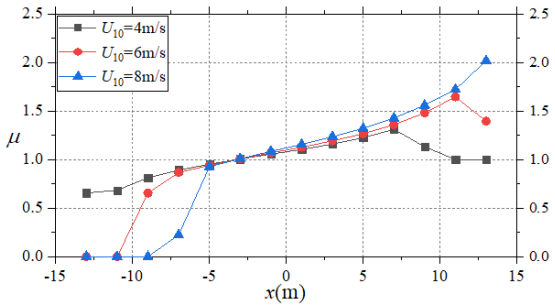
Figure 6. Dimensionless friction velocity on the cylindrical roof under different wind directions

3.2. Patterns of roof snow load

Given the friction velocity on the roof and historical records of required meteorological data, daily roof snow load could be estimated by following the steps presented in section 2.5. As an example, Figure 7 presents the roof snow load factors (roof snow load normalized with ground snow load) on the roof when the wind direction is set at 0°, ground snow depth is taken as 6cm, and the threshold friction velocity u_{*t}=0.2 m/s. Figure 8 shows the snow load factors on the central horizontal cross-section. Note that snow sliding due to the angle of repose of snow particles near the eaves is not considered since the focus of this paper is the influence of wind speed and wind direction on the redistribution of roof snow.

(a) U_{10}= 4 m/s (b) U_{10}= 6 m/s (c) U_{10}= 8 m/s

Figure 7. Variation of roof snow load factors with wind speed when the wind direction is set at 0°, ground snow depth is taken as 6cm, and the threshold friction velocity u_{*t}=0.2 m/s



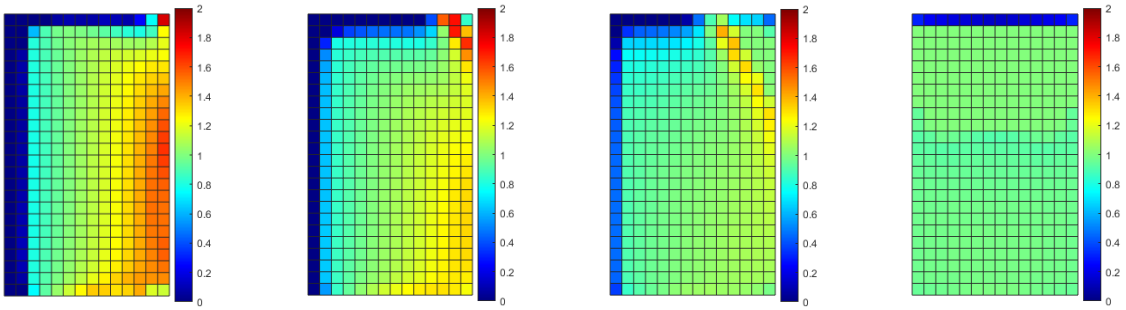


Figure 8. Comparison of roof snow load factors on the central horizontal cross-section for cases shown in Figure 7

It can be seen from Figure 7 and Figure 8 that the snow is tended to drift from the windward side of the roof to the leeward side, and more snow is drifted downstream when the wind speed increase. This is consistent with common sense in real life and can be explained by the distribution of friction velocity shown in Figure 6a. According to the basic assumption of FAE as presented in section 2.1, erosion or deposition of snow is related to the acceleration or deceleration of the wind, but not related to the absolute value of the wind speed. It's indicated by Figure 6a that the wind speeds up on the windward side, remains at a high level near the ridge, and decreases on the leeward side. Therefore, it's natural that erosion is observed on the windward side of the roof, and deposition is mainly observed on the leeward side. As the inlet wind speed increase, more area elements become erosive, and the peak of the deposition move downstream.

Figure 8 indicates that the roof snow load factor near the ridge is roughly 1.0, this implies that the snow is neither eroded nor deposited in this place. This phenomenon is not consistent with reality, where the snow near the ridge is typically eroded due to the relatively high wind speed. This is caused by the assumption in the FAE model that the snow transport rate is a constant for a given wind speed. In fact, the snow transport rate is an increasing function with the distance before the snow drift reaches its equilibrium state. Consequently, for an area element shown in Figure 1, the snow transport rate on the leeward edge should be greater than that on the windward edge even when the wind speed on the two edges is the same, such that the snow in this area element should be eroded but not keep unchanged as shown in Figure 8. This could be corrected by using a distance-dependent relation for the snow transport rate in the future.

Figure 9 and Figure 10 show the simulation results for different wind directions, where the initial snow depth h_0=6 cm, and the wind speed U_{10}=6 m/s. It can be seen from the figures that as the wind direction changes from 0° to 90°, the roof snow tends to become more evenly distributed. This indicates that the wind direction of 0° is the most unfavorable direction for snow drifting on cylindrical roofs.

3.3. Roof snow load considering historical meteorological data

To study the most unfavorable distribution of snow on the cylindrical roof under actual natural conditions, historical meteorological data of Harbin from 1971 to 2017 are considered to analyze the evolution of the snow on the cylindrical roof. Daily roof snow loads are estimated by following the steps presented in section 2.5 and a statistical analysis of the most unfavorable roof snow load is carried out to determine the representative value of the roof snow load. In the statistical analysis, the unbalanced roof snow load, S_u, defined in Figure 11 is considered, where $\bar{S}_A$ and $\bar{S}_B$ is respectively the average snow load on each half of the roof.

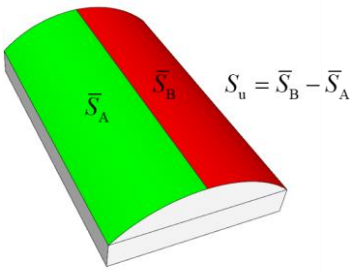

Figure 11. Definition of unbalanced roof snow load considered

Unbalanced roof snow load S_u is calculated for each day, and seasonal maximum value of S_u, $S_{u,max}$, is extracted for each snow season. The roof snow load on the date when $S_{u,max}$ is observed is then taken as the most unfavorable condition of the roof snow in the corresponding snow season. The roof snow load in each area element, $S_{r,ij}$, and the ground snow load, $S_{g,k}$, on that day is extracted and modeled as random

variables. A preliminary fitting exercise to the 43 samples of the variables indicates that both the $S_{r,ij}$ and $S_{g,k}$ could be modeled as a log-normally distributed variate. 50-year return period values of $S_{r,ij}$ and $S_{g,k}$, $S_{r,ij50}$ and $S_{g,k50}$, is then estimated from the fitted model and roof snow load factors for design are derived by normalizing $S_{r,ij50}$ with $S_{g,k50}$. As an example, Figure 12 shows the roof snow load factors for design when the roof is facing north-south and east-west. It can be seen from the figure that the roof snow load for cylindrical roofs in Harbin is more unfavorable when the roof is facing east-west.

(a) Roof facing north-south (b) Roof facing east-west

Figure 12. Roof snow load factors for design for a cylindrical roof in Harbin China: a) when the roof is facing north-south, and b) when the roof is facing east-west

Roof snow load factors for design on the central horizontal cross-section for different orientations of the roof are depicted and compared to the provisions specified in the Chinese load code in Figure 13. It can be seen from the figure that the distribution patterns of roof snow load for different roof orientations are quite similar, except that the magnitude of the roof snow load factors are slightly different. The estimated roof snow load factors are covered by the load provision in the middle of both halves of the roof but are greater than the code in the ridge. The reason for the overestimation of roof snow load near the ridge has been discussed in section 3.2 and is not repeated herein. Therefore, if the discrepancy near the ridge could be eliminated, the modified FAE could provide a reasonable estimation of roof snow load for design by considering the local climate condition.

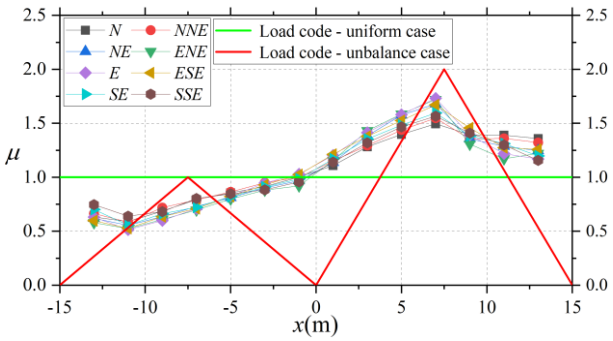

Figure 13. Roof snow load factors for design on the central horizontal cross-section for different orientations of the roof

4. Conclusions

A modified FAE model is proposed and used to simulate the evolution of roof snow load on a cylindrical roof in Harbin China for the period of 1971 – 2017. The modifications include the following aspects: 1) the friction velocity on the roof surface, rather than the wind velocity at a height of 1 m above the roof surface suggested in the original model, is used to calculate the snow drifting rate at each node of the grid; 2)by considering the difficulties in measuring friction velocity in wind tunnel tests, numerical simulation is applied to determine the friction velocity on the roof surface; 3) since hourly records of

meteorological variables are not available in China, daily records of snow and wind data were used in the simulations; and 4) the roof snow depletion due to melting and sublimation is estimated by assuming that the depletion is proportional to the decrease in ground snow depth. The application of the modified FAE model to a cylindrical roof in Harbin China indicates that the modified model is easy to implement and could be a useful tool to aid the design of roof snow load for long-span, complex roofs, except that the assumption that snow transport rate is solely related to the wind speed needs to be further improved by considering the fetch length of the snow drift development.

Abstract

The design of music venues, such as concert halls and open-air concert stages, requires an integrated approach in which the acoustic response of the space being created is evaluated at every stage of the process to inform its formal development and associated performance. Various software exists to assess acoustic performance: *Odeon* is considered by many as the industry standard standalone software for detailed and accurate acoustic analyses, whereas *Pachyderm* is a plugin for *Grasshopper* (*Rhinoceros 3D*), which provides architects and engineers with more rapid feedback on preliminary design ideas because of its integration with a parametric modelling environment. Although an experienced acoustic designer could rapidly learn to use any of these programs, their usefulness during conceptual design or teaching activities is limited by the computational power and time required to get acoustic performance results. In these instances, testing time is more valuable than accuracy. This paper introduces *Aeolus*, an acoustic modelling plugin for *Grasshopper*. Unlike other similar *Grasshopper* plugins, *Aeolus* allows users to control the simulation accuracy and can therefore be used to rapidly test the performance of design ideas. *Aeolus* can also easily be interfaced with various *Grasshopper* optimisation plugins. *Aeolus v0.1* was publicly released on 7 March 2023, and will be the focus of a Masterclass offered at the IASS Symposium 2023 in Melbourne, Australia.

Keywords: acoustic design, shell structures, computational morphogenesis, acoustic optimisation, conceptual design

1. Introduction

In architectural design, computational and performance-oriented approaches are no longer restricted to a niche number of large practices, engineering consultants and researchers: CAD software, particularly *Rhinoceros 3D* in recent years, has progressively facilitated the interface of architectural models with performance analysis software and optimisation algorithms. From Luigi Moretti's essays of the 40s and 50s about a future of parametric architecture and performance optimisation [1] to the Building Optimisation Procedure (BOP), developed by SOM Chicago in the 80s [2], software customisation and the integration of performance criteria in the design process have gone a long way [3-5].

For various reasons that are well beyond the scope of this paper, it can be said that *Rhinoceros 3D* has become a reference CAD environment over the past 20 years for many architects and engineers that make use of, or experiment with, computational design workflows. Whether the purpose concerned exploring and optimising complex geometries or automating design processes for fabrication, user-friendly scripting environments proved to be the answer to developing new tools and interfaces between design ideas and performance assessment. *Grasshopper* for *Rhinoceros 3D* is a visual scripting environment released between 2007 and 2008 [6]. Over the last decade, users have determined its success through numerous innovative performance-oriented design applications and by developing

plugins to enhance its native features and functionalities. For example, thanks to *Karamba 3D*, architects and engineers can now perform finite element analyses and optimise structures directly within *Rhinoceros 3D*, without interrupting their creative design workflows because of annoying operations of exporting and reimporting geometric and performance data [7, 8]. With *Kangaroo*, a plugin focused on simulating physical phenomena, designers can perform structural form finding without using physical models [9]. Thanks to *LadyBug*, integrating environmental aspects during conceptual design has become easier than ever [10].

In this panorama, plugins that allow the optimisation of key building performance criteria, such as structural and environmental, or plugins that manage the flow of data between geometric models and fabrication machines, have been developed much faster than other tools to evaluate secondary – or even invisible – performance requirements. Acoustics falls into this category as it is rarely a performance aspect that informs the design of the built environment, with the only exception of music venues. Moreover, the computational power required to perform an accurate – and therefore useful – acoustic analysis is a major hurdle for developing simple plugins that can provide architects and engineers with real-time feedback within a parametric modelling environment.

Aeolus was conceived to address this problem precisely [11]. It was released as a *Grasshopper* plugin in March 2023 to allow designers, particularly architects and students, to rapidly explore and evaluate formal solutions for the design of acoustic shells [12]. According to acoustician experts, such as Beranek [13] and Long [14], an acoustic shell constitutes a temporary or permanent physical device, a surface as a minimum, either integrated into architectural systems or as a standalone object, designed to reflect sound both towards the audience and to the musicians themselves. The integration with industry-standard software and the extreme simplicity of *Aeolus*, which is based on the Image Source Method rather than FEM, are key features to bear in mind while comparing this product with other software to understand its value fully.

After a brief introduction to acoustic modelling strategies, and a description of commonly used current software and plugins in Section 2, the parametric design workflow with *Aeolus* is explained in detailed in Section 3. Given the applicability of *Aeolus* to the conceptual design of various building typologies, Section 4 focuses on potential uses of the tool inspired by real case studies to stimulate the reader's creativity. This paper should be considered a formal introduction and presentation of Aeolus, which will be complemented by a Masterclass at the IASS Symposium 2023 in Melbourne, Australia.

2. Acoustic modelling in parametric design environments

Acoustic modelling utilises the principles of geometric acoustics to simulate the propagation of soundwaves: at any given time *t*, a point on the wavefront is represented by a vector – an acoustic ray – with magnitude equal to the distance travelled by the sound. The interaction of an acoustic ray with architectural surfaces is modelled using the Snell Law, which states that the angle of reflection must be equal to the angle of incidence. A sound reflection path is computed using basic principles of descriptive geometry by recursively applying the Snell Law: each time the acoustic ray intersects a surface, the reflection angle is computed, and a new ray is cast. The ray casting process aims to either visualise the reflection paths or measure the sound pressure levels (SPLs) at a specific target location.

This process can be implemented through two different methods: "ray tracing" and "image source". The ray tracing method casts a pre-defined number of rays from the sound source in multiple directions [15]. After constructing a certain number of reflection paths, this method computes how many reflected rays intersect with a target surface representing the audience. The accuracy of this method heavily relies on the initial number of rays used, as the distance between two points on the wavefront increases with the square of the wavefront radius. In other words, the sample resolution decreases exponentially with the distance from the sound source. Conversely, the image-source method [16] constructs the reflection paths backwards from specific target points to the sound source. Having specified a reflection order *N*, i.e., how many times a ray bounces off surfaces before reaching the target, the method tests all possible

combinations of reflection paths, which will be equal to the number of surfaces composing the scene raised to *N*. Therefore, the image source method allows the computation of accurate SPLs at one or multiple target locations, which can be visualised as a 2D map. It is worth mentioning that both ray tracing and image source methods have pros and cons. Therefore, the acoustic analysis uses a combination of both methods to model early and late reflections, respectively.

These methods are currently integrated into plugins for *Grasshopper* to various extents. Excluding *Aeolus*, three other *Grasshopper* plugins are currently available: *Equissons*, *Snail*, and *Pachyderm*. *Equissons* focuses on auralisation, *Snail* on visualising ray tracing. However, they do not provide a quantitative analysis of acoustic measures. *Pachyderm* is the only plugin that allows users to visualise ray tracing but also implements the image source method to calculate early reflections. Standalone acoustic analysis software, such as *Odeon* and *Catt-Acoustic*, can simulate sound wave properties for calculating acoustic phenomena: for example, scattering and diffusion. Although the accuracy of these commercial standalone packages is higher than those of current *Grasshopper* plugins, they are primarily focused on detailed analysis: the learning curve is not necessarily practical in an architectural design setting, where simple computation and rapid feedback are required. Table 1 summarises the main features of all the plugins currently available for *Grasshopper*. *Odeon* and *CATT-Acoustic* are also included for comparison since they are commonly considered as the industry standards in acoustic engineering.

Table 1. Comparison of *Aeolus* against industry-standard acoustic analysis software and *Grasshopper* plugins.

Integrating acoustic modelling tools with parametric design software is essential to being able to design architectural spaces that are informed by acoustic performance. *Grasshopper* for *Rhinoceros 3D* allows the direct association between design parameters and acoustic outcome, letting designers receive acoustic feedback rapidly and interactively on preliminary formal ideas.

As mentioned above, *Pachyderm* is the only *Grasshopper* plugin that provides quantitative acoustic data, relatively accurate acoustic analysis, and visualisation and auralisation functionality. However, this plugin does not allow sufficient control over the acoustic simulation accuracy and speed, which makes it unsuitable for single and multi-objective optimisation algorithms.

Aeolus was developed in 2015 by Gabriele Mirra and Eduardo Pignatelli as part of the deliverables submitted with their master's thesis in Architecture (University of Naples Federico II) [11]. The purpose was to create an acoustic modelling plugin that could interface with multi-objective optimisation algorithms directly within the *Grasshopper* environment. At present, *Aeolus* only implements the image source method to accurately compute SPLs for early reflections. Even though the image source is a computationally expensive method, *Aeolus* allows users to select the level of the simulation accuracy to

produce a fast – but reliable – preliminary acoustic analysis. *Aeolus* can therefore be used in performance-oriented design workflows, where the resolution of the acoustic analysis can be reduced to prioritise the efficiency of optimisation algorithms.

It is worth underlining that *Aeolus* has been used in practice, research and teaching settings for the past eight years, even though it was only made publicly available as a free plugin for *Grasshopper* in March 2023. Regarding research, *Aeolus* was applied to the design and optimisation of a temporary acoustic shell in Acireale, Sicily. This acoustic shell, also known as "ReS", was first conceived in 2012 to be assembled and disassembled from wooden components and its design has then been improved and refined on a yearly basis [11], 17]. *Aeolus* was also used by Pugnale [18] in 2018 to study the acoustic performance of some of Frei Otto's most known tensile structures. In teaching and learning, *Aeolus* has been used for the past four years as the parametric acoustic analysis software in an architecture master's design studio at The University of Melbourne: the focus has been the acoustic design and optimisation of a music concert hall and school.

3. The design workflow with *Aeolus*

The section describes how *Aeolus* works and explains a typical acoustic analysis workflow with this plugin, from constructing the acoustic scene to visualising the simulation output as a 2D SPL map (Figure 1). The scene considered is simple to focus on the different stages of the workflow: it consists of a sound source, a curved surface acting as an acoustic reflector and an array of target/receiver locations evenly distributed over a hypothetical audience area (Figure 1, at the top).

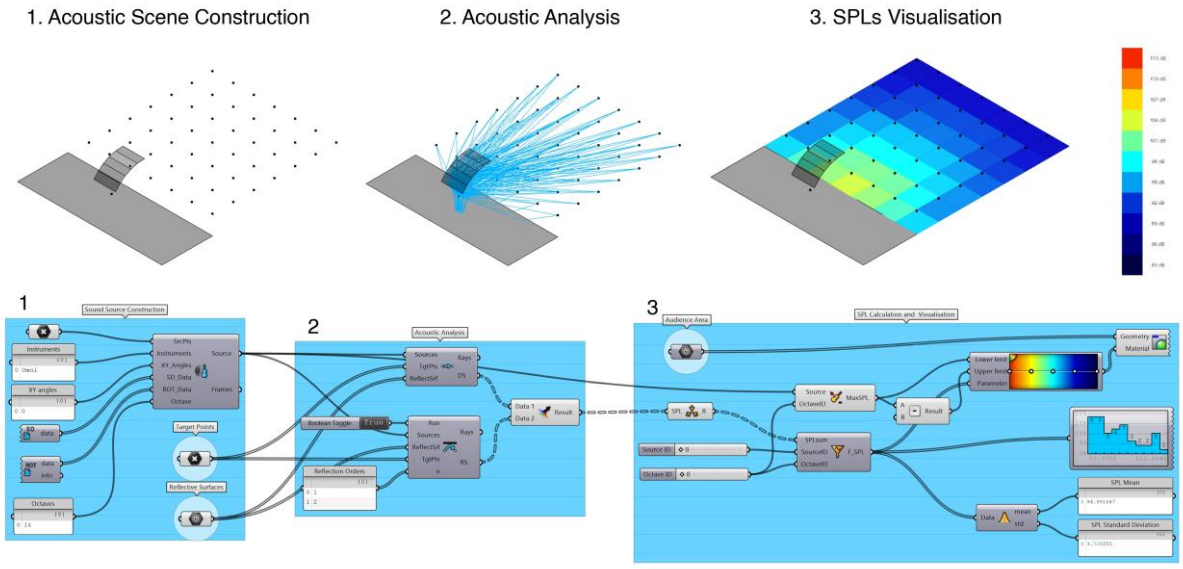

Figure 1. Overview of the design and analysis workflow with *Aeolus*, from constructing the acoustic scene to visualising the simulation output as an SPL map.

3.1. Constructing an acoustic scene

An acoustic scene configuration comprises, as a minimum, three geometric entities: a point, which represents the sound source location; a surface, which acts as an acoustic reflector; and a second point, which identifies the target or receiver location. Such a scene can be analysed with geometric acoustics to construct the sound reflection paths from a sound source to a target location. In acoustic modelling software, the three entities of a minimal acoustic scene can be assigned with physical properties to produce an accurate simulation. For instance, a sound source can be characterised by a sound directivity map, which assigns different SPLs to emission angles according to the instrument or loudspeaker

typology, whereas an acoustic reflector can have sound absorption coefficients which depend on the reflector material. *Aeolus* assumes that all surfaces are perfectly reflective, meaning they do not absorb sound. However, the plugin allows assigning a sound source with the directivity map of up to 15 instruments, which enables a more realistic analysis should the application require it. The following subsections describe how to construct the acoustic scene illustrated in Figure 1 using *Aeolus*: three steps are necessary, one for each of the entities listed above.

3.1.1. Defining the sound source

In *Aeolus*, a sound source object is constructed through a dedicated component by specifying: (1) a point location; (2) the instrument typology; (3) the sound source orientation in degrees; and (4) the octave band, which may include one or more of the seven reference values, i.e., 125, 250, 500, 1k, 4k, 8k, and 16k Hz. The sound directivity and orientation data of the supported instruments can be inputted through the components 'SD Database' and 'ROT Database', respectively. These two components import and perform the formatting of text files that are stored in the *Aeolus* installation folder. Such files reproduce information from the CATT-Acoustic sound directivity database and can be updated in future releases to include additional instruments.

Generally, a preliminary acoustic analysis would not require specifying instrument typology and the corresponding sound directivity values. An omnidirectional sound source can be used in *Aeolus* to perform an analysis that does not consider sound directivity. In this case, the specification of sound source orientation and octave band does not affect the simulation output.

3.1.2. Defining the acoustic reflectors

In *Aeolus*, acoustic reflectors are modelled as flat surfaces because the image source method requires a finite number of planes – one for each surface – to pre-compute all the possible reflection paths. Therefore, to analyse curved surfaces, these must be approximated by flat elements (Figure 1, stage 1).

Although there are no limitations to the number of surfaces that *Aeolus* can process, increasing this number can significantly affect the computational cost of the simulation. A trade-off between geometry approximation and simulation accuracy is required to keep the computational cost within manageable timeframes. It is worth mentioning that, as Section 3.4.1. will describe later, the approximation of a curved surface with flat elements does not overly affect the quality of the simulation. In some cases, a surface approximated by a few flat elements can perform better than a more refined one, thus suggesting alternative design solutions that might also be easier to build.

3.1.3. Defining the targets

In *Aeolus*, a target identifies the end point of sound reflection paths and can be considered as a listener's location in the audience area. The plugin accepts the specification of one or multiple targets to perform an acoustic simulation. If multiple targets are used, arranging them on an evenly spaced grid is preferable so that a map can be generated to visualise the distribution of SPLs.

3.2. Performing an acoustic analysis

Once the acoustic scene is defined, the three geometric entities – sound source, reflectors, and targets – are fed to the two *Aeolus* analysis components, 'Direct Sound' and 'Image Source', to construct the direct and reflected acoustic rays and calculate the SPLs.

The 'Direct Sound' component traces the direct sound paths, that is straight lines connecting the sound source with the target points. The paths that intersect any reflective surfaces in the scene are discarded. The component also computes the SPLs associated with the direct sound paths using the path length and the directivity values of the sound source object. The 'Image Source' component performs the main acoustic simulation. Given an acoustic scene and a reflection order *N*, this component tests all the reflected sound path combinations and keeps only those that connect the sound source with the targets

after *N* intersections with the acoustic reflectors. This component also computes the SPLs using the distance travelled by the reflected sound and the directivity values.

Upon completion of the analysis, these two components produce the direct and reflected sound paths, which can be visualised in the *Rhinoceros 3D* viewport as lines and polylines, respectively (Figure 1, stage 2). By visually inspecting the sound paths, the user can preliminarily assess the performance of the acoustic reflectors. Alternatively, the user can perform a more detailed analysis based on the SPLs computed from the direct and reflected sound paths. *Aeolus* allows users to combine and visualise the SPLs by following the procedure described below.

3.3. Visualising sound pressure levels

Aeolus provides a set of utility components to combine, filter and display the SPLs obtained through the direct and reflected sound analysis. The SPLs are combined using the 'SPL sum' component, which performs a logarithmic sum of the direct and reflected SPLs for every target. The output data structure has the following indices: frequency id, sound source id, and target id. These indices can be used to filter the SPLs by using either the standard data tree functionalities provided in *Grasshopper* or the *Aeolus* 'SPL filter' component.

An SPL map can be constructed from the filtered SPLs by applying a gradient of colours to the cells surrounding the targets (Figure 1, stage 3). *Aeolus* provides a utility component to extract the maximum SPL characterising a sound source object for a specific octave band, which can be used to set the upper bound of the gradient domain. Another component computes the standard deviation and the mean of the SPLs to capture their distribution over the audience area. These values can be used as objective functions for acoustic optimisation applications (see Section 3.5).

A typical use case of the visualisation workflow described above involves selecting a sound source id to extract the SPLs only for that specific sound source and comparing the results with the SPLs corresponding to the other sound sources used in the simulation. Figure 2 shows the SPL maps produced by switching the index of the sound source after completing the simulation of an acoustic scene that included two sound sources placed at the centre and one side of the acoustic reflector. The comparison reveals that the acoustic reflector evenly distributes sound only for the central sound source.

Alternatively, if the user has assigned the sound source object with an instrument and multiple octave bands at the beginning of the simulation, they can switch the frequency id to compare the SPLs for different octave bands. Figure 3 (at the bottom) illustrates the simulation outputs for an acoustic scene in which the sound source is assigned with the directivity values of a violin. The analysis focuses on the 1kHz-8kHz octave band range. By changing the frequency id, the user can visualise in real-time the SPL map associated with a specific sound directivity map (Figure 3 at the top).

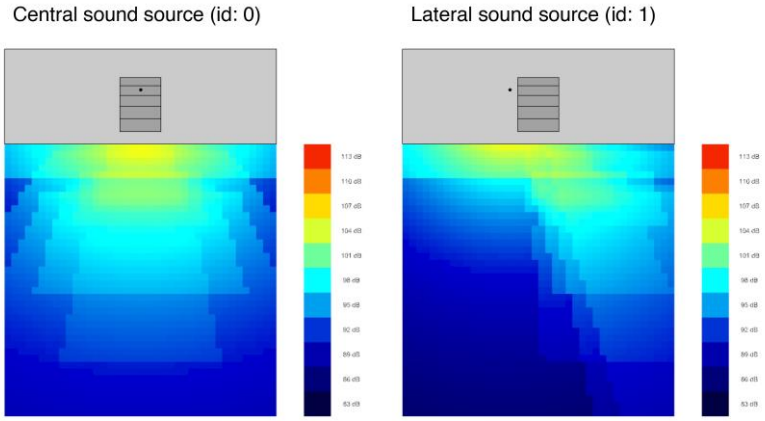

Figure 2. SPL maps produced by switching the sound source id after analysing an acoustic scene with two different sound source locations.

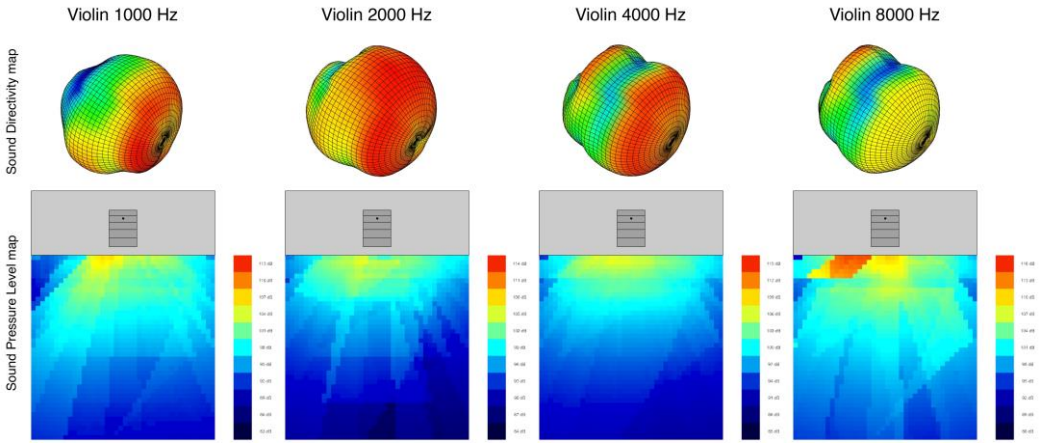

Figure 3. Simulation of an acoustic scene using sound source directivity. At the top: Sound directivity maps of a violin for four different octave bands; at the bottom: SPL maps produced by switching the frequency id after analysing an acoustic scene with a violin sound source for four different octave bands.

3.4. Adjusting the simulation settings

One of the main advantages of *Aeolus* is the possibility of fine-tuning the simulation settings to produce analyses with different degrees of accuracy. This is an essential feature of *Aeolus* because acoustic analyses are computationally expensive, limiting the interoperability of other plugins within parametric design software. This section describes the settings that reduce the computational cost of acoustic analysis in *Aeolus* and the effect these settings have on the simulation output. We do not provide a breakdown of the computational cost for each setting because this information depends on the computer hardware used. We instead compare the simulation outputs through the SPL maps.

3.4.1. Acoustic scene complexity

The complexity of the acoustic scene has a significant impact on the computational cost of the simulation. Increasing the number of acoustic reflectors, sound sources, and targets could provide very accurate information on the performance of a specific design but could also make exploring different formal configurations impractical.

Therefore, the number of acoustic reflectors is the first setting that can be adjusted to speed up the simulation. As mentioned at the beginning of this section, *Aeolus* require all geometries to be provided as flat elements. If the acoustic reflector/s are modelled as curved surfaces, these must be tessellated before running the simulation. The number of individual faces produced through the tessellation will be the actual number of acoustic reflectors used in the simulation. Figure 4 shows different subdivisions of the curved reflector considered in the previous analyses presented in the paper, and the effects these have on the SPL map. Since the reflector was described by a single-curvature surface, the tessellation only controlled the number of subdivisions along the surface V direction, which produced equally sized flat elements. The comparison of the SPL maps reveals that, for this particular geometry, a number of subdivisions of 25 is sufficient to simulate the performance of the original curved reflector accurately. In fact, a higher number of subdivisions did not considerably affect the SPL map, which is characterised by a trapezoidal area with a uniform sound distribution and almost no reflections at the final rows of the audience area. Conversely, tessellations produced from 5 and 10 subdivisions could spread sound to the entire audience area: though these do not capture the shadowing zone at the final rows that characterises the SPL maps obtained from a high number of subdivisions, and only approximate the trapezoidal shape of the strong reflections at the centre. It is worth mentioning that, although less accurate, the analysis suggests that a faceted reflector can be a better design choice since it can reflect sound more evenly.

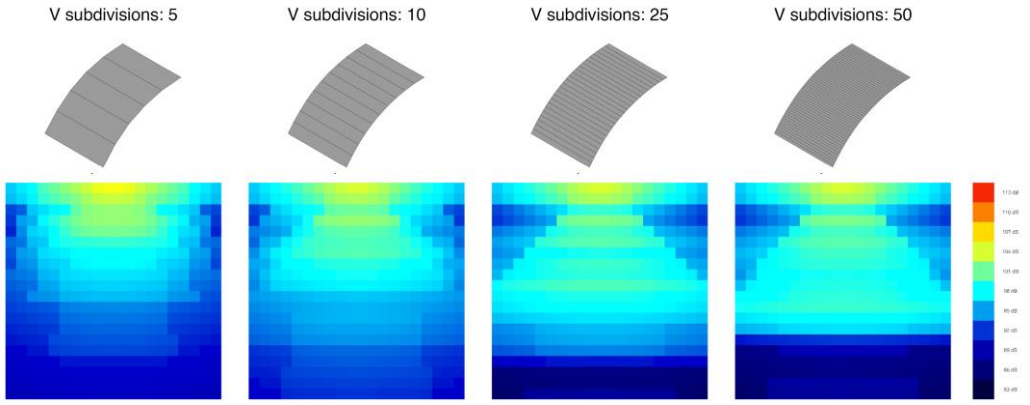

Figure 4. SPL maps for a single-curved reflector tessellated with an increasing number of flat elements.

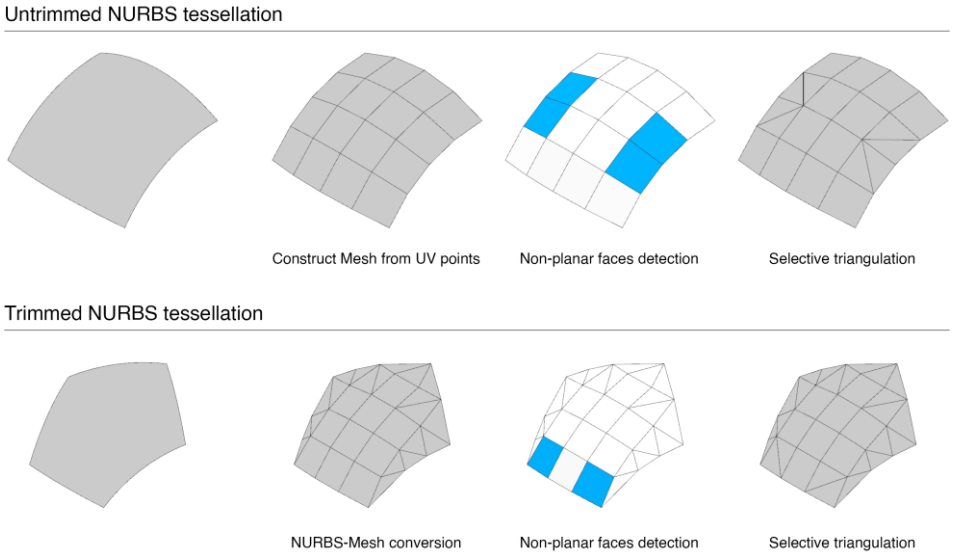

Figure 5. Stages for tessellating untrimmed and trimmed NURBS into a set of planar elements.

A tessellation based on UV subdivisions can also be applied for untrimmed doubly curved surfaces (Figure 5, at the top) by specifying the number of subdivisions for both U and V directions. However, if the surface is not ruled or extracted from a rotational surface, such as a sphere, the tessellation will not produce flat elements, and a planarity analysis is required to detect and triangulate non-planar faces.

Conversely, if the reflector is described by a trimmed surface, e.g., a NURBS with more than four edges, the tessellation cannot be performed through UV subdivisions. The user can convert the surface into a mesh object and control its resolution – i.e., the number of faces – by specifying the min and max length of the mesh edges. A planarity analysis and selective triangulation are also required to guarantee that all the faces are planar and suitable for the acoustic simulation (Figure 5, at the bottom).

Regardless of the input geometry and tessellation strategy, the selection of an appropriate number of faces should be guided by the purpose of the simulation. A low-resolution tessellation might be sufficient in the early exploratory stages of the design process, whereas a more detailed one can be useful to evaluate the performance of the final design accurately.

Another setting that affects the computational cost of the simulation is the number of targets. This parameter influences the resolution of the SPL map and can be controlled through the specification of the grid cell size. Figure 6 compares the SPL maps produced by analysing the same acoustic scene with a different number of targets. The maps are constructed with increasingly smaller grid cells, from 3 m to 0.5 m, in which each cell roughly corresponds to the footprint of a sitting area. The comparison shows

that as the map resolution increases, geometric patterns appear. These patterns are due to the reflections of the 5 panels composing the acoustic reflector and provide information about the contribution of each element to the SPL distribution.

In many cases, measuring the SPL for every point of the audience area might be unnecessary. If the objective of the simulation is assessing the overall distribution of SPLs, a low-resolution grid might be sufficient (see Section 3.5). Moreover, since a target identifies the listener position, the user may select only the actual seats as input for the simulation and discard irrelevant points from the audience area.

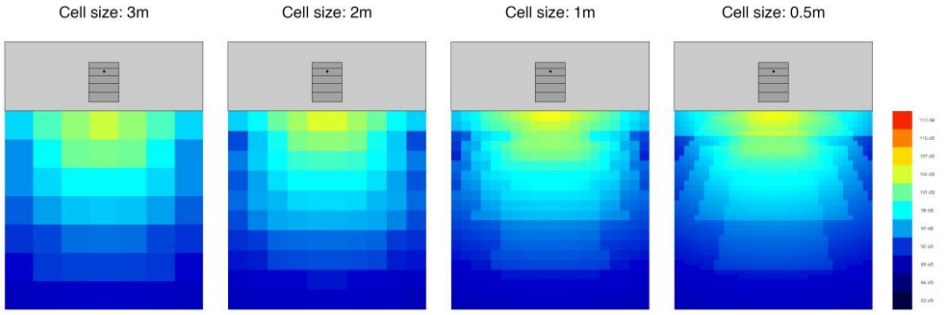

Figure 6. SPL maps at increasingly higher resolutions obtained by specifying a different cell size.

3.4.1. Acoustic analysis accuracy

In *Aeolus*, the accuracy of the simulation mainly depends on the reflection order, which affects the extension of the time domain in which sound waves propagate. A reflection order of 1 will only consider sound paths that arrive at the target location after one intersection with the acoustic reflectors. These paths are generally shorter than those reaching the target after multiple intersections with the reflective surfaces, and therefore do not provide much information about the SPLs associated with late reflections. Although a high reflection order *N* is required to produce a good estimate of the SPL in the time domain, and accurately compute important acoustic parameters such as sound clarity, definition and reverberation time (RT), the computational cost of the simulation grows exponentially with *N*. *Aeolus* can compute any number of reflection orders, but due to this limitation, a number higher than 4 is generally unmanageable even for simple acoustic scenes. Despite that, the information provided with an SPL map generated from up to 4 reflections can still be considered sufficient to evaluate a design option at the early design stages.

Figure 7 shows the effects of the reflection order *N* on the SPL map for two settings: a semi-reverberant field in which the acoustic scene comprises a curved reflector tessellated by 5 flat elements (Figure 7, at the top), and a reverberant field in which the acoustic reflector is surrounded by a rectangular box (Figure 7, at the bottom). Regarding SPL distribution, a reflection order of 2 returned a sufficiently detailed analysis for both settings. In the semi-reverberant field settings, *Aeolus* found no valid reflections for orders 3 and 4. Due to the absence of reflectors at the sides of the sound source, none of the acoustic rays could bounce more than twice before reaching the targets. Conversely, in the reverberant field settings, the reflectors constructed from the faces of the rectangular box always produced valid reflections. Nevertheless, the SPL distribution is almost identical for reflection orders 3 and 4, suggesting that, for this setting, a more appropriate analysis should have considered other acoustic parameters, such as RT, to determine the acoustic performance of the architectural volume. Although *Aeolus* does not currently support RT calculation, the analysis of the early reflections may still prove useful to determine the overall performance of an acoustic scene in a reverberant-field setting. In fact, strong early reflections correlate with good sound clarity and definition [11], and thus can effectively support a performance-oriented approach at the conceptual stages of the design process.

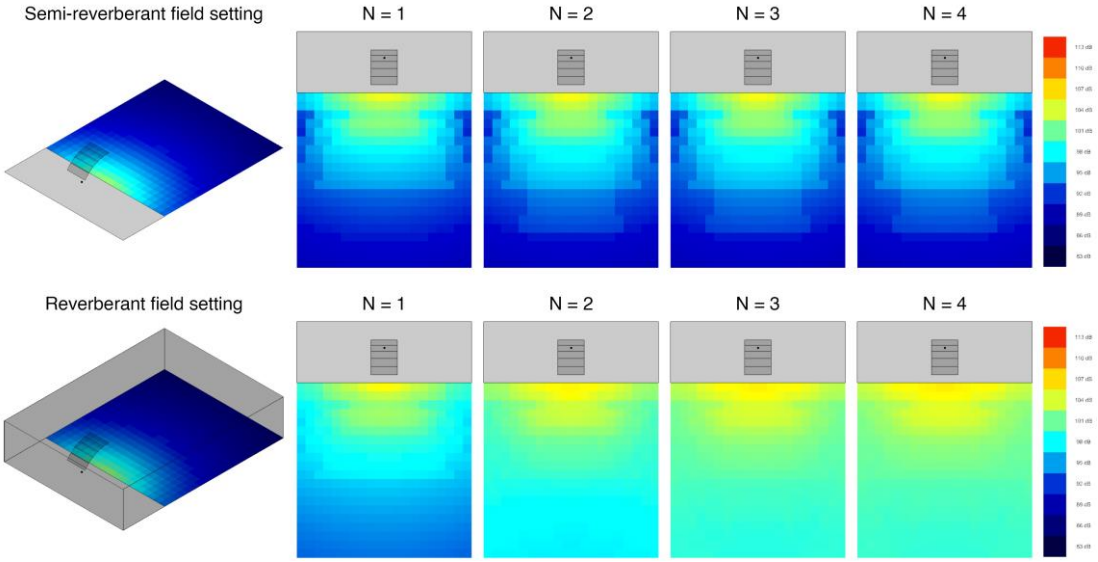

Figure 7. SPL maps for different reflection orders N. At the top, analysis of a single curved reflector (semi-reverberant field); at the bottom, analysis of a curved reflector inside a rectangular box (reverberant field).

3.5. Integration with optimisation plugins

As described in the previous sections, *Aeolus* allows performing more or less accurate analyses by fine-tuning the simulation settings, providing full control over the calculation time. With the appropriate settings, a user can rapidly test the acoustic performance of various design options within the *Grasshopper* environment. Alternatively, they can perform an optimisation process in *Grasshopper* using either the pre-built Genetic Algorithm (GA) component *Galapagos* or third-party plugins, such as *Octopus*.

Figure 8 illustrates a basic acoustic optimisation performed with *Galapagos*. The objective function was minimising the standard deviation of the SPLs distribution on the audience area. Three design variables were selected to control the z coordinate of the three control points defining the base profile of the curved reflector used for all the analyses described in this section (Figure 8, on the left). The acoustic reflector was tessellated with 5 flat elements, while a cell size of 2 m was used for the audience grid. The simulation considered reflections up to the second order. This setting kept the computational cost of each simulation below 100 ms.

The convergence graph in Figure 8 demonstrates that *Galapagos* could retrieve design options producing SPL maps with an increasingly lower standard deviation, which reduced from 3.67 (original design) to 2.36 (after 24 generations). The solution extracted from the 24th generation can be considered an improvement of the original design as the SPL is more uniform across the entire audience, meaning that the optimised design can reflect sound – for a specific sound source location – up to the last row of targets (Figure 8, at the bottom). Figure 8, at the right, compares the SPL maps of the original and optimal design obtained by increasing the resolution of surface tessellation and audience grid after the optimisation process. The optimal design still outperforms the original one in terms of SPL distribution, demonstrating that performing an analysis with *Aeolus* at a coarse resolution is a valid strategy for implementing an effective acoustic optimisation process.

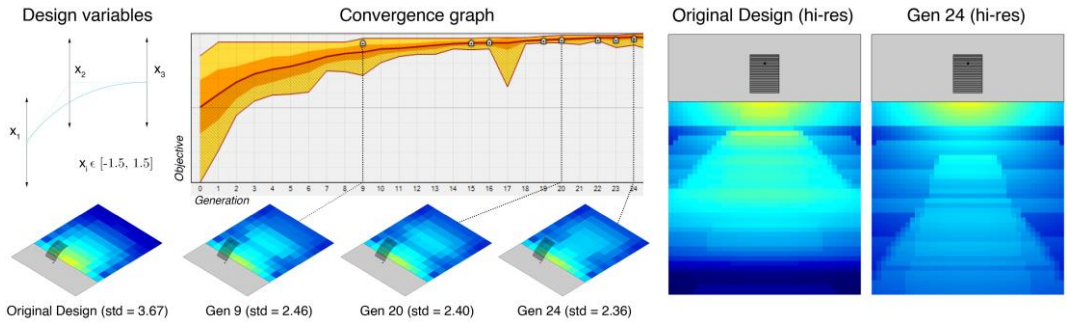

Figure 8. Example of an acoustic optimisation using *Aeolus* with the Genetic Algorithm *Galapagos* for *Grasshopper*; On the left, a representation of the design variables and convergence graph with selected design solutions; on the right, comparison between a high-resolution analysis of the original and optimised design.

4. Potential applications of *Aeolus*

The integration of *Aeolus* with architectural design and parametric modelling tools allows designers to use this plugin beyond applications that are specifically focused on acoustic performance. A brief survey of non-acoustic-oriented projects revealed that many architectural and structural forms could easily be recontextualised to perform as acoustic shells. We identified at least four different categories of architectural forms, which, even though unintendedly designed to be used as acoustic devices, impact the acoustic quality of the space they sit in. Figure 9 illustrates four example projects, and two abstracted variations of each are accompanied by an acoustic analysis to showcase the wider architectural applications of *Aeolus*. For the analyses, a single omnidirectional sound source was used at the centre of the design space, and the cell spacing for SPL analysis was set at 1m.

Facades [F] and openings in building envelopes are generally designed formally as invitational or gathering spaces providing opportunities for events. Naturally, this typology lends itself towards similarities with conventional acoustic performance shells encouraging mono-directional sound projection. In the examples, F1 mimics a canopy-like structure which can be adjusted to focus reflections intimately towards the opening or reflect sound away. [F2] proposes control over the lateral focusing of reflections, encouraging a linear approach towards the opening.

Gallery [G] spaces range from arcades to covered walkways, where sound is reflected from the ceiling treatment and perimeter walls and projected across the length of the primary circulation. The faceted example in [G1] gives a scattering-like effect at a larger scale resulting in an unfocused and lively environment. [G2] simulates a simple canopy or arched structure serving to reflect sound in the bi-lateral directions.

Canopies [C], promenades and marketplaces feature areas that are covered but open laterally for circulation. *Aeolus* can be used in these cases to understand the impact of the ceiling design and its performance in the multi-directional distribution or dispersion of sound in and away from the covered area. The example in [C1] produces similar scattering results to [G1] due to the asymmetrical ceiling treatment, and the density or regularity of the facets could be adjusted to control the level of scattering. The alternating wave canopy structure in [C2] creates clear horizontal banding of louder regions across the site. This analysis could serve to situate programs or functions across the site.

Pavilions [P] can be architecturally programmed for many purposes that vary in acoustic requirements. Using *Aeolus* to study the acoustic quality of pavilions may be useful to qualify the design for specific programs. While the faceted [P1] is larger by footprint, the active acoustic area is relatively smaller compared to the concave shell structure of [P2] which encourages a wider dispersion of acoustic reflections outside the footprint of the pavilion. Interestingly, both these examples also demonstrate a limitation of geometric acoustics, shown by the acoustic shadows generated by the pavilion elements that touch the ground.

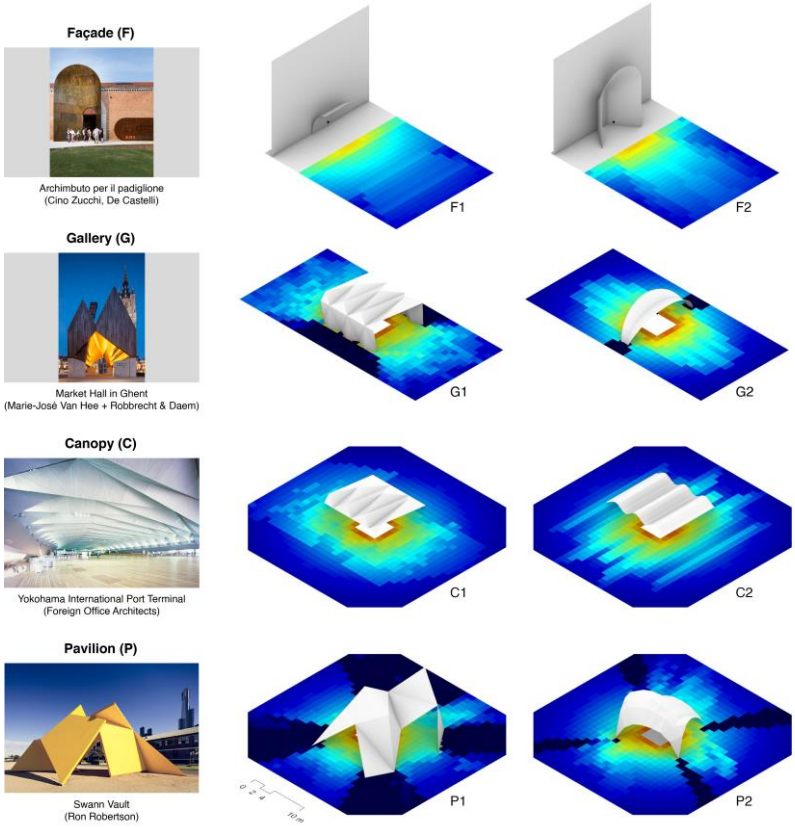

Figure 9. Example of potential applications of *Aeolus* with various architectural typologies. On the left, precedent projects illustrate each typology; on the right, comparison of SPL graphs of abstracted models.

5. Conclusions

This paper describes the development of *Aeolus* and its functionalities as an acoustic modelling software for the design, analysis and optimisation of acoustic shells. Its integration with *Grasshopper* for *Rhinoceros 3D*, i.e. an architectural parametric modelling software and associated optimisation plugins, makes it an effective tool for and performance-oriented design workflows, particularly at the conceptual design stages. Control over the degree of simulation accuracy, number of sound sources, and directivity allows the user to adapt the plugin precision level to different stages of the design process.

Like other available acoustic analysis tools, there are several shortcomings of *Aeolus*. The image source method requires surfaces to be modelled as flat, planar reflectors. This degree of approximation will always result in a trade-off between simulation accuracy, computational cost, and time. Particularly in a reverberant field setting, the reliance on the image source method also limits the accuracy of the SPL calculation and the lack of calculation for RT, though early reflections are suitable for measures of clarity and definition. Despite this, *Aeolus* can perform with a high enough accuracy and provide reliable analysis for preliminary stages in concept design, making it a suitable tool for architectural practice, research, and teaching. Future software development will incorporate additional algorithms to compute late reflections and construct a complete impulse-response graph.

Acknowledgements

Abstract

For analytical simulation of roof snow loads using historical meteorological data, meteorological data with high time resolution is required as input to obtain accurate results. Wind speed is the main factor in determining the distribution of roof snow load, and the simulated results are usually much more sensitive to the time resolution of the input wind speed. However, for the long-term historical meteorological dataset in China, only mean, and maximum values of 10-min average wind speed are available each day, which is hard to meet the simulation requirements. Therefore, a probability model of two-parameter Weibull distribution is proposed in this study to model the wind speed within each day finely. Then, based on the empirical relation between the transport rate of snowdrift and winds speed, the actual wind speed dataset from field measurement is used to validate the proposed model. Finally, based on the historical meteorological dataset of Harbin, an analytical simulation of snowdrift on a flat roof is carried out, and ground-to-roof conversion factors of snow load are derived.

Keywords: snow load, flat roof, analytical simulation, wind speed

1. Introduction

Snow load is one of the most critical loads that must be considered for structural design in cold and snowy regions, especially for long-span and lightweight structures. Failure of structures induced by snow overload frequently occurs for long-span and lightweight structures (Figure 1), severely threatening the structure's safety. To improve the snow load resistance of those structures, the proper design of roof snow load is of significant importance.

Figure 1. Some typical events of snow-induced structure collapse: (a) Marketplace in Russia, (b) Exhibition Hall in Poland, (c) Ice rink in Germany.

Plenty of research has been conducted to investigate snow distribution on roofs, and several approaches have been proposed and available till now. These methods include field measurements, wind tunnel/water flume tests, and numerical simulations (Figure 2). Field measurement is considered a

reliable approach to determining roof snow load, but it is time-consuming, and its results depend highly on the natural environment. Therefore, wind tunnel/water flume tests and numerical simulations, which are feasible to carry out and have more controllable working conditions, have become the mainstream research methods in the design of snow loads. These methods have also been applied to investigate the snow load around or above building for several structures, for example, the Concordia Scientific Research Station in Antarctica [1], Tongren Olympic Sports Center Stadium [2], and Beijing south station [3] et al. However, it is essential to note that these methods generally determine the roof snow load under the condition of a blizzard or storm, i.e., the design snow load is studied under the combination of heavy snowfall and strong wind as inflow condition, which failed to consider the evolution of roof snow load under the action of long-term natural climatic conditions. Thusly, the simulating result cannot provide a clear exceedance probability for roof snow load, and the result is hard to directly apply to structures' limit state design based on probability theory.

Figure 2. Methods for studying roof snow load: (a) field measurement, (b) wind tunnel test, (c) numerical simulation.

On the other hand, several researchers have studied the impact of actual meteorological conditions on roof snow loads and have proposed simulation methods based on historical meteorological data, such as the Finite Area Element Method (FAE) [4] and analytical simulation methods[5,6]. These methods simplify the process of roof snowdrift and make the simulation much more efficient. Thusly, this method can be combined with long-term meteorological data to analyze roof snow loads continuously over time. In contrast to the methods based on a single event, these methods consider the impact of actual meteorological conditions on roof snow loads and can provide a design roof snow load with a clear exceedance probability. Since these methods use meteorological data as inputs, the inputs significantly affect their results, especially wind speed. Hence, obtaining high-resolution meteorological data is necessary for more accurate simulation results. While for the historical meteorological dataset in China, daily wind speed data only include the maximum and mean value of 10-minute average wind speed and the maximum value of 3-second gust wind speed, which are coarse and cannot meet the requirements of simulation.

In this study, the analytical simulation method proposed by Qiang *et al*. [6] is used to study snow load on a flat roof. The historical meteorological data for Harbin, China, covering the time range of 1971 to 2018, are considered to study the evolution of roof snow load, and the two-parameter Weibull distribution is used to model the daily wind speed data. Finally, the time history of the snow load on the roof is derived, and the ground-to-roof conversion factors of the flat roof are also obtained.

2. Simulation setting and meteorological data

2.1. Simulation setting

The studied roof is shown in Figure 3. The snow transport model developed by Qiang *et al*. [6] is used to describe the snowdrift process on the studied roof. Considering the impact of threshold wind speed on snowdrift, this model classified snow transportation into snowdrift during snowfall and snowdrift without snowfall, and a sine function is used to describe the development of snowdrift on the roof. Following one of the cases studied by Qiang *et al*. [6], the studied roof is set as a two-dimensional

isolated flat roof without interference from nearby buildings, and the roof size is set as 50m in length and 10m in height and the inflow wind during the simulation is assumed to remain in a single direction.

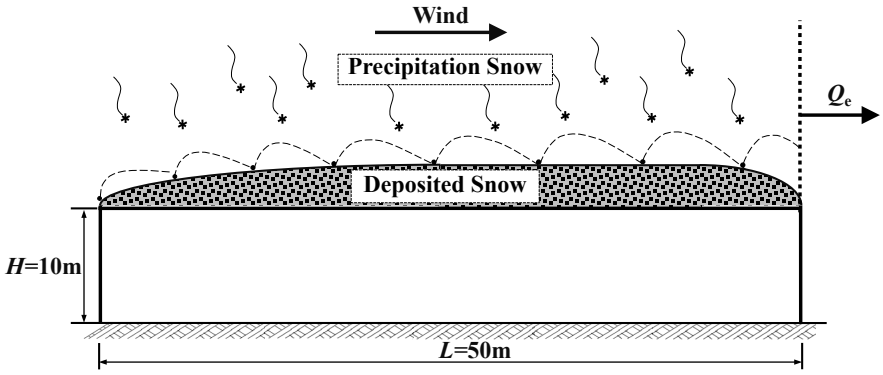

Figure 3. Schematic sketch of snow transport on flat roofs.

2.2. Meteorological data and data processing

2.2.1. Meteorological data

The historical meteorological data for Harbin, China, is used for snowdrift simulation. This dataset is collected from China Metrological Data Service Center (CMDSC) and contains daily records of wind speed, snow depth, air temperature, and precipitation lasting from 1971 to 2018.

The wind speed is measured at 10 m for open country exposure, corresponding to terrain categories B in the Chinese load standard. For roofs under different terrain categories, wind speed at roof height, V_H, can be calculated by:

$$V_H = G(\frac{H}{\delta})^{\alpha} \tag{1}$$

$$G = V_{600}(\frac{350}{10})^{0.15} \tag{2}$$

where V_{600} is the 10-min average wind speed at 10 m height from the meteorological dataset, H is the roof height, G is the geostrophic wind speed, δ is the thickness of the boundary layer, α is the power-law exponent. The value of δ and α for different terrain categories are shown in Table 1.

Table 1: Values of α and δ for the four terrain categories specified in the Chinese load code

Terrain category	Power-law exponent α	Boundary layer height δ (m)
Category A	0.12	300
Category B	0.15	350
Category C	0.22	450
Category D	0.30	550

Snow depth is measured for the days when more than half of the surrounding ground in vision is covered by snow, and the snow depth is converted to snow mass using a density of 150kg/m^3. Air temperature is observed at the height of 1.5m above the ground, and the data set for air temperature contains daily minimum, daily mean, and daily maximum air temperature. The precipitation data is recorded as the cumulative snow water equivalent (*SWE*, mm).

In Harbin, ground snow accumulation and subzero temperatures are rarely observed from May to September. Thusly, a winter season is defined as from October 1 to April 30 (of next year), and the meteorological data were partitioned into the winter season, resulting in a total of 47 complete seasons. The daily meteorological records for a typical winter season in Harbin are shown in Figure 4.

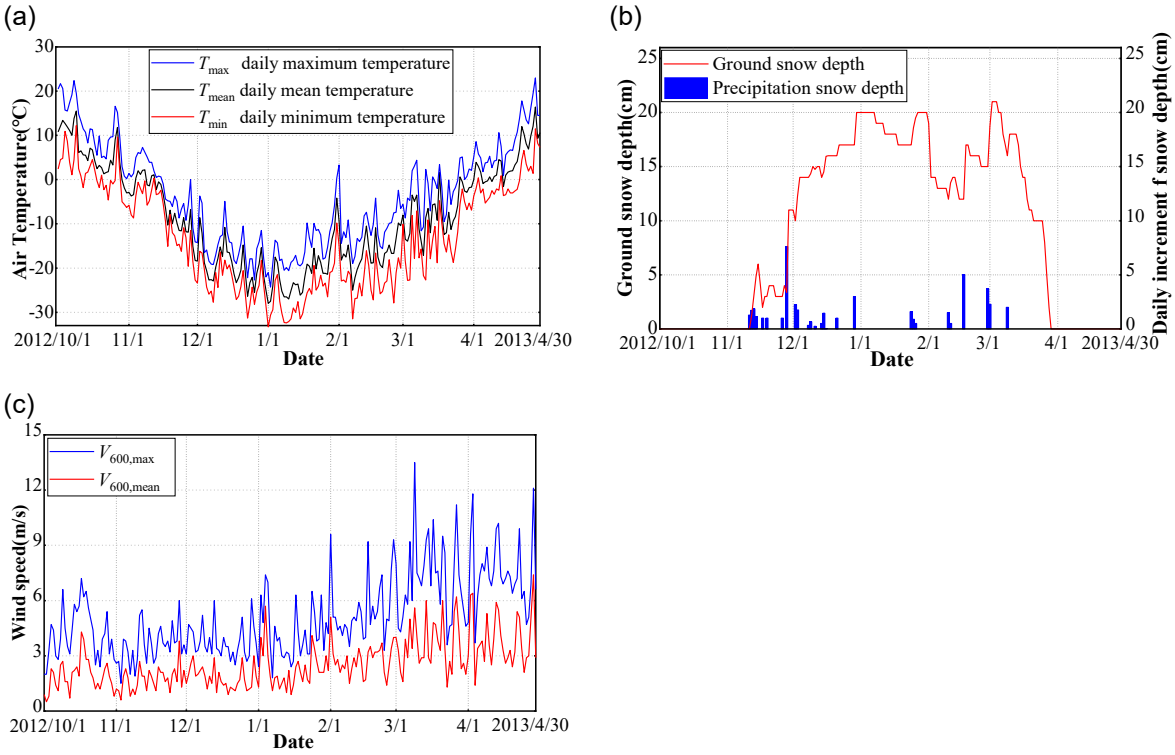

Figure 4. Daily meteorological records in Harbin for a typical winter season: (a) air temperature, (b) ground snow depth, (c) wind speed.

2.2.2. probabilistic modeling of wind speed

In this study, the two-parameter Weibull distribution (referred to as Wbl_2 hereafter) is used to model the frequency distribution of the daily wind speed, i.e., the frequency distribution of the 10-min average wind speed, V_{600}, within a whole day can be approximated by Wbl_2.

The probability density function (pdf), $f_w(x)$, and cumulative density function (CDF), $F_w(x)$, of Wbl_2 can be expressed by:

$$\begin{cases} f_W(x) = \dfrac{k}{\alpha}\left(\dfrac{x}{\alpha}\right)^{k-1}\exp\left[-\left(\dfrac{x}{\alpha}\right)^{k}\right] \\ F_W(x) = 1-\exp\left[-\left(\dfrac{x}{\alpha}\right)^{k}\right] \end{cases} \quad (x>0) \tag{3}$$

where x value of the random variable represents V_{600} in this study, α is the scale parameter; k is the shape parameter.

As mentioned above, the long-term historical wind speed dataset offers limited samples of $V_{600,}$ and only daily mean and maximum values of V_{600} are available daily. The commonly used parameter estimating methods, such as the method of moment (MOM), the method of maximum likelihood (MML), and the method of L-moments (MLM), cannot be applied. To fit Wbl_2 using $V_{600,max}$ and $V_{600,mean}$ offered in the daily wind speed dataset. We assume that: 1) the mean value of V_{600} represents the expectation of probability distribution of daily wind speed; 2) and the 144/145 percentile of the fitted distribution

equals $V_{600,\max}$. Based on those assumptions, a parameter estimation method, which combines the method of moment and method of cumulative probability, is proposed, and the parameters of Wbl_2 can be derived by:

$$\begin{cases} E(V_{600}) = k\Gamma[1+\dfrac{1}{\alpha}] = V_{600,\mathrm{mean}} \\ F_{\mathrm{W}}(V_{600,\max}) = 1-\exp[-(\dfrac{V_{600,\max}}{\alpha})^{k}] = \dfrac{144}{145} \end{cases} \tag{4}$$

where $\Gamma(\cdot)$ is the gamma function. An example of wind speed records during a whole day and its probabilistic modeling is shown in Figure 5.

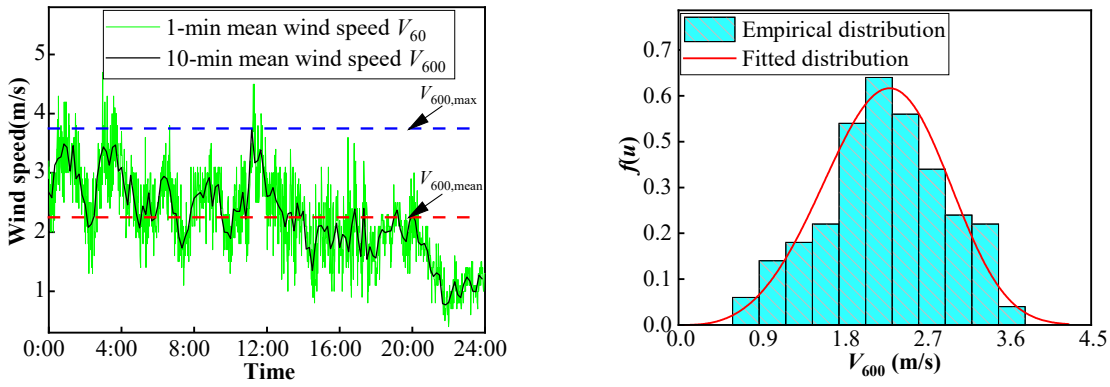

Figure 5. An example of wind speed records during a full day: (a) record and simple statistics of the wind speed, (b) frequency distribution of the wind speed and the fitted Wbl_2.

3. Results and discussion

3.1. Simulation results

Based on the long-term historical meteorological dataset and the proposed Wbl_2 of wind speed, the roof snow load for the studied case is simulated continuously. Figure 6 shows the time history of the roof and ground snow loads for typical winter seasons for category B. Due to the lower threshold friction velocity for snow particles during snowfall, snow particles are more likely to drift. Therefore, roof snow drift mainly occurs during snowfall, and the proportion of snow loads drifting off the roof after the snowfall is relatively small. Meanwhile, due to snow drift, precipitation snow cannot deposit on the roof, and the maximum ground snow load and the maximum roof snow load may appear on different dates.

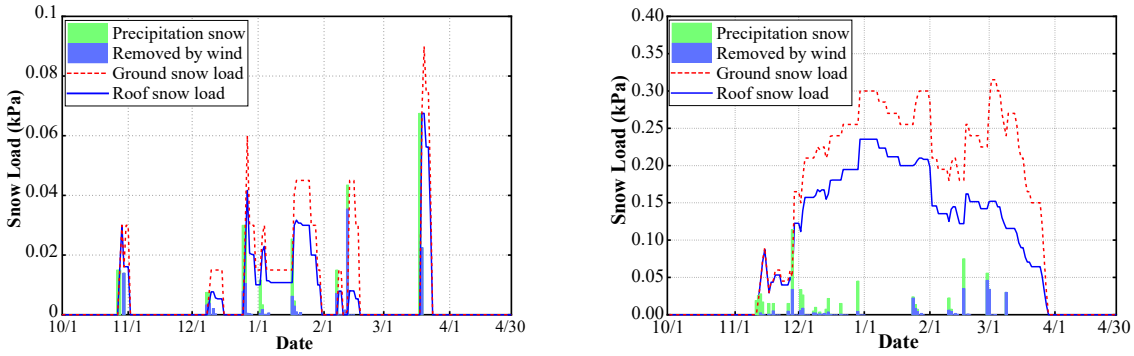

Figure 6. Ground and roof snow loads for typical winter seasons: (a) winter season of 1997-1998, (b) winter season of 2011-2012.

3.2. Ground-to-roof conversion factors

Simulations are also carried out considering other three terrain categories, i.e., categories A, C, and D. Based on the simulating result, the ground-to-roof conversion factors, C_s, defined as the ratio between the annual maximum roof snow load to the annual maximum ground snow load, are calculated for the studied roof, and the results are summarized in Table 2.

The result indicates that the conversion factor increases as the terrain category changes from A to D; since category A is typically associated with stronger winds, and category D usually leads to lower wind speeds. The opposite trend is observed for the deviation of the conversion factors, i.e., the deviation decreases with the terrain category changes from A to D. The different wind conditions in different terrain categories also cause this.

Table 2. Summary of ground-to-roof conversion factors C_s for the studied roof in Harbin, China

Terrain category	Mean	Standard deviation	COV
Category A	0.579	0.221	0.381
Category B	0.641	0.213	0.332
Category C	0.788	0.171	0.217
Category D	0.912	0.102	0.112
All Categories	0.730	0.223	0.306

We noted that some pioneering research had been conducted to investigate the conversion factors between the roof and ground snow load. For example, O'Rourke [7] analyzed the ground and roof snow load dataset across 199 United States buildings, suggesting conversion factors with a mean value of 0.67 and a standard deviation of 0.27. Furthermore, Thiis and O'Rourke [8] studied the snow load dataset measured in Norway and suggested a mean value of 0.73, with a standard deviation of 0.12, for the conversion factors.

The comparison of the conversion factors derived in the current study under all categories to that obtained by O'Rourke *et al*. [7] and Thiis and O'Rourke [8] is shown in Figure 7. The result indicates that the mean value of the conversion factors obtained in this study is close to those outlined in references[7,8], and the standard deviation is comparatively more significant. This standard deviation discrepancy is primarily attributable to the substantial differences in wind conditions across the four terrain categories.

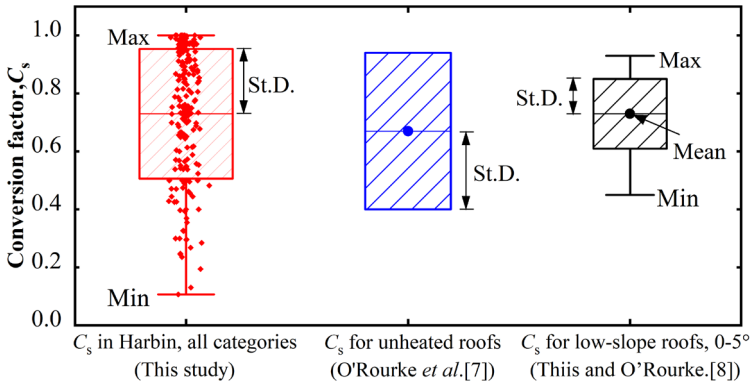

Figure 7. Comparison of C_s calculated in this study and some other studies.

4. Conclusion

In this study, an analytical simulation of snowdrift on a flat roof is carried out for a flat roof in Harbin, the long-term historical meteorological dataset for 47 winter seasons is used for the simulation, and daily wind speed records are modeled into higher time resolution by the proposed 2-parameter Weibull

distribution. Based on the simulation result, the ground-to-roof conversion factors, C_s, defined as the ratio between the annual maximum roof snow load to the annual maximum ground snow load, is calculated for the studied flat roof and the comparison of the conversion factors with that suggested by other studies illustrates the validation of the simulation.

Abstract

Qingdao International Airport is a regional airport hub and a portal to Japanese and Korean, with total area of 478,000 square meters. Its long span steel roof with side skylights brought challenges to structural engineers. We adopted the discontinuous curved lattice shell structure as the structure. By comparing multiple schemes, we found the discontinuous curved lattice shell ensured both structural stiffness and aesthetic effects by properly arranging V-shaped strut. This discontinuous curved lattice shell has now been used in many airports, including the brand new Chengdu Tianfu International Airport, the largest one in the 13th Five-Year Plan of China.

Keywords: discontinuous, lattice shell, skylight, Qingdao Airport, Chengdu Tianfu Airport

1. Introduction

The Qingdao Airport (Fig.1) is located 40 km northeast of Qingdao, on the west bank of the Da-gu River. This airport is positioned as a "regional airport hub and a portal to Japanese and Korean". The total architectural area of this airport is 478,000 square meters, and two runways have been constructed. Its annual passenger capacity is 35 million and cargo shipment capacity is 500,000 tons. Aircraft take-off and landing are 300,000 sorties. In the long run, its passenger capacity will reach 55 million.

Figure 1. Qingdao Airport

The plane size of the airport terminal is 948.3m×1090.2m. The terminal adopts a starfish layout and is divided into six independent structural units: the main hall (Zone F) and the five fingers (Zone A to E). The size of the main hall is 326m×388m (narrowest point) to 507m×415m (the widest point). Its steel

roof adopts an economically long span discontinuous curved lattice shell, with the lower part of the lattice shell supported on concrete filled tubular columns. The average column grid is 36m×62m in the main hall.

2. Architectural restrain

According to the requirements of natural lighting, ventilation, and architectural style, the architect required that a total of 9 skylight strips (Fig.2) should be placed on the long span steel roof. Due to aesthetic requirements, the skylight strip needed to be as transparent as possible and web members cannot be set (Fig.3). These skylight strips led to discontinuity of the roof shell and resulted significant reduction in strength and stiffness of the roof shell, which must be particularly strengthened.

3. Structural scheme

By comparing commonly used long span steel structures like unidirectional truss, bi-directional truss and spatial lattice shell, we selected spatial lattice shell as the roof structure. This structure has strong benefits in fitting complex curved surface, good structural integrity, high redundancy and ability to resist unexpected loads and to resist collapse. It is also with obvious advantages in fast construction and low cost.

However, where skylights strips are installed, the roof shell's continuity was broken. The discontinuity of the roof shell, as well as the removal of diagonal web members at skylight strips, has greatly weakened the performance of the roof lattice shell. So we had to adopt a new configuration for all skylight strips in order to strengthen the roof shell's load capacity. Further calculation and analysis indicated that it could meet the structural requirements. We call this lattice shell with new configuration at skylight strips the Discontinuous Curved Lattice Shell.

The key characteristic of this long span Discontinuous Curved Lattice Shell is the skylight strips of the shell are concise and transparent, and which can maximize the architectural effect. This configuration is to set a spatial truss at the skylight strip. The transverse section of the truss is a diamond shape and a steel connecting member is set on the diagonal of the diamond shape (Fig.4). The entire transverse section is a stable shape. The side surfaces of the skylight strip are covered by decorative planks, so diagonal rods can be arranged on two side surfaces to enhance the rigidity of the skylight strip. For the skylight strip's top and bottom surfaces, which directly facing passengers, diagonal web members must be removed, so the rigidity of the structure on the top and ground surfaces is greatly weakened. To ensure the rigidity of the top and bottom surfaces, we retain two diagonal web members at top and bottom surfaces on a certain spacing. These two retained web members form a V-shaped brace (Fig.5). When spacing of the V-shaped brace is proper, it can ensure the rigidity of the roof lattice shell, and hence achieves a transparent and concise architectural effect.

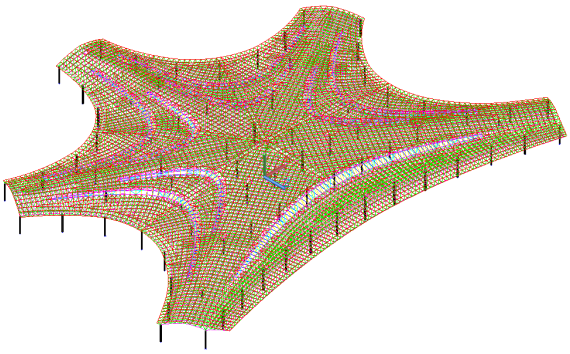

Figure 2. Analysis model

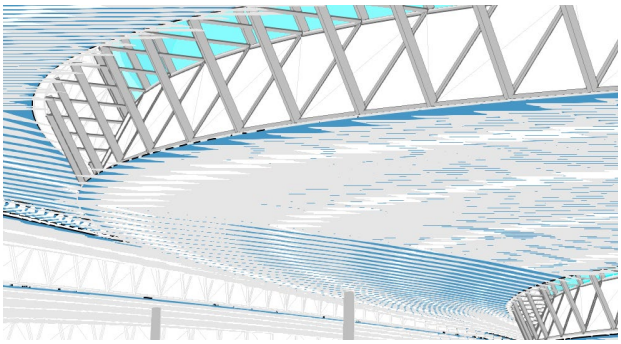

Figure 3. Skylight strip

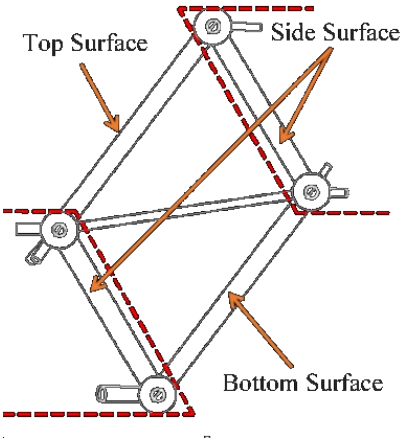

Figure 4. Section of skylight strip

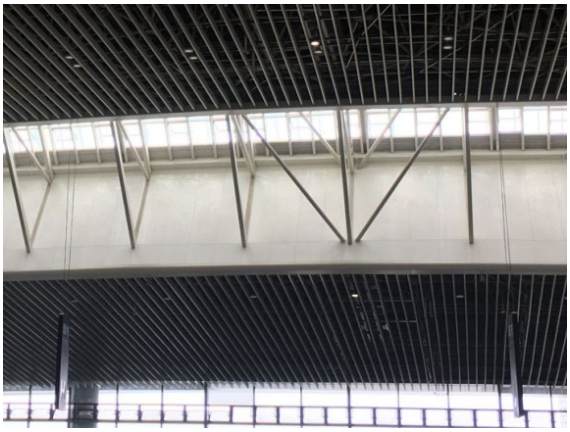

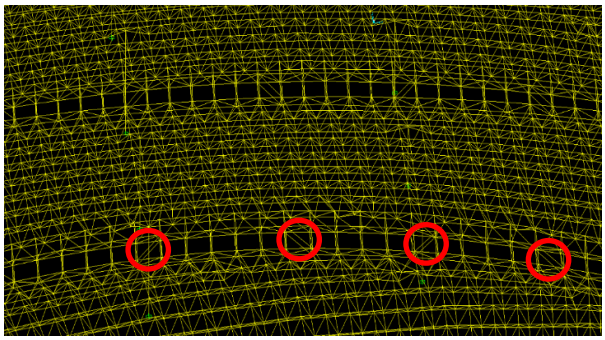

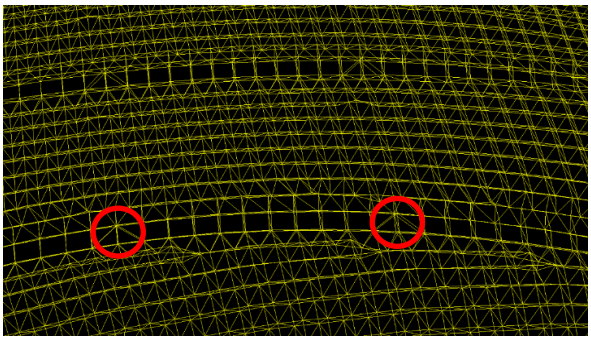

Figure 5. Skylight strip and V-shaped brace

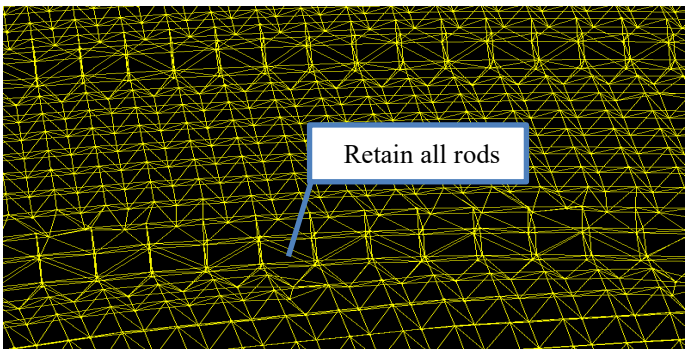
The most important thing for this discontinuous curved lattice shell is to determine the spacing and position of V-shaped braces. In order to compare the mechanics differences between discontinuous curved lattice shells and ordinary curved lattice shells, designers have established several analytical models for ordinary curved lattice shells and discontinuous curved shells. Three respective schemes are considered for the discontinuous curved lattice shell. Scheme 1set one diagonal rod every 36m and Scheme 2 set two diagonal rods every 72m. Scheme 3 retain all diagonal rods. (Fig.6)



The analysis model includes the lattice shell and its supporting columns. The shell members employ truss elements, but the skylight strip and its adjacent members use beam elements to reflect their bending moments. The support columns use beam elements and are connected with the lattice shell by hinges. A supplementary model using beam elements for all grid shell members has also been established, and the results are consistent with the model with beam elements used only at the skylight strip and adjacent members.

(a). Scheme 1 - one rods every 36m

(b). Scheme 2 - two rods every 72m

(c). Scheme 3 – retain all diagonal rods

Figure 6. Three schemes for skylight strips

Calculation result shows that the natural vibration period of the discontinuous curved lattice shells are all slightly longer than that of the ordinary lattice shell, but the difference is not significant (only 8.3%). The first three order natural vibration periods of the three schemes are listed in the table below (Table 1). The natural vibration period of the scheme 1 and scheme 2 is almost the same. Comparing with these two schemes, scheme 3's natural vibration period slightly shorter, which means its stiffness is slightly higher. The stiffness of these three schemes is not significantly different from ordinary lattice shells.

Table 1. Natural period for discontinuous shell and ordinary shell

period（s）	Scheme1	Scheme2	Scheme3	Ordinary
Mode 1	2.690	2.690	2.673	2.467
Mode 2	2.462	2.458	2.435	2.453
Mode 3	2.107	2.095	2.088	2.345

Under 1.3D+1.5L load case, the stiffness of discontinuous curved lattice shell increases and the deflection decreases compared to ordinary grid structures in the skylight strip area. The reason is that the spatial truss is formed due to the height difference of the skylight strip, and hence increases thickness of the lattice shell at the skylight strip and improves the vertical stiffness of the shell here. In the skylight strip area, the deflection of discontinuous curved shell is 43.7% lower than the ordinary lattice shell. In the other area (no skylight strip area), the deflection of the discontinuous curved shell is the same as that of the ordinary shell. The deflection of scheme 1 is the same as that of scheme 2. And scheme 3's deflection is 10% lower than scheme 1 and scheme 2.

The comparison of the main mechanics and economic indicators between discontinuous curved lattice shells and ordinary lattice shells is listed in Table 2. The steel usage for a discontinuous curved lattice shell increases by 12% comparing to an ordinary lattice shell and its structural stiffness is equivalent to that of an ordinary lattice shell.

Table 2. Comparing for discontinuous shell and ordinary shell

index	Scheme1	Scheme2	Scheme3	Ordinary
Steel usage	6813	6827	6951	6001
Stress ratio	0.8	0.8	0.8	0.8
Period	2.690	2.690	2.673	2.467

From the above comparing, we see there is no significant difference for in-plane stiffness between discontinuous curved lattice shells and ordinary lattice shells (only 8.3%). Under vertical load, the discontinuous curved lattice shell's deflection in common areas (no skylight strip) is close to that of ordinary shell and deflection of the discontinuous curved lattice shell at skylight strip is smaller. The steel usage of the discontinuous curved lattice shell is about 12% higher than that of the ordinary lattice shell, but it can satisfy aesthetic requirement from architects. Three schemes of discontinuous curved lattice shells are compared, Scheme 3 shows the best mechanics performance. Scheme 1 and Scheme2 have almost the same mechanics performance and are slightly worse than the Scheme 3. For the Qingdao airport's long span steel roof, the discontinuous curved lattice shell is a reasonable structural solution. Through properly arranging V-shaped braces, we can ensure the mechanics capacity of a discontinuous curved lattice shell is similar to that of an ordinary lattice shell. And although its steel usage has slightly increased, a discontinuous curved lattice shell's overall architectural effect is better.

(a). Overall view (b). Inner view and skylight strip

Figure 7. Qingdao Airport after completion

Using discontinuous curved lattice shells have solved the key problem of the long span steel roof of Qingdao Airport and achieve good architectural effects on skylight strips. The airport was designed in 2017 and put in use in 2021. (Fig.7)

Discontinuous Curved Lattice Shell has a more transparent and aesthetically skylight strip than traditional grid shells. Compared with trusses, Discontinuous Curved Lattice Shell is more adaptable for complex curved surfaces. So it has better applicability and architectural performance when using for long-span buildings like airports, bus stations, exhibition hall and etc.

4. Other application

The discontinuous curved lattice shell provides a transparent and concise aesthetic effect at skylight strips by evacuating some diagonal rods, and meanwhile maintains the steel shell's in-plane and out-of-plane stiffness. It is particularly suitable for long span buildings like airports, railway stations and traffic hubs constructed in recent years. Therefore after being applied in Qingdao Airport, this structural form has been used in multiple projects as Chongqing Jiangbei International Airport and Chengdu Tianfu International Airport. All of these projects have achieved promising effects.

Figure 8. Chengdu Tianfu airport

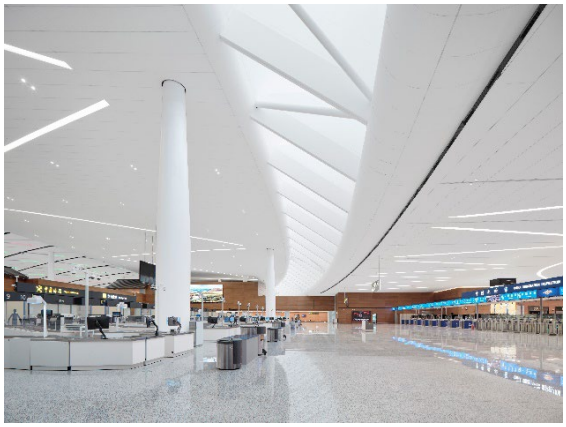


Figure 9. Skylight strip

Figure 10. Column free space and skylight strips

The newest Chengdu Tianfu International Airport (Fig.8~10) is located in city Chengdu of southwest China. It is the largest airport built during the 13th Five-Year Plan of China. Its terminal has a total area of 710,000 m^2 and opens up in April 2021. The biggest challenge for this airport is a 74 m×500m column-free space at the main hall and a large skylight strip with height difference of 7m is adopted there. The discontinuous curved lattice shell is used as the roof structure system and successfully forms the column-free space and also the skylight strip, which achieves decent architectural effects and aesthetic beauty.

Abstract

The paper introduces two prefabrication projects: New Lawuga School (2015) and Meili Transitional School (2018). These two projects have different scales and contexts: New Lawuga School is a charity school of 200 m^2 built in a plateau village; Meili Transitional School is a public transitional school of 5275 m^2 built in a high-density urban condition. The authors participated in the projects in person and applied Building Information Modelling (BIM) technology from design to construction. Details of BIM application in these two prefabrication projects, particularly those related to fabrication, are explained and reviewed to provide a springboard to explore the BIM potential in practice.

Keywords: building information modelling, prefabrication, modern construction, fabrication, case studies, architectural practice, supply chain

1. Introduction

Building Information Modelling (BIM) has been widely used in different regions of the world today. While the advantage of BIM adoption in promoting construction efficiency is widely recognised by the industry, there are also critiques of the approach. These criticisms are not only about the tool's functionality such as unintuitive user interfaces, but rather political in nature.

In the book "Atlas of Digital Architecture", the authors indicate an apparent condition that clients of big projects particularly like BIM as it "keep a handle on budgets, and nudges architects and engineers to work together towards optimising their use of materials [1]". This brings the BIM's strongest criticism of its "giving commercial interests, project management, and the bureaucracy of very large and therefore mighty clients the upper hand over architects as space creators [1]". Besides, BIM also entices "planners to use pre-defined construction elements [1]" and "liable to produce 'Lego architecture [1]'".

Yet, the authors rectify the criticisms by explaining that BIM is an approach with a mindset that changes the way of doing things, hence it is one of the cultural changes which tends to meet with resistance. They defend the technology by mentioning Zaha Hadid and AEC *Architectes* Rotzer & Kaempfer (from the French-speaking part of Switzerland) whose built creative and original projects with the help of the tool. They take the perspective that BIM after all is a technology in progress, and architects should determine the approach that takes to it.

This paper supplements the perspective by introducing two innovation projects: New Lawuga School, a charity school of 200 m^2 built in a plateau village in 2015, and Meili Transitional School, a transitional school of 5275 m^2 built in a high-density urban condition in 2018. Both schools are designed and built by a research team from the School of Architecture, The Chinese University of Hong Kong (CUHK) (Architecture Integrity and Innovation Association (AIIA) is the research team led by Prof Zhu Jingxiang in CUHK which has focused on lightweight prefabrication since 2008. UNITINNO is AIIA's

execution partner.) This paper's authors are the core architects who participated in both projects and applied BIM in the design and fabrication stages. This paper explains the details of BIM application in different stages to offer first-hand in-person experience illustrating how BIM technology could contribute to small-to-medium scaled innovative prefabrication projects.

2. New Lawuga school

2.1. Project introduction

In the 2010 earthquake in Yushu, Qinghai China, the one-storey brick-made buildings in the Lawuga School in a remote village in the Plateau area with an altitude of 3900m were damaged. Since then the school had used sandwich panel container houses as classrooms. In 2015, a philanthropist committed AIIA to design and build a charity schoolhouse to provide a better education environment for the local minority nomadic families.

The New Lawuga School is a 2-storey building with a floor area of 200 m2. It includes 4 classrooms, 1 stair hall and 1 storage, and serves around 160 students. It is constructed with a system of structural insulated panels (SIPs). The sectional profiles are I, C and Z. There are in total 81 panels in the main building structure system. These panels have widths of ~1.2m and lengths varied from 3m to 8m. Among the 81 panels, only two panels are identical. The differences among the other panels come from the geometry, opening, finish and connection detail. Besides the panels, the building includes other components such as lighting, windows and doors, and trombe wall units.

The New Lawuga School won the First Prize in the Local Academia Group of 3015 Construction Industry Council Innovation Award from Hong Kong, and the FuturArc Green Leadership Award (Institutional Group) in 2016.

Figure 1. New Lawuga School

2.2. BIM application in Lawuga

BIM was implemented in the New Lawuga School when the schematic design was finished. Because of the complicated geometries of the components, the project team recognised that BIM would be an appropriate tool to examine the components' detailed design. For example, the distribution of solid wood

trims in the SIPs should be guaranteed so that screws could be cut in; the finish materials of the SIPs should be designed to fit in other panels.

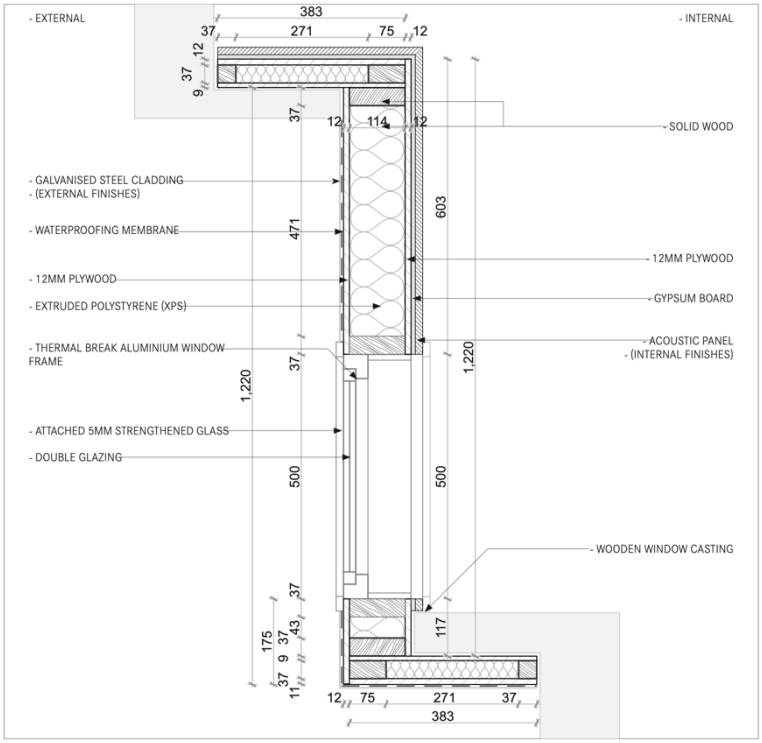

Figure 2. Details of SIPs

Then the BIM model was used to generate the two types of drawings. The first type was schematic drawings, which include plans, sections, and elevations. The second type was fabrication drawings, which were delivered to suppliers or manufacturers. In total there were around 260 drawings (regardless of revisions),which include:

- Composition drawings of SIPs for fabrication;
- Finishing drawings of SIPs for fabrication and installation;
- Geometrical drawings of steel cladding and steel connector for fabrication;
- Location drawings of metal claddings for installation;
- Schedules of windows and doors for purchasing metal frames;
- Composition drawings of wooden doors for fabrication;
- Composition drawings of wooden components (openings casting, staircase, etc) for fabrication;
- Geometrical drawings of PVC sheets (for trombe wall) for fabrication;
- Composition drawings of trombe wall units for fabrication;
- Schedules of solid wood trims for material cutting.

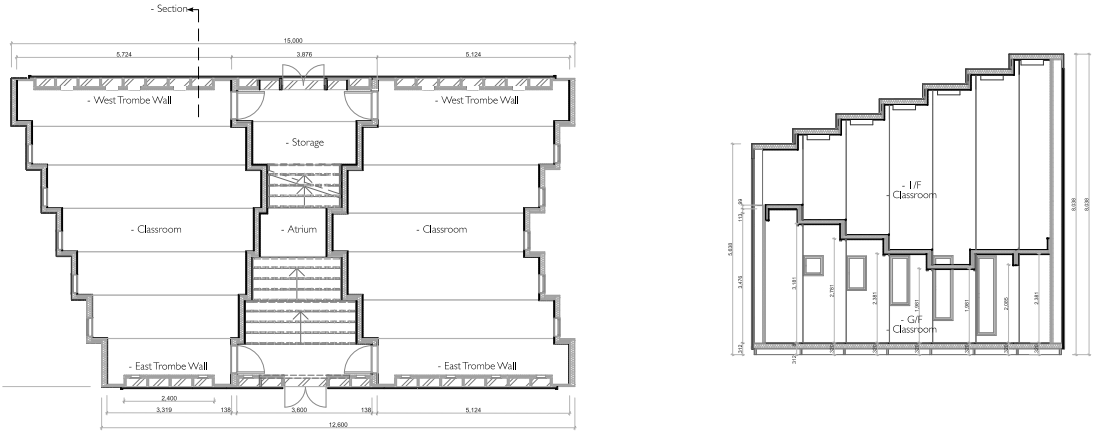

Figure 3. Schematic drawings: G/F plan & section

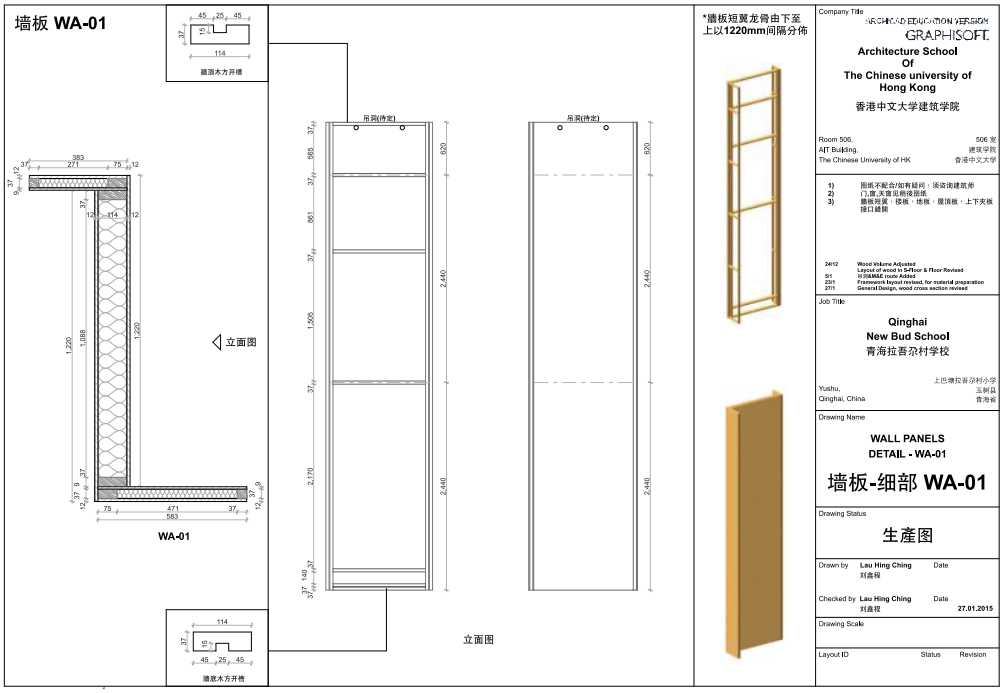

Figure 4. Fabrication drawings: Wall panel

The fabrication took place in Chengdu, a city 750km away from Yushu. There were two wood manufacturers involved: the big one with standard factories responsible for the SIPs production, and the small one which is a workshop responsible for the small wooden components (trombe wall units, staircase, doors, furniture). Another small manufacturer produced steel components and glass panels (for windows). The rest components such as window and door frames and electrical devices were purchased from the local building material market. Everything was delivered to Yushu by trunks, except the PVC Sheets which were sponsored by a Shanghai Company and delivered to the construction site from their warehouse.

Figure 5. Factory in Chengdu

3. Meili transitional school

3.1. Projects introduction

In 2018, the original Meili school located in Futian Shenzhen, China was planned to be deconstructed and rebuilt. The Planning Bureau invited the project team to design and build a transitional school on a nearby open space in an urban context to house the students during the construction period of the original school. The transitional school should be built fast, capable to be deconstructed and reassembled in other locations after use.

The Meili Transitional School commenced site work in mid of July 2018. The superstructure construction started on 29 July 2018. The school was ready to be used by 30 Nov 2018, but users only moved in on 25 Dec 2018. The two-storey school took 4.5 months to be built. It provides 32 standard classrooms (9.6m x 6.6m), and other supplementary facilities such as functional classrooms, offices and toilets, serving 1320 students.

The Meili Transitional School used a "Light Steel Post-and-Lintel System", which is a modular system characterised by the use of light steel members with small cross sections (80x80mm & 80x160mm) standardised bolt-and-nut joints. The system was later applied to build 4 more transitional schools in Shenzhen from 2019 to 2020, providing a total building floor area of 21610 $m^{2.}$

The Meili Transitional won the First Prize in the Science and Technology Award of the 2019 Guangdong Excellent Engineering Survey and Design Award, and the Highly-Commended Prize in Social Equality Award of the 2020 WA Awards for Chinese Architecture (WAACA). The other two transitional schools built in Longhua Shenzhen using the same system are shortlisted for the Technological Innovation Award and City Regeneration Award of 2020 WAACA.

Figure 6. Meili Transitional School

3.2. BIM application in Meili

BIM software had been applied in the project since the early design stage. It was used to build a "Scheme Model" which generated the overall basic drawings and 3D renderings for communication among different parties: bureaus, users and consultants. Schedules calculating the floor area and different materials were also produced from this model.

While the proposal was developing, another BIM model based on one standard classroom from the "Scheme Model" was built to study the detail of every component and the relationships between them. This "Unit Model" is composed of many independent "Component Models" which were used to generate the fabrication drawing. In the later stage, "Unit Models" of other facilities such as staircases, bridges, guard house, and water tower were also built.

In short, the "Scheme Model" was used for design and administration, while the "Unit Models" were used for fabrication. The two types of models were maintained by two different teams. Whenever there was a need for collaboration, the two teams abstracted the necessary parts of their models and exported them as "Intermediate Models" for the other team. Such practice could ensure efficient communication but not interfere with the working rhythm of two teams.

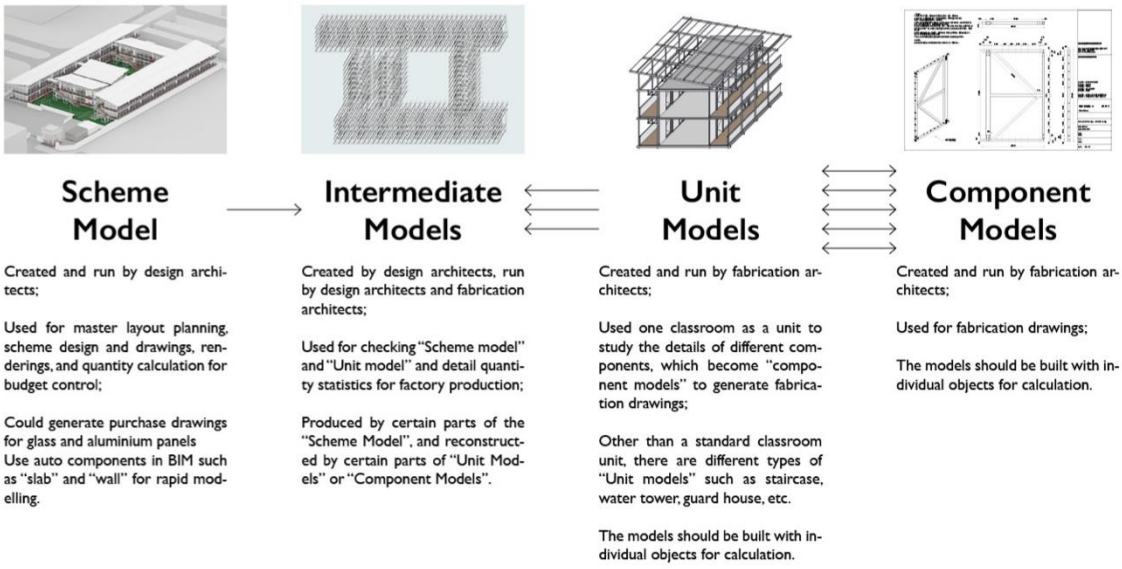

Figure 7. Bim models organisation

The main manufacturing factory was located in Henan Province, which could process both wood and steel components. It is worth mentioning that the factory used laser-cutting technology for machining the steel components. Even though direct output from BIM models to the laser cutting machines is theoretically practicable, the project team could not achieve this in this project, due to the incompatibility between the software formats.

Figure 8. Factory in Henan

4. Findings

These two projects, even though led by an academic team, are well grounded on local supply chains and embody generic value. Reviewing the projects could provide insights into academia and contribute to the practice industry.

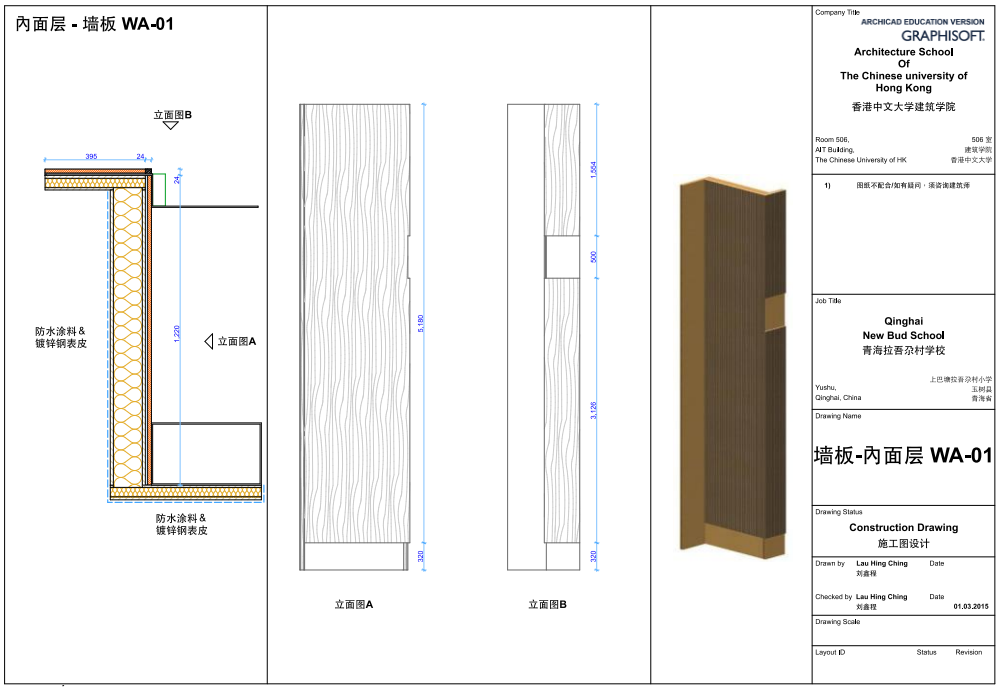
Both schools use standardised industrialised products in the market and ordinary production technologies in common factories to develop innovative building systems fitting the specific project contexts. However, the SIPs in Lawuga School are differentiated panels with the same composition, while Meili Transitional School used a standard modular system for all the functions.

4.1. BIM merits

In the design stages, adopting BIM technology allowed the architects to generate comprehensive outputs under limited human resources and time. In the Meili Transitional School, the project schedule was very tight: it was established in February 2018 and the site work commenced in July 2018. Even though this project has a special nature that the project team was "invited" to solve a social problem and there was relatively less interference in the design compared to typical school projects, the comprehensive output still promoted effective communication among bureaus and users, which was critical to the project's success.

In the fabrication stages, there are several benefits of adopting the technology.

Firstly since 3D diagrams could be easily generated from the BIM model, they were used as a powerful communication tool to illustrate the design concepts with the local suppliers and factories during the quotation and fabrication stages. This was particularly critical as both the projects (Meil is a public project, Lawuga is a charity project) had strict budget control and could only involve ordinary suppliers, who basically manufactured according to the drawings.



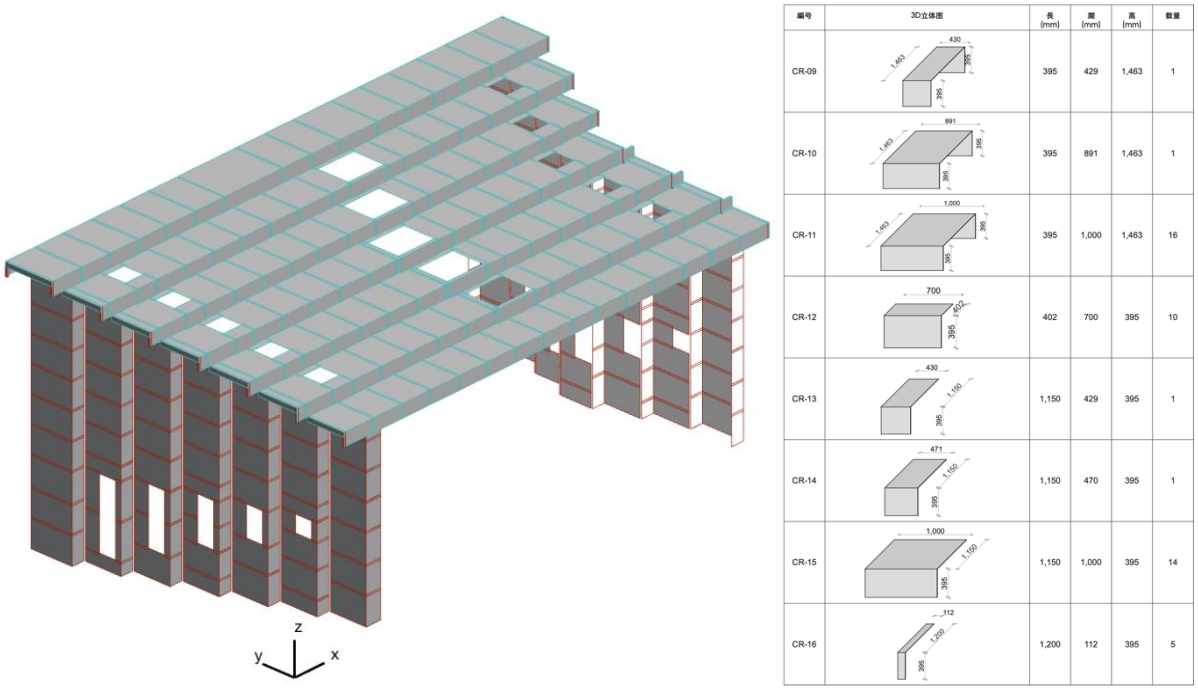


Figure 9. Wall panel finish drawing (Lawuga School)

Secondly, since the drawings were the direct output of the 3D model, the chance of errors in drawings was greatly reduced. For example, In Lawuga School, the most critical and complicated are the SIPs, which their composition and finishing drawings were found correct during the assembly stage.

Thirdly, the auto-generated schedules facilitated the fabrication process. In Lawuga School, schedules of solid wood trims inside the SIPs and metal claddings were generated from the BIM model, which listed out the requirements of form, dimension and quality. Workers could start preparing the materials once they received the schedules. These schedules also assisted the project team to calculate the budget cost and building weight.

編号	3D立体图	长 (mm)	闊 (mm)	高 (mm)	数量
CR-09		395	429	1,463	1
CR-10		395	891	1,463	1
CR-11		395	1,000	1,463	16
CR-12		402	700	395	10
CR-13		1,150	429	395	1
CR-14		1,150	470	395	1
CR-15		1,150	1,000	395	14
CR-16		1,200	112	395	5

Figure 10. Metal cladding model and auto-generated schedule (Lawuga School)

Fourthly, the BIM tool allowed all the fabrication drawings to be auto-updated when the model changed.

4.2. Discrepancies

Yet there are also lessons to learn. The followings are some observations about applying the BIM in the fabrication stage, specifically connecting to ordinary factories and workshops in the two mentioned projects, which may be regarded as reminds to improve the approach.

Although BIM software streamlines drawing production, it still requires tremendous effort to produce fabrication drawings, since each component is needed to be isolated and generated its own set of drawings. This process of isolation and drawing generation could be more intuitive. The best application of this aspect in the two cases is the steel cladding of the Lawuga School, in which the schedule generated from the BIM model was directly used for manufacture.

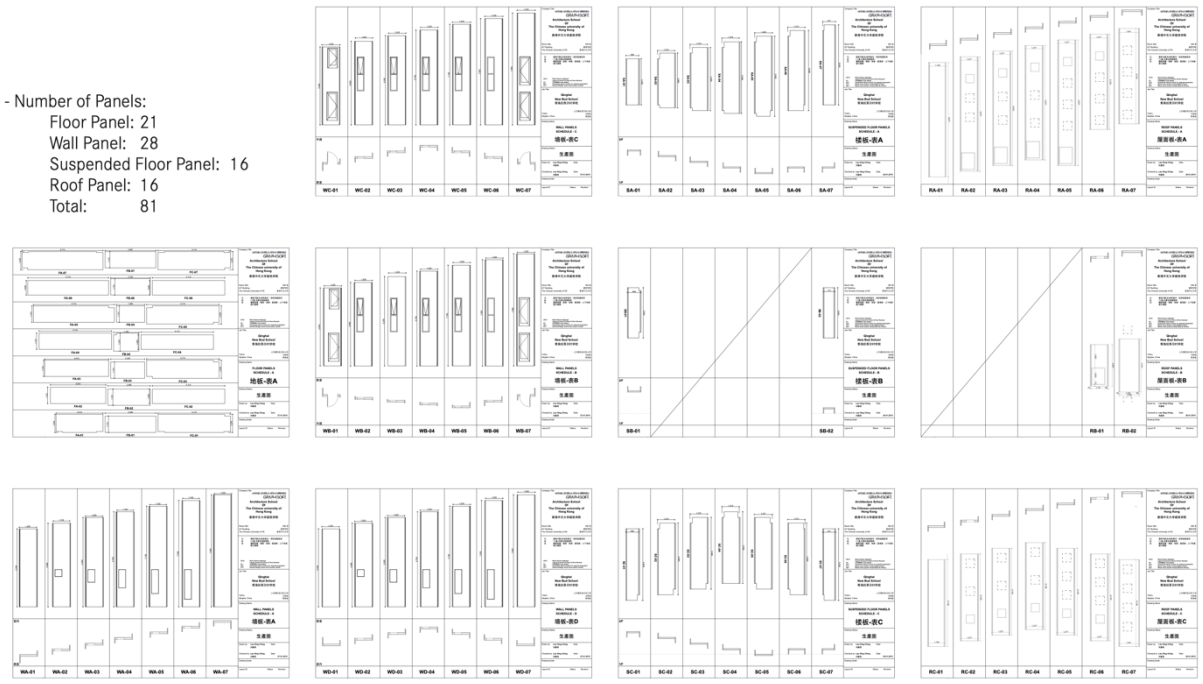

Figure 11. Lawuga School Schedule of all panels

The auto-generated schedule in the BIM calculates the components' quantity, which helps determine the material cost. However, the true materials used also include waste materials, which depend on the relationship between the raw materials and the designed components. Hence the project team should make studies of the raw materials and design accordingly to understand and control the discrepancy.

Another deviation comes from the tolerance and error from construction. The digital world is perfect and precise, but the real world is not. The fabrication drawings transfer the idealistic design into physical reality and hence should consider tolerance. For example in the New Lawuga School, 5mm space was reserved between the SIPs for error control (which was later proved insufficient). However, incorporating these imperfections in the BIM model makes it complicated. The Meili School had different models for design and fabrication. Measures against tolerance only appear in the fabrication model, hence keep the design model simple.

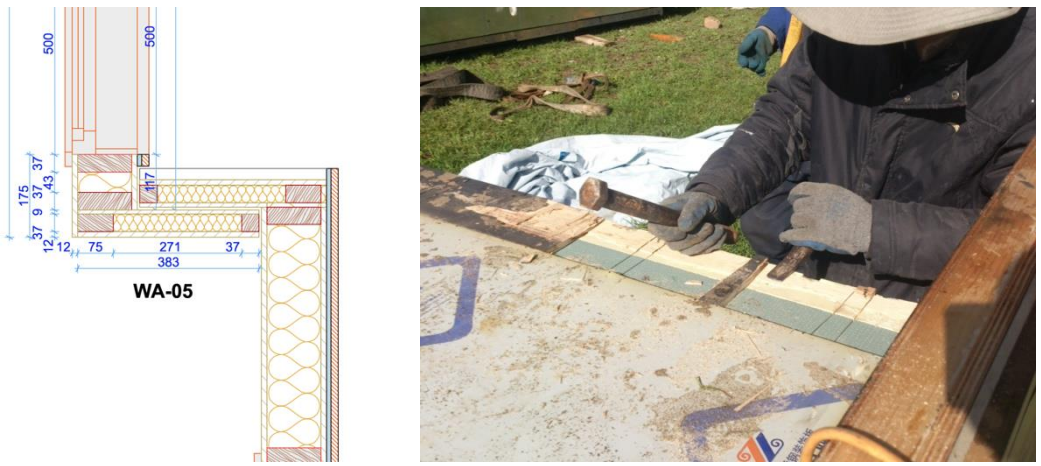

Figure 12. Tolerance in BIM model and reality

5. Conclusion

This paper explains the practices in two school projects to illustrate how BIM may contribute to small-to-medium scale innovative projects. They are first-hand experiences, as the authors participated actively in the projects throughout the design and build period.

The projects use standardised industrialised products in the market and ordinary production technologies in common factories to develop innovative building systems for specific project contexts. These design ideas persist as the BIM tool allows the project teams to control the fabrication effectively, thanks to its power to produce great visibility of design and consistent sets of information, and its streamlined outputting process.

This paper also discusses the demerits when applying BIM in the fabrication stage. These discrepancies between digital applications and reality provide an opportunity to improve the practice.

The emergence of BIM challenges the specialisation of the role of practitioners in the industry including the architects since the tool provides a platform to involve in different stages of the project. We have heard a metaphor from an architect that BIM is a “roadster” and practitioners need to be equipped to master the tool. This paper provides basics to extend the tools’ application in the connection with industrial supply chain and manufacturing technology, which is influential under the modernisation of the building industry in which integration of design, fabrication and assembly is taking place.

Built environment prototyping for design-value

Darcy ZELENKO[a,*], Duncan MAXWELL[a]

[a,*] Future Building Initiative, Monash University
darcy.zelenko@monash.edu

Abstract

The built environment is hindered by issues relating to laggard productivity, with practitioners looking to pursue sector-wide industrialisation and digitisation to improve this issue. Contrastingly, industries that have achieved widespread industrialisation and digitisation also possess developed prototyping cultures. Within these industries, prototyping approaches are tailored to suit the nature of the specific output product. Prototyping in the built environment acts as a tool for representation, testing, and communication. Prototyping approaches vary across the constituent disciplines with a lack of influential approaches or methods of the kind illustrated in other industries. This paper uses critical analysis to review prototyping literature from influential approaches found in engineering design, software development, and design management. These are compared to approaches used in the built environment disciples of architecture, engineering, and construction research. The findings confirm that prototyping is a value-adding activity, but suggest that prototyping cultures and outcomes in the built environment are inhibited by fragmentation that is inherent in the discipline. Future research could surround the development of prototyping approaches that enable practitioners to get the most out of the process. Such a protoyping approach would that also recognises that the creation of buildings requires both idea conceptualisation, and physical implementation to deliver quality outcomes.

Keywords: prototyping, design-value, built environment, architecture, engineering, construction

1. Introduction

The built environment is a production-based sector that creates high-cost goods that are produced in a one-off manner, at sites that change, and by teams that are temporary in nature [1]. The result is a fragmented project delivery process often leading to cost and time overruns that combine to negatively affect productivity in the sector [2]. There are efforts in the built environment to explore industrialisation and digitalisation to overcome these challenges. Within this context, prototyping is being specifically explored as a tool to mitigate these overruns, but is not commonly utilised in the built environment for purposes beyond representation, compared to other production-based sectors [3], [4].

Prototyping is defined broadly as "a first full-scale and usually functional form of a new type or design of a construction (such as an airplane)" [5]. The approach exists as a tool to explore product development and is used across a range of sectors with each developing specific definitions that are influenced by the needs of the field in which the approach is used. Sectors in which prototyping is common are: engineering design, software development, and design management, and some of these definitions will be explored by this paper as a means of developing a more critical and clear definition of prototyping for the varied requirements of the building industry [4], [6]. In their influential paper, 'What Do Prototypes Prototype?', Houde & Hill suggest that the main importance of prototypes lies in how the designer utilises them as part of an exploratory design process, or for demonstration purposes [7]. However, as noted, prototyping for the built environment (beyond representation) is a relatively uncommon endeavour, and a range of approaches and definitions exist that inhibit collaboration, knowledge sharing, and problem solving. This paper seeks to establish the value of prototyping in the

context of design for the built environment and by means of a critical review of literature to speculate on new prototyping definitions that will assist the building industry to build better buildings.

The critical review of this paper will develop an understanding of the variety of prototyping methods and terminology currently used by different practitioners in the built environment, and compare them to influential approaches developed in engineering design, software development, and design management. It is suggested that there is a link between the uncommon practice of prototyping in the built environment , and a lack of understanding about the benefits prototyping can provide. This is due to a lack of a built environment context-appropriate framework, to map prototyping purposes and classes, in ways similar to that found in disciplines where prototyping is a common practice. The critical review of literature undertaken from built environment disciplines helps to understand the different ways prototyping gets used. This is complimented by a review of prototyping literature from a three disciplines to understand more formalised approaches. This will be synthesised to propose a model for prototyping in the built environment that reflects the complex nature of building.

There are a number of unique factors that inhibit a greater uptake of prototyping in the built environment. The scale of construction often necessitates the production of large prototypes. Artefacts of such size require large amounts of materials, take time to produce, may require logistics to move, and storage space once completed. Built environment prototypes can be complex in nature, possessing a detailed scope, requiring input from multiple trades to complete, which can potentially be a costly endeavour. Even at a reduced scale, prototypes can also be costly to make[8]. Buildings are a high-cost product to create due to the sheer amount of materials and labour required. As construction tends to favour cost-minimisation over achieving best value, prototyping can be viewed as too costly [9]. Most conventional construction projects are one-off in nature which minimises the impact that prototyping can have, when compared to other industries that use mass production to create goods.
There is a sector-wide perception that the benefits to be gained from prototyping are low, especially on projects where perceived design complexity is low. When compared to the above-mentioned costs associated with built environment prototyping, the perceived cost-benefit ratio is skewed. As the built environment is fragmented in nature, the separation of the design and construction teams hampers the process of evaluation and subsequent learning associated with the prototyping. Prototyping in construction is observed to occur on projects possessing design complexity. It could be suggested that the construction sector doesn't consider prototyping on projects featuring conventional products and processes, as there is a view that there is nothing gleaned from the activity. The factors discussed above see prototyping carried-out in small amounts on construction projects. This hampers the development of prototyping cultures that would see built environment-specific methods could become more formalised.

2. Prototyping theory and uses outside built environment

While uncommon in the built environment, other fields such as engineering design, software development, and design management heavily rely on the use of prototypes as a part of their design process. Each discipline has developed frameworks and terminology that form a theoretical base to describe its use of prototyping. What has resulted is the the creation of varying definitions of the term prototyping that differ from the generalised definition stated above. This reflects in that they all highlight the act as a method employed as part of the design process.

2.1. Design engineering

An interpretation of prototyping from the perspective of technically-oriented industries like engineering or industrial design, is for it to be linked to predetermined design stages. This perspective sees prototyping defined as the process of creating a physical or digital embodiment of critical elements of an intended design, that is used as a tool to communicate and learn, and aid decision-making [10]. This approach recognises the ability of prototyping to act both as a learning tool, but also as a vessel through which to communicate a design to internal stakeholders. Prominent mechanical engineering academic

David G. Ullman describes four different classes of prototype being created that roughly correlate to different stages of the design process the field [11].

Table 1 - Ullman's classes of Prototyping

Prototype Function	Description
Proof-of-Concept	Undertaken in initial project stages to help direct design approach
Proof-of-Product	Used to refine components and subassemblies of a product
Proof-of-Process	Involves the production of samples that verifies both the geometry and manufacturing process
Proof-of-Production	Validates the entire production process where the prototype is the result of a pre-production run

The field of engineering design concerns the technical design of physical systems and machines, and heavily uses prototyping as part of the design process. The use of prototyping in mechanical engineering concentrates on the development of solutions to technical problems, as is reflected by the nature of the field itself, with less emphasis being placed on the overall use or form of the product.

Horton and Radcliffe detail the creation of a number of rapid proof-of-concept prototypes to create a pineapple de-topper that consisted of the designers experimenting with ways to remove the tops themselves [12]. Elverum et al. describe the use of rapid prototypes created with 3D printing that are created to assess size and appearance of parts early in the design process, that can be considered proof-of-product prototypes [13]. Liou describes the first complete Boeing 777 created that can be classified as a proof-of-production prototype as it required the entire manufacturing process to be defined to enable its creation [14]. These examples of prototyping are physical in nature, and possess varying levels of fiddelity, and workmanship.

2.2. Software development

Software development is a branch of computer science that concerns the design, programming, deployment, and maintenance of software. The nature of the products created in this industry differs from design engineering in that the scope of work leans more towards being more digital, so products tend to be virtual, with less of a physical presence. This has impacted the development of influential prototyping processes in the industry, in that they focus more around the development of the underlying concept that drives the product.

An evolutionary approach to software development is often employed, which sees a product built, then it is continually improved through feedback obtained from customers [15]. The need for such an approach reflects the fact that within software development, it is difficult to test a system that isn't fully complete, and that user needs change as projects evolve [16]. Within this context, prototyping is viewed as the production of early working versions of a future software application that are used for testing purposes [17]. Houde and Hill propose a model that helps designers ask what their prototypes 'prototype' and includes the classes; Role, Implementation, and Look and Feel [7]. They see their model helping to separate design problems into three classes of questions, that often require different kinds of prototypes to answer.

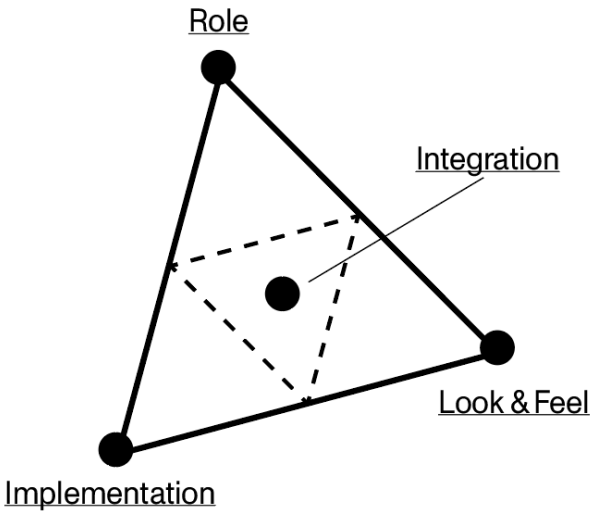

Figure 1. Houde and Hill's model of prototyping [7].

In this model, "Role" refers to questions surrounding what function a product (known as artefact) brings to the life of the user. "Look and feel" concerns questions about the physical sensory experience a user has when using a product. "Implementation" refers to the specific technology or programming that enables a product to perform its Role. "Integration" prototypes bring together the three classes to communicate an approxiamtion of the final product, and used to understand the design as a whole.

Bischofberger and Pomberger outline TOPOS, a software development environment that enables designers to prototype software in a controlled setting, separate from the real-life version [18]. Beaudouin-Lafon & Mackay define 'Paper and Pencil' prototypes as a way for developers to quickly answer questions relating to Look and Feel [19]. Camere et al. describe the prototype for an interactive mirror kit that was used to simulate the way a user interacted with the product, or "Role" according to Houde and Hill [20]. Their prototype consisted of a laptop and webcam that was used to run a specially-designed mirror software that tracked users facial expressions. These examples of prototypes from software development are a mix of physical and virtual, and tend to be low fidelity and possess low levels of workmanship. They also tend to be more nuanced and tailored to target specific aspects of the software design process, as defined by Houde and Hill.

2.3. Design management

Design Management is a broad field that concerns the organisational processes that are used to support the creation of new products and services [21]. Tom Kelley, a renowned design manager, defines prototyping broadly as a way to solve problems, further adding that anything can be prototyped [22]. Acklin describes the creation of a prototype model to guide and track the absorption of design knowledge in small and medium-sized enterprises [23]. This prototype is conceptual in nature, but was used to test and refine the underlying idea. Droz outlines the use of 'early-stage modeling' — a form of low fidelity and workmanship prototyping — by companies as a means of defining and strategising a new product [6]. He uses an example from Sony where small blocks of wood were used to envisage the design goals behind the creation of a Walkman; size and simplicity. The prototyping used by people working in design management is used to drive the conception of ideas, or ways of working in design, and does not necessarily have to be physical in nature. As these two examples are conceptual in nature, they can't be considered possess fidelity or workmanship.

2.4. Implications for built environment prototyping

The approaches to prototyping listed above can be thought of as defining a spectrum between idea conceptualisation, and physical implementation. As software development involves the creation of highly complex digital systems with limited physical engineering required, the approaches to prototyping have coalesced around the use of simple ways to tease-out ideas, and the creation of prototype virtual environments in which to test versions of software. Design engineering is a highly technical industry that concerns the creation of complex physical devices, and has seen its approaches to prototyping reflect this nature.

The above-mentioned spectrum illustrates that it is possible to prototype both conceptual and physical ideas. The creation of buildings requires both conceptual and physical embodiments of design. This suggests that a method of prototyping that utilises both ends of these poles is required to be able to adequately test all elements of a building. The development of such a method could be a useful tool to enable more comprehensive built environment prototyping.

3. Built environment prototyping

This section will now turn to analyse the use of prototyping in the built environment, through looking at the methods used by different professions that work in the discipline. The use of prototyping in the built environment is not as ubiquitous as in the above-mentioned fields, and more likely to be carried-out more extensively on projects possessing design complexity [24]. As a result, the literature concerning prototyping theory in the built environment is nascent. This has led to a lack of convergence in terms for prototyping in the same way Ullman's work has influenced mechanical engineering, or how the work by Houde & Hill has influenced software development. The design-focussed fields of architecture and engineering will be first analysed to understand how they approach and value prototyping, before turning to how these ideas are carried through into construction.

3.1. Architecture

Architectural design heavily relies on the creation of scale models as a tool in the design process [25]. Scale models explore form, spatial quality, and inform the design process of buildings [26], [27]. Scale models can be created to explore iterations of the actual built product, or can be made as a tool to explore concepts that inform the design process. They are created to varying levels of fidelity, but generally, scale models that are used in the design process tend to be created in haste, with low fidelity and varying degrees of workmanship. Scale models are also used to communicate the project to external stakeholders such as the client, local authorities or the wider community. This is most often for explanatory purposes at project presentations and are created with high levels of fidelity and workmanship [28]. However, there are instances where scale models can be used as a tool in a participatory design process, where models enable an exchange of ideas between laypeople, and designers. These are created with low-fidelity means and low levels of workmanship.

The term mock-up is also a term that is used commonly in the field to refer to a full-scale model, similar to a proof-of-process model. In their book on the topic, Burry and Burry acknowledge that in architecture, there is overlap in the use of the terms 'prototype' (in this case, a proof-of-process prototype) and 'mock-up', but add that level of fidelity can be used to further categorise mock-ups [29]. Naboni suggests that mock-ups enable a wide range of stakeholders to comprehend issues relating to building, in better ways than digital renderings, drawings, or 3D models are able to [30].

Özsel Akipek and Kozikoğlu offer a way to classify prototypes produced in a contemporary architectural education setting — in the digital era — as; Material, Conceptual, or Digital (Figure 2) [31]. They differentiate their model from Ullman's (Table 1), arguing that it concentrates mainly on process validation, and neglects the potential for the prototype to act as an ideator in a generative design process. Within their model, 'Material' prototypes are physical embodiments of a given complex system that is

being designed. The prototyping process serves to actualise the system, subject it to forces found in a materialised reality, and analyse the results. 'Conceptual' prototypes are seen to be diagrams of the input datasets, and their abstractions, that influence the design of a given complex system. The purpose of these prototypes is to act as a schematic for the entire system, such that it can be communicated and refined as a design tool. 'Digital' prototypes are vessels for design, where the tools of a chosen software are used by the designer to experiment and refine a given complex system. The nature of digital prototypes allows a range of design inputs, and serves to also introduce the student to computational design and programming concepts, through engaging with the interface. Özsel Akipek and Kozikoğlu's model offers a framework for designers to prototype an idea from concept, through to physical embodiement.

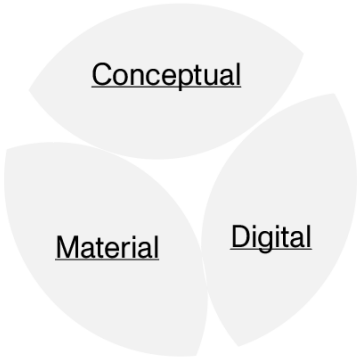

Figure 2. Özsel Akipek and Kozikoğlu's model of prototyping [31].

The advent of Building Information Modeling and computational design tools has enabled architects to undertake virtual prototyping more easily. A virtual prototype refers to a digital model that has been created using 3D modelling software, that is used for presentation, testing, or simulation purposes, and can be displayed in a variety of means [32], [33]. Tools like Ladybug for Grasshopper enable designers to simulate a number of environmental considerations relating to daylighting and climate [34]. When paired with powerful optimisation algorithms, many design iterations can be simulated and evaluated quickly, in ways physical models could never be used [35]. Virtual prototyping may be favoured over physical prototyping as they can be created with fewer resources, and in less time [36]. The underlying geometry used to virtual prototypes can be used across multiple testing environments in ways that physical prototypes cannot.

3.2. Engineering

Before the advent of computers, scale models were also used as important tools by engineers as part of the building design process, especially on projects possessing high design complexity. Addis defines four kinds of structural scale models that developed during the twentieth century by engineers;

- form-finding models that used by structural engineers as a method to arrive at a viable structural form and communicate its viability;
- small low fidelity elastic models made from homogenous materials for initial testing purposes;
- high fidelity strength models made at larger scale to yield more accurate test results; and,
- large low fidelity models for wind effects testing [37].

Azagra and Hay propose an alternative framework to categorise the use of scale models by engineers that concentrates mainly on the purpose of the model; conceptual models are created to explore design

ideas, form-finding models are used to determine a structure's shape according to predefined parameters, and experimental scale models are made to gather quantitative data about structural performance [38]. embodiement. This is similar to Ullman's prototyping model in that each component is linkeed to a stage of the design process

Virtual prototypes gained prominence as computers began to be utilised to perform structural analyses, and also began to be used in combination with experimental models [37]. As this endeavour became more expensive, virtual models superseded the use of the physical experimental model. The advent of software packages like Kangaroo and Karamba3D for the Rhino/Grasshopper environment provided designers with more instantaneous feedback than the real-word form-finding model [39], [40]. However, as these models can be time-consuming to create, conceptual scale models continue to be used in early project stages as a way to provide haptic feedback to the engineer [38]. While the use of virtual prototyping has become more prevalent in recent years, they cannot fully replicate their physical counterparts. For example, despite advances in computational fluid dynamics that has enabled the virtual simulation of the effect of wind on buildings and their surrounding context, physical prototypes are still used alongside them to counter a range of limitations [41].

3.3. Prototyping in construction research

There is a noticeable research gap in the prototyping cultures of those working in the construction trades. Gopinath & Messner suggest that the creation of prototypes can be used as a tool for; visualisation, identification of constructability issues, obtaining acceptance of design detail, and physical testing of specific products or systems [36]. Elvin notes the potential for onsite prototyping to act as an ideation tool, and to further foster direct communication and shared understanding across the wider project team [42].

The construction industry has been considered a low technology sector and has struggled to adopt digital technology [43]. This has hindered the amount of virtual prototyping occurring in construction. Sarshar and Christiansson also suggest that barriers to implementing virtual prototyping in construction relate to: culture and risk in information sharing, and a lack of pilot research projects [44]. Despite this lack of technology uptake, construction process (or 4D) planning has developed to enable practitioners to visualise drawings, and plan processes accordingly [45], [46].

Despite the research gaps that exist in academia concerning construction prototyping, there has been a recent increase in industry interest towards developing its culture of prototyping [47]. International engineering and construction company Laing O'Rourke have been utilising extensive prototyping to develop a system to 3D print complex concrete formwork at scale [48]. Vaz-Serra et al detailed a collaboration with an industry partner to produce a bathroom 'wet' wall for use in high rise construction, based on modular and design for manufacture and assembly (DfMA) principles and used prototyping as part of the development process [49].

4. Discussion

As shown in the literature and example cases above, prototyping is used as a tool in the design process by architectural designers and engineers to explore and refine conceptual ideas or aesthetic issues. It is also used to communicate these factors to internal and external stakeholders. This use of prototyping enables richer design outcomes to be realised that helps to increase the value of the built outcome. Prototyping can be used by project teams to test construction tectonics or building systems that serve to validate design decisions and resolve detail issues before construction commences. This minimises future time spent on site resolving issues at a time when many design decisions may already be locked-in. This enables buildings to be created more efficiently — in less time, or with fewer materials. The current purpose of prototyping in the built environment is aimed towards serving the needs of each specific field. While the fields mentioned above demonstrate that prototypes can add value to the built

outcome, the siloed nature of their prototyping prohibits knowledge from being shared with the wider team. Pietroforte et al. highlight that more integrated prototyping can play a social role in connecting projects teams; to help designers understand construction realities, and communicate design intent to tradespeople [50]. Integrated prototyping could be an enabler for DfMA in construction that shows promising benefits [51].

The goal of using prototyping in the built environment is to ultimately create better buildings that offer more output, from less input. However, design is the vessel through which data collected from the prototyping process flows. Each building created by a designer can be seen as a prototype to improve their design process, with the knowledge generated being utilised across future projects.

There are multiple terms for prototyping-like activities that are used within the built environment such as scale model, and mock-up. While there could be benefit gained from proposing a single system of definitions for all stakeholders to use, the chance of take-up is low because each term is ingrained into the profession that utilises them. What is of more use to built environment practitioners, is to communicate the range of benefits that possessing a strong prototyping culture affords — that this paper has done through using design value — and to propose techniques that enable stakeholders to get the most out of prototyping. The model of prototyping proposed by Houde and Hill (Figure 1) encourages users to formulate their design issues into questions that fall into three initial classes that culminate to a single Integration class. There is a slight similarity to the model proposed by Özsel Akipek and Kozikoğlu in that both models can be used to conceptualise the prototyping process. Both these models aren't directly applicable to the prototyping needs of built environment practitioners, however they would benefit from following a similar process. Practitioners should structure the issue to be prototyped as a question that needs to be answered, which will guide further decisions relating to the configuration of the prototype. Using such an approach helps to streamline prototyping endeavours to concentrate the scope to avoid unnecessary expenditures of time or money.

5. Conclusion

Figure 3. Potential conceptual approach to prototyping in the built environement.

This paper has reviewed literature in three industries about influential uses of prototyping. Future research work could expand on the number of industries analysed to develop a more comprehensive understanding about the use of prototyping. The findings of this paper has shown that prototyping is utilised in the built environment to varying amounts by different practitioners. The critical review of literature from other industries suggests the existence of research gaps concerning the comprehension of the use of prototyping in the sector as a whole. It is particularly pertinent to understand the use of prototyping activities by the construction trades. Future research activities could be used to quantify the use of prototyping by different practitioners in the built environment and understand their methods more deeply. The literature review also revealed two approaches to prototyping used by other industries as relating to; idea conceptualisation, and physical implementation, that are influenced by the main form of output of each respective field. As both approaches are required to create outcomes in the built environment (Figure 3), an approach to prototyping that accounts for this unique factor would be useful to encourage a more integrated approach. A quantitative study about built environment prototyping could also inform the development of an integrated model for prototyping that accounts for design conceptualisation, and implementation. Such a model could be tested on a subsequent pilot project to assess its validity.

Abstract

Under specific conditions of snowfall and wind, a large amount of snowdrift forms on buildings. At the worst, a significant amount of snowdrift will result in building collapse or cracking because of the unbalanced snow loads. This study aims to provide a new numerical approach, and apply it to the investigation of snowdrift development on a long-span dome roof. Firstly, the CFD prediction accuracy for snowdrifts was confirmed by comparing simulated results with field measurements. Then, the roof snow distribution characteristics on a long-span dome roof was predicted for different inflow wind velocities and roof spans. It is found that the uneven distribution of roof snow is weakened with the decreasing wind velocity and the increasing roof span.

Keywords: snowdrift, snow load, non-equilibrium, dome roof, inflow velocity, roof span

1. Introduction

Under specific conditions of snowfall and wind, a large amount of snowdrift forms on and around buildings. Snow blown by incoming flow on the windward side of an obstacle will accumulate in the regions around the obstacle, where the wind velocity is sufficiently low allowing snow to settle out and form a drift. Therefore, snowdrift is formed as the result of complicated interaction between snow particle motion and flow field affected by building geometry. At the worst, a significant amount of snowdrift will result in building collapse or cracking because of unbalanced snow loads and over-hanging snow on roofs [1]. Therefore, to develop suitable measures for handling difficulties and hazards due to snow in built-up environments, it is necessary to predict the spatial distribution of snowdrifts on and around buildings with high accuracy. Of all the methods, field measurements and experiments have been regarded as the most reliable approaches to deal with the complex interaction. However, their applicabilities are limited to specific weather conditions and similarity criterion, respectively. Fortunately, computational fluid dynamics (CFD) has been applied to simulate snowdrift around buildings recently, based on the dramatic increases in computational power together with advances in computer software [2].

The CFD method has been studied in the field of the applicability of turbulence models to a flow around a bluff body and in the field of the simulation of snowdrift process since 1990s. Much studies have focused on the aeolian sediment transport in a boundary layer flow developed on a flat terrain and snowdrifts around buildings. However, in the prediction of snow loads on building roofs, unbalanced snow accumulation due to wind flow is a difficult problem because it involves a complex interaction between snow particle motions and fluid flow affected by roof configurations [2]. So far, only a few

attempts have been made to apply CFD to roof snow issues. Thiis et al. [3,4] predicted the snow distribution on the curved roof of a sports hall located in Oslo and compared the results with field measurements. Generally, the simulated snow distribution pattern fit the measured shape well. Tominaga et al. [5] studied the CFD prediction of snowdrifts on a gable roofed building with different slopes. In the study, the predicted drift coefficients for different inflow velocities were compared against a series of observational results [6]. The simulation results generally corresponded well with the observational data for the exposed roof. Recently, Zhou et al. [7] proposed a quasi-steady method to simulate the redistribution of snow on a flat-roof building. In this method, the process of snow drifting was divided into several phases according to the characteristics of meteorological data. In each phase, the erosion or deposition of snow was regarded to occur in steady state. The snow redistributions obtained from the numerical simulation agreed well with those obtained in the wind tunnel tests.

It should be noted that the concepts and parameters used in the past snowdrift modeling have been mostly derived empirically from observations or experiments. Many of the observations and experiments were conducted based on a simple drifting boundary layer developed on a flat plane. For example, an estimation model for the transport rate of drifting snow attributable to saltation proposed by Pomeroy and Gray [8] has often been used in many previous CFD studies. The constant in the model was determined by the observation in a drifting boundary layer. Therefore, the proposed relation gives a saturated transport rate of drifting snow based on the assumption that drifting snow in the saltation layer has reached its equilibrium state, where neither wind velocity nor changes in the streamwise direction. However, Okaze et al. [9,10] investigated the change in the spatial distribution of for non-equilibrium flow in a developing saltation layer and its relationship with wind velocity by conducting a wind tunnel experiment using actual snow particles. Through comparison, the values obtained from Pomeroy's relation are greatly overestimated in almost the entire region. Thus, it is problematic to apply Pomeroy's relation (which is based on the equilibrium condition) to a flow around a building in which drifting snow is in non-equilibrium state because of acceleration and deceleration. It is necessary to further consider the applicability and validity of the modeling of the saltating process at the developing stage (non-equilibrium state). Tominaga et al. [11] lately proposed a new approach to account for the developing process of drifting snow with a one-way coupled drifting snow density transport equation, instead of the empirical saltation flux relationship. The new approach made some improvement, but some substantial deviations remained from experimental measurements. It was partly caused by the fact that the effect of snow particles on flow field and the increasing drifting snow density induced by building blocking were not fully considered, as the snow phase was simply treated as a scalar variable.

To fully account for the interaction between snow particle motion and fluid flow as well as the drifting snow density at a developing stage, a two-way coupled two-phase model was developed and adopted for the simulation of snowdrift development on a long-span roof. Besides properly accounting for two-way coupling of air and snow phases, this CFD model is free from all equilibrium assumptions used in the past approaches introduced above. In this study, the prediction accuracy of CFD on the snowdrift by comparing simulation results with field measurement results for a step roof was confirmed firstly. Next, the proposed snowdrift model was applied to predict snow distribution on the dome roofs. For this application, the snow load requirements of the ISO4355 ‘Basis for design of structures – Determination of snow loads on roofs’ [12] was compared with the simulated results. Finally, the snowdrift characteristics for different inflow velocities and roof spans were discussed.

2. CFD model for drifting snow

2.1. Governing equations

The air-snow flow is simulated by using the Mixture model in ANSYS FLUENT. The Mixture model equations consist of the continuity and momentum equations for the mixture phase, the continuity equation for the snow phase and the algebraic equation for the slip velocity between air and snow phases. Specifically, the transport equations for the air-snow mixture phase are given by.

$$\frac{\partial \rho_{\mathrm{m}}}{\partial t}+\nabla\cdot\left(\rho_{\mathrm{m}}\mathbf{u}_{\mathrm{m}}\right)=0 \tag{1}$$

$$\frac{\partial}{\partial t}\left(\rho_{\mathrm{m}}\mathbf{u}_{\mathrm{m}}\right)+\nabla\cdot\left(\rho_{\mathrm{m}}\mathbf{u}_{\mathrm{m}}\mathbf{u}_{\mathrm{m}}\right)=-\nabla p_{\mathrm{m}}+\nabla\cdot\left[\rho_{\mathrm{m}}c_{\mathrm{s}}\left(1-c_{\mathrm{s}}\right)\mathbf{u}_{\mathrm{as}}\mathbf{u}_{\mathrm{as}}\right]+\nabla\cdot\boldsymbol{\tau}_{\mathrm{Gm}}+\rho_{\mathrm{m}}\mathbf{g} \tag{2}$$

where, the subscripts "m", "a", "s" represent mixture, air and snow phases, respectively; $\boldsymbol{\tau}_{\mathrm{Gm}}$ is a generalized shear stress tensor, which is calculated according to Eq.(3); c_{s} is the mass fraction of snow phase; $\mathbf{u}_{\mathrm{as}}$ is the slip velocity vector between air and snow phases; ρ_{m} is the mixture density; $\mathbf{u}_{\mathrm{m}}$ is the mixture velocity vector; μ_{m} is the mixture viscosity.

$$\boldsymbol{\tau}_{\mathrm{Gm}}=\left(\mu_{\mathrm{m}}+\mu_{\mathrm{Tm}}\right)\left[\nabla\mathbf{u}_{\mathrm{m}}+\left(\nabla\mathbf{u}_{\mathrm{m}}\right)^{T}\right]-\frac{2}{3}\rho_{\mathrm{m}}k_{\mathrm{m}}\mathbf{I} \tag{3}$$

The snow volume fraction f_{s} is derived by solving the continuity equation for the snow phase, as shown in Eq.(4), where D_{Mp} is the diffusion constant. The third term on the left-hand side accounts for the slip between air and snow phases. Furthermore, based on the force balance and a local equilibrium assumption, the algebraic equation for the slip velocity $\mathbf{u}_{\mathrm{as}}$ is derived, as shown in Eq.(5).

$$\frac{\partial f_{\mathrm{s}}}{\partial t}+\nabla\cdot\left(f_{\mathrm{s}}\mathbf{u}_{\mathrm{m}}\right)+\nabla\cdot\left[f_{\mathrm{s}}\left(1-c_{\mathrm{s}}\right)\mathbf{u}_{\mathrm{as}}\right]=D_{\mathrm{Mp}}\cdot\nabla f_{\mathrm{s}} \tag{4}$$

$$\mathbf{u}_{\mathrm{as}}=\frac{t_{\mathrm{s}}}{f_{\mathrm{drag}}}\frac{\left(\rho_{\mathrm{s}}-\rho_{\mathrm{m}}\right)}{\rho_{\mathrm{s}}}\left[\mathbf{g}-\left(\mathbf{u}_{\mathrm{m}}\cdot\nabla\right)\mathbf{u}_{\mathrm{m}}-\frac{\partial\mathbf{u}_{\mathrm{m}}}{\partial t}\right] \tag{5}$$

In Eq.(5), t_{s} is the relaxation time of a particle; f_{drag} is the drag function, taken from Schiller and Naumann [13]; d_{s} is the diameter of snow particle; $\mathbf{g}$ is the gravitational acceleration. The k-ε turbulence model is applied to solve the flow turbulence quantities and turbulent viscosity for the mixture phase.

2.2. Treatment of deposition and erosion

The first grid adjacent to the snow surface is selected as a Control Volume (hereafter, CV) for evaluating the balance of snow concentration and calculating the total deposition. The total deposition flux q_{total} on the bottom surface of the CV is given by:

$$q_{\mathrm{total}}=q_{\mathrm{dep}}+q_{\mathrm{ero}} \tag{6}$$

Snow deposition per unit of time and unit of area q_{dep} is expressed as Eq.(7). Here, w_{f} is the snowfall velocity; Φ is the drifting snow density at the first grid adjacent to the snow surface, which is calculated as the product of the snow density ρ_{s} and snow volume fraction f_{s}.

$$q_{\mathrm{dep}}=-\Phi w_{\mathrm{f}}=-\rho_{\mathrm{s}}f_{\mathrm{s}}w_{\mathrm{f}} \tag{7}$$

Erosion flux q_{ero}, caused by the shear stress at the snow surface, is given by Eq.(8). This follows the expression, proposed by Anderson and Haff [14]. Here, c_{a} is a constant; u^{*} is the friction velocity; u^{*}_{t} is the threshold friction velocity.

$$q_{\mathrm{ero}}=\begin{cases}-c_{\mathrm{a}}\rho_{\mathrm{s}}u^{*}\left(1-\dfrac{u_{\mathrm{t}}^{*2}}{u^{*2}}\right) & for\ \ u^{*}>u_{\mathrm{t}}^{*}\\ 0 & for\ \ u^{*}\le u_{\mathrm{t}}^{*}\end{cases} \tag{8}$$

In this analysis, the total deposition mass q_{total} is incorporated into Eq.(4) as the source term to consider the snow concentration change within the saltation layer.

3. Validation of CFD model

3.1. Prototype

In order to validate the accuracy of the proposed snowdrift model, a field measurement of the snowdrift on a two-level step building model carried out by the authors was adopted as the analyzed flow field. The field measurements were carried out on an open flat base within the campus of Harbin Institute of Technology (HIT), Harbin, China. The prevailing wind experienced in this area was from south during winter, which was well suited for the measurements of snowdrifts. In previous researches of snowdrifts around buildings, the small precipitation condition was usually selected to only investigate the effects of wind flow on particle motion over the snow surface [15]. However, high precipitation condition shows a more complicated transport process in the case of the snowdrift formation on building roofs, as the source of snow on the roof is mainly limited to the precipitation and complex flow field around buildings seriously affects the transport of falling snow particles. Therefore, measurements were only carried out with high precipitation.

Before the snowstorm, a two-level step building model was placed on the measurement site with its lower edge facing against the prevailing wind, as shown in Figure 1. The dimension of the higher-level part was 1000 (x)×3000 (y)×1000 (z) mm, while the size of the lower-level part was 1500 (x)×3000 (y)×500 (z) mm. The wind profile was measured with three cup type anemometers, mounted on a 3 m mast and positioned 0.5, 1.0 and 3.0 m above the ground surface. The sampling interval was 10 minutes. Air temperature and humidity were measured by a PC-4 weather station, with an accuracy of 0.1 °C and 0.1 %. To measure the snow distribution on the building, a snow scale gauge was used to obtain the snow depth at each measuring point. Thereafter, the snow surface was generated using spatial interpolation. After each set of measurement, the remaining snow on the field was removed for the next set of measurement. Here, the snowfall event that occurred on 28th December 2018 was selected as the prototype to validate the snowdrift model. During the whole observational period, the mean wind velocity was approximately 1.1 m/s at 1.0 m height, and the snowfall volume fraction was 6×10^{-7}.

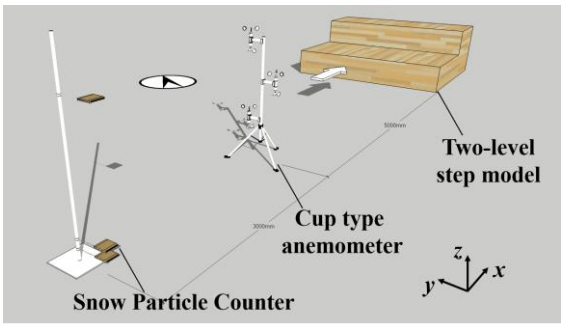

Figure 1: Schematic view of the field measurement site

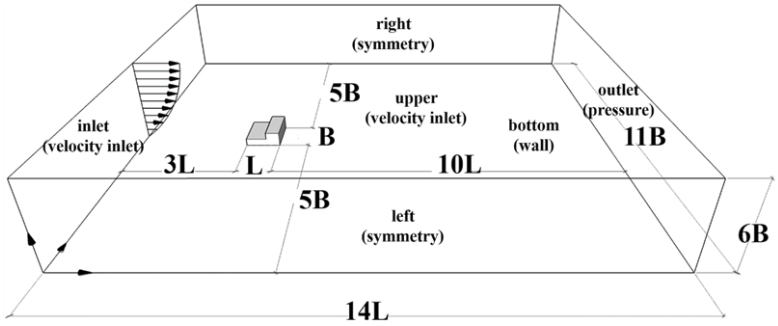
3.2. Computational conditions

The computational domain and boundary conditions are summarized in Figure 2. The whole domain covers 14L (x-axis)×11B (y-axis)×6B (z-axis), where L represents the overall length of the two-level step model (2.5 m) and B represents the overall width of the two-level step model (3.0 m). Each side of the domain is assigned 201(x-axis), 172(y-axis) and 100(z-axis) grids, with the minimum size being 0.01H. The height of the first grid adjacent to the ground h_p is set to be 0.01H (0.01m). The computational conditions follow the guidelines provided by AIJ [16]. The Realizable k-ε model was employed as the base model to calculate the eddy viscosity. The semi-implicit method for the pressure-linked equation (SIMPLE) algorithm was used for the pressure-velocity coupling. The Green-Gauss cell based scheme was used for gradient discretization. The advection terms were discretized using a QUICK scheme.



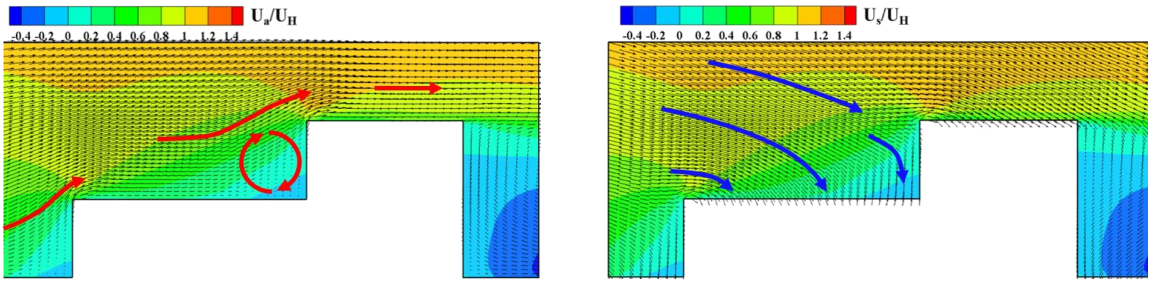


Figure 2: Computational domain and boundary conditions for the simulation of snowdrift on the two-level step building

3.3. Results and discussions

Figure 3 compares the vertical distributions of the streamwise velocities for air and snow phases, respectively. Obviously, the trajectory of air flow differs a lot from that for snow particles. The air flow moves upward and generates a strong separation flow from the end of the lower-level roof, forming an eddy current on the lower roof. Conversely, snow particles fall downward toward the building roof under the action of aerodynamic force and gravity. Figure 4 gives the spatial distribution of the drifting snow density Φ around the two-level step building. Due to the blocking of the high-level part, snow particles gather in large quantities at the windward edge of the high-level roof. High snow concentration leads to a peak value of snowdrifts formed right close to the foot of the high-level wall. Due the existence of upwind recirculation, a slight erosion is formed in front of the high-level wall. Generally, the snowdrift profiles obtained by the ratio of snow depths between the roof and open ground, shows good correspondence with the field measurements by comparison as shown in Figure 5.

4. Snowdrifts on dome roofs with various inflow velocities

4.1. Building configuration

Dome is a common roof shape for large-scale stadiums, exhibition halls, warehouses, etc. However, due to the light-weight roof structure, large roof area, complex building shape and other problems, it is extremely easy to cause snow-induced building collapse accidents. Therefore, It is very necessary to investigate the snow distribution characteristics on dome roofs in depth. Figure 6 provides a schematic view of the dome roofed building used in this study. An isolated dome roofed building, with an eave height (H_e) of 10 m and a span (L) of 50 m, was placed perpendicular to the approaching wind flow. The height of the dome roof (H_r) was 10 m with a rise-span ratio being 1:5.

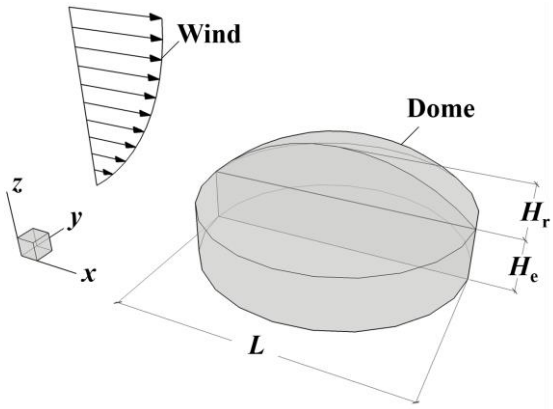

Figure 7: Schematic view of the dome roofed building

4.2. Computational conditions

The computational conditions used in this study were based on guidelines from the Architectural Institute of Japan (AIJ) [16]. The computational domain comprised a volume measuring 5L (x-axis)×5L (y-axis)×6(H_r+H_e) (z-axis). A power law profile with an index of 0.20 was assumed for inflow velocity; the profile for k was determined using a turbulent intensity equation proposed by the AIJ [18]. The ε values were determined from the local equilibrium assumption, P_k=ε. The mean wind velocity at the inflow boundary at the building height U_H was set to 2.0, 3.0, 4.0 and 5.0 m/s respectively to investigate the development of snowdrifts, referring to the requirements of snow distributions under various wind velocity conditions from AIJ guideline. The drifting snow density Φin at the inflow and top boundaries was given as a constant value by assuming that the standard snow depth, h^*, that resulted from snowfall

during the whole period of time. Here, the specific inflow snow volume fraction was set to 1.3×10^{-5}, referring to the snow disaster in Shenyang City, China in 2007. The parameters relating to the physical properties of snow were set as listed in Table 1.

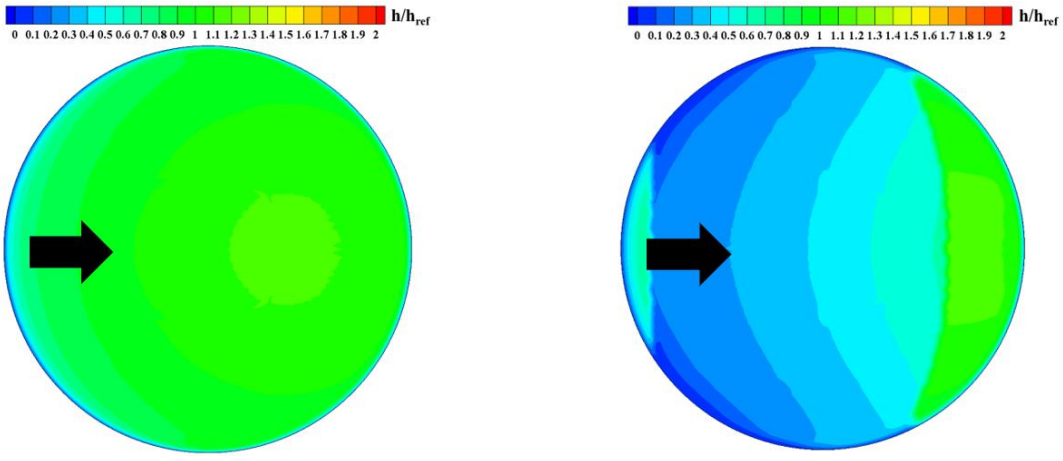

Table 1: Parameters relating to physical properties of snow

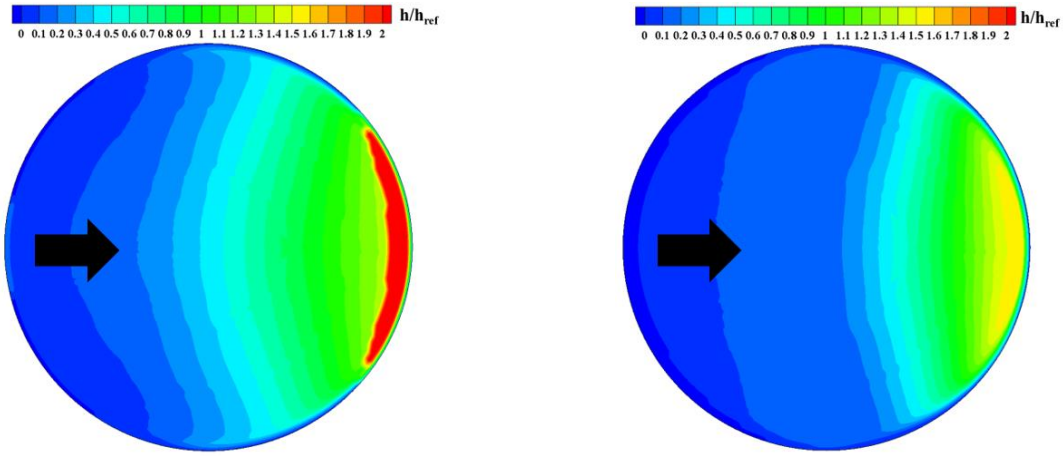
Threshold friction velocity u_t^*	0.2 m/s	Snowfall velocity w_f	-0.2 m/s
Snow paticle density ρ_s	250 kg/m^3	Diameter of snow particle d_s	5×10^{-4} m

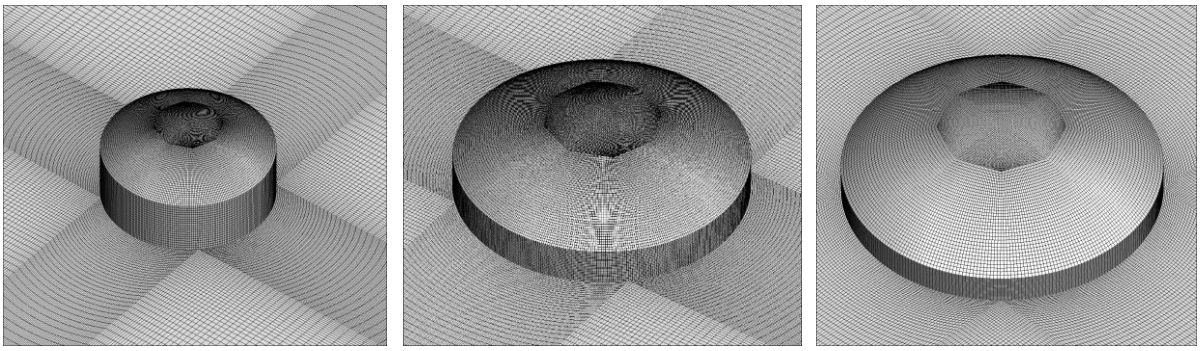


4.3. Results and discussions

Figure 8 indicates the contours of snow depth ratio q_{total}/q_{stan} on the dome roof for four different inflow velocities. The snow depth ratio was defined as the ratio between the total deposition flux q_{total} and the standard deposition flux q_{stan}. The standard deposition flux was calculated using the ground total deposition flux at a reference point, which was not affected by the building. For the case of lower inflow velocity (U_H=2 m/s), only very small undulations are observed due to the low friction velcotiy. No significant snow drifting occurs on the roof and the snow load on the dome is approximately evenly distributed. For U_H=3 m/s, erosion starts to occur in the windward area and extend in the lateal sides of the roof. However, a small accumulation of snow is formed on the windward eaves. For U_H=4 m/s, The windward erosion zone spreads further downstream and the deposition along the windward eave disappears. The uneven distribution of snow on the roof becomes more obvious, showing a half-span snow distribution pattern. For U_H>4 m/s, with more snow particles blown off the roof, the uneven distribution of snow on the roof begins to weaken, and the roof snow load turns to decrease.

In general, the snow load on the dome roof shows three kinds of distribution patterns, i.e., the full-span balanced distribution (U_H≤2 m/s), the half-span unbalanced distribution (U_H=4 m/s) and the transitional distribution between them (U_H=3 m/s). Snowdrift formed on the leeward side of the roof tends to increase with the increasing inflow velocity, when the inflow velocity is no more than 5m/s. Here, the inflow velocity (U_H=2 m/s) at which the snow distribution turns from uniform to non-uniform is defined as the lower critical inflow velocity, while the inflow velocity (U_H=5 m/s) at which the snow load turns from increasing to decreasing is defined as the upper critical inflow velocity. For this dome roofed building, the risking inflow velocity ranges from 2 m/s to 5 m/s, above which the snow load on the roof begins to decrease.

(a) (b)



(c) (d)

Figure 8: Contours of normalized snow depth q_{total}/q_{stan} on the dome roof: (a) 2m/s; (b) 3m/s; (c) 4m/s; (d) 5m/s

5. Snowdrifts on dome roofs with various spans

5.1. Building configuration and computational conditions

In addition to the serious influence of inflow wind velocity on the snow distribution, O'Rourke and Auren [17] pointed out that the parameters of the roof shape, such as the roof slope, roof width, also have a significant impact on the drift size on roofs. Furthermore, the American Society of Civil Engineers (ASCE) [18] gave additional surcharges that extend downwind from the windward surface for some specified distance to account for the drifting snow load. Obviously, the roof snow load is not only related to the inflow conditions, but also related to the building dimensions. Considering that the dome roof is mostly applied to long-span structures, which are snow load sensitive, it is necessary to explore the size effect of the building roof on snowdrifts. Figure 9 provides a schematic view of the building model of different sizes used in this study. The same rise-span ratio of 1:5 and eave height (H_e) of 10 m were selected for all the buildings. The only difference is that the building model considers three different spans: 30 m, 70 m, and 110 m, respectively. Regarding computational conditions, The mean wind velocity at the inflow boundary at the building height U_H was set to 4.0 m/s, at which the snowdrift is obvious. Except for this, all the computational settings are the same as above.

(a) (b) (c)

Figure 9: Schematic view of building models with different spans: (a) 30m; (b) 70m; (c) 110m

5.2. Results and discussions

Fig. 10 indicates the contours of dimensionless snow depth ratio (q_{total}/q_{stan}) on the roof for different roof spans. Generally, erosion occurs in the windward area and extends along the lateal sides of the roof, while deposition is mainly formed in the leeward of the roof. However, with the increasing of roof span, too many snow particles accumulate on the roof to move downstream further under the same capacity of airflow to transport snow particles. Therefore, the uneven distribution of roof snow is weakened under the same inflow velocity condition. For example, the snow load on the dome roof shows a half-span unbalanced distribution when the span is 30 m, while it turns to become a full-span unbalanced snow load when the span expands to 110 m. As a result, for a long-span structure, a higher inflow wind velocity is required to achieve the same significantly uneven snow distribution pattern, that is, the upper critical inflow velocity at which the snow load turns from increasing to decreasing is higher, and the risking inflow velocity range will be wider. It should be noted at the structural design stage that the long-span roofs are more likely to experience the most adverse snow loads compared with the ordinary buildings.

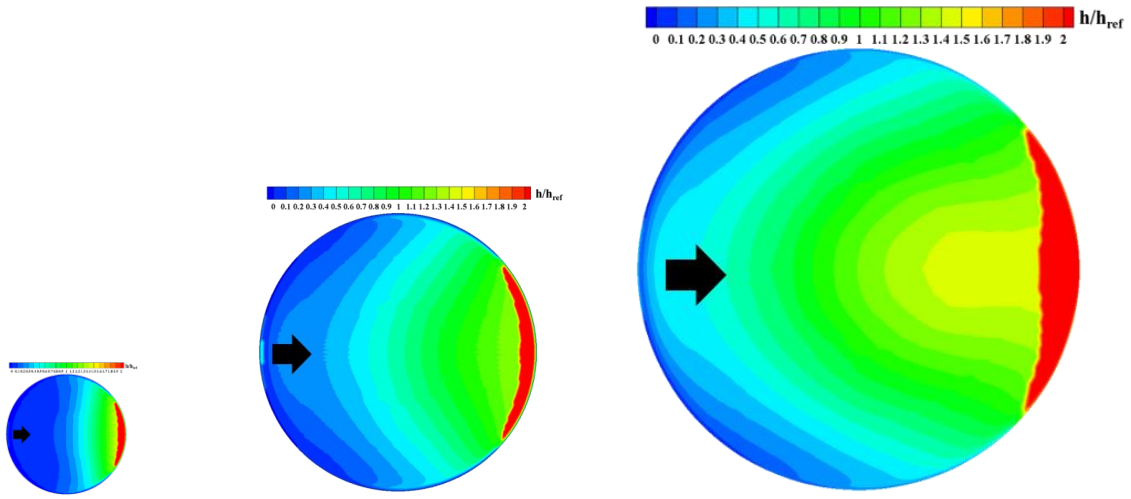


Figure 10: Contours of normalized snow depth q_{total}/q_{stan} on the dome roof: (a) 30m; (b) 70m; (c) 110m

6. Conclusion

This study proposed a new approach to account for the snowdrift in a non-equilibrium state. The simulated accuracy was examined by comparing results with the observational data. Based on this CFD model, the snowdrift development on an isolated dome roof with various inflow velocities and roof spans was explored. As a result of this work, the following conclusions can be drawn:

Through comparison, the proposed CFD simulation approach was generally able to reproduce the snowdrift on building roofs. Specifically, the snow accumulation on the windward side of the building due to building blocking and the trajectories of snow particles under the action of aerodynamic force and gravity are both well reproduced by adopting a two-way coupled multiphase flow model and considering the slip velocity between air and snow phases.

The snow load on the dome roof shows three kinds of distributions patterns, i.e., the full-span balanced distribution, half-span unbalanced distribution and transitional distribution between them. Snowdrift piled up on the leeward side of the roof tends to increase with the increasing inflow velocity. Here, the inflow velocity (2 m/s) at which the snow distribution changes from uniform to non-uniform is defined as the lower critical inflow velocity, while the inflow velocity (5 m/s) at which the non-uniform load changes from increasing to decreasing is defined as the upper critical inflow velocity. The risking inflow

velocity for this dome roof ranges from 2 m/s to 5 m/s, above which the snow load on the roof begins to decrease.

With the increasing roof span, the uneven distribution of roof snow is weakened under the same inflow velocity condition. Hence, for a longer roof span, the upper critical inflow velocity at which the non-uniform load changes from increasing to decreasing is higher. The risking inflow velocity range for a larger building will be wider, namely, the long-span roofs are more likely to experience the most adverse snow loads.

Abstract

The potential to produce CLT (Cross Laminated Timber) panels in sizes as large as 12m by 3m was key to all design and building processes for this project. By using such large panels, we could reduce the number of parts and joints, resulting in a shorter construction period. However, this large size panel is not robust enough for the anticipated bending forces. To overcome this issue, the first author developed a V-shaped beam composed of two 12m by 1.2m CLT panels bolted together at 90 degrees. When a flat CLT floor panel is fixed across the open arms of the V, the structure formed is robust enough to take the anticipated floor loads. To support the V-shaped beams, an open-grid diagonal lattice wall was developed. The V-shaped beams mate with the bottom corners of the diagonal grid modules to create a rational support structure. The roof is formed of 12m by 3m CLT panels fixed together in a V-shaped folded plate structure that is supported directly on the top ridges of the diagonal lattice walls. The whole architectural design process was governed by three specific solutions (V-shaped beam, V-shaped roof, and a diagonal lattice wall) to take full advantage of large-panel CLT construction. The other key element of the design process is the matrix chart, referred to as the INDEX. It was developed by the first author to help all parties involved come up with an optimal solution to the challenges of assembling these structural elements, and enables the implementation of a new design approach required by the use of CLT, where all disciplines work together in an integrated process.

Keywords: design and construction method, CLT, folded-plate structure

1. Introduction

The building presented in this paper is an office building with a floor area of 1000m^2 (Fig.1).

(a) (b)

Figure 1. Office building of MK: (a) Facade, (b) Building interior

Copyright © 2023 by Yoko MASUDA and Yuko MIYAMOTO. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

The owner of the office, MEIKEN LAMWOOD Corp. (hereafter MK), is a manufacturer of CLT and laminated timber, and also performs on-site assembly. The building is a showroom for CLT. The owner requested not only design quality but also a short construction period. The latter is one of the biggest advantages of CLT, and the authors tried to enhance construction speed further by using large panels in order to reduce the number of components. In addition, pre-build techniques were also used, in which insulation and moisture-proof sheets were pre-fitted to CLT panels at the factory.

2. Outline of structural system

The structural system is shown in Fig.2. Eight diagonal-lattice glulam walls are placed parallel to each other and a maximum of 10.5m apart. These walls act like bridge piers supporting V-shaped CLT beams and roof panels that span between them. The V-shaped beams and roof panels are connected to the diagonal-lattice walls using only dowels (Fig.2(c)), while CLT panels are fixed to each other with bolts and screws.

Earthquake-resistant elements are CLT walls and diagonal-lattice glulam walls. The former resists lateral forces in the X-direction and the latter in the Y-direction.

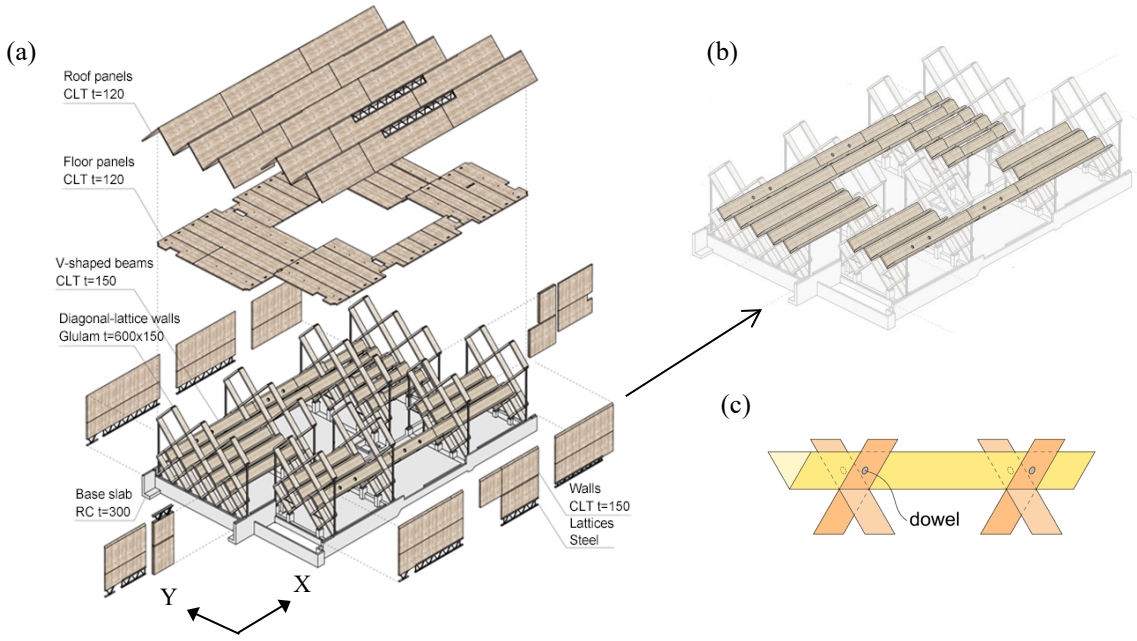

Figure 2. Structural system diagram:(a) whole, (b)arrangement of V-shaped beams, (c)concept of system

3. Design methods for each structural element

The key to structural design of wood construction is joints. The detail design of joints not only determines the performance of the structure, but also greatly affects workability on site. For large CLT panels in particular, the method of assembly determines the detail of the joints. Other factors that must be considered include ease of maintenance, aesthetics, coordination of structure and services, etc. The authors developed a new design approach to find the optimal solution for joint design that satisfied all conditions by bringing all parties together to discuss all issues (Fig.3). Section 4 briefly describes the main elements of the structure, with the joints which were determined by this new approach circled in red. The specific method is described in Section 5.

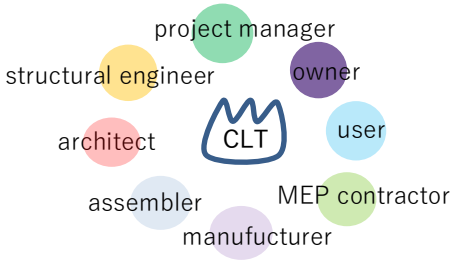

Figure 3. Participants in design discussions

4. Structural elements and the details

4.1. V-shaped beam

Details of V-shaped beams are shown in Fig.4. V-shaped beams are constructed of 150mm thick CLT panels a maximum size of 12 m long by 1.2 m wide. CLT floor panels run across the tops of the V-beams, with their long edge set at 90 degrees to the span direction of the beams (see Fig.2(a)andFig.4(a)). Steel dowels (diameter 90mm, length 120mm) connecting the V-beam to the diagonal-lattice walls are shown in Fig.4(b).

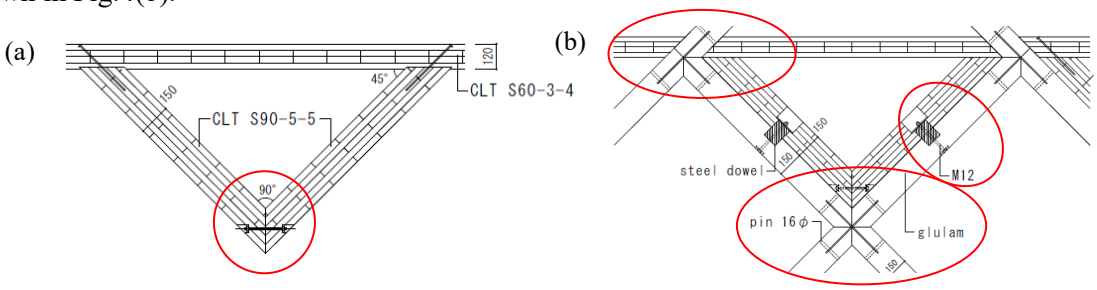

Figure 4. V-shaped beam: (a) detail, (b) V-shaped beam on diagonal-lattice glulam wall

4.2. Roof

The roof is a folded-plate structure made of CLT panels 120mm thick and 3m wide. Openings are formed in some roof panels for smoke exhaust and rooflights (Fig.2). These openings are reinforced with diagonal steel plates the same as those used at the lower part of CLT walls (Fig.7). Roof panels are connected to diagonal-lattice walls using the same dowels that connect V-beams to diagonal-lattice walls.

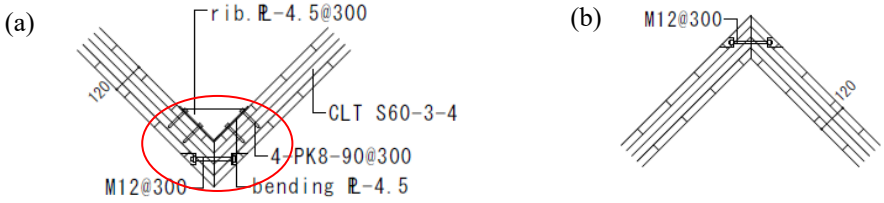

Figure 5. Detail of folded-plate roof panels: (a) valley junction (b) ridge junction

4.3. Diagonal-lattice glulam wall

To support the V-shaped beams and roof panels, the first author developed a diagonal-lattice glulam wall (Fig.6). The bottom corner of each grid can receive and support a V-shaped beam in a rational manner. Roof panels are supported directly on the top ridges of diagonal lattice walls. The lattice is composed of glulam members 150 mm thick by 600 mm wide. Four glulam members are connected at each node by inserted X-shaped steel flitch plates and drift pins (Fig.4(b)). The whole structure is supported by 75mm by 150mm solid steel columns at each end.

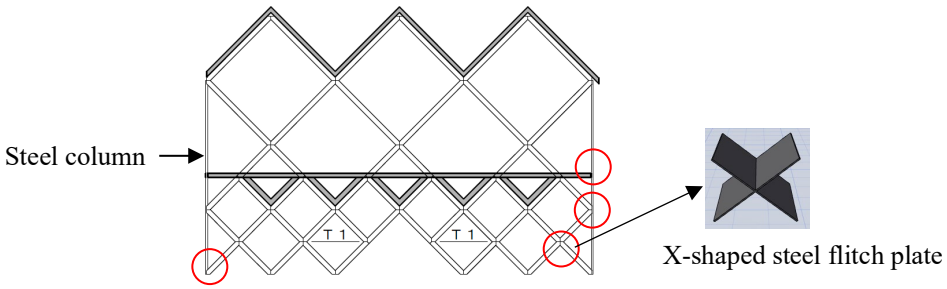

Figure 6. Diagonal-lattice glulam wall

4.4. CLT wall

CLT wall construction is shown in Fig.7. Axial forces resulting from the rocking of the walls during earthquakes are transmitted by bolts (indicated by the red circle). The walls are constructed of large horizontal panels with no openings. The steel lattice below the wall is a structural element that connects the wall to the foundation and also functions as a window.

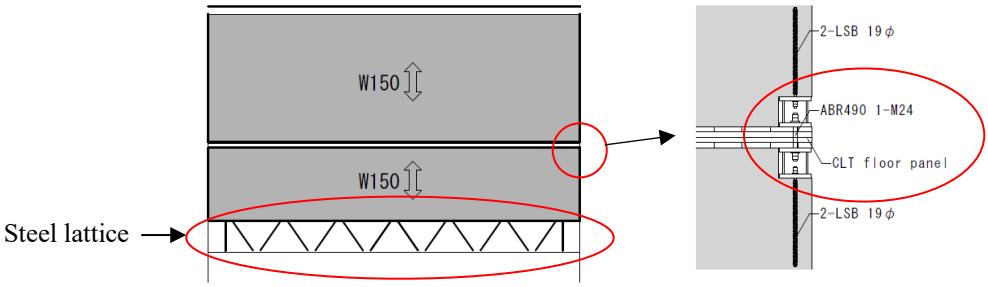

Figure 7. CLT wall construction

5. New approach to design

5.1. Controversy “Bolt or screw？”

Of all the joints, those forming the corner of the V-shaped beam had to be specified first (Fig.4(a)). This was crucial because no data existed for this type of construction and so full-scale testing was required for structural analysis. Therefore, details had to be determined during the schematic design phase in order to prepare the test specimens.

There were several possible methods of connecting panels, and the choice was not determined solely by mechanical rationality but through the integration of fabrication, assembly and design. The authors, along with the project manager, interviewed all project members, from the architect, builder, and manufacturer to users and the company president, focusing on the three joint possibilities shown in Fig.8.

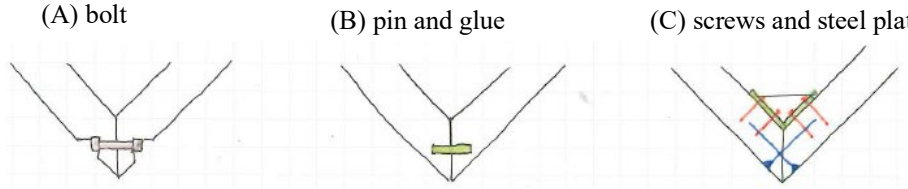

Figure 8. Detail of V-shaped beam

Advantages and disadvantages of each joint solution are shown in Table 1. The most advantageous is (A). However, the architect preferred (C) for its appearance, because in (C) only the heads of small

screws are visible. The authors argued that ease of construction and maintenance should be prioritized. Also, exposing bolts can express how the joint is made, and fits with the culture and character of the company.

To resolve the debate between the choice of bolts (A) or screws (C), respective full-scale mock-ups were made. It took two months to reach the conclusion that (A) should be chosen, based on the full-scale mock-ups. Following this decision, we decided to show, not hide, all jointing hardware.

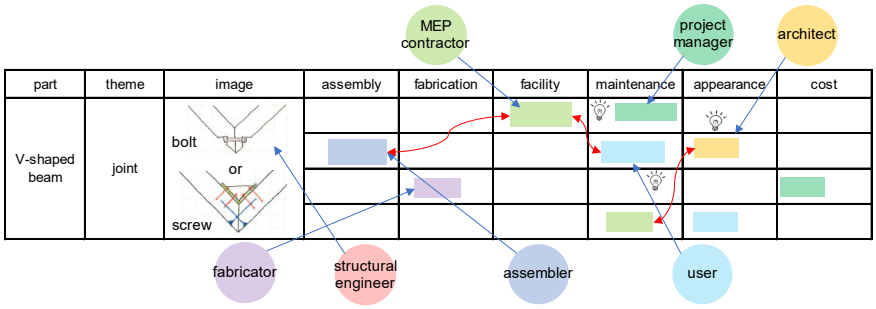
Table1. Matrix for comparison of performance

	A	B	C
rationality of mechanics	simple	simple	complex
performance guarantee	very good	Dependent on construction	good
workability	very good	bad	midle
cost	low	high	midle
maintenance	easy	impossible	difficult
appearance	standing out	invisible	visible

5.2. INDEX MATRIX CHARTS and related meetings

Through the controversy over "Bolt or screw" during the schematic design phase, the authors realized that, in comparison to conventional materials, CLT challenges us to change our ways of thinking and working. Compared to conventional structures, CLT requires the design and assembly process, the details, and the overall structural system to be thought of holistically. The reason for this is the enormous size of the CLT panels. As most of the structural elements were designed to be visually exposed, these challenges needed to be considered carefully. (Fig.1(b))

To facilitate this, the first author developed a series of "INDEX MATRIX CHARTS" (hereinafter "the INDEX"), shown in Figure 9. This encouraged a new approach, and called for all the actors from design, fabrication, construction and maintenance phases to participate in regular joint discussions during the detailed design phase. [1]



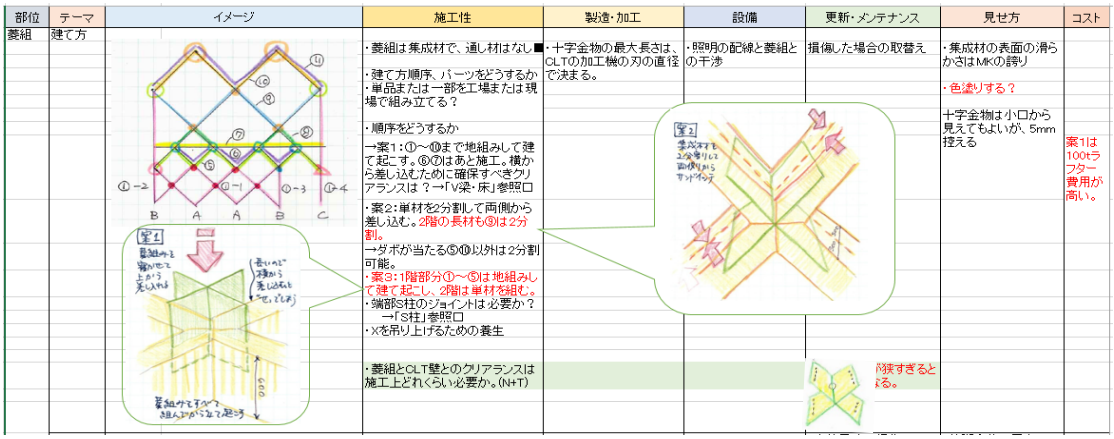


Figure 9. INDEX MATRIX CHARTS for the detail design of V-shaped beam

The authors produced separate INDEXES for respective structural themes, and the participants tried to reach the optimal solution for each theme. Themes were categorized by structural elements such as V-shaped beam or CLT slab, and participants discussed both design details and construction procedure in accordance with the factors listed in the INDEX. The importance of discussions for design integration with different parties has been addressed these days but it is not clarified who should chair and lead actual meetings. In this project, the first author chaired the meetings to ensure that design details were determined in the right order for structural analysis. The necessity for structural engineering resulted in design integration with fabrication and construction. The project manager drafted minutes to ensure the decisions and undecided issues at every meeting. An example from among many indexes is shown in Table.2. The assembly method of diagonal-lattice glulam walls was discussed using this INDEX. It was decided during this discussion that diagonal members should be split at the nodes. We noticed that some

members could not be inserted diagonally in the air due to geometry, so we decided to cut the width in half for these members and insert them from both sides of the X-shaped steel flitch plate. (See illustration on the right in Table.2.)

Table.2 Actual INDEX for erection of diagonal-lattice glulam wall

6. Analytical model

6.1. Specifications of CLT

The type and elastic modulus of CLT used in this design are shown below. The material of S90-5-5 is cypress, while the material of S60-3-4 and S60-5-5 are cedar. The elastic modulus (E) of cypress is 9000N/mm^2 and that of cedar is 7000N/mm^2. Table 3 shows that the elastic modulus decreases when made into CLT, and that the properties vary greatly depending on the direction.

Table 3. Elastic modulus of CLT

Used part	Thickness (mm)	Strength grade	Layer compositions	In-plane				Out-of-plane			
				E [N/mm^2]		G [N/mm^2]		E (N/mm^2)		G (N/mm^2)	
				Major axis	Minor axis	Major axis	Minor axis	Major axis	Minor axis	Major axis	Minor axis
V-shaped beams	150	S90-5-5	5-layer 5-ply	5400	3600	500	500	7128	1872	81.8	40.9
Floor panels	120	S60-3-4	3-layer 4-ply	3000	3000	500	500	5250	750	40.1	93.7
Roof panels	120	S60-3-4	3-layer 4-ply	3000	3000	500	500	5250	750	40.1	93.7

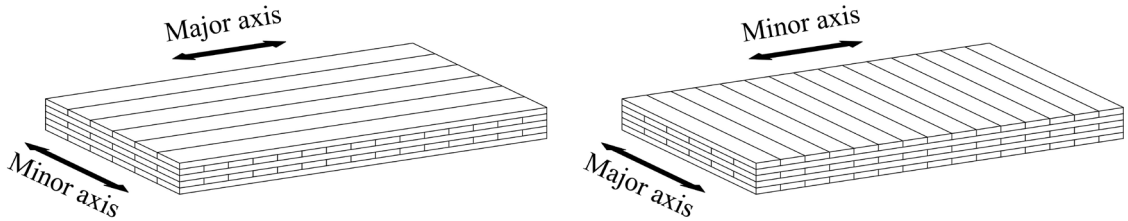

Figure 10. Axis orientation of CLT

6.2. Outline of analytical model

During structural analysis, the V-shaped beams with floor panels, roof panels, diagonal-lattice walls, and CLT walls were modelled separately. Finite element models were used for roof panels, V-shaped beams and floor panels shown in Fig.11 and Fig.12. The finite element mesh was approximately 150 mm. All fixings were treated as springs with appropriate stiffness.

The support points in Fig.11 and Fig.12 occur where roof panels or V-shaped beams and diagonal-lattice walls were connected with dowels, and at CLT walls at both ends. These supports were modelled as springs with appropriate stiffness. Long-term load and seismic load were applied to the roof in Fig.11, and floor in Fig.12. The reaction force occurring at the support points were applied as external forces on the diagonal-lattice walls and CLT walls. Diagonal-lattice walls and CLT walls are modelled by line component respectively.

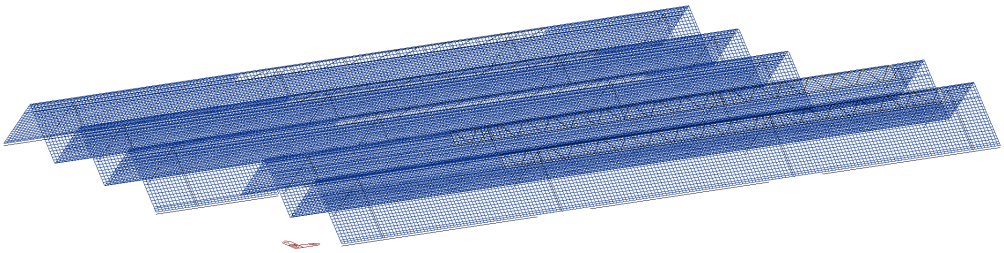

Figure 11. Finite element model of roof panels

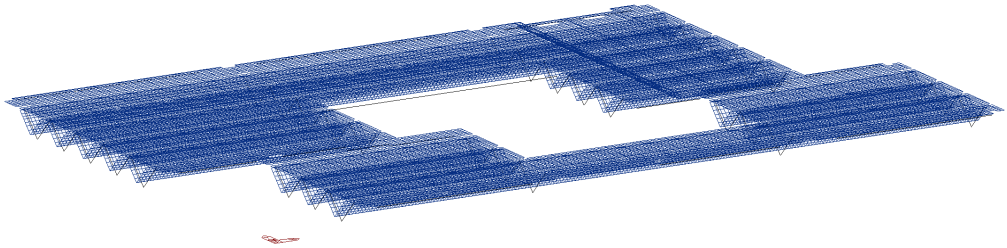

Figure 12. Finite element model of V-shaped beams and floor panels

6.3. Analytical model of joint

Joints in wood construction are less rigid than those in steel or reinforced concrete construction since stresses and deformations vary greatly depending on the stiffness of the joints. And so, joints were modelled as springs for the analysis. The detail of the roof joint is shown in Figure 13. The analytical model for Fig.13 is shown in Fig.14.

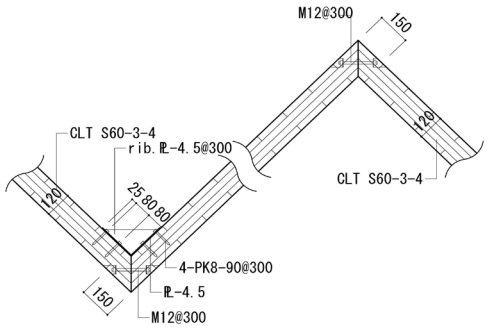

Figure 13. Cross-sectional view of roof panels

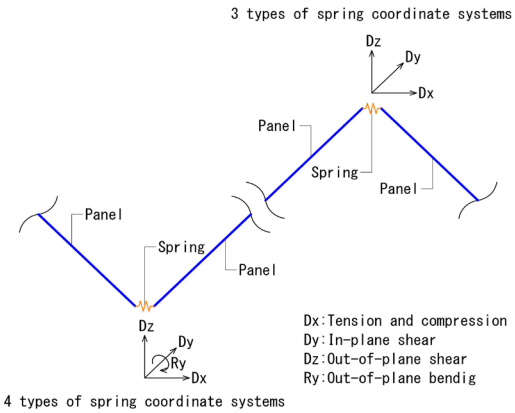

Figure 14. Analysis model diagram of roof panels

CLT has a short history in Japan and the CLT-related Building Standards Act was only enacted in 2016. Therefore, test data are usually used to design joints. As there are no test data for obliquely joined members like those in Fig.13., the authors conducted tests to obtain the yield strength and stiffness.

Tests were conducted with bolts, screws, and dowels. Using test data, the structural models for the roof were decided with spring stiffnesses for in-plane shear, out-of-plane shear, tension and compression, and out-of-plane bending.

6.4. Design load

Long-term load was assumed to be dead loads and live loads for the office floors. The specific gravity of CLT was assumed to be 4.9 kN/m^3. The construction site is in the inland area of Okayama Prefecture, and the snow load is assumed as the medium short-term load. A snow accumulation of 63 cm was assumed. Seismic load is assumed in accordance with the Building Standard Act. Wind load is not taken into account because it is smaller than seismic load.

7. Roof stress and deformation

The following figures show the stress contour map under snow load and the deformation contour map under long-term load. The deformation is after creep. Creep deformation is assumed to be twice the initial deflection.

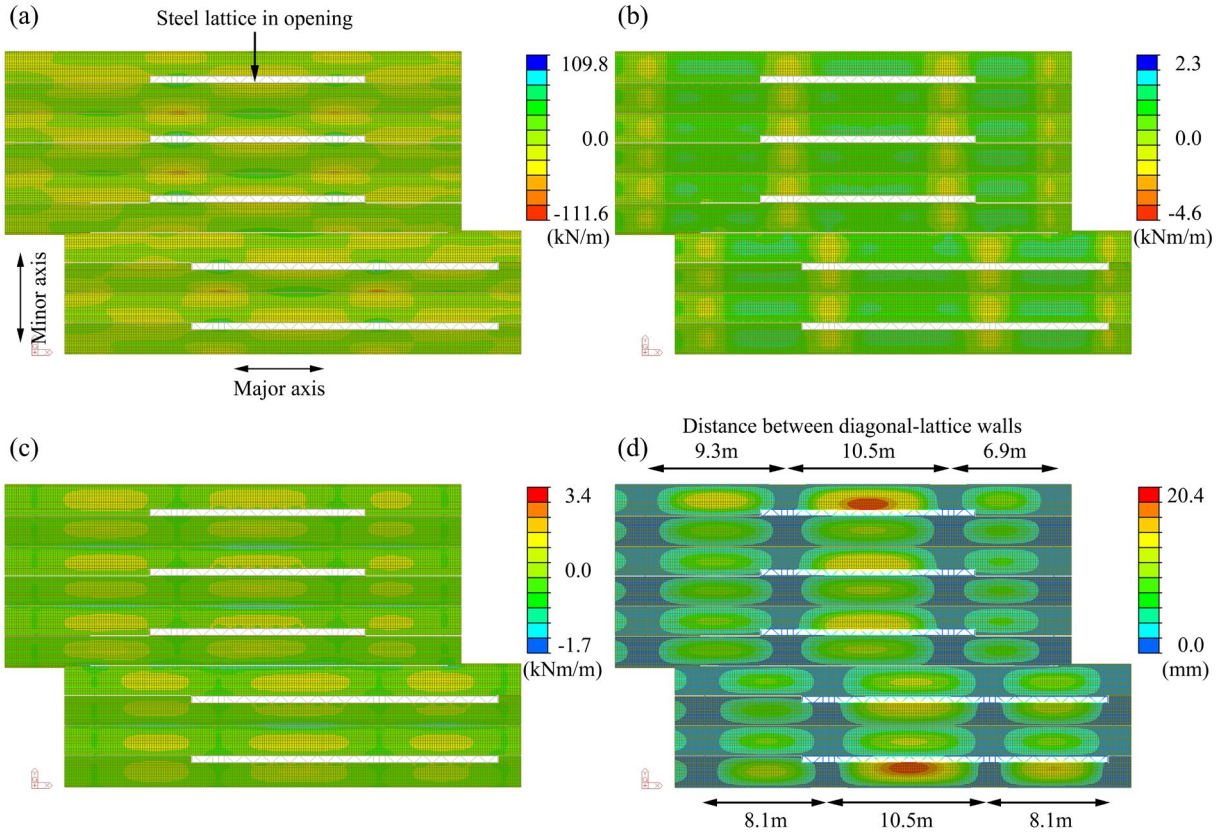

Figure 15. Stress contour map under snow load and Deformation contour map under long-term load: (a) axial stress in major axial direction, (b) out-of-plane bending stress in major axial direction, (c) out-of-plane bending stress in minor axial direction, (d) deformation after creep

Looking at the Axial stresses in major axial direction, it can be seen that tensile stresses of the upper panels are greater at the location supported by the diagonal-lattice walls, and the tensile stresses of the lower panels are greater in the center of the span. This is the stress state of a continuous beam. Out-of-plane bending stresses in major axial direction have similar trend. Out-of-plane bending stresses in minor axial direction are greater at the center of the panels and at valley junctions.

The deformation contour map shows that the maximum value is near the lattice in the center of the span, which is about 20 mm. The maximum deformation occurred at the outermost edge of the roof, the panel with the longest span. The reason is that the lower part of the panel is less restrained and the upper part is also less restrained due to the openings.

However, in the center of the roof for the same span, the panels are folded and continuous, so the deformation is about half. The fact that the deflection is about 1/1000 of the span with 120mm CLT panels spanning 10.5m shows the effect of the folded plate structure.

When CLT is used as flat panels, out-of-plane deformation increases due to the low modulus of elasticity of the out-of-plane minor axis. However, by folding it in the minor axial direction and making it continuous, as in this case, the weak point can be overcome.

8. Pre-build at the factory

Utilizing large-size CLT panels as a base, we tried several "pre-build" techniques in order to reduce the number of processes on site. V-shaped beams were made into a V shape at the factory and transported to the site. Ventilation ducts were installed inside the V-shaped beams at the factory (Fig.16). Insulation and waterproof sheets were attached to CLT panels for exterior walls at the factory (Fig.17). Pre-build not only shortened the construction period, but also improved quality because it was assembled in the factory with a good working environment.

Early involvement of an MEP contractor to the design discussion realized pre-installation of ventilation ducts. The location of ventilation duct joints on site, timing of onsite ducting works during erection, and air volume adjustment and maintenance method were reviewed using the INDEX.

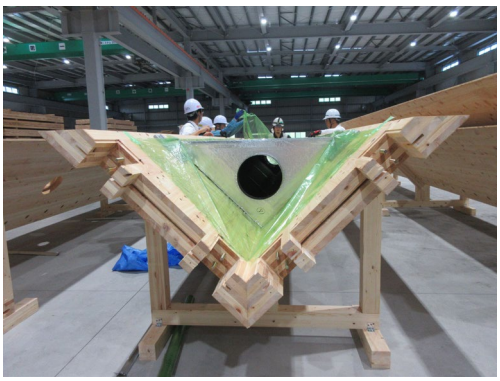

Figure 16. Duct installed in V-shaped beam

Figure 17. CLT wall covered with waterproof paper

9. Construction

A three-month preparation period was set aside prior to construction to ensure that there would be no rework. CLT construction is difficult to change or modify on site. Electrical wiring and piping for equipment were checked by the MEP contractor, the CLT fabricator and the architect using BIM.

Any issues expected during construction were reviewed by new INDEXES. Although a new general contractor joined at last, they smoothly communicated with the project members about the design intent of each detail through INDEX.

As constructability of timber joints were already studied in the design discussion using INDEX, structural timber erection works completed in 1 month as planned. In this way construction was completed in exactly 6 months. Fig.18. shows the construction site during the election.

(a) (b)

Figure 18. Construction:(a) Erection of diagonal-lattice glulam walls (b)Setting of V-shaped beams

10. Conclusion

Large size CLT panels are suitable for folded-plate construction and can lead to bold structural plans. When panels in the minor direction are made continuous by using a folded plate structure, the weak point of low bending stiffness can be overcome. Using larger size panels and reducing the number of pieces shortens the construction time of the building process. It is also possible to pre-build insulation and ductwork in a factory. Thus, CLT structural system can open up new construction process possibilities when off-site study is carefully done.

When encountering a new structural material such as CLT, it is important to think structurally in order to design a building that takes advantage of the material's specific features. CLT, due to its size, requires us to think carefully about how it is handled, assembled and joined. The authors invented a matrix chart (INDEX), which brought together not only the architect but also assembler, fabricator, and through discussion, they arrived at a method for finding the optimal solution that integrates design, assembly and fabrication.

Fig.19 shows that all jointing hardware is represented without being hidden. Joint is the key to wood construction. Only a structural engineer understands the mechanisms of joint. In this project, because the structural engineer, the first author, improved the quality of communication with the various parties involved, gathered their wisdom, and provided a platform, INDEX, for the optimal solution to the key issues, it was possible to create the building that was rationally constructed.

It was important for this project that the structural engineer had not only the capability of structural design and analysis but also the sensitivity to identify the critical issues in fabrication and construction phase through the communication with respective parties.

This report demonstrates how the structural engineer expanded her role beyond usual tasks, when CLT, the new structural material, was introduced. It implies a structural engineer’s potential key role when a new structural material is introduced in the future. By the efforts of structural engineer, never-before-seen of architecture may emerge which thoroughly represents the character of the new material.

Figure.19. Building interior

Acknowledgements

When the INDEX was born, it was project manager Ayako Omura (Naya Company) who quickly recognized its value. Because of her empathy and her efforts to manage this project, INDEX has evolved beyond my imagination.

Abstract

Complex forms necessitate a detailed understanding of form, structure, and architecture through a multi-disciplinary collaboration of the core players of the design team. The impact of design changes on the project's total cost becomes more detrimental as the project develops. The desired design efficiency is a result that is aesthetically pleasing, structurally efficient and easy to build for sustainable and innovative structures that comply with the budget [1]. Some scholars state that to optimise form, the designers need structural intuition, a skill that is explained as an innate understanding of the functional requirements of a structure [2]. This paper will explore how structural intuition affects design efficiency from an architectural point of view by looking at the work of the world-renown Brazilian architect Oscar Niemeyer. His work stands out with intrinsic detail to fine architecture, early-stage contribution of structural intuition and interdisciplinary design development. This paper identifies the critical elements of his design workflow which are exemplified through two case studies of his works: The University of Constantine (1972) and the National Congress (1960). Qualitative and quantitative analysis is conducted through a structured precedent analysis involving computational modelling, literature review and 3D printing to prove structurally intuitive design methods. The output of this evaluation demonstrates efficient workflow through learning from precedent studies and the application of parametric modelling.

Keywords: conceptual design, morphology, form finding, parametric design, digital fabrication, optimisation, concrete shells, precedent-based design, efficiency, workflow

1. Introduction

The disciplines of architecture and engineering have been inextricably linked throughout the history of the built environment. The evolution of new technologies, encompassing advanced tools, materials, and production techniques, has consistently spurred changes in these domains [3]. Moving away from the rectilinear paradigm, modern architectural trends push the limits of material and expression. The interaction between the two disciplines spans a broad range, from a cohesive vision of structure and architecture to a complete disregard for structural performance in favour of aesthetics [4]. This interplay is reflected in the collaborative relationship between architects and engineers during the design process.

The inseparable nature of the two disciplines merged within the work of master builders, single handedly designed, managed, and executed. In earlier times, architects or builders possessed only limited knowledge of construction but were ultimately responsible for all aspects of the building process. This required a multifaceted skill set, including artistic talent, materials expertise and an understanding of structural behaviour [5].

Despite the integration of complex forms and efficient design workflows, a prevailing trend exists where structural engineering considerations are seldom the primary focus at the beginning of an architectural design process, owing to the multitude of other concerns that need to be addressed. Conversely, architectural considerations are often not prioritized in structural engineering projects [6]. Key discussions within this interdisciplinary tension involve material selection, form and structure exploration, and proportion determination.

By incorporating complex forms and adopting efficient design workflows, architects and engineers can cultivate a stronger collaboration and develop more comprehensive solutions that effectively balance aesthetics, structural performance, and constructability [7]. This integrative approach has the potential to reshape the future of the built environment, as professionals from both disciplines work together to push the boundaries of design and engineering.

2. Workflow from the conceptual design phase

Modern construction projects often involve a linear design workflow where stakeholders possess separate goals and complications, leading to fragmented development of the project [8]. This fragmented process results in over-budget and inefficient buildings, particularly in large-scale complex projects where many stakeholders, materials, design challenges, and environmental impacts are involved [9].

Architects, structural engineers, civil engineers, and building services engineers have declared their commitment to addressing climate and biodiversity emergencies [10] [11]. However, achieving these common goals is challenging due to the fragmented nature of traditional linear workflow. Historically, architects and engineers have been associated with different parts of the building industry, leading to a lack of common design language [6] [12]. This fragmentation is reinforced by education and specialization of disciplines [13]. Despite advancements in modern digital tools and construction techniques, linear workflow fails to achieve a balance between aesthetic, structural, functional, and construction-related objectives. A more efficient and collaborative workflow model is required.

Modern architecture has introduced new dimensions to the traditional methods of construction, and it has had a tremendous effect on introducing new approaches to the aesthetic understanding of the built environment. Complex geometric forms in modern architecture can be designed more efficiently, cost-effective, and construction-friendly with minimal use of material when there is more structural intuition involved, and the project remains true to the early design decisions. Additionally, incorporating environmental considerations as early as the conceptual design phase can reduce the cost of later changes, as indicated by the MacLeamy Curve, shown in Figure 1.

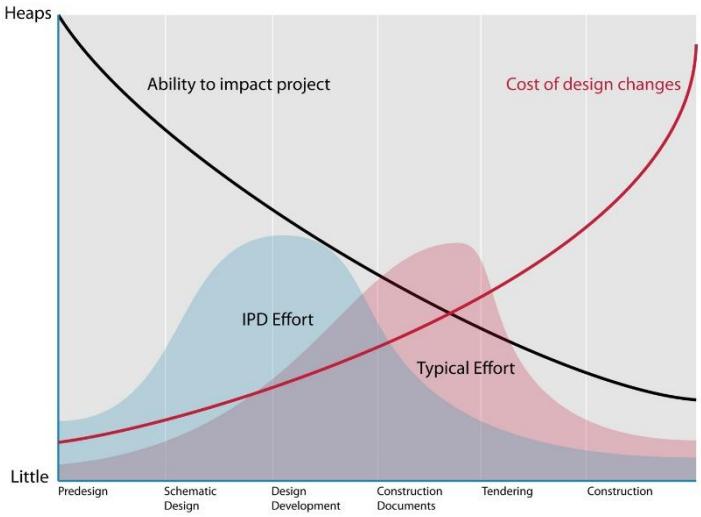

Figure 1. The MacLeamy Diagram [14]

The MacLeamy Design Effort/Effect Curve is a chart used to demonstrate the need to optimize the design process of complex design projects. According to the curve, the earlier in the design process that decisions are made, the more efficient the design process will be. This is because early decisions can be made that take account of structural intuition, which allows for a more accurate and efficient design process. The curve also suggests that the later in the design process that changes are made, the more costly and time-consuming they become.

Digital form-finding tools can facilitate efficient design of complex forms, but they require a change in workflow approach and seamless collaboration between architects and engineers. The Foundation Louis Vuitton by Frank Gehry, which exceeded its budget eight times, exemplifies the inefficiency that can result from post-rationalization of form despite using modern digital tools [15] [16].

3. Methodology and case study analysis

This paper focuses on Oscar Niemeyer and his works as contemporary examples of efficient design workflow that is demonstrated through a structured analysis of his distinguished projects. This study is a part of a broader research agenda that introduces a novel approach on how precedent and case studies can be used to address the issues that define efficient design, development, and production. The approach uses computational modelling and qualitative analysis of precedent case studies to determine the design workflow. A range of MEng Structural Engineering with Architecture (SEA) dissertation students was involved in understanding the possible impact of using digital tools and precedent studies and identifying the relationship between architecture, structure, and construction. This part of the research concentrates on the consistent collaboration between the architect Oscar Niemeyer and a small group of engineers throughout his career a conceptual design stage through exploring digital trends to extract information from case studies.

The two selected projects from Niemeyer demonstrate slightly different versions of Niemeyer's preferred workflow. The first one is the National Congress of Brasilia (1956) which relied on the expertise of the structural engineer Joaquim Cardozo [17]. The Congress was only one of the many buildings within the large-scale project that was the construction of the Brazilian capital, and due to its importance, it is also one of Niemeyer's most well-known projects. The second project is much less well known and it is the Auditorium of the University of Constantine 2 (1969) in Algeria. The university project is interesting as a whole because it is not one that immediately comes to mind when thinking of Niemeyer, but the story behind it contains valuable clues into Niemeyer's working dynamic with engineers.

4. Oscar Niemeyer

Oscar Niemeyer (1907-2012) is arguably Brazil's most renowned architect, with over 600 projects completed around the globe over the 78 years of his career [18]. He is widely considered one of the most significant names in modern architecture, with his use of concrete, glass, and curves as the main aspects of his signature style.

Niemeyer is often viewed through a primarily aesthetic lens. However, to fully understand his style and workflow, there are some important details in his early career that showcase a side to Niemeyer's works not often mentioned, a deep concern for both structure and construction.

4.1. Influences

4.1.1. Studies

Going as far back as his time in university the first detail is the courses he completed while studying at Escola Nacional de Belas Artes (ENBA), or National School of Fine Arts, 1930-34 [19] While there were curriculum changes during his time there, note that courses on construction, material sciences and

applied physics were always present while advanced mathematics was a later addition [20]. This alone shows that Niemeyer has some had been taught aspects structural behaviour. There are also interviews and letters from engineers that worked with Niemeyer where they mention having long discussions about the structural behaviour of Niemeyer's proposals from which the architect would learn from and then apply in subsequent projects [21]. This background of his studies provides an important clue as to his experience, as this background knowledge most likely played a part in his designs, meaning he knew when to push the materials and when to compromise for the sake of structural effectivness and practical construction.

4.1.2. Concrete revolution

The next major influence to be considered is the material Niemeyer used, which throughout his career was mostly reinforced concrete. The context required to understand the connection is both in the international and Brazilian scenarios of the time. The development of concrete began in the later years of the 18th Century in France but by mid-19th Century it had already become widespread with the evolution of reinforced concrete [18]. This new material could take advantage of the flexibility of concrete being moulded into varying shapes but also counted on the steel reinforcement taking the tensile stresses that concrete was weak against. Through this time several experiments and systems were developed finally in the 20th Century many key names in architecture and engineering were largely associated with the material, a few examples being Robert Maillart, Pier Luigi Nervi, Eugène Freyssinet amongst many others [22]. Meanwhile in Brazil, the document stating the standard for the calculation of reinforced concrete was first published in 1931, during Niemeyer's studies, therefore it would likely have been something discussed within his courses.

4.1.3. Le Corbusier

Finally, it is nearly impossible to talk of modern architecture without there being some reference to the Swiss-French architect, Le Corbusier (1887-1965) [18]. Niemeyer had the opportunity to work with Le Corbusier not long after graduating, and the influence on his style can be seen in the subsequent projects. Niemeyer, much like Le Corbusier gave importance to light, air, and space in his works, using the same five elements of Le Corbusier as the base of his early style. An example is the Obra do Berço (1938), where Niemeyer re-worked his preliminary study from 1935 after having worked on the building for Ministry of Health and Education in Rio de Janeiro with Le Corbusier [23]. However, it is also important to know that from those early works, Niemeyer developed his own language which he describes as being more suitable to Brazil, with curves and spaces to meld and reflect the curves of the country's rivers and mountains. In the documentary about his life and career titled "Life is a Breath", Niemeyer says: "Our architecture is very different from Le Corbusier's. We evolved to an architecture that has more to do with our weather: it's lighter, has more hollowed surfaces, more empty space." [24]

4.2. Style and workflow

This evolution from having Le Corbusier's five elements as a base to developing his own form of language in architecture can be seen through the different periods of Niemeyer's career. A study of thirty buildings from different periods of Niemeyer's career, ranging from 1943 to 2003, were analysed and one of the trends showed that through the years the control mechanisms he used became more sophisticated as he gained experience [25]. José Carlos Sussekind, a structural engineer that often worked with Niemeyer, says that despite not being an engineer, Niemeyer had an innate knowledge in addition to the many years of experience [26].

These events all explain how Niemeyer arrived at the aesthetic expression of his work, but these projects wouldn't be possible without the aid of structural engineers to fill in with their expertise on structural behaviour. Curiously, the architect himself recognised the importance of the engineers to the realisation of his projects and admitted in his own books that he would accept sacrifices to aesthetics for best result

[27]. Furthermore, he has repeatedly stated the sentiment that "once the structure is ready, the architecture is already there" [26]. Because of his long career it was inevitable that Niemeyer worked with many engineers on the hundreds of projects he completed, but there are also certain names that keep recurring in the list of collaborators. Early in his career it was Joaquim Cardozo, Bruno Contarini for his years in exile and return to Brazil and José Carlos Sussekind in the second half of his career [21] [26]. Niemeyer's long-standing connections to these engineers can be seen as an indication of cohesiveness of the unit of the design team and is often talked about by these people in their writings. Some examples are Contarini's biography, and the collection of letters exchanged between Sussekind and Niemeyer himself where they discuss Niemeyer's preferred workflow [21] [28].

5. Case studies

5.1 National Congress, Brasília, Brazil, 1960

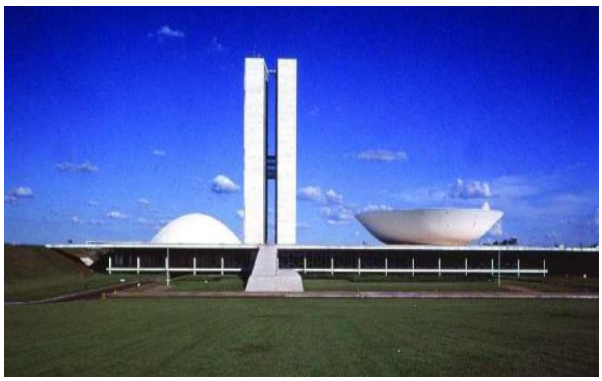

Figure 2. National Congress, Brasília, Brazil, 1960 [29]

The National Congress, shown in Figure 2, was one of the buildings commissioned in 1956 by President Juscelino Kubitschek within the larger scheme of what was to become the new capital of Brazil, Brasilia [30]. At the time, Niemeyer, with Lucio Costa (French-Brazilian architect and urban planner), prepared a plan that was eventually nicknamed the 'Monumental Axis' [31]. The congress is central to this plan, as the access ramp and the gap between the two towers align with the main axis of the city.

Niemeyer describes the design concept of the buildings in Brasilia as his search for structural purity, where structure and form are unified, a recurring theme in his work. The National Congress has in itself a few different parts to it: the two chambers (Federal Senate and Chamber of Deputies) shaped as a dome and a bowl sitting on a long horizontal building and the two office towers beside it.

Cardozo had already been working with Niemeyer for approximately a decade at this point and was considered an expert in the reinforced concrete within the country [17]. From Niemeyer's original sketches to the engineer's drawings some differences in shape can be noted, the main one being the inverted dome chamber, where the original intention was a paraboloid, but ultimately became an ellipsoid with a tangent of an inverted cone [32]. Precedent study did play a part here, as Cardozo introduced layers to the structure that resemble some of Robert Maillart's works [17].

Due to the magnitude of the project and the limited information released, there is no confirmed cost associated to the construction of Brasilia, although many scholars have made estimates, and this does therefore limit what can be said about the efficiency of the methods employed. However, there is some information on the workflow between Niemeyer and Cardozo related specifically to the congress, for example the story of Cardozo's morning call to Niemeyer to say he had found the ideal tangent to the inverted dome that would best suit Niemeyer's vision [21].

The congress building has been modelled in 3D multiple times and in multiple software, but going through the process based solely on the notes of the architect and engineer allow for a more practical insight into how the structure works. As mentioned before, the structure has several individual elements defined by Cardozo, these are shown in Table 1 and Figure 3:

Table 1. Structural Elements of the Chamber of Deputies as Defined by Joaquim Cardozo, see *[32]*

Number	Element
1	Lower Pillars
2	Concrete Curtains
3	Supporting Beams
4	Lower Compression Ring
5	First Shell
6	Intermediate Ring
7	Second Shell
8	Lining Slab
9	Ceiling Pillars
10	Third Shell
11	Upper Pillars
12	Upper Ring
13	Upper Slab

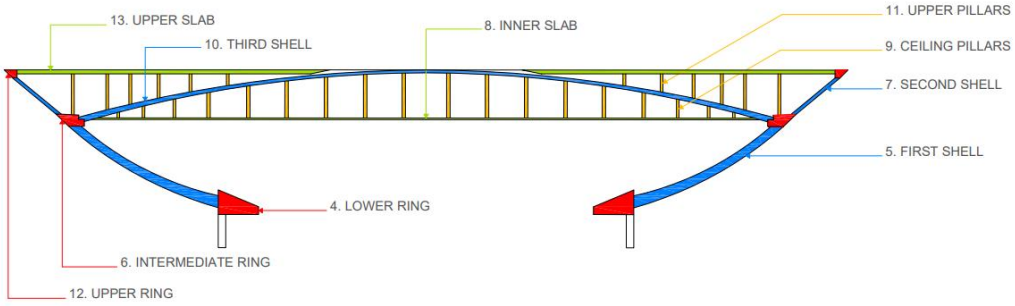

Figure 3. Section of the Chamber of Deputies with labelled elements corresponding to Table 1 [33]

Due to limitations in the modelling software (Rhino3D and Grasshopper) used certain aspects of the geometry had to be adapted and additional assumptions had to be made, and Figure *4* was the final result. For example, the software couldn't map the grid of pillars onto the surface of the third shell, and in their place imaginary support points were mapped onto the surfaces of the upper slab and third shell. Furthermore, the compression and intermediate rings also were divided into 1m segments and were called beams in the software. Lastly, the load cases were determined following the British Standard EN 1991-1-1 [33].

Figure 4. Rotated shape of the section of Figure 3 [33]

Elements 10 and 11 form a structure that resembles Maillart's Schwandbach Bridge (1933), with the thin bridge arch being equivalent to the inner shell and the stiff deck to be the upper slab. Therefore, when it came to analysing the structure, it was expected for these to act in a similar manner, where the

deck (or upper slab) would have a smaller deflection than the arch (or third shell). The results from the model confirm this, with the worst-case scenario having a deflection of 0.075cm in the upper slab and 0.567cm in the third shell [33].

From the results of the 3D model analysis, the other interesting occurrence was the behaviour of the intermediate ring. The deflection results of the third shell, show that the deflection was in the vertical direction, which is reasonable as the support conditions were set to be at the interface with the intermediate ring which restrained it from deflecting to the sides [33]. This resulted in the ring, defined as beams in the model, acted differently than it would have under pure gravity. Under normal conditions, the beams would sag, showing compression in the upper fibres and tension in the lower fibres. However due to the third shell pushing outwards, the opposite was observed, with upper fibres of the rings being under tension and the lower rings under compression.

5.2. University of Constantine, Constantine, Algeria, 1969

Commissioned by President Houari Boumediene, the Constantine University, now called Université Frères Mentouri de Constantine, is a large collection of educational and administrative buildings. Niemeyer was adamant to reduce the number of buildings from what was originally over twenty buildings to a simplified plan of only seven [24].

Figure 5. University of Constantine Auditorium, Constantine, Algeria, 1969 [34]

The auditorium, shown in Figure 5, is the most distinct looking of these buildings with the thin shell-like roofs, resembling a bird's wings or an open book, which meet in the middle with a single beam between them and contain no interior support. The 60 m long beam in the middle can be seen over the seam where the shells meet, while these span 30 m outwards. Niemeyer admits that he enjoyed pushing the limits of his preferred material of reinforced concrete.

One factor that seemed to be against Niemeyer's vision was the difference in technological advancements between Algeria and Brazil, which could have potentially set the construction back. However, the projects were designed in such a way that in addition with the cooperation between the Algerian and Brazilian workers it resulted in a smoother execution [35].

The information available on Niemeyer's process for the auditorium specifically is scarce as most of the literature available is surrounding the main classroom building. The story goes that when Niemeyer proposed the 50m span between columns the French engineers completing the calculations stated that a 1.5m thick wall would be required for structural stability. Niemeyer, unsatisfied with this, called in the Brazilian engineer Bruno Contarini who had worked with him in previous projects. Contarini then determined that only 0.3m thick walls were required and thus he was brought into the project [28].

The lack of information on this building meant that modelling it was a challenge and without anything to compare it to two versions were made, one following the tapering section as built in Constantine and a hypothetical version where the shell remains at a constant thickness. The tapering shell has a thickness

ranging from 3m where it meets the ground and 30cm at its highest point, while the uniform shell was chosen to be 30cm throughout [33].

The modelling software caused another limitation for this model where the program could not create the tapered shell as was designed, therefore the shell was broken up into strips with the average thickness of what it would have been. This seemed to have worked appropriately as the calculated mass of the adapted tapered shell was only 0.2% smaller than that of the hand calculated original tapered shell [33]. Once again, the load cases were determined following the British Standards EN 1991-1-1, and summarised in Table 2.

Table 2. Loading conditions for the tapered shell [33]

Load #	Name	Category	Eurocode	Value	Safety Factor
1, 2, 3	Self-Weight	Dead Load	-	Calculated from mass	1.35
2	Wind (x-dir)	Live Load	EN 1991-1-4	0.7 kN/m^2	1.5
3	Access	Live Load	Roof category H from EN 1991-1-4	0.4 kN/m^2	1.5

Figure 6. Complete model of the auditorium [33]

Since the two designs were so similar, the largest difference within the analysis was the self-weight of the tapered shell being larger than that of the shell with constant thickness. This proved to have a difference in deflection where the heavier, tapered shell had a deflection of 1 cm while the hypothetical shell only deflected 0.82 cm [33].

The more significant difference however is in the stress distribution across the shells. The wings become narrower on the side where it meets the ground, they go from 50 m wide in the middle where they meet the beam to 12m where it meets the ground [33]. This variation means that the stresses become more concentrated thus the expectation is that the model will show darker colours towards the foundations. This turns out to be true in the case of the shell with constant thickness, however the shell with tapered cross section, has a thicker section where it meets the ground which then counteracts the narrowing width [33].

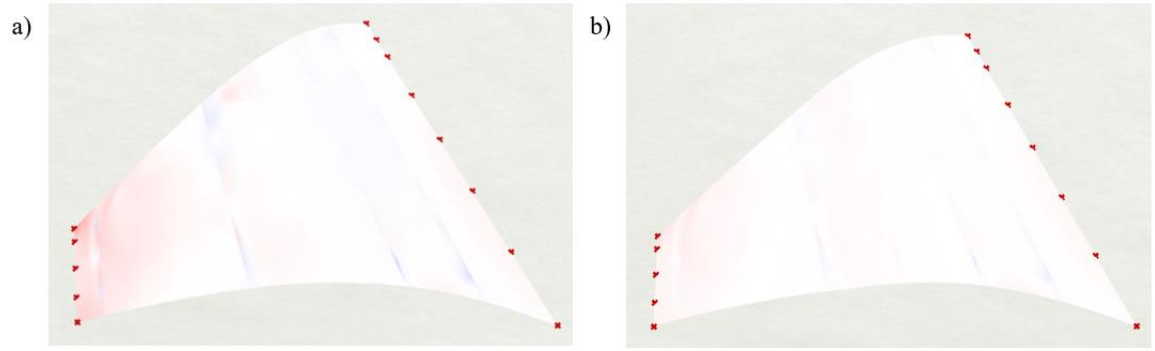

Figure 7 Principal stresses on the different shells a) constant 30cm thick shell b) variable thickness Shell [33]

Following this, the next point of concern would be the buckling of the constant thickness shell as the moments reach -81kNm/m, while the tapered section has a maximum bending moment of 27kNm/m at its thinnest point [33].

Unsurprisingly, the beams behave as would be expected, with displacement being at its highest in the middle of the beam, Figure 8.a , and compression on the top fibres and tension in the bottom fibres, Figure 8.b.

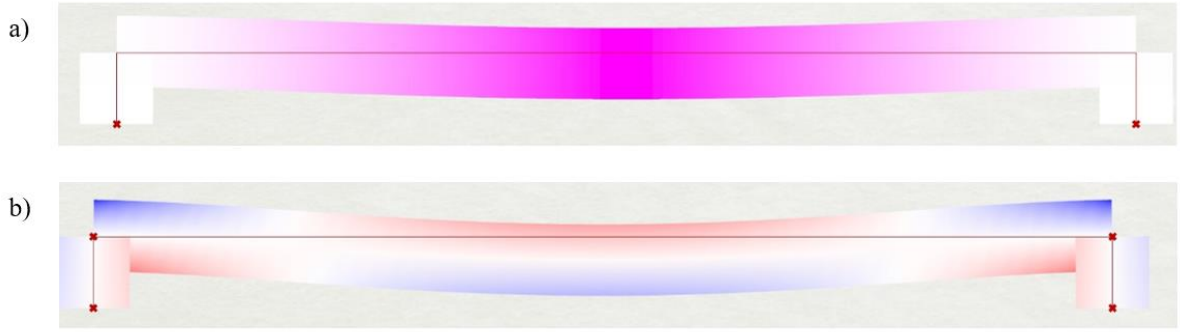

Figure 8. a) Displacement of beam b) Principal stresses on the beam. [33]

Recreating the 3D digital model of the case study and 3D printing of the structure provides great insights into design, behaviour and construction. In this case, individual shells and beam sections are printed separately giving clues in the complex nature of the tapered shells. The structure is designed for stability when the two shells work together. The beam stiffens as the tapered shells are attached to complete the two wings.

6. Discussion

"That in good architecture, when the structure is ready, architecture is already present." – Oscar Niemeyer [36]

This quote succinctly surmises Niemeyer's philosophy of design, where the structure and architecture are born together and coexist as a single entity. The engineers that worked with him, such as Contarini and Sussekind both repeatedly reaffirm this attitude in interviews and this is an example of Niemeyer's structural intuition at play [21] [28].

The structures observed in the case studies are visually different, however they do have similarities in terms of the rationalisation of their geometries. For the Congress, Niemeyer's design originally called for a parabola but he conceded to Cardozo's change to a revolved ellipsoid and tangential inverted cone, demonstrating Niemeyer's willingness to compromise his original idea for a more structurally intuitive option.

The way that Niemeyer designed these two buildings at the time used more conventional type of the design with hand calculations and drawings, while nowadays there are more advanced tools and softwares that allow for new ways of form-finding and faster iterative process. In this study the software used was Rhino3D, with the Grashopper, Karamba3D and other plugins to investigate how digital tools can be used to understand conventional structures with today's opportunities.

Despite the advancement in available tools there are still limitations to these that will affect the outcome and possibilities of the designs. In this particular set of case studies, the limitations with the software revolved around the geometric properties of the elements of the structure. For the National Congress the rings that had to be broken into 1m segments for the software to analyse them as beams, and for the auditorium, the tapered shell that had to be filleted into sections to show different thicknesses rather than a single continuous shell.

Whilst trying to understand the construction sequence and the rationalisation of form, the 3D model was useful to visualise and prove that the rationalised geometry was easy to build, thus fulfilling the ease of construction criteria of efficient design.

7. Conclusion

Ultimately, the examples of today's design explorations demonstrate that a more efficient and collaborative workflow is essential for modern construction projects. By addressing the fragmented nature of traditional linear workflow, stakeholders can work together to create buildings that simultaneously satisfy aesthetic, structural, functional, and construction-related objectives, while also contributing to climate change mitigation and sustainability.

Oscar Niemeyer, through his comprehensive education and the structural concern prioritised for his projects, carried a similar workflow throughout his career. He had a strong relationship and design collaboration with his engineers which allowed for cutting edge designs with the relatively new materials and techniques of the time. His innovation and precision to intrinsic detail rooted from the structurally intuitive nature of his design workflow.

There are many quotes from Niemeyer and his engineers on their collaboration process, perhaps one of the most insightful sources of these is the book with the collection of letters exchanged between Niemeyer and Sussekind [21]. In these Niemeyer writes: *"I attentively followed your explanations to the structural problems, not rarely caused by myself, certain that you always solve them in a masterful way."* and then continues *"I have felt how important you have been to me, in the development of my projects, a friendship that has seemed to do us both a lot of good."* [21]. The engineer also mentions a few projects where he and Niemeyer would discuss a design and come to a solution before submitting the final design to the client [21].

The structured analysis of two case studies have been demonstrated to provide an insight into a successful example of a collaborative workflow of aesthetically pleasing, structurally efficient and construction aware approach that results in Iconic architecture. Through physical modelling in this study, the fundamental principle behind the design and construction related challenges were identified. It was decided that 3D printing can serve as a valuable tool for feedback on the design at the early conceptual stages. Its implementation in the design workflow is recommended as it has been one of the earliest a tool for architectural design.

From the qualitative analysis in this study, it is seen that Niemeyer valued the engineers' point of view seeing them as a part of the initial design team to derive the concept. In the traditional design workflow where the architect receives the glory, often the engineer is responsible from facilitating the post-rationalisation of form to realisation where manufacturing becomes cumbersome and costly. Research into collaborative design strategies, learning from precedent and emphasis on practices with efficient design workflows becomes even more important when we consider the advantages of advanced digital opportunities in response to climate emergency.

Abstract

The construction industry is responsible for much of the global resource depletion and greenhouse gas emissions. New methods are needed to significantly reduce resources and emissions associated with load-bearing structural elements. Conventional floor slabs embody up to 50% of the total structural mass in buildings to satisfy deflection limits and provide the required bending stiffness. Significant mass savings can be achieved by reducing actively the deflection response against loading using sensors and actuators. Fluidic actuators have been therefore developed to be embedded in the compression region of reinforced concrete slabs under bending action. Through the controlled expansion of such fluidic actuators, deflections and stresses caused by vertical loads are reduced within the required limits. This paper offers a benchmark study evaluating the effect of actuator placement and actuation forces for two different objectives: reduction of displacements and reduction of bending moments. A method to fulfil both objectives simultaneously has also been investigated. Depending on the direction of the actuation forces caused by pressurized regions within the cross-section of the slab, there are two main actuation modes: uniaxial and biaxial. Results show that the efficacy of uni- and biaxial actuation modes depend on the control objective. To compensate for displacements and moments simultaneously, biaxial actuation is most effective and requires the lowest actuation forces.

1. Introduction

1.1 Motivation

The construction industry is responsible for much of the global resource depletion and greenhouse gas emissions [1, 2]. The construction industry is facing hard challenges to provide new living and working spaces required by population growth [3] and increasing urbanization [4] against resource scarcity of resources and the effect of climate change.

Structures are typically designed to take extreme loading events to satisfy safety and serviceability requirements [5]. Most structures, for example, flat roofs, car park slabs, stadiums, event halls, etc. are subject to variable loads. However, conventional methods such as prestressing and pre-cambering cannot respond to such variable loads, which, typically causes significant overdesign.

Conventional floor slabs embody up to 50% of the total structural mass in buildings [6, 7]. Floor slabs are typically built in reinforced concrete [6]. Large quantities of high-quality sand are required for the production of concrete. Such high-quality sand is already in short supply in some parts of the world [8]. In addition, CO_2 emissions from cement production account for 10% of the greenhouse gases of anthropic origin [9]. For this reason, one of the focuses of the research at ILEK is the development of lightweight and sustainable concrete structures. In concrete slabs, additional mass is typically required to provide sufficient bending stiffness to satisfy deflection limits under vertical loading [10]. Concerning structures subjected to bending stress, in general, the material near the neutral fibre is almost unused. To save mass, the load should be transferred using axial stiffness, as the bending stiffness is significantly lower. Material savings and thus weight reductions of reinforced concrete slabs can also help reduce the size of other components, such as columns and foundations.

Previous work has shown that the mitigation of the structural response through active control of stress and displacement (i.e., adaptation to loading), is an effective strategy to save the material mass required in load-bearing components [11–13]. Through the integration of sensors and actuators, structures can react against external loads to reduce deflections and stress peaks, which typically results in significant savings in mass and emissions [14, 15]. Adaptation offers great potential for material savings for stiffness-governed structures [16–18].

Previous design methodologies and experimental testing of adaptive structures have focused on truss and frame configurations including high-rise buildings and bridges [19–21]. Preceding work has also addressed the development of 2-dimensional thin-walled adaptive structures including shear walls, plates and shells [22–24]. The potential of adaptive concrete slab structures has received comparatively smaller attention.

1.2. Background, actuation through integrated fluidic actuators

New types of actuators for beam and slab components have been developed within the project "Integrated Fluid Actuators" [25–27] which is part of the Collaborative Research Centre (SFB) 1244 Adaptive Skins and Structures for the Built Environment of Tomorrow (University of Stuttgart).

Fluidic actuators have been strategically embedded in the cross-section of reinforced concrete components, within the compression zone, as shown in Figure 1. Referring to Figure 1 (a), the pressurization of the chambers and their consequent expansion causes a pair of opposite forces that, due to the eccentric position above the neutral fibre of the beam, results in a moment pair. This moment pair can counteract the bending moment caused by vertical loads. This way it is possible to artificially increase the bending stiffness which enables better use of the axial stiffness.

If the chambers are separated, several of them are needed to act over a certain distance. Due to dissipative effects, the force produced by a single actuator decreases gradually moving away from the chamber,

which has been modelled numerically in [25, 28]. Multiple actuators, in general, involve a more complex control system architecture, for example due to power distribution issues. As discussed for the uniaxial load transfer case (i.e., beam), to avoid increasing the number of chambers required to act over long distances, the distance between the application region of the actuation forces must be increased. This requires the development of new types of actuators that enable the generation of moment pairs acting over long distances without creating large cavities in the pressure chambers. Typically, large cavities affect negatively the load transfer in the passive state and, depending on the actuator shape (e.g., prismatic) could cause unwanted vertical actuator forces. A formulation to develop these new actuator types is given in [27]. However, if the distance between chambers is extended as shown in Figure 1 (b), the generated moment pair can act over a longer distance using only one actuator. To avoid the forces generated by the pressurization of the two ends of the chambers working against each other, one possible concept previously shown in [27] is to create a small gap filled with a low-stiffness material, which is indicated by empty regions in Figure 1 (b). This way, in principle, no force is applied onto the internal surfaces B and C when the chamber is pressurized resulting in the desired moment pair from the forces applied to the surface pair A-D. The actuation forces cause a compression zone on the outer sides of the surface-pair AD and a tension zone inside the region between B-C, as indicated in Figure 1 (b). For uniaxial load transfer, experimental verification of this actuation concept has been given in [26].

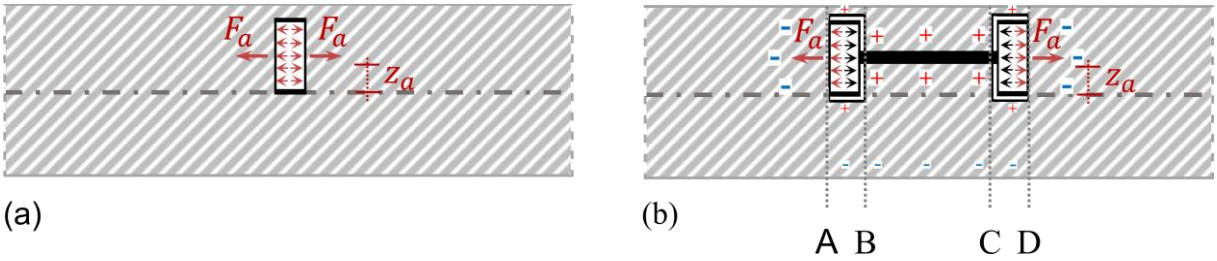

Figure 1: Actuation working principle in beam, a) single pressure chamber, b) extended pressure chamber.

An approach to developing such an actuation concept for slabs with multi-axial load transfer is given in [29]. Since this work focuses on numerical aspects, the actuator effect is simplified in the form of moment pairs (Figure 2).

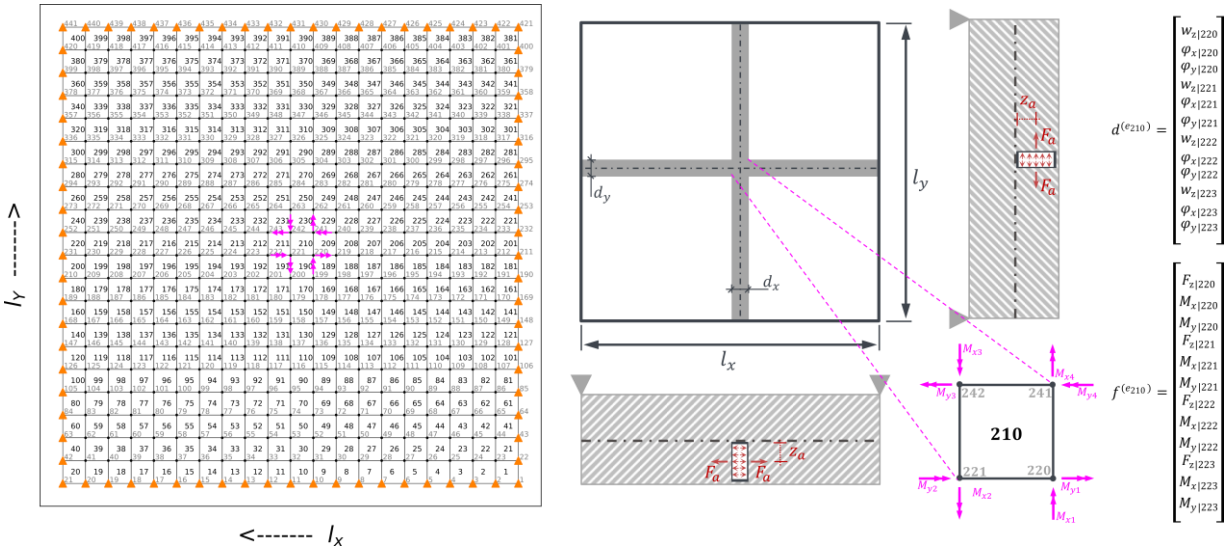

Figure 2 Actuation working principle in a plate. The actuator actions are illustrated as pairs of moments, Finite-Element-mesh, element labels are indicated in black and node labels in grey, deformation and force vector at element 210.

1.3. New contribution

This paper builds on the work presented in [29] which is summarized in section 2.1 to develop new actuation concepts for slabs. Actuation influence matrices [29, 30] are employed for deriving suitable placement, which includes the actuator form and topology as well as the control forces. The control objectives taken into consideration are displacement reduction and bending moment reduction. The effects of these two control objectives on actuator placement, actuation modes (i.e., the direction of applied actuation loads) and actuation loads are investigated. An approach to address both objectives simultaneously is also formulated. Simulations are carried out based on the dimensions of the floor slabs that will be installed in a prototype of an adaptive high-rise experimental building [21].

2. Analysis of a simply supported two-way slab

2.1. Summary of the general formulation of influence matrices

Assuming small strains and displacements, the adaptive state can be formulated as a superposition of a passive and an active state. The passive state is the structural response caused by conventional loads (e.g., self-weight and dead load) while the active state is the response caused by actuation forces. Influence matrices can be employed to analyse the effect of conventional and actuation loads on the different system states (active, passive, adaptive) [30]. For a chosen actuation mode (cf. section 2.3) the response caused by a unit actuation force can be quantified for each structural element. In other words, since the actuator layout is not known, each structural component is thought of as a candidate site to host an actuator. For the investigated slab, with *DOF* degrees of freedom and $i^{\#}$ active elements, equilibrium and compatibility conditions can be written as:

$$\boldsymbol{K}\boldsymbol{d} = \boldsymbol{f} = \boldsymbol{f}_{pas} + \boldsymbol{f}_{act} \tag{1}$$

Where $\boldsymbol{K} \in \mathbb{R}^{\mathrm{DOF\ x\ DOF}}$ is the stiffness matrix, $\boldsymbol{d} \in \mathbb{R}^{\mathrm{DOF}}$ is the deformation vector and $\boldsymbol{f} \in \mathbb{R}^{\mathrm{DOF}}$ is the force vector. The force vector can be separated into forces of the passive state $\boldsymbol{f}_{pas}$ and forces of the active state $\boldsymbol{f}_{act}$. In this work, the superscript # indicates the total number of the respective counting variable. An actuator allocation matrix $\boldsymbol{A} \in \mathbb{R}^{\mathrm{DOF\ x}\ i^{\#}}$ collates column-wise the forces produced by the unit actuation of each element in turn. The vector $\boldsymbol{u} \in \mathbb{R}^{\mathrm{DOF}}$is used as an actuation input:

$$\boldsymbol{f}_{act} = \boldsymbol{A}\boldsymbol{u} \tag{2}$$

If only the active system state is considered, for example, to generate influence matrices or influence surfaces, the actuation input vector $\boldsymbol{u}$ can be formulated as the identity matrix of dimensions $\mathbb{R}^{i^{\#}\mathrm{x}\ i^{\#}}$, which can therefore be omitted. Replacing Equation (2) in (1) yields the equation to compute the actuation influence matrix for displacements:

$$\boldsymbol{E}_d = \boldsymbol{K}^{-1}\boldsymbol{A} \tag{3}$$

By selecting every third global *DOF* of the influence matrix of displacements $\boldsymbol{E}_d \in \mathbb{R}^{\mathrm{DOF\ x}\ i^{\#}}$, the influence matrix for translational displacements, $\boldsymbol{E}_{d(w)} \in \mathbb{R}^{n^{\#}\mathrm{x}\ i^{\#}}$ is obtained (in the case of Finite-Element-mesh shown in Figure 3 $\boldsymbol{E}_{d(w)} \in \mathbb{R}^{2601\ \mathrm{x}\ 2500}$). $n^{\#}$ denotes the total number of element corner nodes. To compute actuation influence matrices for stress resultants, the element deformation vectors caused by unit actuation forces are multiplied with the strain-displacement as well as the stress–strain material matrices. A full description of the computation and use of the individual influence matrices is given in [29].

Influence matrices can be evaluated row or column-wise [31]. Each row indicates the influence of each element (considered active) on a component of the structural response, e.g., translational displacements or moments in the x-direction. Each column indicates the influence of the corresponding element on the structural response (i.e., on all DOFs).

As described in [30], influence matrices can also be used to calculate the actuation forces required to control the structure into a specific state $\boldsymbol{y}_{ada}$:

$$\boldsymbol{y}_{ada} = \boldsymbol{y}_{pas} + \boldsymbol{y}_{act} = \boldsymbol{K}^{-1}\boldsymbol{f}_{pas} + \boldsymbol{E}_d\boldsymbol{u} \tag{4}$$

Since influence matrices are typically not square, the Moore–Penrose pseudoinverse, denoted with $(\cdot)^+$, is employed to compute the actuation input $\boldsymbol{u}^*$:

$$\boldsymbol{u}^* = \left(\boldsymbol{E}_{d,comb}\right)^+ (\boldsymbol{y}_{ada} - \boldsymbol{y}_{pas}) \tag{5}$$

2.2. Adopted numerical model

The configuration considered in this work is a floor slab that is modelled as a quadratic plate with a span of 5 x 5 m, which is simply supported along all edges. The dimensions and material properties, indicated in Table 1, have been selected based on the floor slabs of the adaptive high-rise demonstrator D1244 [21]. The floor slab is discretized by subdividing each edge into 50 elements (2500 elements) as shown in Figure 3. All simulations have been performed using quadratic Elements with bilinear shape functions based on Reissner Mindlin Plate Theory, implemented in Python 3.7.8 [32].

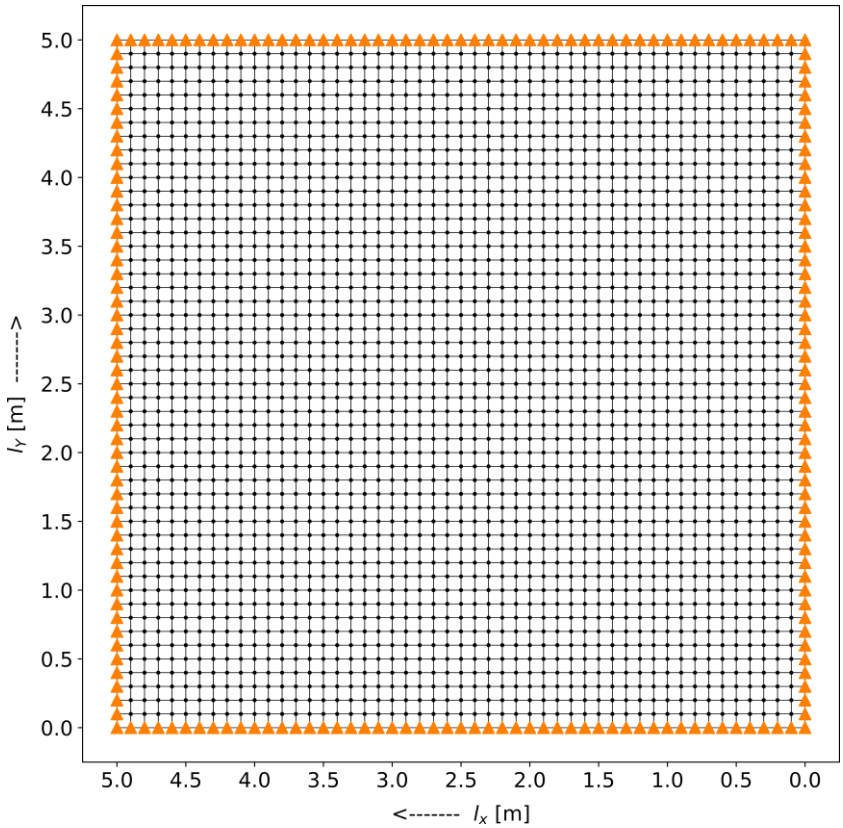

Figure 3: Finite-Element-mesh.

Table 1. Floor slab dimensions and material properties.

Properties	Value	Unit
Span $l_x = l_y$	5	m
Thickness	0.12	m
Element size $l_{a,x} = l_{a,y}$	0.1	m
E-modulus	37	GPa
Poisson's ratio	0.2	-

2.3. Actuation modes

Actuation modes are understood as the working direction of actuation forces caused by pressurized regions embedded within the cross-section of the slab. In this work, the effect of such pressurized regions is simplified with moments. Therefore, the actuation modes indicate the direction of the moments in the active state of an element. A general overview of possible actuation modes is given in [7]. Figure 4 gives an overview of the actuation modes considered in this work. The labels 45° and 135° refer to the axis of the resulting moments with reference to the coordinate system shown in Figure 4.

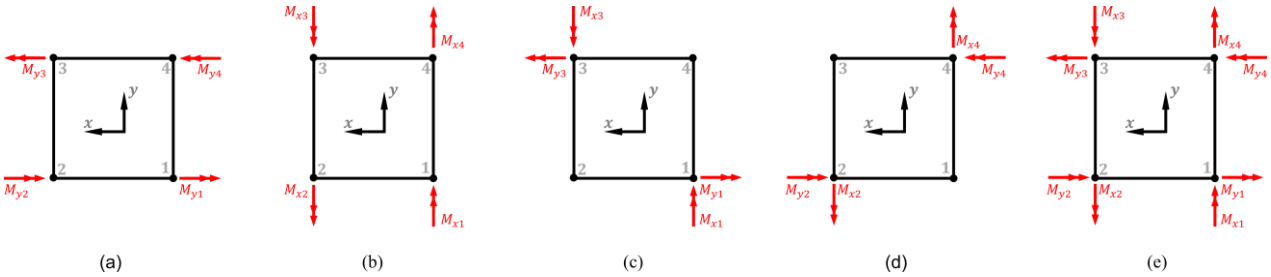

Figure 4: Considered actuation modes, (a) uniaxial actuation along Y-Axis, (b) uniaxial actuation along X-Axis, (c) uniaxial actuation 135°, (d) uniaxial actuation 45 °, (e) biaxial actuation.

The efficacy of the individual actuation modes depends on the control objective (cf. section 2.4). Summing the entries of a column yields a characteristic value of the influence of the corresponding element and actuation mode on the control objective which can be employed to evaluate the efficacy of a candidate site for actuation [29].

2.4 Control objectives

The choice of actuation mode depends on the control objective. First, each actuation mode presented in section 2.3 is evaluated by studying the efficacy of the actuation of each element on the reduction of deformations and bending moments. Figure 5 shows the plot of the summed influence on translational displacements *w* for all elements under (a) biaxial actuation, (b) uniaxial actuation 45° and (c) uniaxial actuation X-Axis. Due to symmetry, the plot for uniaxial actuation 135° and Y-Axis can be obtained by rotating that for 45° and X-Axis, respectively, by 90° degree. Figure 5 indicates that concerning displacement reduction, a biaxial actuation is effective in the centre of the slab and the uniaxial actuations 45° and 135° are effective on the diagonals. Uniaxial actuation X- and Y-Axis are comparatively ineffective to control displacements. Note that the actuation influence is independent of the effective of external loads. The summed influences indicate the effect of an actuation mode for each element of the slab (i.e., each element is assumed to be an actuator in turn) on the control objective.

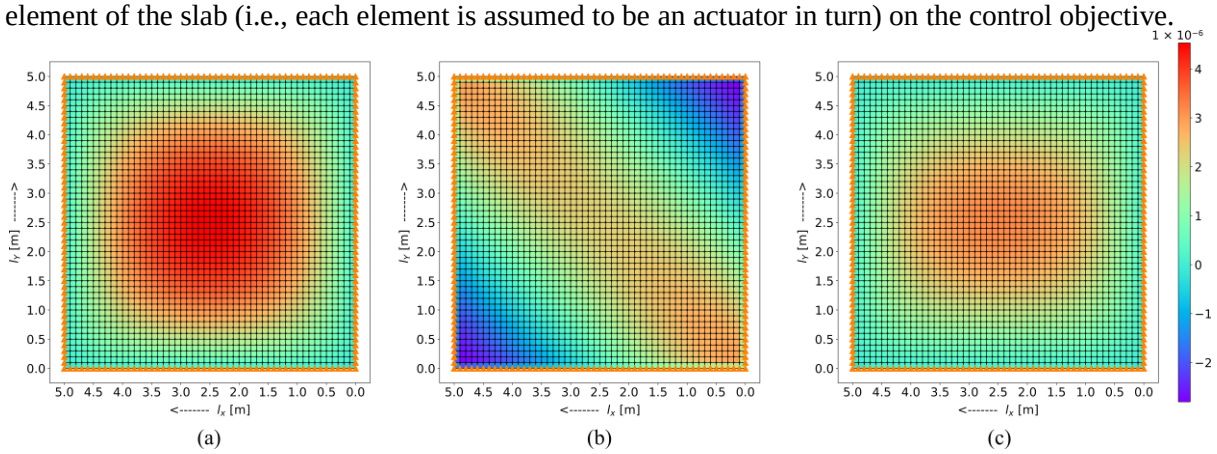

Figure 5: Summed influence on the displacements *w* for biaxial actuation (a), 45° (b) and X-Axis (c) uniaxial actuation.

For the analysis of the influence on the reduction of bending moments, the principal moments are considered. Figure 6 shows the summed influences on the principal moment m_1 for all elements of a biaxial actuation (a), uniaxial actuation 45° (b) and uniaxial actuation X-Axis (c). Due to symmetry, the plot for uniaxial actuation 135° and Y-Axis can be obtained by rotating that for 45° and X-Axis, respectively, by 90° degree. The same applies to the principal moment m_2. In this case, biaxial actuation is also effective along the diagonals. The uniaxial actuations 45° and 135° are only effective in the corners of the slab. In addition, the uniaxial actuations X- and Y-Axis are effective in the perimeter area along the respective main axes.

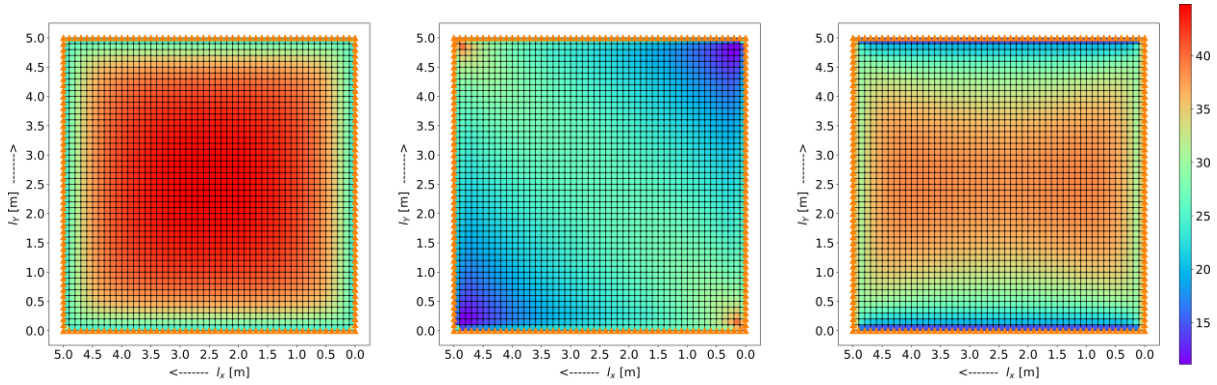

Figure 6: Summed influences on the principal moments m_1 of biaxial actuation (a), 45° (b) and X-Axis (c) uniaxial actuation.

A combination of the actuation modes with the highest influence for each control objective is shown in Figure 7. Actuation mode (a) combines elements with high actuation efficacy for the control of displacements and mode (b) for the control of principal moments m_1. Biaxial actuation is predominant for both control objectives, it avoids orientation issues of uniaxial actuation (cf. corner areas Figure 7 (a)) and the need for different actuator types is reduced. For these reasons, mode (c) which is a fully biaxial actuation mode is also considered in the following (Figure 7 (c)). Since no integrated fluidic actuators can be placed in the region of the supports (edges) and the influence is practically negligible regardless of the control objective, no active elements are placed along the edges (cf. Figure 7).

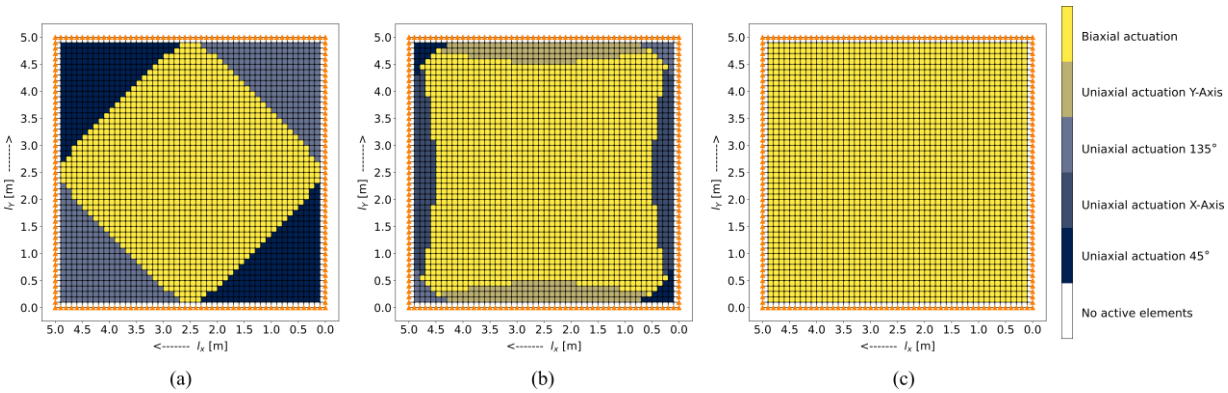

Figure 7: Actuation modes for reduction of deformations (a) reduction of bending moments (b) and complete biaxial distribution (c)

2.5 Adaptive system state

The efficacy of the combined actuation modes presented in section 2.4 is evaluated to reduce displacements and moments caused by vertical downward loading. A uniformly distributed load of 3 kN/m² and a quasi-point load of 3 kN applied on each element in turn are considered. To calculate the actuation input $\boldsymbol{u}^*$ (cf. equation (5)) the adaptive nominal state $\boldsymbol{y}_{ada}$ (control objective) is set to the negative passive state under the respective load case (i.e., complete reduction of translational and rotational deformations from the passive state). All three combined actuation modes (cf. section 2.4) are evaluated. Table 2 shows a summary of the results for the uniformly distributed load. The table indicates the maximum percentage reduction of translational displacements (column max. % red. *w*) in relation to the passive state, as well as an average value for all nodes to give an indicator of the global behaviour (columns avg. % red. *w* and avg. % red. m_1). A value of 100 % indicates complete compensation, and values below 100 % indicate that the target state is not fully achieved. Values above 100 % indicate a change of sign or deterioration from the passive state; for example, for the translational displacements, a value above 100 %, indicates an upward displacement or in the case of bending moments a change of sign or an increase of the respective bending moment. If only the node in the slab midspan, which shows the highest displacement and moment in the passive state is considered, all three approaches show very similar values near 100%. In some cases, the percentage change of principal moments m_1 is misleading. Large changes occur in areas where the bending moment is close to zero in the passive state. Therefore, the reduction of the maximum moment from the passive to the adaptive state is given (column homog. % red. m_1) as an indication of homogenization. To evaluate the effort required to achieve the adaptive state, table 2 also shows the required maximum actuation moments in the active system state. This value in column max. f_{act} indicates the maximum moment required for a single active element, which must be applied by an actuator. The average values refer to the average of the maximum moments of all active elements.

Table 2. Reduction of displacements and principal moment under a uniformly distributed load.

Control objective	**Uniformly distributed load 3 kN/m²**			
	max. % red. *w*	avg. % red. *w*	homog. % m_1	avg. % red. m_1
Displacements (mode a)	99.95	99.82	88.38	112.54
Principal moments (mode b)	103.09	99.68	69.54	124.59
Disp. + moment (mode c)	99.89	99.82	98.26	102.17

	max. f_{act} [Nm/m]	avg. f_{act} [Nm/m]
Displacements (mode a)	761.97	168.49
Principal moments (mode b)	1,363.98	285.89
Disp. + moment (mode c)	248.90	118.08

Table 3 shows a summary of the results under the quasi-point load and is structured analogously to table 2. As values close to the edges deviate strongly from the average, it is more informative to evaluate the maximum and the minimum reduction across all load cases instead of the average value. At the point of maximum displacement (slab midspan), all values are slightly above 100%, which indicates a marginal over-compensation.

Table 3. Reduction of displacements and principal moment under quasi-point load.

Control objective	**Point load 3 kN**			
	max. % red. w	min. % red. w	homog. % m_1	avg. % red. m_1
Displacements (mode a)	104.81	26.77	98.87	103.48
Principal moments (mode b)	„	„	98.88	„
Disp. + moment (mode c)	„	„	98,79	100.78

	max. f_{act} [Nm/m]	avg. f_{act} [Nm/m]
Displacements (mode a)	1.00	0.21
Principal moments (mode b)	4.00	0.88
Disp. + moment (mode c)	2.96	0.55

3. Result discussion

In most stiffness-dominated problems, compliance with deformation limits is the governing design criteria. However, if moments can be compensated at the same time, there is potential for reducing the required reinforcement. Compared to conventional slabs, the active load case plays a significant role in the design. The generation of the active moments through pressurization of the chambers can cause large in-plain stresses, (cf. Figure 1), making the actuation load dominant for the design. Concepts with low actuation loads are therefore advantageous.

As expected, the combined actuation mode based on the influence of displacement manipulation performs best in terms of displacement reduction. In comparison with the other actuation modes, the difference in displacement reduction is small while Larger differences can be observed in the moments and required actuation loads.

The summed influence plots provide information on how a single active element performs with regard to a control objective. However, no information can be gained about the interaction of several active elements with each other. Interaction means the superposition of the active moments as shown in Figure 8.

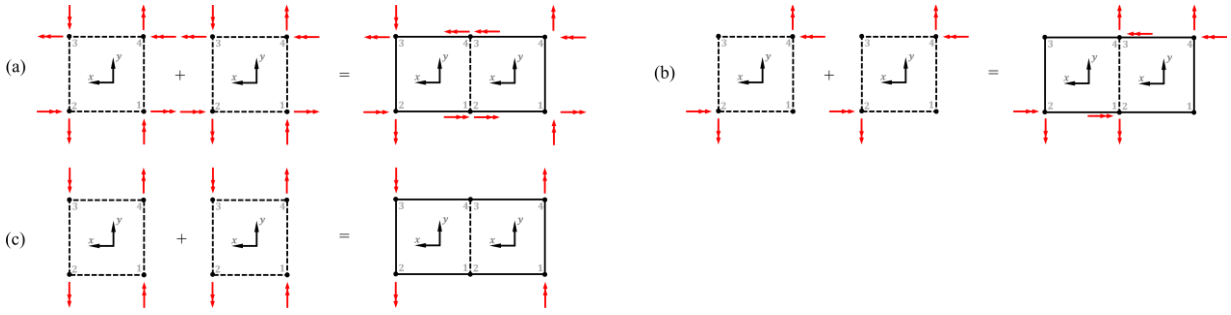

Figure 8: Superposition of actuation moments between adjacent elements using (a) biaxial actuation, (b) uniaxial actuation 45° and (c) uniaxial actuation along X-Axis.

This problem of superposition is also shown by the plots of the principal moment m_1 in the adaptive state (Figure 9). The least improvement in comparison to the passive state (Figure 9 (a)) is in the areas where different actuation modes interact.

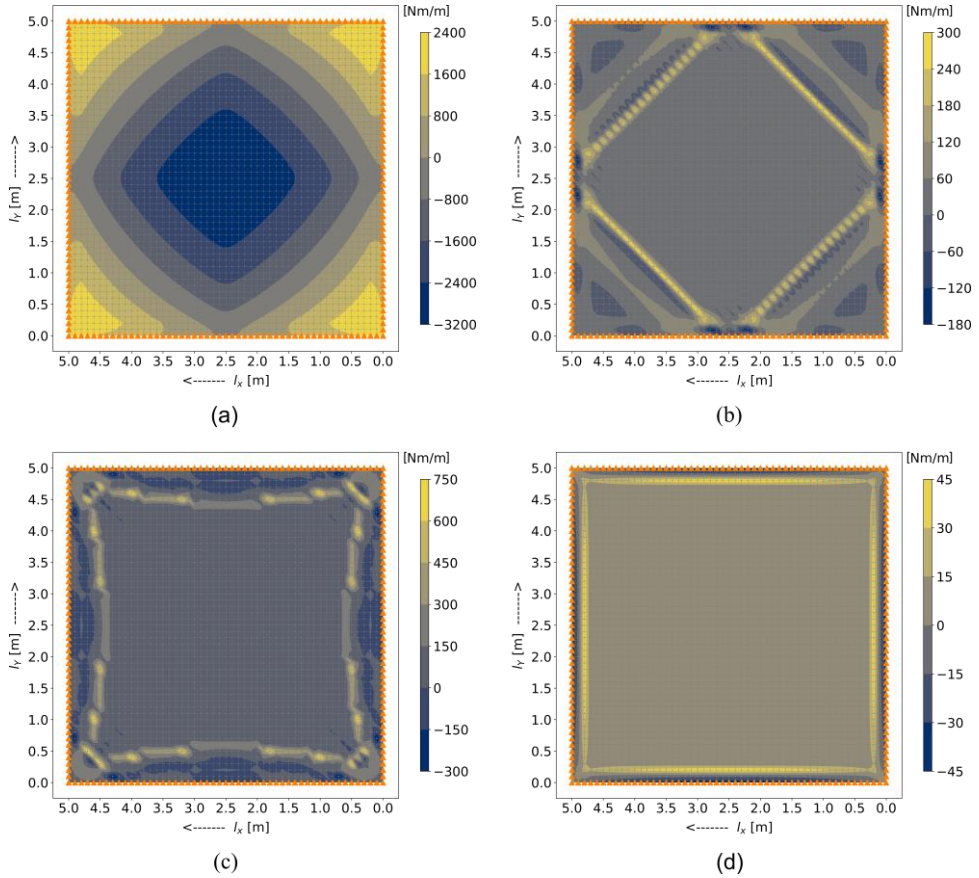

Figure 9: Plot of the principal moment m_1 under a uniformly distributed load of 3 kN/m² in the passive state (a) and in the adaptive state using the actuation mode for reduction of displacements (b) principal moment m_1 (c) and fully biaxial actuation (d)

A fully biaxial actuation has the greatest potential for an efficient superposition and therefore performs best. If biaxial actuation cannot be implemented for practical reasons (e.g., physical actuator limitations), uniaxial actuators can be placed according to their efficacy (i.e. influence) as shown in Figures 5 and 6.

4. Conclusion

This study shows that different combinations of actuation modes (directions of actuation) are advantageous depending on the choice of the control objective. Uniaxial actuation is more effective in certain regions of the slab when considering a single control objective.

To reduce simultaneously displacements and moments caused by external loads, biaxial actuation is the most effective strategy. In addition, the required actuation loads are lowest with pure biaxial actuation.

The theoretical investigations of this work can be used to specify requirements of the actuation concept on the actuator design.

Future work will evaluate the mass-savings potential for different actuation modes including simultaneous reduction of bending stresses and out-of-plane deflections. The actuation and actuator concept will also be investigated experimentally in future work.

Abstract

Open-top storage tanks are prone to buckling under wind loads due to the lack of top restraint. As a typical cylindrical shell, the buckling capacity is very sensitive to initial imperfections and the first buckling eigenmode is generally considered to be the most unfavorable imperfection shape, i.e., the consistent imperfection modal method (CIMM). However, this assumption has not been fully verified and the randomness of actual tank imperfections is not taken into account. In this study, a stochastic imperfection modal superposition method (SIMSM) is utilized to analyze the randomness of imperfections. The first ten buckling eigenmodes are superposed and corresponding participation coefficients are treated as random variables conform to normal distribution. Through Monte Carlo simulation, the stochastic structural buckling analyses are carried out on 1000 samples. The results show that the first buckling eigenmode is not always the most unfavorable initial imperfection shape, but the difference in buckling load factors between the two imperfect tanks can be minor. Besides, multi-parameter empirical formulas to accurately estimate the knock-down factor η of unstiffened and stiffened open-top tanks with different geometries are obtained through parameter fitting, which can provide safe guidance for structural design.

Keywords: open-top storage tanks, buckling of cylindrical shells, the most unfavorable imperfection, Monte Carlo simulation, knock-down factor

1. Introduction

Large petrochemical storage tanks mostly adopt the type of floating roof tank with open top, which are prone to buckling failure under empty conditions due to the combined effect of wind pressure on the outer and inner surfaces of tank walls and the lack of top restraint [1, 2]. It is difficult to repair the damaged storage tank, which will interrupt the production process, bring security risks, and may lead to serious economic losses and environmental pollution.

At present, many researchers have studied the wind-induced buckling characteristics of cylindrical tanks. For example, Flores and Godoy [3] analyzed the bifurcation buckling, nonlinear buckling and dynamic response of storage tanks damaged during hurricane Marilyn by numerical method. Portela and Godoy [4], Uematsu et. al [5] measured the wind pressure on grouped tanks in various arrangements through wind tunnel tests, and then the effects of arrangement pattern and gap spacing on the buckling of tanks were analyzed. The strengthening effects of the tank bottom were studied by Bu and Qian [6] and the optimal analysis to minimize the weight of wind girders for a given wind load was performed numerically. In addition, by conducting wind tunnel tests on elastic cylindrical shells, the relationship between the geometries and wind-induced buckling behavior has been studied in [7 - 9].

Since the diameter of a large storage tank can exceed 100 meters and the ratio of radius to thickness R/t is usually more than 2000, initial imperfections can greatly reduce the buckling capacity of this typical thin-walled structure. Godoy and Flores [10] studied the imperfection sensitivity of open-top storage tanks of four geometric sizes and compared the change of potential energy. Zhao and Lin [11] analyzed the wind-induced buckling of finite element tank models and found that short storage tanks are more sensitive to the first buckling eigenmode imperfection than the weld imperfection. In addition, in other studies covering initial imperfections of various shapes [10 - 13], it was also found that the first buckling eigenmode is more damaging. Regarding the first buckling eigenmode as the most unfavorable imperfection shape is called the consistent imperfection modal method (CIMM). The reduction of buckling capacity is usually represented by the knock-down factor η. In [11 - 15], the factor is between 0.5 and 0.9 for tanks with different geometries and imperfection amplitudes. In the American tank design standard API 650 [16], its value is fixed at 0.8, while Greiner and Derler [12] proposed that $\eta = 0.7$ under the effect of wind pressure, without considering changes in tank geometries and imperfection amplitudes. Chen and Rotter [17] discussed the influence of the first buckling eigenmode imperfections and obtained an empirical formula of buckling capacity for imperfect cylindrical shells, but only for the two cases of the aspect ratio $H/D = 1.5$ and 3.5. For large storage tanks with much smaller H/D, nonlinear buckling analysis based on the finite element method is usually required to predict the imperfection sensitivity.

However, the above studies only analyzed several imperfections of specific shapes and did not take into account the randomness of actual tank imperfections. For other structures such as spatial lattice shells, stochastic imperfection modal method considering the random imperfection of joints and members has been used in some studies [18, 19]. Although it has higher accuracy, the computing cost is usually large for complex structures. Liu et al. [20] proposed the stochastic imperfection modal superposition method (SIMSM) for a single-layer reticulated shell, which combines several modes to form the initial imperfection shape and takes the participation coefficients as random variables satisfying different probability distributions. The computing cost is lower than the traditional stochastic method.

Therefore, in order to reflect the randomness of tank imperfections and examine the reliability of CIMM and SIMSM, Monte Carlo simulations are firstly performed in this paper to sample the participation coefficients of buckling eigenmodes and determine the initial geometric imperfections. Then, an open-top cylindrical tank with $H/D = 0.2$ is selected as an example. The nonlinear buckling analysis is carried out to calculate the buckling capacity after applying the superposed initial imperfections. Based on the results of a large number of samples, the most unfavorable imperfection shape is determined and compared with the results of CIMM. Finally, considering the lack of quantitative method to evaluate the adverse effects of initial imperfections directly, the knock-down factor η of tanks with different geometric sizes and imperfection amplitudes are calculated through plenty of imperfection sensitivity analyses, and multi-parameter empirical prediction formulas are proposed to provide a reference for structural design.

2. Process of SIMSM

In the CIMM, only the first buckling eigenmode of the structure is applied with low computing cost, while the traditional stochastic imperfection modal method regards the imperfections of all nodes as random variables, which greatly increases the consumption of computing resources. The SIMSM combines these two thoughts, which uses the first m buckling eigenmodes of a tank, and coordinate deviations of all nodes are the stochastic superposition of the eigenmodes:

$$\{\Delta x\} = \sum_{i=1}^{m} c_i \{U\}_i \tag{1}$$

where $\{\Delta x\}$ is the node coordinate deviation caused by the imperfection, and c_i is the participation coefficient of the i-th eigenmode $\{U\}_i$, which is assumed to be a random variable conforming to normal

distribution. For each eigenmode, the modal displacement of all nodes should meet the following requirement:

$$\max\left(U_{1i},U_{2i},...,U_{ni}\right)=1 \tag{2}$$

where n is the total number of degrees of freedom of tank nodes. For the initial geometric imperfection with a given amplitude ξ, it is necessary to normalize the node coordinate deviation to obtain the imperfection $\{\Delta x\}'$:

$$\{\Delta x\}' = \xi * \Delta x / \max\left(\Delta x_1,\Delta x_2,...,\Delta x_n\right) \tag{3}$$

Then the node coordinates of the tank are:

$$\{x\} = \{x_0\} + \{\Delta x\}' \tag{4}$$

where $\{x_0\}$ is the initial node coordinate of the perfect tank, and $\{x\}$ is the modified coordinate with stochastic imperfection. Through Monte Carlo simulation, the geometric nonlinear finite element analysis is performed based on the j-th sampling result $\{c\}_j$, and then the critical buckling load factor λ_j is calculated. If the total number of samples is T, the load factor λ_{cr} corresponding to the most unfavorable imperfection shape obtained by the SIMSM is:

$$\lambda_{cr} = \min\left(\lambda_1,\lambda_2,...,\lambda_T\right) \tag{5}$$

3. Example analysis

3.1. Finite element model

The commercial software Abaqus is used for finite element analysis of the large open-top tank. The tank height H is 22.5m, diameter D is 112.5m, and the aspect ratio H/D = 0.2. The simplified uniform wall thickness is adopted as t = 15mm. The material is isotropic steel with elastic modulus E = 206Gpa, density ρ = 7850kg/m3, and Poisson's ratio v = 0.3. Since the buckling of the tank wall always occurs in the elastic range, the yield of material is not considered here [13].

The 4-node reduced integration element "S4R5" is used to avoid shear locking, and the thickness integration is calculated by the Simpson method with 5 integration points. Meshing the tank wall uniformly along the circumferential and axial direction. Through convergence analysis, the size of the quadrilateral element is about 0.5m × 0.5m, and the total number of elements is 28800. For the anchored tank with open top, the bottom of the finite element model is fixed and the top is free, as shown in Figure 1. The imperfection amplitude is set to $\xi = 1t$ and $\xi = 2t$.

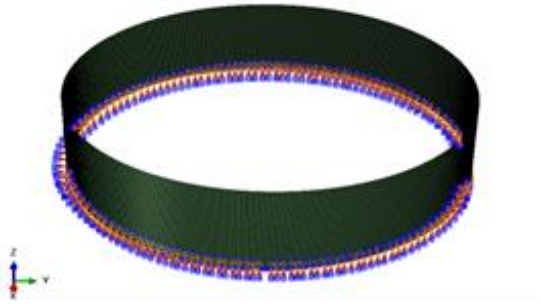

Figure 1. The finite element model of the open-top tank with H/D = 0.2.

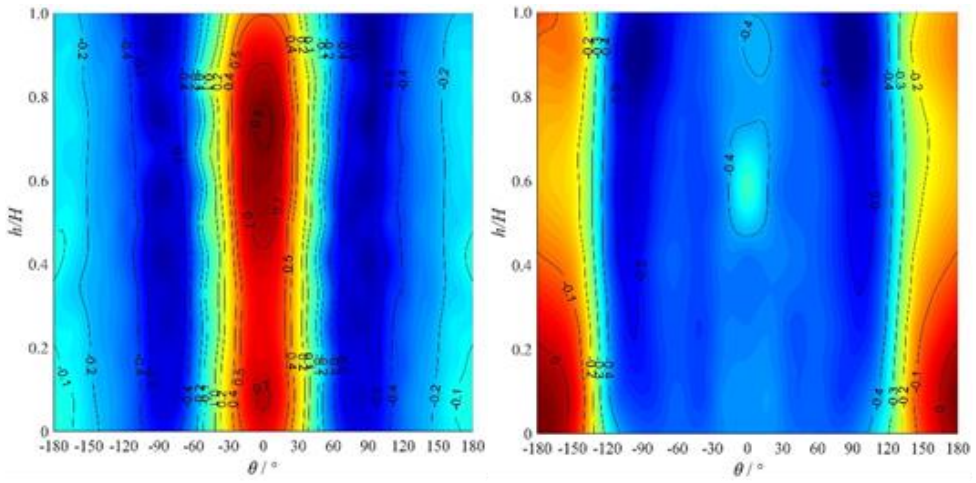


3.2. Wind load

The mean wind pressure on the outer and inner wall surfaces is obtained by wind tunnel tests on a rigid model with the same aspect ratio, as shown in Figure 2. Since the construction sites of large petrochemical storage tanks are mostly coastal ports, the boundary layer wind field of terrain type A (open country exposure) in Load Code [21] is selected. The scale ratio is 1:75, and the wind tunnel blocking rate is less than 5%. Pressure taps are arranged uniformly on the outer and inner surfaces to measure the wind pressure simultaneously. The effects of Reynolds number are not considered in the boundary layer flow field [22].

Figure 2. Wind tunnel test on the open-top tank model.

Taking the tank height H as the reference height, Figure 3 shows the mean wind pressure coefficient distribution on the outer and inner surfaces obtained from the test. It can be seen from the figure that the windward side of the outer surface is subject to large positive pressure, while the inner surface is subject to negative pressure. The superposition of the outer and inner wind pressure makes the thin-walled tank prone to buckling on the windward side.

(a) (b)

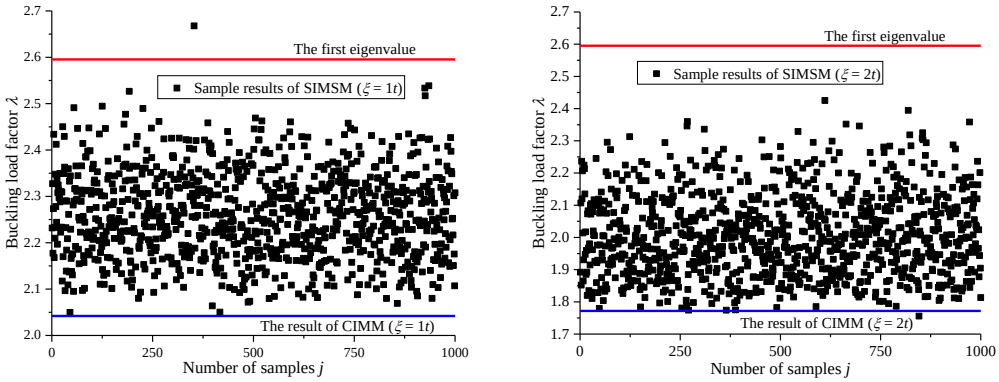
Figure 3. Mean wind pressure coefficient distributions on the tank surfaces: (a) outer surface, (b) inner surface.

3.3. Buckling analysis

Through eigenvalue buckling analysis, the first 10 eigenmodes of the tank are obtained and superposed stochastically. Change the initial coordinates of the finite element model nodes, and geometric nonlinear buckling analysis is carried out with the arc-length method. Figure 4 shows the buckling load factor for all samples when $\xi = 1t$ and $\xi = 2t$. The total number of samples is 1000 and the reference wind pressure is 100Pa.

It can be seen that when the imperfection amplitude $\xi = 1t$, the first eigenmode is the most unfavorable imperfection shape, indicating the reliability of CIMM. However, when $\xi = 2t$, the buckling load factor of samples moves down due to the increase of the imperfection amplitude, and even lower than the result

of CIMM, indicating that the first eigenmode is not always the most unfavorable imperfection shape. The lowest sample result of SIMSM is 1.756, and the result of CIMM is 1.772. The difference between the two is within 1%.



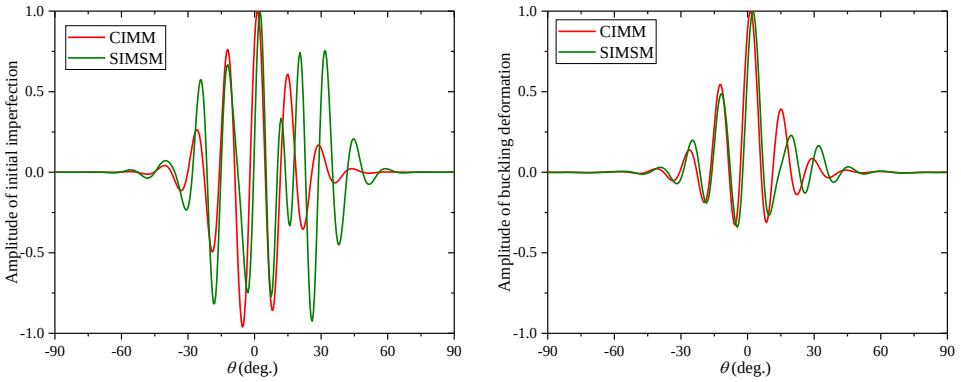


Figure 4. Comparisons of buckling load factors of the tank model.

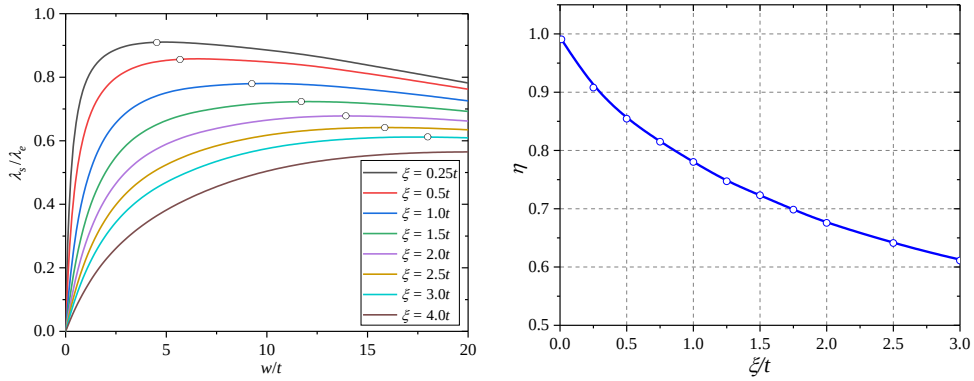
Figure 5 shows the differences of the initial imperfection shape and the critical buckling deformation between the CIMM and the most unfavorable sample of SIMSM when $\xi = 2t$. The initial imperfection shape is obviously different, especially on the right side, and the deviation degree of the most unfavorable sample is higher than that of the first eigenmode. But from the perspective of critical buckling deformation, the difference between the two is relatively small. The buckling deformation is almost the same except for a slight difference on the right side. Therefore, the buckling capacity and deformation obtained from the two methods are very similar. It is reasonable to regard the first buckling eigenmode as the most unfavorable initial imperfection shape for convenience in practical engineering.

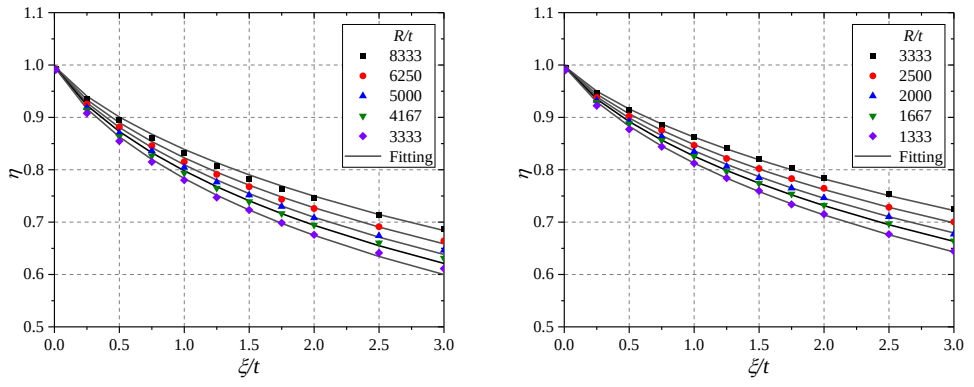


(a) (b)

Figure 5. Comparisons of the CIMM and the most unfavorable sample of SIMSM: (a) initial imperfection shape, (b) critical buckling deformation.

4. Quantitative analysis of imperfection sensitivity

Due to the lack of a direct evaluation method for the adverse effect of the initial imperfection, the change of wind-induced buckling capacity of storage tanks with different imperfection amplitudes ξ is studied by taking the first eigenmode as the initial imperfection shape. Figure 6(a) shows the load-displacement curves obtained by nonlinear analysis, where the vertical coordinate represents the ratio of the load factor λ_s to the first eigenvalue λ_e, and w represents the maximum radial displacement of the tank wall. The inflection point of the curve corresponds to the critical buckling state, where the knock-down factor η as shown in Figure 6(b) can be obtained.

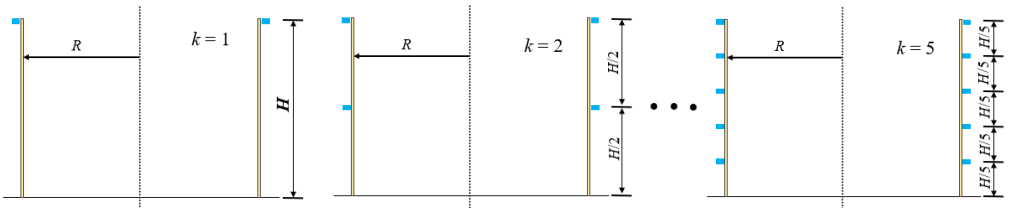


(a) (b)

Figure 6. Nonlinear analysis results of tanks with different imperfection amplitudes ξ: (a) load-displacement curves, (b) imperfection sensitivity curve.

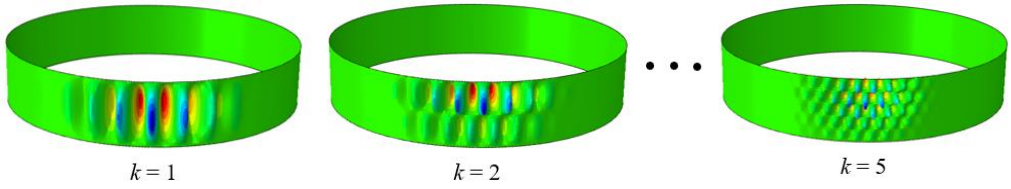
As can be seen from Figure 6, the nonlinearity of load-displacement curves becomes more significant as ξ increases. The tank undergoes the limit-point buckling instead of bifurcation buckling, and the critical buckling load factor decreases gradually. When the imperfection amplitude $\xi = 0.25t$, the buckling capacity of the tank decreases by nearly 10%, and when $\xi = 2t$, the capacity decreases by about 32%, indicating that the tank is very sensitive to initial geometric imperfections. However, the decline of the knock-down factor η gradually slows down. With the further increase of ξ, no obvious downtrend of the load-displacement curve occurs, and the radial displacement of the inflection point is increasing. Taking $w/t = 20$ as a limit [23], if no inflection point appears before this value, it is considered to be a limit deformation problem rather than buckling, so only cases of $\xi/t \leq 3$ are discussed below.

In order to obtain empirical fitting results, a large number of parametric analyses are carried out. Considering the common size range, a variety of tanks with aspect ratios H/D = 0.2, 0.5, 1.0 and 1.5 and wall thicknesses t = 5, 6, 8, 10, 12, and 15mm are selected to analyze the influence of geometric parameters on imperfection sensitivity. The results of tanks with H/D = 0.2 and 0.5 are shown as the scatters in Figure 7. It can be seen that tanks with smaller R/t are more sensitive to initial imperfection. When R/t = 3333, η of the tank with H/D = 0.2 is lower than the result of H/D = 0.5 under the same imperfection amplitude, indicating that the initial geometric imperfection has a more significant adverse effect on the lower tank.



(a) (b)

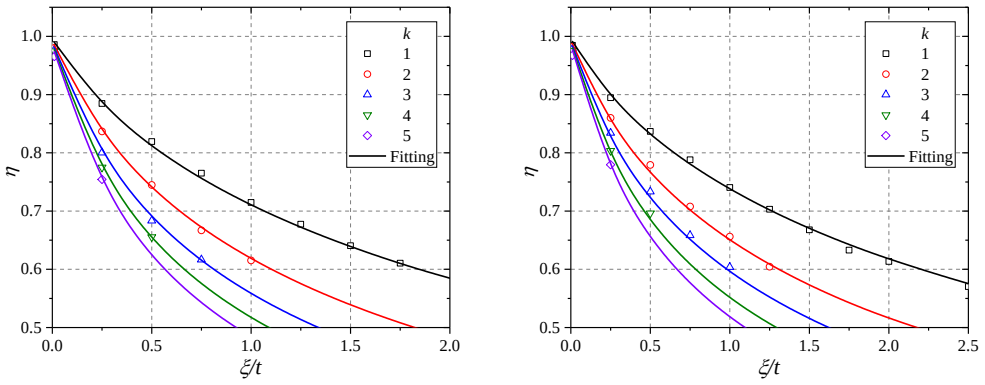
Figure 7. Imperfection sensitivity and fitting results of tanks: (a) H/D = 0.2, (b) H/D = 0.5.



By fitting the geometric parameters of all analyzed cases, an empirical formula for the knock-down factor η is obtained as Equation (6). The fitting curves are shown in Figure 7, which are close to the scatters and have high accuracy.

$$\frac{1}{\eta}=1+4.2\left[\frac{\xi}{t}\left(\frac{H}{R}\right)^{-3/4}\left(\frac{R}{t}\right)^{-1/2}\right]^{4/5} \tag{6}$$

For actual tanks built according to the design standard [16], several wind girders (stiffener rings) are usually installed on the wall to strengthen the tank and improve its buckling capacity. The bending stiffness of wind girders are large, which can be regarded as rigid compared to the tank wall generally [24] and also change the imperfection sensitivity of the tank. Figure 8 shows the arrangement of wind girders and their different first buckling eigenmodes, where k represents the number of wind girders. k = 1 is to set the top wind girder, and other girders are arranged at equal intervals in the middle when k > 1.



(a)

(b)

Figure 8. The arrangements of wind girders and their different first buckling eigenmodes: (a) arrangements with different k, (b) the first buckling eigenmodes.

The scatters in Figure 9 show the imperfection sensitivity of stiffened tanks with H/D = 0.5 and 1.0. Compared to the unstiffened tank in Figure 7, the stiffened tanks are significantly more sensitive to initial imperfections. For the case of the top stiffened tank with k = 1 in Figure 9(a), the knock-down factor η is about 0.71 when $\xi = 1t$, while the value for the unstiffened tank of the same size is about 0.86. It can be considered that wind girders can reduce the effective height of the tank, that is, a tank with smaller H/D and higher buckling capacity, which is more sensitive to initial imperfections with lower knock-down factors.

(a) (b)

Figure 9. Imperfection sensitivity and fitting results of stiffened tanks: (a) H/D = 0.5, R/t = 3333, (b) H/D = 1.0, R/t = 1667.

Through the parameter fitting of all cases, an empirical formula for the knock-down factor η of the stiffened tank with k wind girder(s) is obtained, as shown in Equation (7). The fitting curves in Figure 9 are in good agreement with the scatters, indicating that the formula has high prediction accuracy.

$$\frac{1}{\eta}=1+10.5\left[\frac{\xi}{t}\left(\frac{H}{kR}\right)^{-3/4}\left(\frac{R}{t}\right)^{-1/2}\right]^{4/5} \tag{7}$$

5. Conclusion

The SIMSM is utilized to analyze the effect of initial geometric imperfections on the buckling of open-top storage tanks, which can reflect the randomness of imperfections and save the computing cost. Nonlinear analysis results show that the first eigenmode is not always the most unfavorable imperfection shape, or even quite different from it, but the buckling capacity and critical deformation between the two imperfect tanks are relatively close. It is reasonable to apply the first eigenmode (the CIMM) for convenience in practical engineering.

Initial imperfections can result in a significant reduction in buckling capacity. For the unstiffened tank with H/D = 0.2, the knock-down factor η is about 10% when the imperfection amplitude $\xi = 0.25t$, and about 32% when $\xi = 2t$. In addition, tanks with smaller H/D and R/t, as well as stiffened tanks with wind girders are more sensitive to initial imperfections. Through plenty of case analysis and parameter fitting, empirical formulas to accurately estimate the knock-down factor of unstiffened and stiffened tanks with different geometries are obtained, which can provide safe guidance for structural design.

Experimental study on estimation of water content and compaction of soil by SDS test

Abstract

Much of the land in Japan is mountainous, and embankments sites are often used.In new embankments, harmful settlement of buildings is often occurred.In Japan, when designing small buildings, the soil is often investigated by the screw weight sounding test (SWS test).This test is often used because it is quick and inexpensive.The purpose of the SWS test is to estimate the strength of the soil, and it cannot clearly estimate the soil type, water content ratio, and compaction degree, which greatly affect settlement.On the other hand, the screw driver sounding test (SDS test) is an improved version of the SWS test.The SDS test, the rotational resistance torque of the rod is measured. It provides more information about the soil than the SWS test.The authors considered that it is possible to estimate the water content ratio and the compaction degree of the soil from the measured torque. In order to verify the validity of this assumption, several simulated soils with different water content and compaction degree were created, and the correlation between the measured values of the SDS test, water content, and compaction degree was confirmed. The target soils were decomposed granite soil and Kanto loam, both of which have been frequently reported to cause settlement damage in Japan. The results showed that the ratio of vertical load energy to rotational resistance torque energy was correlated with the compaction degree, and that the amount of change in the ratio depended on the water content, and that the tendency of the correlation differed depending on the soil type.

1. Introduction

Japan has many mountainous areas. For this reason, buildings are often constructed on the ground with embankments. In this case, if the ground is not sufficiently compacted during construction, there is a possibility of harmful settlement occurring in the building. To verify this possibility, it is necessary to accurately understand the characteristics of the ground in question. To do this, it is necessary to perform indoor tests with samples collected, and to collect samples properly, extensive investigative equipment is required. For small-scale buildings where cost reduction is desired, a simple investigation method that can determine the presence or absence of subsidence on-site is required. On the other hand, there are construction standards for embankments[1], and the specified compaction degree varies depending on the purpose of the embankment. The specified value is determined based on past examples and numerous experiments to ensure that harmful subsidence does not occur for the weight of commonly-sized buildings according to their intended use. If this compaction degree can be estimated through a simple ground investigation, it would have significant social significance.

As a simple ground investigation method, there is the Screw Driver Sounding (SDS) test[2], which involves rotating a rod into the ground and measuring the resistance. The purpose of this paper is to estimate the compaction degree of the ground using the SDS test.The compaction degree of the ground is the ratio of the density of the ground to the density at which the ground is compacted to the limit. This

limit state of compaction is reproduced by mechanically compacting the soil taken from the ground and reducing the internal air content as much as possible. At this time, the amount of air that can be reduced varies depending on the soil water content, so the density is determined by changing the water content. The water content at which the highest density is achieved is called the optimum water content. The dry density of the soil at the time when the highest density is achieved is called the maximum dry density. In this paper, a simulated ground was created using soil samples with varying compaction degrees and moisture contents. The SDS test was conducted on the simulated ground, and the relationship between the resistance energy obtained and the compaction degree and moisture content was investigated. In Japan, settlement damage often occurs when using either decomposed granite soil or Kanto loam as material for embankments. This paper focuses on these two types of soil samples. Decomposed granite soil is soil that is formed by the weathering of slowly cooled lava and has properties of sandy soil. Kanto loam is soil derived from deposited volcanic ash and has properties of clayey soil. The study investigates the effect of these differences on the SDS test and considers the possibility of soil classification based on these differences.

2. Strength measurement experiment by SDS test

2.1. Outline of experiment

We created model ground with varying water content and compaction degree, and conducted SDS tests. The properties of the test soils obtained from the soil test and the experimental conditions are shown in Table 1. The water content of the test samples was set to be higher or lower than the optimum water content. Hereafter, these conditions are referred to as high water content and low water content, respectively. The target values for the compaction degree of the test samples were set to 70%, 75%, 80%, 85%, and 90%. In the case of the decomposed granite soil, we were able to create test samples with a compaction degree of 90% with room to spare, so we also created test samples with a target compaction degree of 93%.

The preparation method of the test specimens is described. A steel mold (Figure 1, inner diameter 298.5 mm, height 985 mm, thickness 10 mm) was used as the soil tank. The sample soil was packed into the mold with a certain regularity, and the compaction degree of the sample soil was controlled by the density of the soil at that time. The mold was divided into 16 layers by height, and the weight of the sample soil to be packed in one layer was determined from the specified density. After placing the soil into a mold, a circular loading plate with a diameter of 280 mm was placed on top of it.The weight was repeatedly dropped onto the loading plate until the volume of the soil matched the volume of each layer. The volume of the soil was controlled by the distance from the top of the mold to the soil surface, and the distance was measured each time the weight was dropped. The weight of the compacted soil sample m_i was calculated using equation (1), where D_c is the degree of compaction, ρ_{dmax} is the maximum dry density, w is the water content, and V_i is the volume of each layer.

$$m_i = \frac{\rho_{dmax}\left(\frac{1+w}{100}\right)V_i D_c}{100} \tag{1}$$

Figure 1 shows photographs of the mold and test specimen used. The SDS test was performed using Geocarte III (manufactured by Nitto Seiko Co., Ltd.). An overview of the SDS test will be described in the next section. Three SDS tests were conducted on the same test specimen with the position changed. Figure 2 shows the appearance during the test.

Table 1. Experimental conditions

Soil name		Kanto loam	Decomposed granite soil
General	Density of soil particle ρ_s [g/cm^3]	2.680	2.702
	Natural water content ratio ω_n [%]	49.5	12.2
Particle size	Stone(over75mm) [%]	0	0
	Pellet(2~75mm) [%]	0.2	15.4
	Sand(0.075~2mm) [%]	17.1	62.1
	Silt(0.005~0.075mm) [%]	42.2	15.6
	Clay(under0.005mm) [%]	40.5	6.9
	Maximum grain size [mm]	4.75	19.00
Compaction	Maximum dry density $\rho_{d\max}$ [g/cm^3]	0.816	1.699
	Optimum water content ratio ω_O [%]	74.7	16.2
	Low water content ratio ω_L [%]	60.0	10.0
	High water content ratio ω_H [%]	85.0	20.0
	Target values for the compaction degree [%]	70,75,80,85,90	70,75,80,85, 90,93

Figure 1. Steel Mold (left) and test specimen (right)

Figure 2. During the test

2.2. Penetration energy by SDS test

Figure 1 shows the procedure of SDS test. The load is applied to the constantly rotating penetration rod, and the load is increased every rotation. The load increases in six steps from 0.25 kN to 1.00 kN until the penetration depth reaches 25 cm. After that, the load is kept constant at 1.00 kN while the penetration rod continues to rotate. When the penetration depth reaches 25 cm, the load is removed, and the reloading and rotation penetration begin. During this test, the load, rotation torque, and penetration depth are measured.

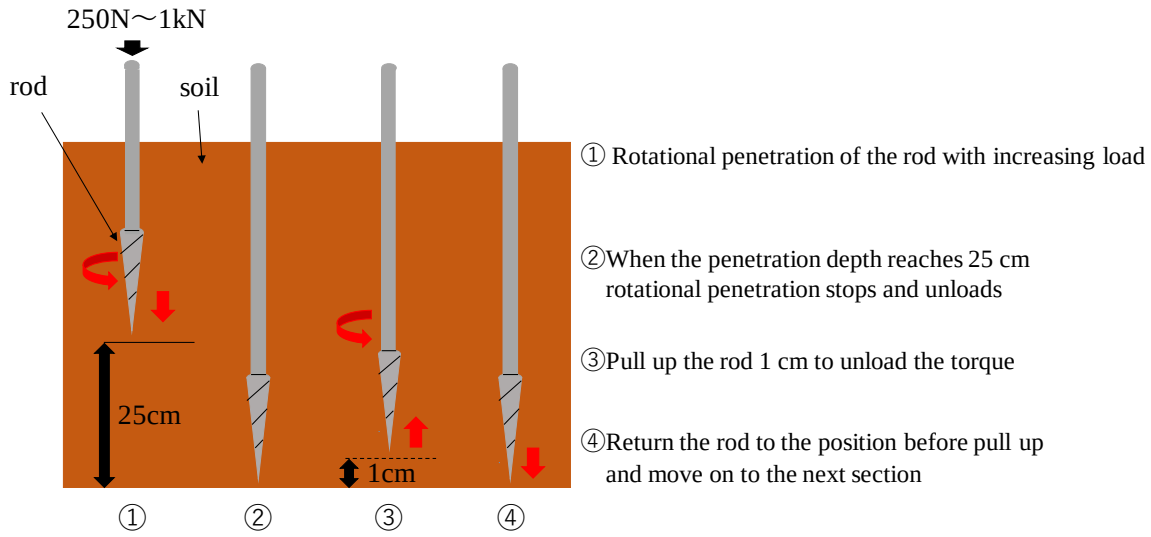

Figure 3. procedure of SDS test

In this paper, we focus on the energy *dE* required for penetration in each loading phase. *dE* is considered to be the sum of the energy weight *EW* obtained from the load *W* and the amount of penetration, and the energy torque *ET* obtained from the maximum torque *T* during one rotation. These values are defined as equations (2) through (4)[2].

$$ET = \pi T dn_{ht} \qquad T = T_a - T_f \tag{2}$$

$$EW = W ds_t \qquad W = W_a - W_f \tag{3}$$

$$dE = ET + EW \tag{4}$$

T is the corrected torque, T_a is the measured torque, T_f is the horizontal circumferential friction force and dn_{ht} is the number of half turns. W is the corrected load,W_a is the measured load, W_f is the vertical circumferential friction force and d_{st} is the 25 cm unit penetration.

2.3. Result of experiment

Figures 4 and 5 show examples of *ET* and *EW* obtained from SDS tests. Figure 4 is for a decomposed granite soil and Figure 5 is for a Kanto loam, both at 90% compaction degree. The vertical axis is the depth of penetration and the horizontal axis is *ET* or *EW*. Low water content is indicated by blue lines (legend GL, LL) and high water content by red lines (GH, LH). We focus on the range of 0.25 to 0.75 m because the penetration depths of 0.00 to 0.25 m and 0.75 to 1.00 m are immediately after penetration or close to the mold bottom plate, resulting in underestimation or overestimation of the values.

ET and *EW* increase as the load increases, and decrease when unloading occurs (when the penetration depth reaches 25cm). It can be seen that in the high water content sample, the penetration depth reached 25cm in the first or second load stage, whereas in the low water content sample, it reached the final load stage.

In *ET*, despite the same compaction degree, the values of low water content ratios are about 2-3 times higher than those of high water content ratios. In addition, it can be seen that *ET* shows a nonlinear relationship with penetration depth except for the Kanto loam, which has a small number of measurement points, indicating that decomposed granite soil has a larger variation in each 25cm interval.

In *EW*, both low and high water content ratios show a linear relationship with penetration depth. Since high water content ratios have a larger penetration depth even with a smaller load, *EW* is large from the initial load stage. Furthermore, there is no significant difference in the maximum values of *EW* based on water content ratios.

Indicating that the ratio of *ET* to *EW* varies with water content ratios. In particular, in the case of low water content ratios, there is a tendency for *ET* to increase significantly.

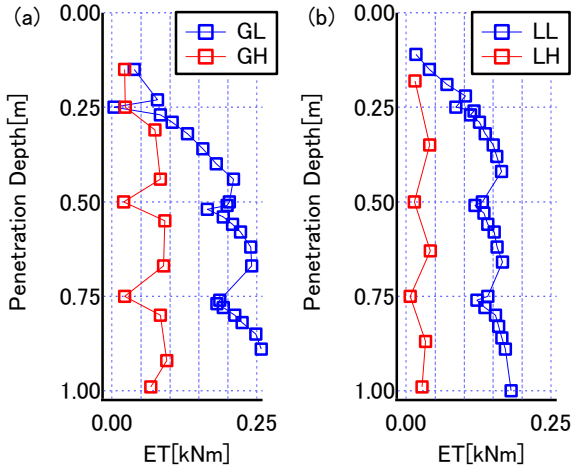

Figure 4. Variation of *ET* with depth of penetration

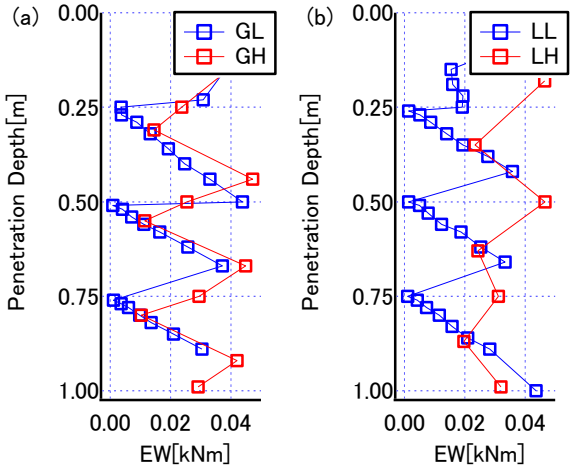

Figure 5. Variation of *EW* with depth of penetration
(a) decomposed granite soil, (b) Kanto loam

3. Determination of the compaction degree and soil texture by total penetration energy

3.1. Interpolation and evaluation methods for penetration energy

We investigate the relationship between energy (ET, EW) obtained from SDS testing and the degree of compaction or soil properties. In SDS testing, the load is gradually increased in stages, so in coarse soils, the penetration rod reaches 25cm in the initial load stages, while in dense soils, it may not reach 25cm even in the final load stage. Therefore, we considered that evaluating each energy at a specific load stage would not provide a consistent criterion. Instead, we decided to evaluate the total energy within each 25cm interval.

As mentioned above, the number of measurement points within each interval varies depending on the soil conditions. To evaluate the total energy under the same conditions, we normalized the area under the approximate curve for each measurement point by the length of the interval. The approximate curve was created using a power function for *ET* and a linear function for *EW* based on the distribution trend shown in Figure 3. When there were insufficient measurement points, interpolation points were added. Figure 4 shows a conceptual diagram of the process of creating an approximate curve. The vertical axis represents *ET* and the horizontal axis represents depth in 25cm increments. Figure 4(a) shows the case where there is only one measurement point, in which case the approximate curve is a linear function with a slope of 0. Figure 4(b) shows the case where there are two measurement points, with an interpolation point added at the midpoint of the two points. Figure 4(c) shows the case where there are three or more measurement points, and a power function was used to approximate all the measurement points. *EW* was also approximated using the same method with interpolation points added as necessary.

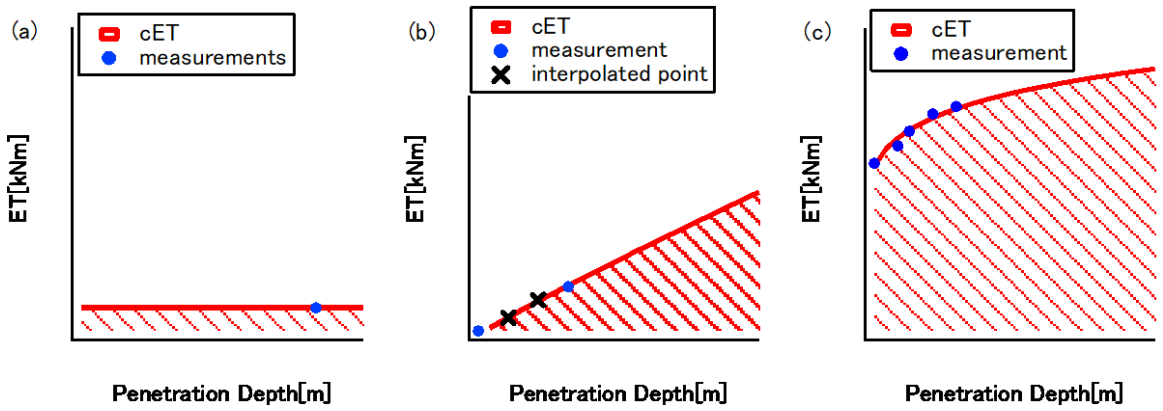

Figure 6. *ET* Approximate curves and interpolation points of *ET*:
(a) In the case of 1 point, (b) In the case of 2 points, (c) In case of 3 or more points

The total energy torque obtained from the *ET* through the above procedure is referred to as *cET*, and the total energy weight obtained from the *EW* is referred to as *cEW*. Furthermore, their sum is the total penetration energy, referred to as *cE*. *cET* and *cEW* are calculated using equations (5) and (6).

$$cET = \frac{\int_{0.25}^{0} az^b dz}{0.25} \tag{5}$$

$$cEW = \frac{\int_{0.25}^{0} (az + b) dz}{0.25} \tag{6}$$

The coefficients *a* and *b* in the equations are coefficients for creating approximate curves, and the values are obtained by the least-squares method using the measured *ET* and *EW* and the 25cm unit depth *z* at those measurement locations. The values of *a* and *b* are determined separately for each penetration point and each 25cm interval (depth range of 0.25 to 0.50 m and 0.50 to 0.75 m).

3.2. Relationship between compaction degree, water content ratio and total penetration energy

The relationship between total penetration energy *cE*, compaction degree *Dc*, and water content is shown in Figures 7 and 8. Figures 7 is for a decomposed granite soil and Figures 8 is for a Kanto loam. (a) is for the penetration depths of 0.25 m to 0.50 m and (b) is for the 0.50 m to 0.75 m. The vertical axis is *cE* and the horizontal axis is the compaction degree *Dc*. Although each specimen was prepared with the compaction degree in Table 1 as the target value, some specimens were over- or under-compacted because fine adjustment could not be made by dropping weights. In these cases, the density was recalculated using the amount of settlement caused by the falling of the weight, and the compaction degree was corrected. The red markers in the figures indicate specimens with high water content (legend names GH25, GH50, LH25, LH50), the blue markers are low water content (GL25, GL50, LL25, LL50) and the black markers are optimum water content (GO25, GO50, LO25, and LO50). The lines in each color in the figure are approximate curves obtained from those colored markers. The approximate curves were created using an exponential approximation for the decomposed granite soil and a linear approximation for the Kanto loam, based on the trend of their distributions.

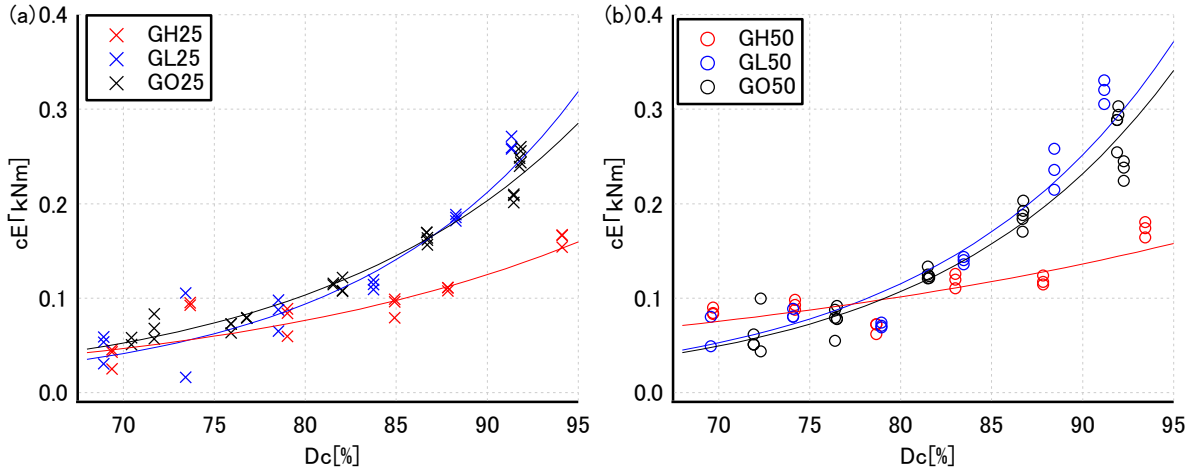

Figure 7. Relationship *cE* and compaction degree Dc of decomposed granite soil:
(a) 0.25～0.50m section, (b) 0.50～0.75m section

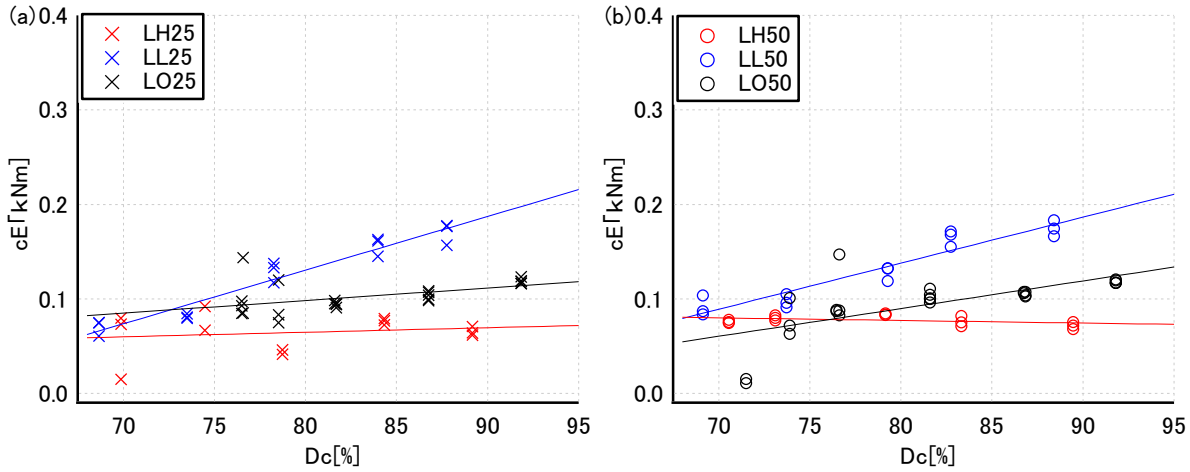

Figure 8. Relationship *cE* and compaction degree Dc of Kant loam:
(a) 0.25～0.50m section, (b) 0.50～0.75m section

In the case of decomposed granite soil, for all water contents, in specimens with a compaction degree of 70-80%, the penetrating rod reached 25cm at the first or the next stage of loading. As a result, the value of *cE* is very small and the change in *cE* with respect to the degree of compaction is minimal. When the compaction degree exceeded 80%, *cE* increased quadratically. *cE* values at low and optimum water contents were similar, while *cE* at high water contents was smaller than those at the other two levels. Therefore, it can be concluded that the strength does not decrease even if there is less water than the optimum water content, but it decreases with higher water content.

The *cE* for Kanto loam increased linearly. Differences due to the water content became apparent in *cE* from a compaction degree of 70%. In the case of high water content, the rod reached 25cm in the first or second load stage for all compaction degrees of the test specimens, resulting in a very small *cE* value. On the other hand, for low water content, the change in *cE* due to compaction degree was significant, and at a compaction degree of 90%, *cE* was about three times larger than that of the high water content case. This indicates that the strength decreases with higher water content than the optimum water content, and increases with lower water content.

Comparing the *cE* of the decomposed granite soil and the Kanto loam, the *cE* of the Kanto loam is larger at lower compaction degrees, and the *cE* of the sand becomes larger as the compaction degree increases. Furthermore, comparing (a) and (b), it can be seen that *cE* is larger at greater depths. This trend is particularly strong in the case of decomposed granite soil.

3.3. Soil identification by penetration energy

Next, we will discuss the possibility of soil identification. Figure 9 is a graph that summarizes the previous data with *cET*/*cEW* on the vertical axis and *Dc* on the horizontal axis. The circle markers represent the decomposed granite soil and the cross markers represent the Kanto loam. The dashed line is the approximate curve for decomposed granite soil, and the solid line is the approximate curve for Kanto loam.

For decomposed granite soil, *cET*/*cEW* increases rapidly from a compaction degree of around 80%, and changes exponentially. For Kanto loam, it changes linearly. In both cases, it can be seen that the slope changes depending on the water content. Therefore, it is possible to identify the soil type by using *cET*/*cEW* when the compaction degree is high and the water content is optimal or less. In cases where the compaction degree is low or the water content is high, it is difficult to identify the soil type because cET/cEW interferes with each other. In this paper, two type of soil was used, so the trend is limited. In the future, by increasing the number of soil samples, it is expected that more prominent trends can be confirmed.

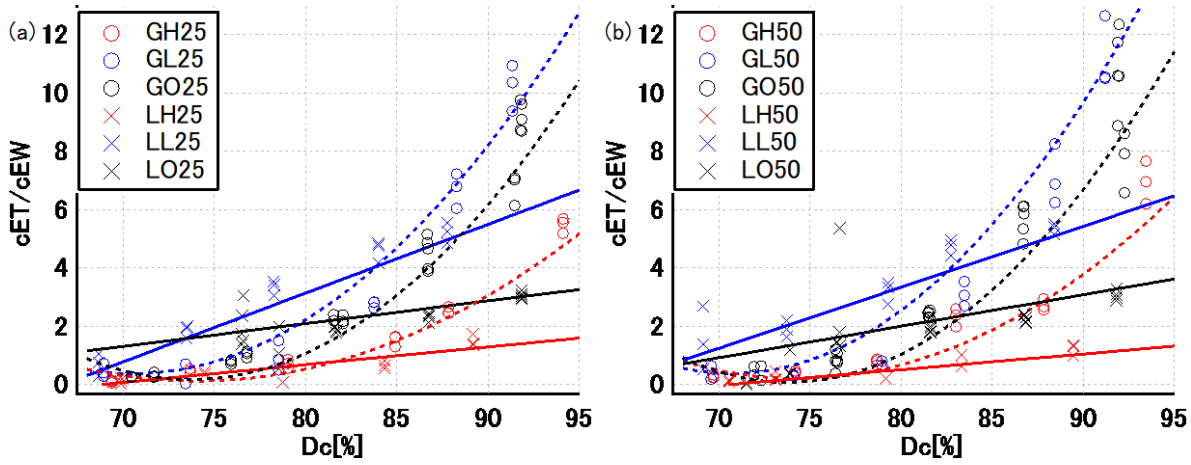

Figure 9. Relationship *cET*/*cEW* and *Dc*: (a) 0.25～0.5m section, (b) 0.50～0.75m section

4. Conclusion

The findings of this paper are as follows. When compaction is performed using the same type of soil, the lower the water content, the greater the strength, and differences in water content can result in a threefold or greater difference in penetration energy for the same compaction degree. In the case of decomposed granite soil, there is a difference in energy depending on the compaction depth of the soil, but there is not much difference in the case of Kanto loam soil.

When the vertical axis is *cET*/*cEW* and the horizontal axis is Dc, the energy increases quadratically for decomposed granite soil and linearly for Kanto loam, suggesting that *cET*/*cEW* may be able to discriminate between sandy soil and clayey soil. As a future prospect, we will conduct experiments at deeper depths to examine the correlation by depth method. We also plan to conduct experiments on soils other than decomposed granite soil and Kanto loam.

Abstract

Snow-induced building collapses are on the rise in long-span structures, as extreme weather events such as blizzards become more frequent. According to the accident investigation, the sudden increase in the snowfall and unbalanced snow distribution, which leads to an excessive snow load in a local area, are the main reasons for such collapses. However, due to the lack of related data, the rationality of Chinese load code for building structures need a further investigation. Therefore, based on a revised multiphase model, the numerical simulation of snowdrifts on a long-span curved roof was carried out with different inflow velocities and inflow directions. It is found that the unbalanced distribution of snow on the roof becomes more obvious with the increasing inflow velocity, showing a half-span snowdrift on the leeward side. Furthermore, for different inflow directions, the snow distribution pattern is mainly related to the building cross section parallel to the downstream direction. When the direction of the incoming flow is perpendicular to the eave, it is easier to form an uneven distribution.

Keywords: snow load, non-equilibrium, curved roof, inflow velocity, inflow direction

1. Introduction

Snow-induced building collapse often occurs in long-span structures, for example, the collapse of the Katowice Trade Hall (Poland, 2006), the collapse of the Minnesota Vikings membrane stadium (USA, 2010) and the collapse of an ice rink in Bad Reichenhall (Germany, 2006), etc. Generally, under specific conditions of snowfall and wind, a large amount of snowdrift will form on and around buildings, where the wind velocity is sufficiently low enough to allow snow particles to settle down. The uneven local snow load is believed as one of the main causes of building collapse or cracking (O'Rourke [1]). Therefore, it is very necessary to develop suitable methods to analyze and predict hazards due to snowdrift in built-up environments with high accuracy. Of all the methods, field measurements and experiments have been regarded as the most reliable approaches to deal with the snowdrift related problems. However, their applicabilities are limited to specific weather conditions and similarity criterion, respectively. Fortunately, computational fluid dynamics (CFD) has been applied to simulate snowdrift around buildings recently, based on the dramatic increases in computational power together with advances in computer software (Tominaga [2]).

Snowdrift on the ground is usually described as a solid particle transport process. Depending on whether the wind velocity reaches a threshold value, three different particle transport mechanisms are defined, namely, creep, saltation and suspension. Creep is a subprocess in which snow particles roll on the surface under a height below 0.01 m; saltation is a transport process at the height of around 0.01~0.1 m, in which

snow particles leap up and jump on the snow surface; suspension is a phenomenon in which particles are blown up into the air and transported far downwind. Among the subprocesses, saltation is the dominant particle transport process which causes approximately 67% of the overall drifted mass (Delpech et al. [3]). Therefore, many CFD studies have focused on the saltation transport process in a boundary layer flow developed on a flat terrain. However, snowdrift on a building roof is more complex because of the complicated interaction between snow particle motion and flow field affected by building geometry (Tominaga [2]). So far, only a few attempts have been made to apply CFD approach to roof snow issues. Thiis et al. [4] predicted the snow distribution on the curved roof of a sports hall under specific weather conditions and compared the results with field measurements. Generally, the simulated snow distribution pattern fit the measured shape well. Tominaga et al. [5] predicted the snowdrift on a gable roofed building with different roof slopes and wind velocities. In the study, additional snowdrifts formed on the leeward side under different inflow velocity conditions were compared against a series of field measurement results (Thiis et al. [6]). The simulation results generally corresponded well with the observational data for the exposed roof. Recently, Zhou et al. [7] proposed a quasi-steady method to simulate the redistribution of snow on a flat-roof building. The snow redistributions obtained from the numerical simulation agreed well with those obtained in the wind tunnel tests.

It should be noted that the relations and parameters used in the past snowdrift modeling have been mostly derived empirically from observations or experiments. Many of observations and experiments were conducted based on a simple drifting boundary layer developed on a flat plane. Among the empirical relations, an estimation model for the transport rate of drifting snow attributable to saltation Q_{sal} proposed by Pomeroy and Gray [8] has often been used to predict the snow concentration within the saltation layer. The proposed relation gives a saturated transport rate of drifting snow where the air-snow mixed flow has been fully developed. Okaze et al. [9] further investigated the prediction accuracy of the empirical relation for the non-equilibrium flow in a developing saltation layer by conducting a wind tunnel experiment. Through comparison, the values obtained from Pomeroy's relation were greatly overestimated in almost the entire region. Thus, it is problematic to apply Pomeroy's relation (which is based on the equilibrium condition) to a flow around a building in which drifting snow is in non-equilibrium state because of the complex flow field. It is necessary to further consider the applicability and validity of the modeling of the saltating process at the developing stage (non-equilibrium state). Tominaga et al. [10] lately proposed a new approach to account for the developing process of drifting snow with a one-way coupled snow concentration diffusion equation, instead of the empirical saltation flux relationship. The new approach made some improvement, but some substantial deviations remained from experimental measurements. It was partly caused by the fact that the effect of snow particles on flow field and the increasing drifting snow density induced by building blocking were not fully considered.

Besides the non-equilibrium developing process, the interaction between snow particle motion and fluid flow should also be accounted for. In this respect, Naaim et al. [11] introduced additional terms into the transport equations of k and ε to consider the turbulence damping by the presence of particles, based on a drifting snow density approach, which was firstly proposed by Uematsu et al [12]. Similarly, Okaze et al. [13] developed a new k-ε model to consider the aerodynamic effects of snow particles on the flow field, based on the canopy model concept for moving obstacles [14]. Three extra terms were added to the governing equations of air flow momentum, k and ε, respectively, to express the damping effect. Unfortunately, both approaches did not solve a snow phase momentum equation. Instead the snow velocity was set equal to a constant or a proportion value of wind velocity derived from empirical and experimental considerations [15]. This may be reasonable for a flow over a flat terrain but does not work appropriately for the flow around buildings. To fully account for the interaction between snow particle motion and fluid flow as well as the drifting snow density at a developing stage, a two-way coupled two-phase CFD model was developed and adopted for the simulation of snowdrift development on a long-span roof. Besides properly accounting for two-way coupling of air and snow phases, this CFD model is free from all equilibrium assumptions used in the past approaches introduced above.

In this study, Firstly, the CFD prediction accuracy for the snow distribution on a long-span curved roof was validated by comparing the simulated balanced and unbalanced results with the Chinese load code (MOHURD, [16]) and the design code developed by ISO4355 [1]. Thereafter, the snowdrift characteristics were investigated with different inflow velocities including 2 m/s, 3 m/s and 4 m/s, based on the validated CFD model. Finally, the effect of wind direction on snowdrifts was explored with three inflow directions including 0°, 45° and 90°.

2. CFD model for drifting snow

2.1. Governing equations

The air-snow flow is simulated by using the Mixture model in ANSYS FLUENT. The Mixture model equations consist of the continuity and momentum equations for the mixture phase, the continuity equation for the snow phase and the algebraic equation for the slip velocity between air and snow phases. Specifically, the transport equations for the air-snow mixture phase are given by.

$$\frac{\partial \rho_{\mathrm{m}}}{\partial t}+\nabla\cdot\left(\rho_{\mathrm{m}}\mathbf{u}_{\mathrm{m}}\right)=0 \tag{1}$$

$$\frac{\partial}{\partial t}\left(\rho_{\mathrm{m}}\mathbf{u}_{\mathrm{m}}\right)+\nabla\cdot\left(\rho_{\mathrm{m}}\mathbf{u}_{\mathrm{m}}\mathbf{u}_{\mathrm{m}}\right)=-\nabla p_{\mathrm{m}}+\nabla\cdot\left[\rho_{\mathrm{m}}c_{\mathrm{s}}\left(1-c_{\mathrm{s}}\right)\mathbf{u}_{\mathrm{as}}\mathbf{u}_{\mathrm{as}}\right]+\nabla\cdot\boldsymbol{\tau}_{\mathrm{Gm}}+\rho_{\mathrm{m}}\mathbf{g} \tag{2}$$

where, the subscripts "m", "a", "s" represent mixture, air and snow phases, respectively; $\boldsymbol{\tau}_{\mathrm{Gm}}$ is a generalized shear stress tensor, which is calculated according to Eq.(3); c_{s} is the mass fraction of snow phase; $\mathbf{u}_{\mathrm{as}}$ is the slip velocity vector between air and snow phases; ρ_{m} is the mixture density; $\mathbf{u}_{\mathrm{m}}$ is the mixture velocity vector; μ_{m} is the mixture viscosity.

$$\boldsymbol{\tau}_{\mathrm{Gm}}=\left(\mu_{\mathrm{m}}+\mu_{\mathrm{Tm}}\right)\left[\nabla\mathbf{u}_{\mathrm{m}}+\left(\nabla\mathbf{u}_{\mathrm{m}}\right)^{T}\right]-\frac{2}{3}\rho_{\mathrm{m}}k_{\mathrm{m}}\mathbf{I} \tag{3}$$

The snow volume fraction f_{s} is derived by solving the continuity equation for the snow phase, as shown in Eq.(4), where D_{Mp} is the diffusion constant. The third term on the left-hand side accounts for the slip between air and snow phases. Furthermore, based on the force balance and a local equilibrium assumption, the algebraic equation for the slip velocity $\mathbf{u}_{\mathrm{as}}$ is derived, as shown in Eq.(5).

$$\frac{\partial f_{\mathrm{s}}}{\partial t}+\nabla\cdot\left(f_{\mathrm{s}}\mathbf{u}_{\mathrm{m}}\right)+\nabla\cdot\left[f_{\mathrm{s}}\left(1-c_{\mathrm{s}}\right)\mathbf{u}_{\mathrm{as}}\right]=D_{\mathrm{Mp}}\cdot\nabla f_{\mathrm{s}} \tag{4}$$

$$\mathbf{u}_{\mathrm{as}}=\frac{t_{\mathrm{s}}}{f_{\mathrm{drag}}}\frac{\left(\rho_{\mathrm{s}}-\rho_{\mathrm{m}}\right)}{\rho_{\mathrm{s}}}\left[\mathbf{g}-\left(\mathbf{u}_{\mathrm{m}}\cdot\nabla\right)\mathbf{u}_{\mathrm{m}}-\frac{\partial\mathbf{u}_{\mathrm{m}}}{\partial t}\right] \tag{5}$$

In Eq.(5), t_{s} is the relaxation time of a particle; f_{drag} is the drag function, taken from Schiller and Naumann [17]; d_{s} is the diameter of snow particle; $\mathbf{g}$ is the gravitational acceleration. The k-ε turbulence model is applied to solve the flow turbulence quantities and turbulent viscosity for the mixture phase.

2.2. Treatment of deposition and erosion

The first grid adjacent to the snow surface is selected as a Control Volume (hereafter, CV) for evaluating the balance of snow concentration and calculating the total deposition. The total deposition flux q_{total} on the bottom surface of the CV is given by:

$$q_{\mathrm{total}}=q_{\mathrm{dep}}+q_{\mathrm{ero}} \tag{6}$$

Snow deposition per unit of time and unit of area q_{dep} is expressed as Eq.(7). Here, w_{f} is the snowfall velocity; Φ is the drifting snow density at the first grid adjacent to the snow surface, which is calculated as the product of the snow density ρ_{s} and snow volume fraction f_{s}.

$$q_{\mathrm{dep}} = -\Phi w_{\mathrm{f}} = -\rho_{\mathrm{s}} f_{\mathrm{s}} w_{\mathrm{f}} \tag{7}$$

Erosion flux q_{ero}, caused by the shear stress at the snow surface, is given by Eq.(8). This follows the expression, proposed by Anderson and Haff [18]. Here, c_{a} is a constant; u^* is the friction velocity; u^*_{t} is the threshold friction velocity.

$$q_{\mathrm{ero}} = \begin{cases} -c_{\mathrm{a}} \rho_{\mathrm{s}} u^* \left(1 - \dfrac{u_{\mathrm{t}}^{*2}}{u^{*2}}\right) & for \;\; u^* > u_{\mathrm{t}}^* \\ 0 & for \;\; u^* \le u_{\mathrm{t}}^* \end{cases} \tag{8}$$

In this analysis, the total deposition mass q_{total} is incorporated into Eq.(4) as the source term to consider the snow concentration change within the saltation layer.

3. Validation of CFD model

3.1. Computational conditions

As no measurement or experimental data of snow distribution on a curved roof was available, the balanced and unbalanced snow distributions in Chinese load code (MOHURD, [16]) and ISO load code (ISO, [19]) were selected for validation. For both distributions, the inflow velocities were determined by referring to the AIJ load code (AIJ, [20]), which elaborates the relationship between the velocity and the snow distribution.

Figure 1 a) provides a schematic view of the curved roof building used in this study, with an arc span of 50 m and a longitudinal span of 100 m. The height of the curved roof was 10 m with a rise-span ratio being 1/5. The eave was placed perpendicular to the approaching wind flow. The computational domain comprised a volume measuring 250 m (x-axis)×300 m (y-axis)×70 m (z-axis), as shown in Figure 1 b). In this study, special care was taken to allocate an adequate number of hexahedral cells along the curved roof. In order to simulate the saltating process, the height of the first grid adjacent to the roof surface was set to 0.01 m, approximately the height of the saltation layer.

a) b)

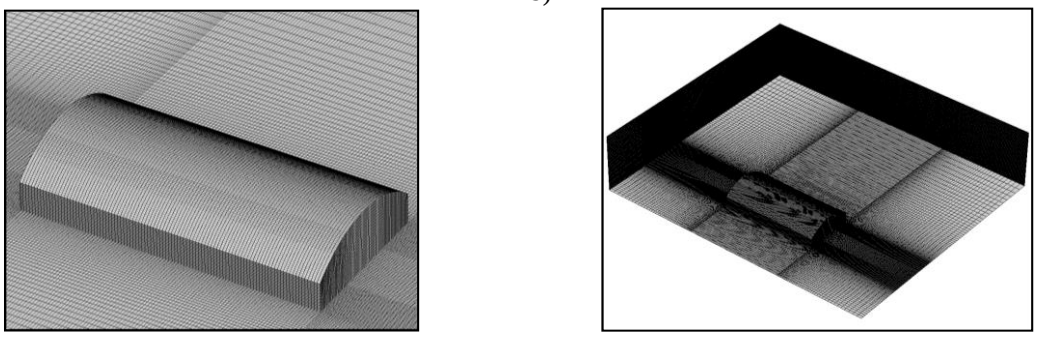

Figure 1. Grid overlay: a) schematic view of the curved roof building; b) schematic view of the domain

A power law profile with an index of 0.20 was assumed for inflow velocity; the profiles for k and ε were determined using the equations proposed by the AIJ [20]. The mean wind velocity at the inflow boundary at the building height U_{H} was set to 2.0 m/s, 3.0 m/s and 4.0 m/s, respectively to investigate the development of snowdrifts. The drifting snow density Φ_{in} at the inflow and top boundaries was given as a constant value by assuming that the standard snow depth, that resulted from snowfall during the whole period. Here, the specific inflow snow volume fraction was set to 1.3×10^{-5}, referring to the snow disaster in Shenyang City, China in 2007. The threshold friction velocity u^*_{t} was set to 0.2 m/s and snowfall velocity was set to 0.2 m/s. The snow particle density was selected as 250 kg/m^3.

3.2. Results and discussion

The distributions of friction velocity are shown in Figure 2. The friction velocity u^* was normalized by the threshold friction velocity u^*_t. For the case of 2 m/s, the friction velocity of the whole roof is lower than the threshold friction velocity; while for other cases, the friction velocity starts to exceed the threshold value from the windward area and increases with the increasing inflow velocity. Therefore, no snow drifting will occur on the roof with the 2 m/s inflow velocity. As for the distribution pattern, a high value of friction velocity is observed in the windward area for different inflow cases, and this area expands downstream with the increasing inflow velocity. However, a strip-shaped low friction velocity zone always exists along the leeward eave, where the wind velocity is low enough allowing snow to settle out and form a drift. Figure 3 illustrates the distribution of normalized drifting snow density Φ within the saltation layer. The drifting snow density shows small value along the windward eave. Much more snow particles are blown up and move further downstream under the action of strong shear stress in the windward area. Finally, the snow particles gather in the low velocity area along the leeward eave.

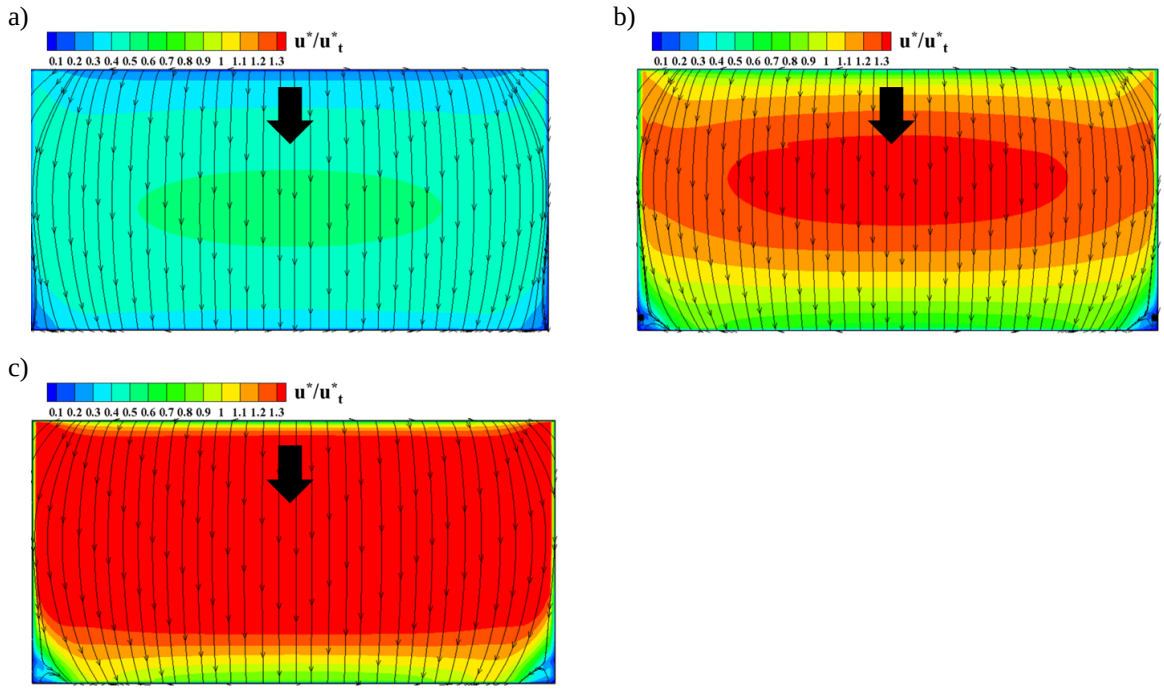

Figure 2. Contours of dimensionless friction velocity u^*/u^*_t: a) 2 m/s; b) 3 m/s; c) 4 m/s

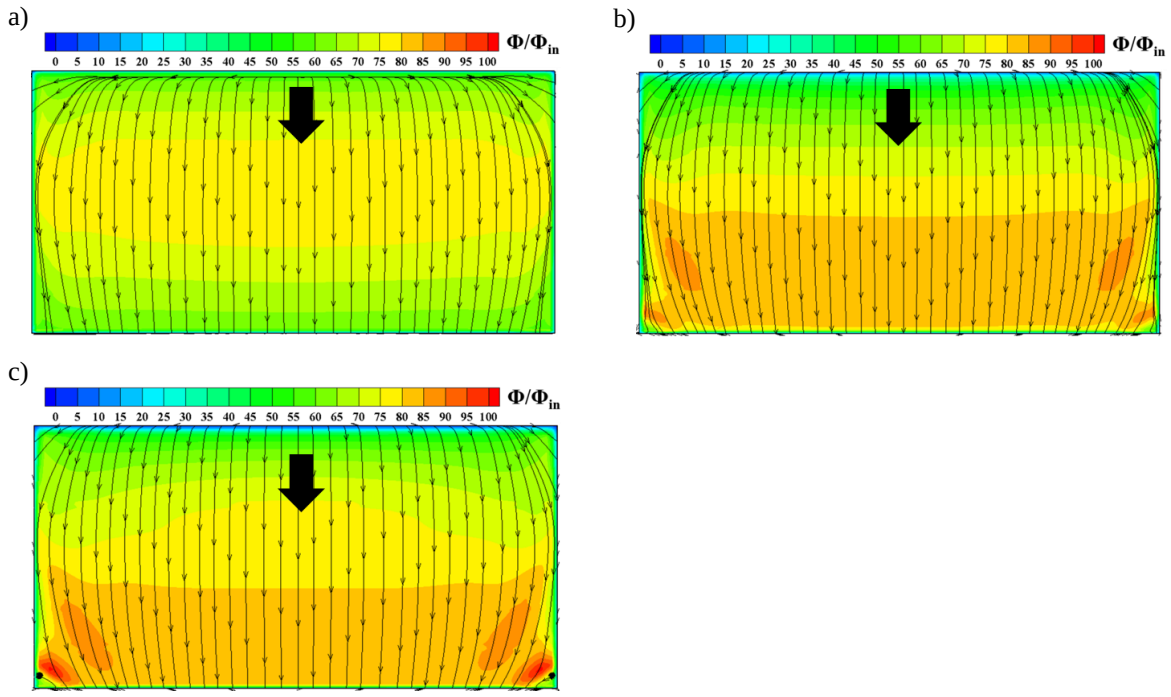

Figure 3. Contours of dimensionless snow concentration Φ/Φ_{in}: a) 2 m/s; b) 3 m/s; c) 4 m/s

Figure 4 indicates the contours of snow depth ratio h/h_{ref} on the curved roof. The snow depth ratio was defined as the ratio between the total deposition flux q_{total} and the total deposition flux q_{stan} at a reference point, which was not affected by the building. For U_H=2 m/s, only very small undulation is observed due to the low friction velocity. No significant snow drifting occurs on the roof and the snow load on the roof is approximately evenly distributed. For U_H=3 m/s, erosion starts to occur in the windward area. However, a small accumulation of snow is formed on the windward eaves. For U_H=4 m/s, the windward erosion zone spreads further downstream and the deposition along the windward eave disappears. The uneven distribution of snow on the roof becomes more obvious, showing a half-span snow distribution pattern. In general, the snow load on the curved roof shows three kinds of distribution patterns, i.e., the full-span balanced distribution (U_H=2 m/s), the half-span unbalanced distribution (U_H=4 m/s) and the transitional distribution between them (U_H=3 m/s).

Figure 5 shows the balanced and unbalanced snow distribution requirements for the curved roof provided in the Chinese load code (MOHURD, [16]) and the ISO 4355 load code (ISO, [19]). The balanced snow distributions in both codes correspond to the snowdrift with a lower inflow velocity (U_H=2.0 m/s). Consistent with ISO load code, the simulated snow depth continues to decrease gradually from the roof ridge to eaves. However, the snow depth remains the same in Chinese code as shown in Figure 5 a). The unbalanced snow distribution in ISO code is more likely the snowdrift formed at a higher wind velocity (U_H=4.0 m/s). The snow on the windward side is severely eroded, and a lot of snow accumulates on the leeward side. Different from the ISO code and CFD results, a large amount of snowdrift has formed in the high wind speed zone on the windward surface, which needs a further investigation.

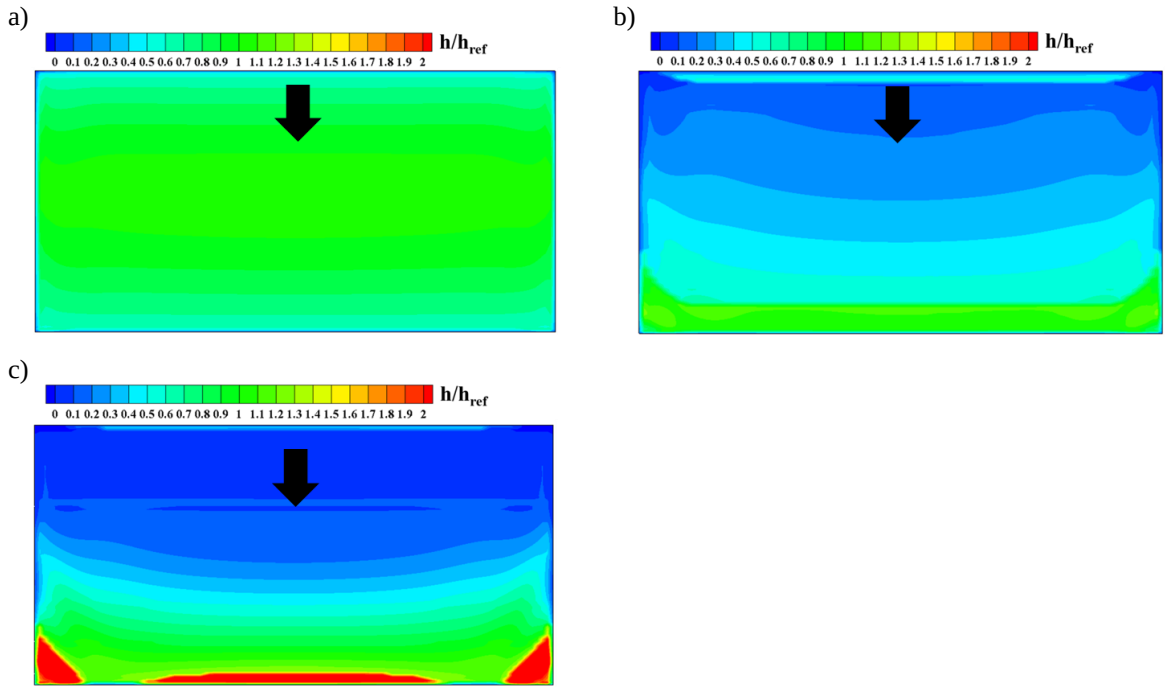

Figure 4. Contours of dimensionless snow depth h/h_{ref}: a) 2 m/s; b) 3 m/s; c) 4 m/s

4. Snowdrifts on curved roofs with various inflow directions

4.1. Computational conditions

In addition to the wind velocity, the wind direction also has a significant impact on the snow distribution parttern. In order to clarify the adverse wind direction, the snow distributions under three wind direction conditions were simulated, as shown in Figure 6. Regarding computational conditions, The mean wind velocity at the inflow boundary at the building height U_H was set to 4.0 m/s, at which the snowdrift was obvious. Except for this, all the computational settings were the same as above.

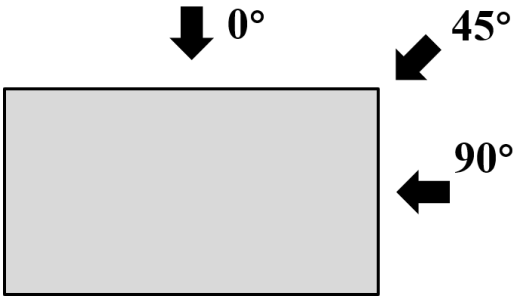

Figure 6. Computational cases for snowdrifts under different inflow direction conditions

4.2. Results and discussion

The distributions of friction velocity under different wind direction conditions are shown in Figure 7. The friction velocity u^* was normalized by the threshold friction velocity u^*_t. For the 0° inflow direction, the overall friction velocity exceeds the threshold friction velocity except for the low velocity zone along the leeward eave. The friction velocity is distributed in a strip shape parallel to the longitudinal eave. When the inflow direction turns to 45°, the strip-shaped friction velocity starts to tilt, and its value starts to decrease in the downstream region. For the 90° inflow direction condition, the overall friction velocity is below the threshold friction velocity, especially in the recirculation zone at the windward edge. Therefore, for the 0° inflow direction condition, the snow drifting phenomenon is more obvious; while for the 90° inflow direction condition, no snow drifting occurs on the roof. Figure 8 illustrates the distribution of normalized snow concentration within the saltation layer. A few snow particles gather in the windward region, while more particles are brought to the leeward area.

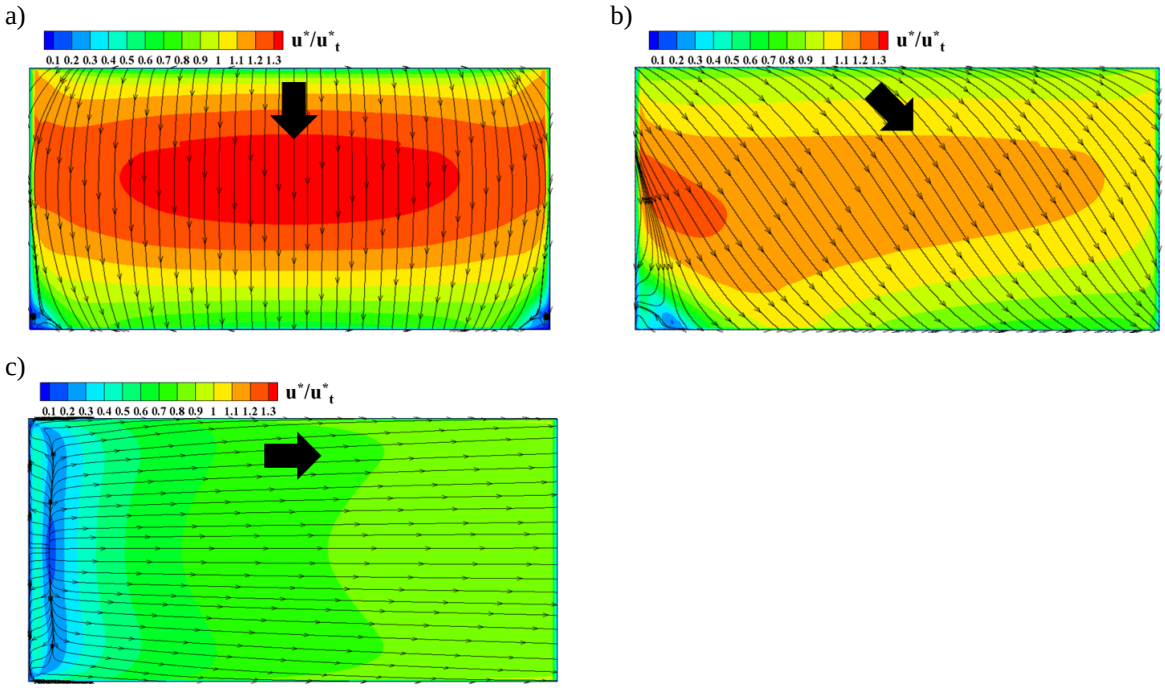

Figure 7. Contours of dimensionless friction velocity u^*/u^*_t: a) 0°; b) 45°; c) 90°

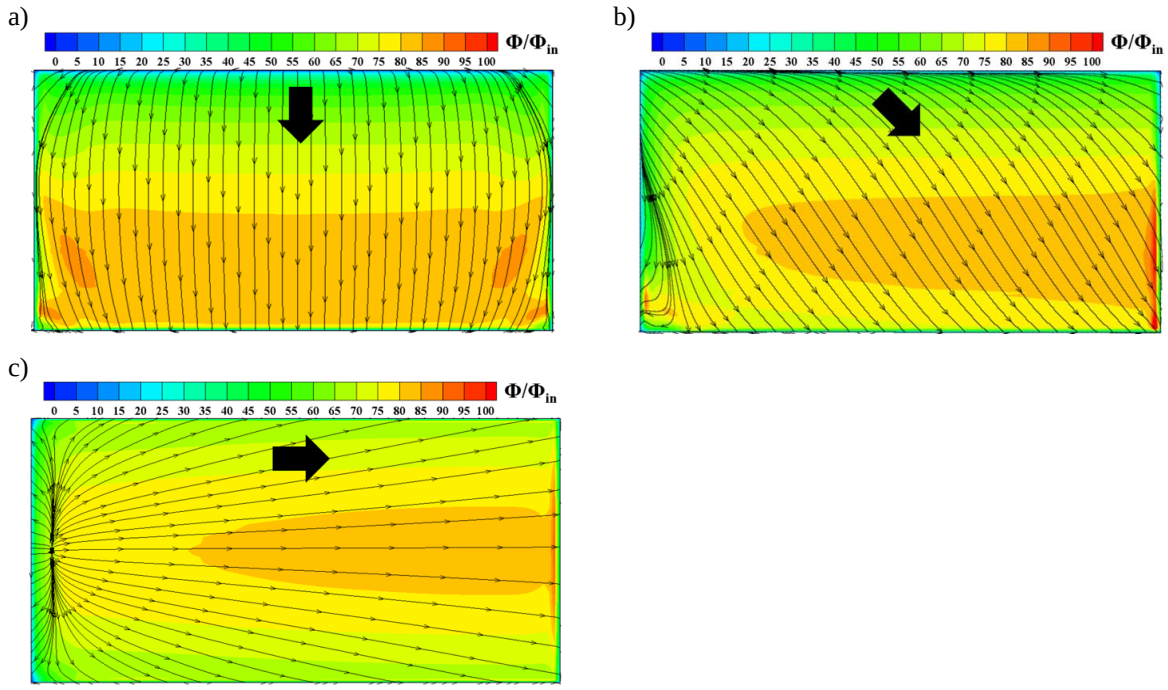

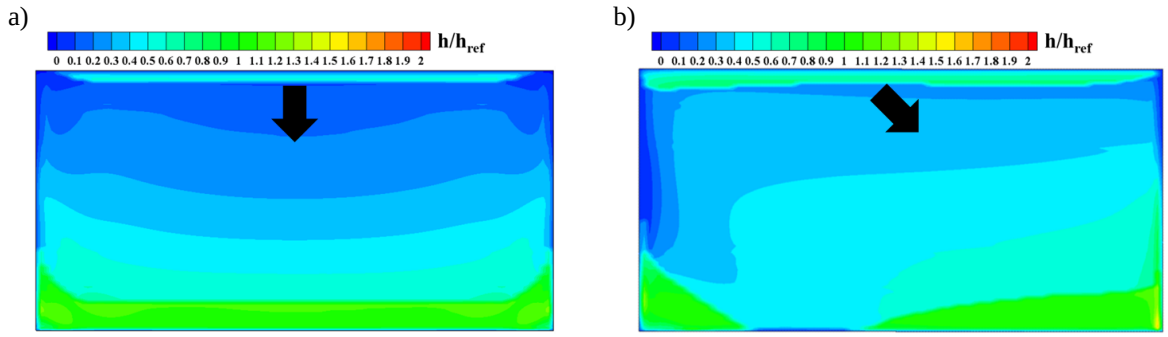

Figure 8. Contours of dimensionless snow concentration Φ/Φ_{in}: a) 0°; b) 45°; c) 90°

Figure 9 indicates the contours of snow depth ratio h/h_{ref} on the curved roof for different inflow directions. For the 0° inflow condition, since the friction velocity on the windward roof is much higher than the threshold friction velocity (as shown in Figure 7), many snow particles on the windward surface are carried to the leeward surface of the roof by the airflow (as shown in Figure 8). The snow distribution on the roof shows an obvious half-span distribution pattern. For the 45° inflow condition, due to the decrease in the value and area of the friction velocity on the windward surface, the uneven distribution of snow on the roof begins to weaken, and the overall pattern is triangular accumulations formed in the leeward corners. For the 90° inflow direction, as the friction velocity is lower than the threshold value, no snow drifting occurs on the roof. Only some falling snow particles from the sky are carried to the leeward side by the airflow. Therefore, the roof snow shows a uniform distribution, and only a small amount of snow accumulates around the leeward roof ridge. In general, for the curved roof, when the direction of the incoming flow is perpendicular to the eave, it is easier to form an uneven distribution.

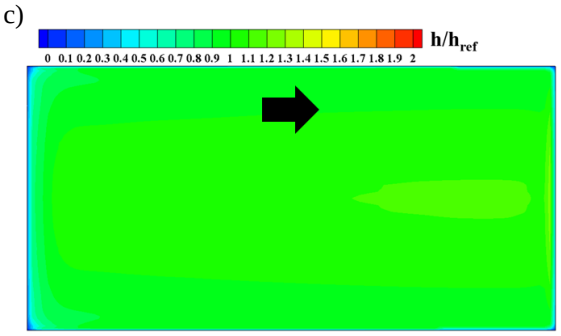

Figure 9. Contours of dimensionless snow depth h/h_{ref}: a) 0°; b) 45°; c) 90°

5. Conclusion

This study investigated the snowdrift development on an isolated curved roof with various inflow velocities and directions based on a revised multiphase model. As a result of this work, the following conclusions can be drawn:

1) By comparing with the Chinese load code and ISO load code, the revised CFD numerical model can accurately restore the balanced and unbalanced snow distribution pattern in the ISO code. Specifically, the movement of particles induced by airflow and the trajectorie of snow particle under the action of aerodynamic force and gravity are both well reproduced. However, some substantial deviations remain from the Chinese code, which needs a further investigation.

2) The snow load on the curved roof shows three kinds of distributions patterns, i.e., the full-span balanced distribution, half-span unbalanced distribution and transitional distribution between them. Snowdrift piled up on the leeward side of the roof tends to increase with the increasing inflow velocity.

3) With the change of wind direction from perpendicular to the eave to parallel to the eave, the uneven distribution of snow on the curved roof starts to weaken. In general, for the curved roof, when the direction of the incoming flow is perpendicular to the eave, it is easier to form an uneven distribution, which should be fully considered.

Abstract

In 2016, Kumamoto was struck by two earthquakes. The condominium I was living in was destroyed. We decided to search locally for a new section to build a home. The place we chose was a rich in groundwater so we thought to use it and so contributed to our hometown. The first floor would be an example of disaster relief architecture by using it as a public bath, and would provide water in times of disaster. The second floor would be our private home with no bath, we would use the public bath as ours. This report describes our construction process during which first floor ceiling, the latter using superimposed openwork beams of thinned wood. We designed the damaged structure to bear any subsequent earthquake. Since the remaining seismic capacity of a couple of nearby RC buildings dropped to about 60%, the analytical model for subsequent earthquakes assumed a reduced bearing capacity and an effective structural frame.The roof was designed using CLT arches. The joints have close fitting butterfly-shaped timber connectors without metal. Connector bending tests were performed. After the earthquake, construction costs skyrocketed. To reduce costs we took charge of site supervision, carpentry, and became the public bath operator. All this as a direct result of strong feelings for my Kumamoto hometown.

Keywords: timber fitting connector, CLT, superimposed openwork beam, thinned wood, high strength timber shear wall, timber frame structure, multiple earthquakes, disaster reconstruction, recovery utilizing a public bath, community preparedness

1. Introduction

In 2016, Kumamoto in South-Western Japan was severely damaged by a series of earthquakes (Figs.1).The condominium I was living in was destroyed and had to be rebuilt. However, the surrounding area was steadily becoming vacant and losing its liveliness. As the water supply was cut off for several months, I needed to regularly go to a public bath, However the washrooms were over-crowded and drains clogged with hair (Fig.2). My family searched locally for a new section on which to build our home. As there was an abundance of groundwater where we bought, we decided to use it and contribute` to our hometown. The first floor would involve relief architecture that could be used as a public bath and provide water in a disaster. The building would also serve as a small but useful example of community preparedness architecture.

2. Structural design

The building is a two-story, conventional post and beam timber structure. Since the use of the first floor is a public bath. It was constructed with the RC wall raised to a height to stop buckling. The first floor ceiling has superimposed openwork beams made of thinned wood to improve rigidity and strength. We designed the structure to bear any subsequent earthquake even if damaged. The roof is designed as an arch with CLT enabling a loft floor.

Figures 1. Consecutive Kumamoto earthquakes.

Figure 2. Public bath queue.

2.1. Timber frame with superimposed openwork beams

The area of the first floor public bath is small, so the ceiling height was set to 4.75m to allow for a more open bathing experience. Since the Kumamoto earthquake, the number of sub-contractors has increased, and construction costs have risen; so our policy was to consider low-cost construction. The unit price using small cedar square timber (ungraded, 4.0 m) is about 1/3 for that of engineered wood (E120-F330, 4.0 m). Thus 90 mm square cedar is widely used. Since bathers will look up at the ceiling for long periods of time, and also to make it interesting, the ceiling was made of superimposed openwork beams to improve rigidity and strength of the structure. Screw fastening was used for the small square and prop timbers, and the upper and lower flanges of the girders and the columns made of engineered wood (Fig.3,4). The girder was divided to increase bending strength.

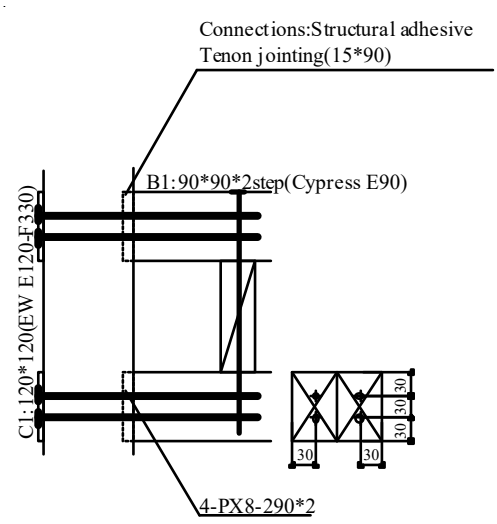

Figure 3. A column-girder joint

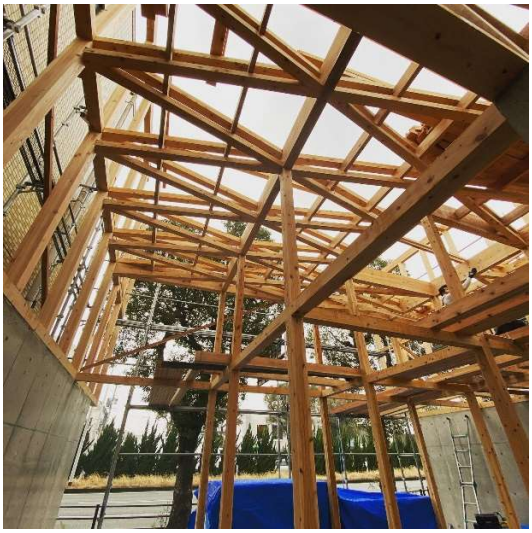

Figure 4. Superimposed openwork girders at the time of erection

Considering the possibility of subsequent earthquakes, high-strength bearing walls of structural plywood (Qa=19.6kN/m) that satisfy the Building Standard Law were used; any future earthquake impact would be borne by the timber frames with superimposed openwork beams. Since the remaining seismic capacity of a couple of nearby RC buildings dropped to about 60%, the analytical model for subsequent earthquakes assumed a reduced bearing capacity and an effective structural frame (Table 1). Framing was planned with the top of the RC wall as the rebound point, and the out-of-plane bearing strength of the RC wall at the bottom of the intermediate level was combined with the timber frame. RC wall tops, timber column legs, and intermediate beams were pinned together (Fig.6). The horizontal structure was borne solely by directly affixed structural plywood of t=24mm.

2.2. CLT connecting arch with fitting

The roof has a loft floor with the CLT connected in an arched shape (Fig.7). Long engineered wood bore the long term thrust force. In the short term, tensile force would be generated between each CLT member, so the CLT were joined by butterfly-shaped close fitting timber connectors (Figs.8). To reduce costs, temporary girders were not used during erection; CLT sections were assembled in a curved shape at the factory and then installed by crane and human power. Joints were closely fitting timber connectors without any metal. Since the arches were cantilevered during erection, connector bending tests were performed (Figs.9,10). Interestingly, in 1968, the Japanese furniture designer George Nakashima made a desk using a butterfly-shaped timber fitting connector as a tensile member.

A total of 12 units were tested for the bending strength of the timber connectors, with and without structural adhesive (polyurethane resin adhesive); and with the strong and weak axial directions of shredding interchanged (Fig.11). To secure units, they were placed on top of the load bearing area and a pantograph was mounted at the center to prevent initial deflection. Force was applied using a

Figures 10. Assembling CLT connecting arches

2000kN universal testing machine with four points with three equal loadings. The monotonic force rate was 5 mm/min until the max proof force was reached and the specimen displacement reached 50 mm. Displacement was measured using a strain gauge displacement transducer at the position shown in the figure. ["] indicates that the shreds are parallel to the CLT strong axis direction; without ["]. [Bond] indicates the application of structural adhesive. The test results confirm P max=12.0 kN (average value), and a long term allowable bending capacity Ma=1.54 kN· m (Fig.12, 13). Since the lamina widths were uncrimped, shear failure of the fitting connector snagging area occurred after rolling shear occurred. Resorcinol-phenol co-condensation resin was used as the structural adhesive joining the laminae. Although a structural adhesive was used, only stiffness increased without any increase in bending capacity. There was also a unit that suffered shear failure of the timber fitting connector after flexural failure of the shear key. The stiffness of the structural adhesive was higher than the stiffness of the timber fitting connector, so there no combined proof stress at the end of the test. Since cracking occurred only in the weak axial direction of the CLT layer, the bearing capacity would have increased if the fittings were in the strong axial direction (Fig.14).

Figures 14. Specimen after completion of the test

The design equation (Architectural Institute of Japan) applies to the fitted timber connector for partial compressive stress perpendicular to the grain in the moment resisting joint equation. The existing

equation overestimates Ma=2.16 kN·m (long-term allowable bending capacity) as it has only three conditions [1] triangular compression to the grain displacement yielding strength, [2] equal compression to the grain displacement, yielding the strength of the wedge, and[3] wedge tensile yielding strength.

Since the type of failure was also different, [4] flexural shear strength at the snagging area and [5] shear strength at the snagging area were added. The design value Ma=1.36 kN·m was determined by the smallest value [5], which was close to the experimental value.

$$M_y=N_y \cdot j \tag{1}$$

$$N_y=\min(\Sigma N_y, N_{y1}, T_{y2})$$

$$\Sigma N_y=\frac{x_p y_p F_m}{2}\sqrt{\frac{C_x C_y}{C_{xm} C_{ym}}} \tag{1}$$

$$N_{y1}=x_0 y_0 F_m \sqrt{\frac{C_{y2}}{C_{yzm}}} \tag{2}$$

$$T_{y2}=A_e \cdot F_{ty} \tag{3}$$

$$Q_m=\frac{Z_c f_{bs}}{H} \cdot \sqrt{\frac{C_{y2}}{C_{y2m}}} \tag{4}$$

$$Q_s=A_s \cdot f_{ss} \tag{5}$$

2.3. Carpentry plan

To shorten the time for carpentry, the CLT connecting arches and the superimposed openwork beams were assembled in a factory and delivered to the site. Several mock-ups were made, and since it was necessary to account for swelling after application of the structural adhesive, the surface of the wood was pounded to temporarily compress wood cells (kigoroshi). The area compressed by kigoroshi swells back as a result of the wood's restorative force, thus increasing adhesion. The roof plate was divided into 5 units (1.5 t/unit) (Fig.17, 18). Manufacturing the CLT members (150 mm thick, S60 strength class, and ungraded cedar). And joint jigs, assembling the CLT connecting arches, and erecting the CLT connecting arches, each took one day. The construction was done by five carpenters.

Figures 15. Erection and horizontal sliding

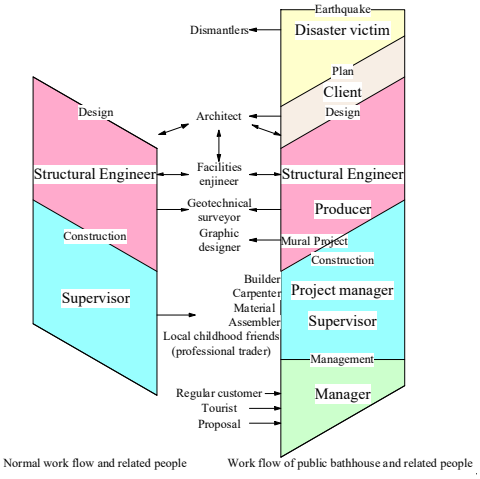

Figure 16. Author's Role

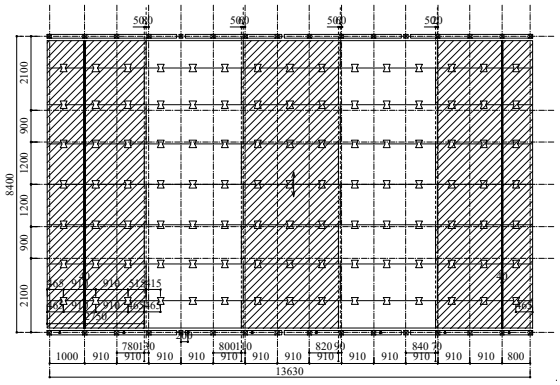

Figure 17. Unit layout

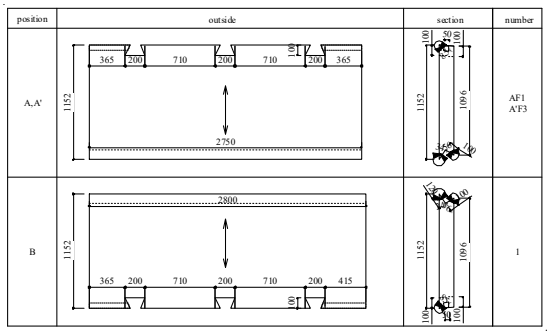

Figure 18. Single Item

The erection process was very difficult as the site was a narrow lot surrounded by power lines. Because CLT is light, the drop was completed by a single carpenter who manually manouvered the CLT connecting arch with a nylon sling (Fig.15). To reduce costs we took charge of site supervision, carpentry, and became the public bath operator. (Fig.16).

Figure 19. Interior and exterior views

3. Conclusion

In Japan CLT is still considered a new building material. Hence construction companies seek to avoid risk and involve a brokers. Thus, CLT construction costs approximate those of RC construction. This building reflected that double ordering. The CLT construction cost could be reduced to 1/3 (frame cost: 40,000 yen/m2) without the separate order. Although less strong, timber fittings are more reasonable than CLT-specific metal. Timber should also be considered as the fittings are easy to spread because they can be manufactured as long as there are trees. We successfully rebuilt our home. The public bath has been bustling with users, and we look forward to helping community preparedness in the future.

Acknowledgements

Six years have passed since the Kumamoto earthquake. It has not been a smooth road, and the support of my family and friends has been essential. I thank them.

Abstract

Large public buildings are an essential part of the national earthquake emergency relief system, and detecting ceiling damage caused by earthquakes is a crucial part of evaluating the safety of large public buildings as emergency shelters. To overcome the limitations of human-based visual onsite inspections, a vision-based method using the semantic segmentation network Deeplabv3+ with transfer learning (TL) is proposed for the rapid detection of damaged ceilings in large public buildings after earthquakes. Damaged ceiling regions can be located and visualized accurately employing generating different pixel-level masks. A total of 1389 ceiling images of various scenes are used as the dataset after being manually labeled and categorized into four ceiling forms, including intact, fall-off, suspension, and crack. The final fine-tuned model achieved a pixel accuracy (PA) of 97.23% and a mean intersection over union (mIoU) of 84.18% in the test set, which shows that the proposed model has an excellent performance in terms of damage detection and location. The damaged regions of the ceiling can be localized accurately and visualized using generating different pixel-level masks. Some factors that have varying degrees of influence on the detection accuracy are explored. The results in this paper further promote rapid damage detection of post-earthquake ceilings in emergency relief work.

Keywords: ceiling damage detection, large public buildings, semantic segmentation, transfer learning, damage visualization

1. Introduction

Large public buildings, such as indoor stadiums, hospitals, and convention centers, are essential components of emergency shelters, which are transitional places for earthquake evacuees to live and rescue in a concentrated manner for some time after a disaster. Several investigations [1] demonstrated that the main structure of most buildings designated as a shelter can maintain normal service after an earthquake, but the damaged ceilings caused by earthquakes pose a substantial potential hazard to the safety of life and property during aftershocks [2]. Therefore, a rapid detection of the damaged ceiling is critical in evaluating the safety of a building used as a disaster shelter. Considering the limitations of transportation and communication in post-earthquake affected areas and the uncertainty of earthquake occurrence areas, implementing a rapid, reliable, and human-independent damage detection method for ceilings is of great practical significance for post-earthquake emergency relief work.

Nowadays, the visual detection method using convolutional neural networks (CNNs) is widely used [3] in structural damage detection, such as concrete cracks [4, 5], steel cracks [6, 7], masonry surface cracks [8], and road pavement cracks [9-12] due to their efficient and accurate feature extraction and representation of data. To detect ceilings damaged by earthquakes, Wang et al. [13] proposed a deep convolutional neural network (DCNN) method to detect whether the ceiling of a large-span structure is

Copyright © 2023 by Lichen WANG, Shihao YAN and Ken'ichi KAWAGUCHI. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

damaged or intact. A prediction accuracy of 86% is obtained, and the damaged ceiling regions can be visualized and localized using the Saliency-MAP method. In addition, Wang et al. [14] developed a YOLOX-based ceiling damage detection model which can detect different ceiling damage categories. Twelve detection models are established, trained, and compared by variable hyperparameter analysis. The model with the best performance reaches a mean average precision (mAP) of 75.28%, further promoting the automatic ceiling damage detection in large public buildings. The above two intelligent detection methods have gradually achieved rapid detection of whether post-earthquake damage occurred, damage categories, and damage locations of ceilings in large public buildings. However, existing detection methods are still incapable of achieving accurate detection of damage regions and quantitative measurement of the extent of damage.

Semantic segmentation [15] enables the accurate segmentation of pixel regions belonging to different categories in an image by assigning a category label to each pixel in the image. In tasks such as structural damage detection, segmentation results not only achieve classification and localization of targets but results such as the number of pixels in the target region can also be counted simultaneously. Pan et al. [16] developed a novel segmentation network for sewer defect detection based on an improved U-Net (i.e., PipeUNet). It detected the defect's type, location, shape, and boundary with high speed and accuracy and achieved the highest mean intersection over union (mIoU) of 76.37%. Yang et al. [17] established a soil diagnostic horizon identification method based on UNet++, with mIoU of 71.24% and pixel accuracy (PA) of 82.44% in the dataset of major soil types. Segmentation results accurately identified different soil types and delineated soil faults. Xu et al. [18] used SegNet to automatically segment retinal vessels and achieved 95.18%, 96.83%, and 96.53% accuracy on three public datasets, respectively. It effectively solved the problem of the need for more experienced ophthalmologists in remote areas and is important for clinical aid in diagnosing and treating ophthalmic diseases. Yangtao Li et al. [19] proposed a real-time pixel-level dam underwater crack automatic segmentation and quantification framework using the lightweight semantic segmentation network LinkNet and two-stage hybrid transfer learning (TL). The proposed method performed with 89.24% mIoU in the complex underwater scenario test set. Four advanced segmentation methods have been trained for sewer defect detection [20], including DeepLabv3+, FCN, U-Net, and SegNet. Compared to the three other methods, the DeepLabv3+ has the best performance with PA and mIoU of 0.90 and 0.53, respectively, for multiple types of defect detection results. In other studies, DeepLabv3+ has been successfully applied to solving challenges in several fields, including road cracks detection [21], biomedicine [22], automatic road-pothole extraction [23], and disaster prevention [24]. In summary, semantic segmentation methods, especially Deeplabv3+, perform satisfactorily in precise target localization, which can promote further development of damage detection work refinement and quantification.

Therefore, a damage detection method based on semantic segmentation for post-earthquake ceilings of large public buildings is proposed in this paper. It can achieve efficient and accurate damage detection by rapidly classifying and accurately locating the damage of ceilings in large public buildings. After the damage detection method is specifically described, the details of the dataset and the implementation details of the model in terms of training and validation are described. Based on the results of damage detection and visualized images, the effectiveness of damage detection and the influencing factors are analyzed. Finally, some concluding remarks are presented.

2. Methodology

2.1. Overview of detection method

The proposed detection method, as shown in Figure 1, is organized as follows: (1) Images are classified into different ceiling damage categories. (2) Images are preprocessed using damaged region marking and data augmentation. (3) The semantic segmentation model combined with transfer learning is trained using the preprocessed dataset. (4) A set of images that were not used in the training and validation are then applied to test the semantic segmentation model.

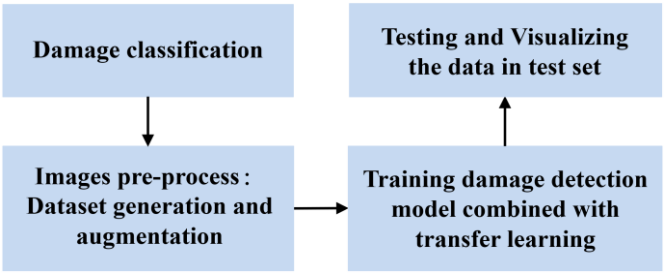

Figure 1. Overview of the proposed detection method.

2.2. Semantic segmentation algorithm

The DeepLabv3+ [25], as shown in Figure 2, is a current widely used semantic segmentation algorithm model that achieves target segmentation by assigning semantic labels to each pixel in an image. The model has an encoding-decoding structure. The rich context information can be captured by feature extraction with down-sampling at different resolutions, and then sharp object boundaries can be obtained by feature amplification with up-sampling.

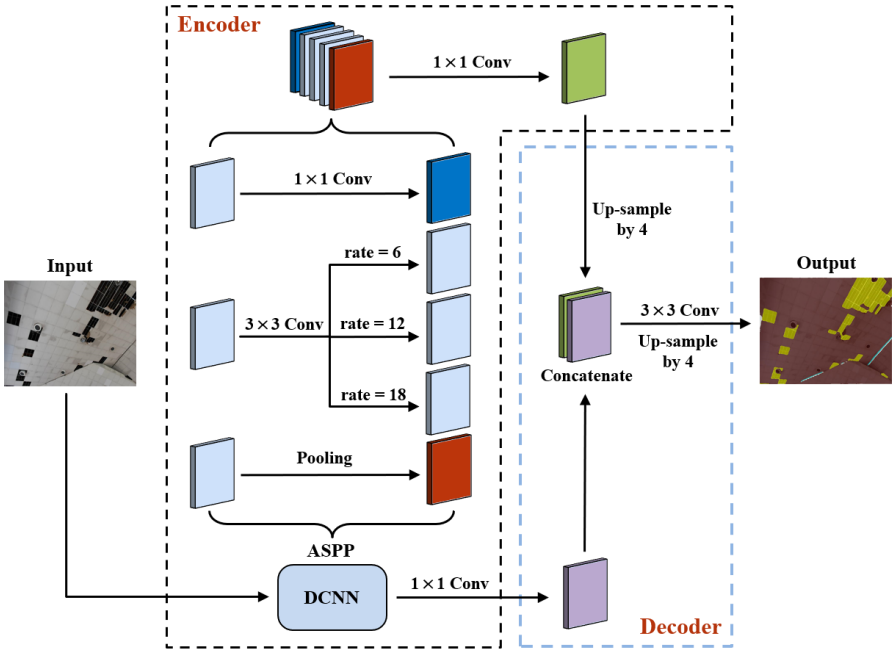

Figure 2. DeepLabv3+ architecture.

The encoder module mainly consists of an atrous space pyramidal pooling structure (ASPP). By combining several deep convolutional neural networks (DCNNs) which apply parallel atrous convolution with different rates, it can acquire multi-scale feature information of images. Compared with standard convolution, atrous convolution changes the size of the convolution kernel distribution by extracting feature points across pixels to increase the receptive field without decreasing the resolution. In the case of input image data, for each location i on the output feature map y and a convolution filter w, the atrous convolution is applied over the input feature map, x, as shown in Eq. (1):

$$y[i] = \sum_k x[i + r \cdot k] w[k] \tag{1}$$

Where the atrous rate r determines the sampling stride of the input signal. Figure 3 illustrates the difference between the atrous convolution with a dilation rate of 3 and the standard convolution. Standard convolution is a particular case in which rate r = 1. The filter's field-of-view is adaptively

modified by changing the rate value. More details are described in other articles. In this paper, the expansion rates are set to 6, 12, and 18 so that the receptive field is expanded to 13×13, 25×25, and 37×37 without changing the 3×3 convolution kernel with nine parameters to achieve the extraction of multi-scale information such as location and semantics. Five sets of features, including standard convolution and pooling layers, are concatenated to reduce the data dimensionality after obtaining multi-scale feature maps from ASPP.

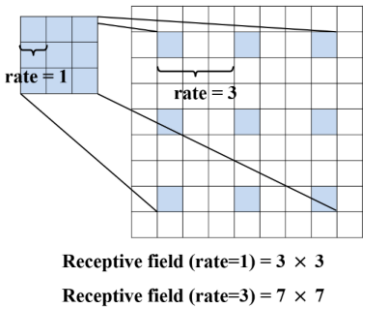

Figure 3. Example of the atrous convolution operation.

In the decoder module, the feature information from the ASPP input is up-sampled using bilinear interpolation to extend the dimensionality of the extracted features. The basic features extracted with the deep convolutional neural network are restored to the original spatial dimension after a series of cascading, convolution, and up-sampling processes to obtain semantically information-rich high-level feature information. Finally, in the output layer, the feature information is mapped to the corresponding pixel classes so that each pixel of the input image is labeled with the corresponding classification label to achieve semantic segmentation of the image.

2.3. Evaluation criterion for detection

This paper employs a group of mainstream evaluation indicators to evaluate the performances of semantic segmentation models in terms of rapid classification and accurate localization of damaged ceiling regions, including the (1) pixel accuracy (PA); (2) intersection over union (IoU); (3) mean intersection over union (mIoU); (4) precision (P); (5) recall (R). The detailed definition formulas for these indicators are defined in other articles [15].

In terms of the overall performance of the detection model, PA indicates the ratio of the number of all correctly detected pixels to the total number of pixels, which is used to evaluate classification correctness. The mIoU is the average value of IoU of each category, which indicates the degree of overlap between detection and true values and is used to evaluate the localization accuracy of the damaged ceiling region. For each different damage category, P and R denote the number of correctly detected true value pixels as a percentage of the total number of pixels in the recognition result and as a percentage of the total number of pixels in their category, respectively. As a result, P and R are used to evaluate the accuracy of the detection results and the completeness of the marked regions being successfully detected.

3. Data and implementation details

3.1. Dataset generation

A total of 1389 raw ceiling images with different pixel resolutions are used, including 760 damaged ceiling images caused by the earthquake. These images were taken from stadiums, indoor pools, transportation stations, lecture halls, industrial planets, and other structures with a large span, and have been collected by Kawaguchi Lab and Wang [13] since the Great Hanshin-Awaji Earthquakes in 1995. As shown in Figure 4, different types of ceiling regions in each image, namely intact, fall-off,

suspension, and crack, were marked as brownish-red, yellow, red, and cyan using the online annotation tool Labelme. Non-ceiling regions were automatically classified as background marking with no color.

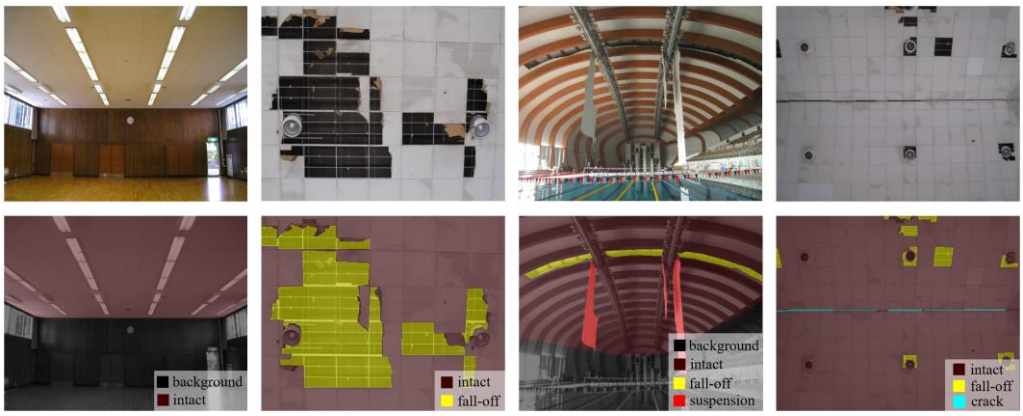

Figure 4. Example of original images and annotations of marked images.

To avoid overfitting, cross-validation was used in the training process. All images were randomly divided into a training dataset of 1111 images, a validation dataset of 139 images, and a test dataset of 139 images in a ratio of 8:1:1. The test dataset was not used in the training process except for the final test. Data augmentation (DA) can increase the number and diversity of samples and enhance the generalization of models [26]. Therefore, DA was used in the construction of datasets, including geometric transformations (e.g., rotation, flip, shift, scaling, etc.) with random combinations of color transformations (luminance, noise, contrast, etc.).

3.2. Implementation details

The code was programmed using Python 3.7 and Compute Unified Device Architecture (CUDA) v11.3. The virtual environment was established by Pytorch on the Pycharm IDE. All training and validation process was conducted on a computer with an Intel Core i9-10940X @3.30GHz CPU, and an NVIDIA Geforce RTX 2080Ti GPU.

The detection model contains several hyperparameters that have different effects on the performance. Batch size represents the number of samples involved in one forward propagation in training. By calculating the loss function in backpropagation, the model can continuously adjust the weights so that the output predictions keep approximating the true values. The optimizer can change how the loss function is calculated and the gradient drop in this process. In addition, the learning rate controls the convergence rate of the model.

More than 50 sets of hyperparameter combinations were trained and validated. Considering the time cost and features learning effect, the epoch of the training phase was set to 600. The details and validated results of four cases with excellent performance are shown in Table 1. All four cases achieved a PA of over 90% in the validation set, and the mIoU reached about 80%. Among them, Case 1 uses the original DCNN from the Deeplabv3+ model and randomizes the initial weights for training. Case 2 uses Mobilenetv2, a lightweight feature extraction network, to significantly reduces the number of training parameters while ensuring the detection effectiveness and improving operational efficiency. The maximum learning rate is set to 5e-4 during the training process while dynamically adjusting the decreasing rate of the learning rate in the form of a cosine function. Transfer learning (TL) can achieve the effect of improving [27] detection accuracy under the same conditions by using weights that have been successfully pre-trained in large-volume datasets (e.g., PASCAL VOC, ImageNet, and COCO, etc.). By comparing multiple sets of experiments, the model can achieve excellent results when the pre-training epoch exceeds 100. Compared with Case 2, the PA and mIoU of Case 3 are significantly improved by 2.42% and 7.06%, respectively, due to the optimization of each hyperparameter,

application of Focal_loss, Adam optimizer, and pre-training. When the pre-training epoch continued to increase to 200 in Case 4, the results of PA and mIoU have a slight decrease. As a result, the optimum value of the pre-training epoch is 100.

Table 1. Training details and validated results of four excellent cases.

	Backbone	Pretrained	Batch	Downsample	Focal_loss	Optimizer	Lr_decay	PA(%)	mIoU(%)
Case1	Xception	0	2	16	/	Sgd	Step	93.56	79.52
Case2	Mobilenetv2	0	2	16	/	Sgd	Step	94.81	80.19
Case3	Mobilenetv2	100	8	8	√	Adam	Cos	97.23	87.25
Case4	Mobilenetv2	200	8	8	√	Adam	Cos	97.11	86.68

Figure 5 shows the curves of the loss value and the mIoU of the validation set after each iteration for the four cases, which exhibit the learning process of the damage recognition model. In general, all cases have similar fitting trends and successfully achieve relatively stable convergence. Since Case 3 and Case 4 use TL, their loss curves do not show large oscillations, drop faster, and have significantly lower final fit loss values than Case 1 and Case 2. A rapid fit of the mIoU curve is also achieved at the early stage of training. The minimum validation set loss for the 562nd epoch in Case 3 is 0.118, and the maximum mIoU of the validation set is 87.25%, which is saved as the best weight.

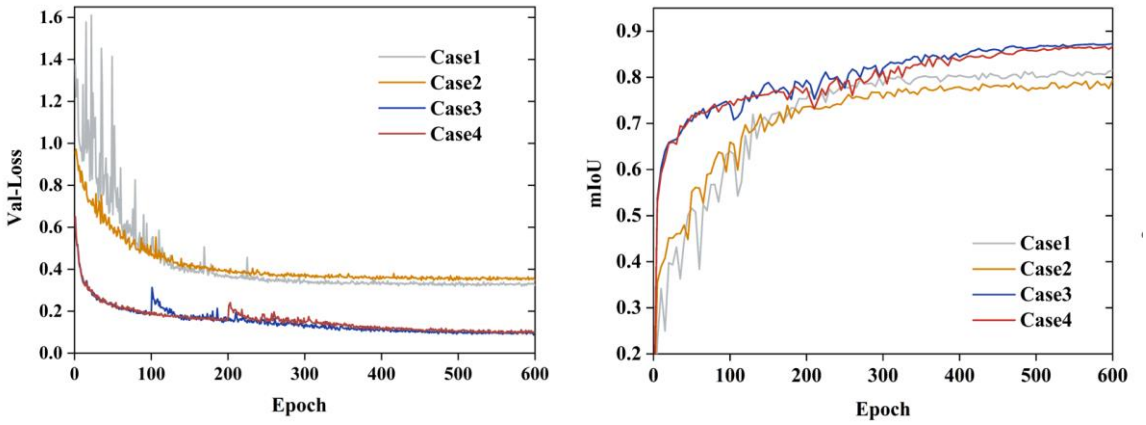

Figure 5. Validation loss and mIoU curve of four cases.

4. Results and discussion

4.1. Detection in the test set

Based on the optimal weights derived in the previous section, the ceiling damage detection model achieves 97.23% of the PA and 84.18% of the mIoU in the test set. The detection time of each image in the test set is about 0.02 s, which satisfies the need for emergency damage detection of ceilings after earthquakes. As shown in Figure 6, details of the detection results of each category can be known by the confusion matrix after normalizing. The main diagonal values of the matrices in Figure 6(a) and (b) represent the precision and recall of each category, respectively. It can be found that the precision and the recall of background, intact, and fall-off are above 95%. The precision and recall of suspension are 95.16% and 91.15%, respectively, and have a 4.17% and 3.70% probability of being incorrectly detected as intact or fall-off. The precision and recall of crack are 63.41% and 73.49%, respectively. The intact ceiling region has interfered with the detection performance of the ceiling crack to some extent. In summary, the testing results demonstrate that the model has excellent detection capabilities including classification and localization for the damaged ceiling region caused by the earthquake.

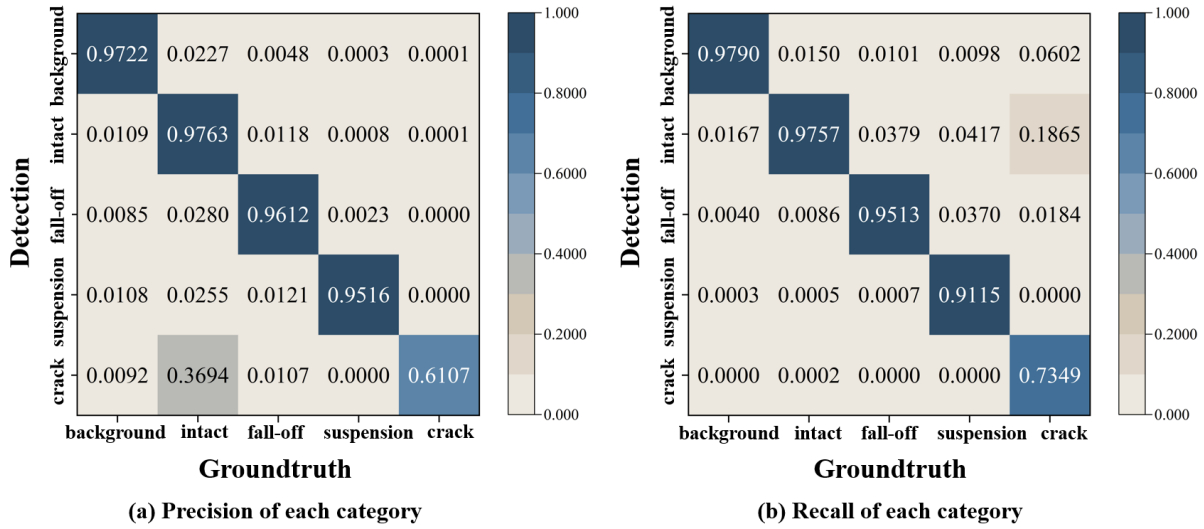

Figure 6. Normalization matrix of the test set.

4.2. Visualization of different categories

The classification correctness and localization accuracy in detection can be demonstrated intuitively using the visualization results. For the intact ceiling regions and backgrounds, 95.32% and 95.23% of the IoU are achieved, which means the detection results and marked region almost completely overlap, as shown in Figure 7(a) and (b). Even in the case of multi-target detection, the edges between the intact ceiling regions and other categories can be accurately identified and classified, as shown in Figure 7(c).

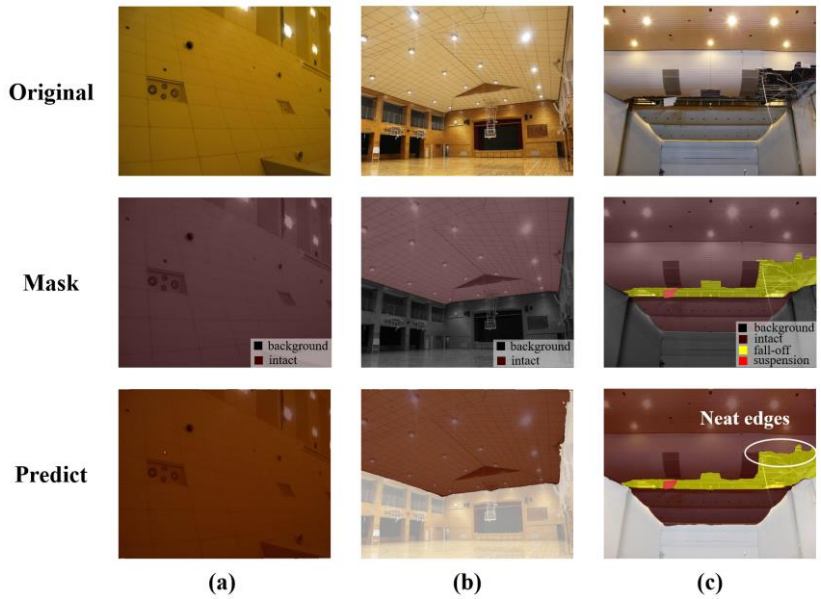

Figure 7. Examples of mask images and detection results of the ceiling intact region.

For the ceiling fall-off, the detection results and marked region overlap highly with the IoU of 91.61%. The fall-off regions have been detected accurately at different capture distances whether edge details and multiple targets, as shown in Figure 8(a)-(c). As shown in Figure 8(d), the model also performed outstandingly in the case of ceiling complete fall-off.

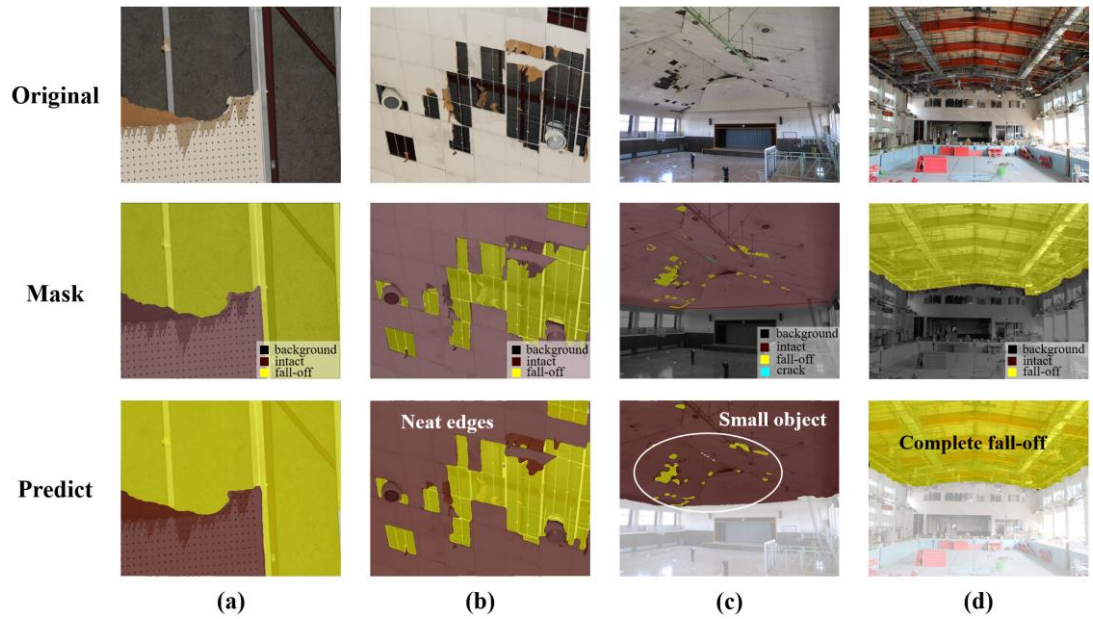

Figure 8. Examples of mask images and detection results of ceiling fall-off.

For the ceiling suspension, a similar high degree of overlap between the detection results and marked region compared with ceiling fall-off is achieved with the IoU of 87.11%. The suspension area can be detected well at different capture distances, as shown in Figure 9(a)-(c). When captured at a close distance, the edges of the suspension can be accurately detected, as shown in Figure 9(a) and (b). When the capturing distance is far, some factors can slightly affect the detection results. The colors of the two sides of the ceiling are sometimes different, as shown in Figure 9(c), and the model can well detect despite the darker color and smaller area of the suspension can visually confuse it with the fall-off region. In addition, since most of the suspensions are in the form of thin plates, their shapes are close to a thin line when captured at a specific angle, as shown in Figure 9(d), which may be missed detected and cause a certain degree of IoU reduction.

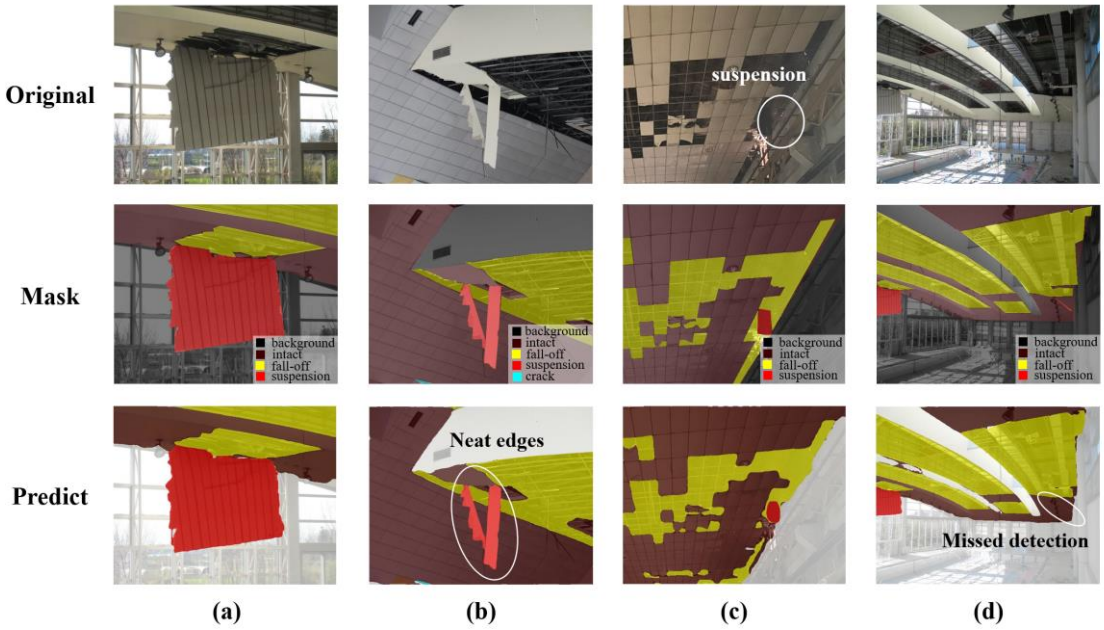

Figure 9. Examples of mask images and detection results of ceiling suspension.

For the detection of the crack, the IoU is 51.61%. Figure 10(a) and (b) reached an accurate detection, especially eight of the nine cracks labeled in Figure 10(b) are well detected although most of the cracks would be smaller targets in the long-distance capture. It indicates that the detection performance of the model is satisfactory at long distances and multiple targets. In addition, as the crack develops, it may cause part of the ceiling to fall off. At this time, the model is also able to achieve good detection for crack regions with adjacent locations and similar shapes to the fall-off, as shown in Figure 10(c). The relatively low IoU of crack compared to other categories are due to its shape which is mostly long or cracked. A significant increase in the area error could be caused by a small deviation in the direction of the short side in the case of a rectangle with a huge aspect ratio. In the example of the partially enlarged area of the crack in Figure 11, the green part represents the region where the detection result in overlaps with the cracked area, i.e., the correctly detected part. Due to the narrow geometry and small size of the crack, the increased area error reduces the IoU substantially when the detection results exhibit little deviation in the short side direction, i.e., the X direction in the figure. The detection areas in Figure 11(a) and (b) basically cover the damaged areas, with precision and recall achieving 90.72% and 83.02%, respectively. Nevertheless, their IoU is only 52.77% and 46.94%. The shape of the detected region in Figure 11(c) is very close to the damaged region, and the recall can reach 61.33% even if the IoU is lower than 50%. Therefore, this part of the error has little impact on the actual detection work. In addition, it can be observed from Figure 6 that the precision and the recall of crack are 63.41% and 73.49%, indicating that the detection has a great performance.

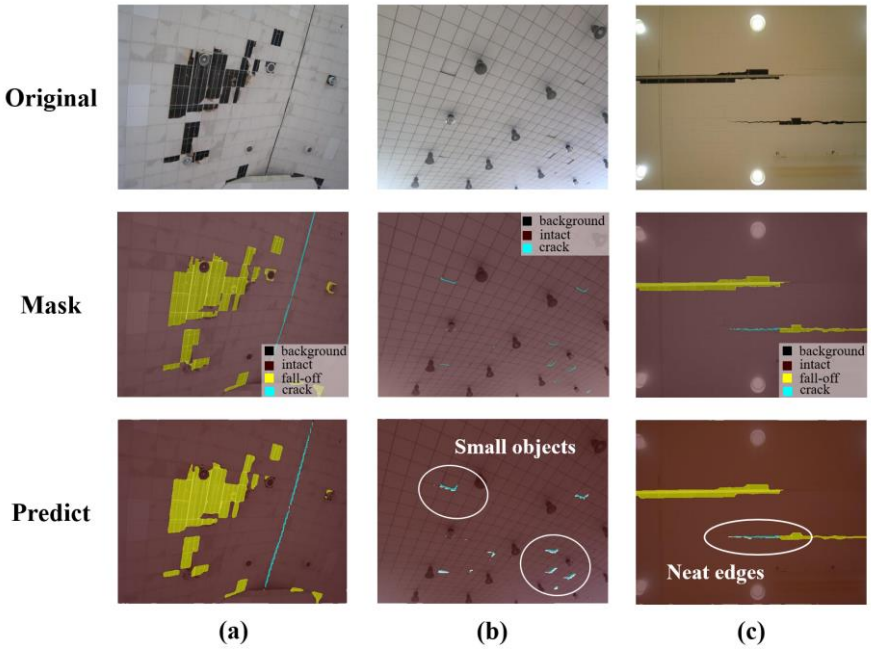

Figure 10. Examples of mask images and detection results of ceiling crack.

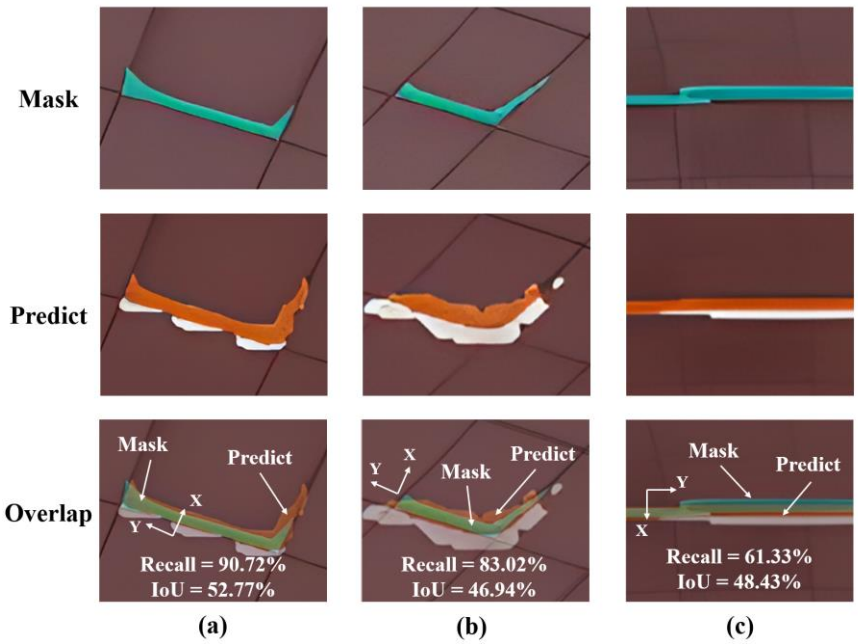

Figure 11. Examples of partially enlarged regions of the crack.

In most post-earthquake detection cases, as shown in Figure 12, several damages in multiple categories would appear in the image at the same time. Achieving accurate detection of small damage regions of different categories is challenging. A total of 36 damage regions with continuous boundaries were labeled in Figure 12(a), of which 31 were successfully detected with an accuracy of 86.11%. In Figure 12(b) and (c), with the shape and color of the suspensions similar to intact, the detection results achieved 70% and 88.89% accuracy despite some errors in some of the detected edges. In summary, the model can also achieve excellent detection results in challenging situations such as long-distance capture in the presence of multiple categories and several damages.

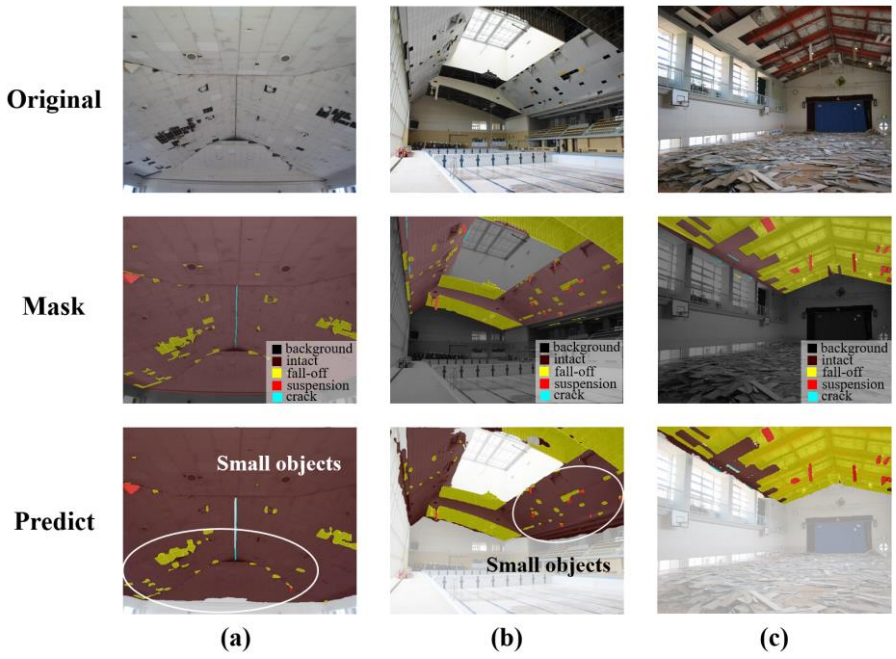

Figure 12. Examples of ceiling damage detection at long distances with multiple targets.

5. Conclusions

A damage detection method based on Deeplabv3+ is proposed for the rapid detection of damaged ceilings in large public buildings after earthquakes. A total of 1389 post-earthquake ceiling images were used to train, validate and test the model. Damage visualization was used to classify and localize the areas of different categories of damaged ceilings. The detection effects of different categories are analyzed based on the indicators of the test set and the results of damage visualization. The conclusions are summarized as follows:

(1) The damage detection model based on Deeplabv3+ obtained a PA of 97.23% and a mIoU of 84.18% in the test set. The proposed method has an excellent performance in correct classification and accurate localization in damage detection for the ceilings of large public buildings after an earthquake.

(2) The IoU of four ceiling categories and background achieved 95.32%, 91.61%, 87.11%, 51.61%, and 95.23%, respectively. The detection results in the test set were analyzed for a variety of situations, including capture distance, multiple categories, and small targets. Due to the narrow geometry and small size of the crack, the increased area error reduces the IoU substantially when the detection results exhibit little deviation in the short side direction. However, the results show that the detection regions for each category are almost identical to the marked real regions, achieving excellent detection performance. It shows that the method can accurately extract different categories of post-earthquake damage features of ceilings, display the contour shape of damaged regions.

ReconWood Slab. Computational design and structural optimization of reconfigurable timber slabs

Anja KUNIC[a], Roberto NABONI[a,*]

[a,*] CREATE - University of Southern Denmark
Campusvej 55, 5230 Odense, DK
ron@iti.sdu.dk

Abstract

In timber buildings lately (re)gaining importance thanks to their environmental and structural performance, it is imperative to rethink material usage to reduce the pressure on the forests and optimize how the harvested material is used. Slab structures in buildings account for a significant amount of material employed due to their load-bearing requirements. To achieve environmental decarbonization and truly circular building construction, this work introduced a stress-driven computational workflow for the design and optimization of reconfigurable timber slabs which rely on automation-driven reversible joints and reusable building elements. The developed workflow was demonstrated on the *ReconWood Slab*, an experimental prototype featuring a stress-based multi-resolution timber frame of primary and secondary *ReconWood beams* stacked one upon the other. The developed research results and the constructed prototype showed the possibility of controlling and manipulating material organization and stress distribution in the structures, providing a virtually infinite automated re-configuration of varying slab structures in response to changing boundary conditions. The work findings show an enhancement of the reconfigurability of timber structures, which is discussed as a fundamental property to extend the life cycle of wood carbon sinks.

Keywords: reconfigurable wood slabs, carbon storage, stress-driven design, voxel-based design, robotic timber construction, circular wood architecture

1. Introduction

Human-induced climate change, exponential population growth, and the consequent increase in consumption and extraction of natural resources are challenging our living environment [1]. The construction industry alone is responsible for 40% of global CO2 emissions and large amounts of extracted non-renewable resources. For this reason, the significance of wood construction, due to its low embodied energy, carbon sequestration capabilities, and renewable nature, has returned to focus after a long history of industrialization. However, the forests are not an infinite resource either, and thus, design, architecture, and material practices are challenged to deal in new ways with complex interdependencies and trades between the forest to be preserved and the city to be built.

To achieve environmental decarbonization and truly circular building construction, it is fundamental to rethink material usage from the point of view of (1) *stress-driven* material allocation [2]; (2) *tectonic flexibility* that invokes disassembly, re-use, and reconfigurability [3]; and (3) *data-driven design workflows* that can accommodate specific features from variable timber sources and allow for material trackability [4]. Slab structures are of interest as they are responsible for the most significant amounts of material usage due to their load-bearing requirements.

Moreover, they are often produced in large sizes and combined with other material layers, making them less flexible for re-use and re-configuration.

In this work, we challenge the massive timber construction which relies on one-time-used and custom-tailored building elements by introducing the *ReconWood* system [5] made out of generic reconfigurable building blocks with reversible [6] and automation-driven [7] joinery (Fig. 1).

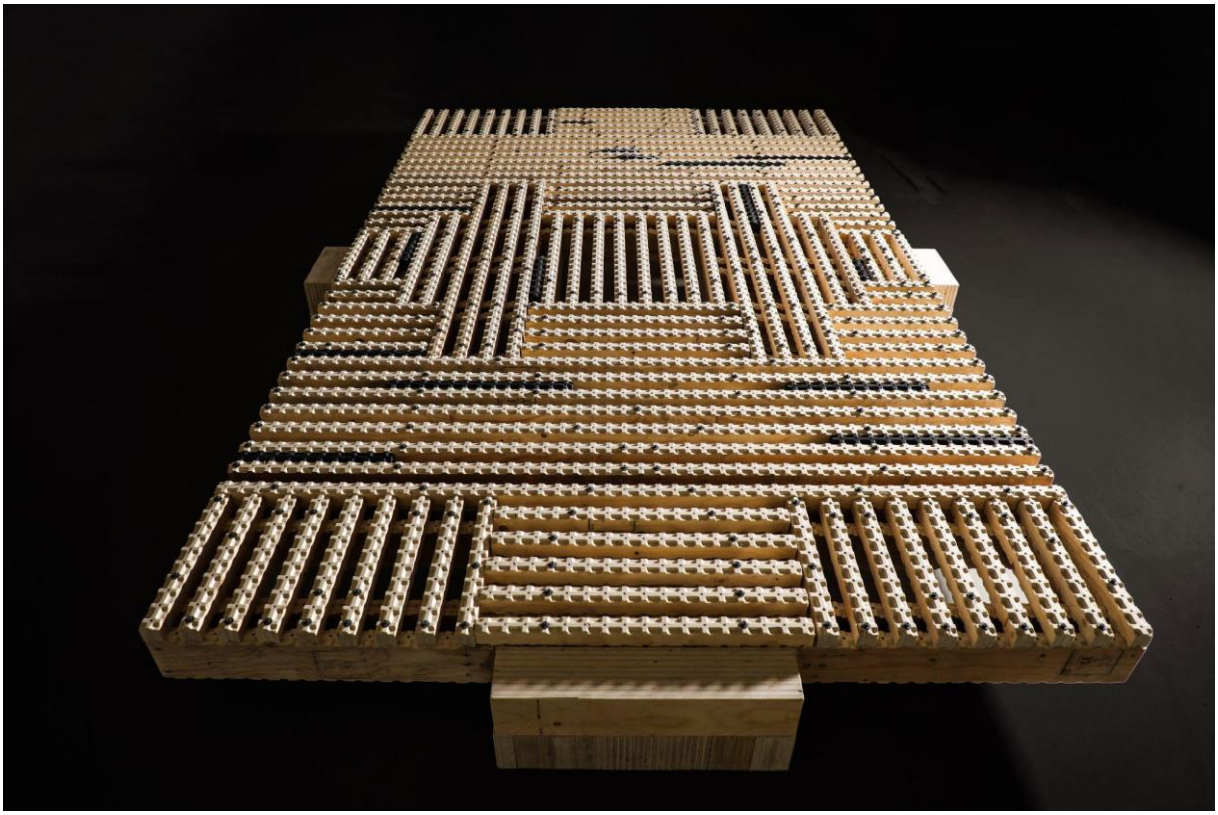

Figure 1. Picture of the ReconWood Slab prototype

2. Related work

Historically, due to the difficulty of finding, transporting, and handling long-span wood beams, the structural slabs were made of stacked and interlocked short beams, providing reciprocal supports [8]. Such systems offered an efficient method of covering large spans with short elements while assuring structurally efficient and durable floor structures.

Nowadays, eastern architecture such as the one of Kengo Kuma [9,10] still preserves the long-lasting tradition of stacking discrete timber girders into several layers to achieve the final load-bearing slab system. This layering of members avoids using massive beams while allowing light to pass through.

In academia, several contemporary research studies have been experimenting with stress-driven and robotically fabricated timber slabs to optimize material usage and structural efficiency. Here, the small-scale timber elements are positioned along principal stress flows in shape-and-span-adaptive stacked grids [11] or individual studs [12,13], reinforcing thin CLT plates and hollow slabs. However, reversibility and circularity properties are limited in these examples to facilitate the automation of the fabrication processes.

Our work is developed along the stress-driven approach, introducing a computational workflow for the design and structural optimization of novel automation and reconfigurability-driven timber slab structures, namely *ReconWood Slab(s)*. The ReconWood Slabs are based on layered stacking of discrete *ReconWood beams* with reversible joints that allow for a virtually infinite automated re-configuration of varying slab structures in response to changing boundary conditions.

3. Methodology

3.1. ReconWood Slab - system design and tectonics

The *ReconWood Slab* consisted of two stacked layers of laminated veneer lumber (LVL) beams, namely *primary* and *secondary ReconWood beams*, which formed a timber frame structure. Two lateral semi-threaded wood screws connected the primary beams at each intersection. On the other hand, the secondary beams were stacked on top of the primary ones by aligning three-dimensional male-female joints, facilitating automated assembly and disassembly while providing structural and positional stability during construction. 5 mm steel bolts fastened the joints with washers applied from the male side of the connection and steel insert nuts on the female side (Fig. 2). The cross-section height of the primary beams (117mm + 5mm joint height) was three times larger than the secondary ones (39mm + 5mm joint height), while the width of both was kept constant (39mm). The three-dimensional joints with holes in the middle were modularly repeated throughout the whole beam's length, with the distance between the holes equal to the width of the beams. This allows for many different connectivity patterns and high (re)configuration flexibility. The beams were discretized into a range of lengths divisible by the width value, ranging from 117 mm to 2028 mm, which allowed for variable structural resolution of the timber frame.

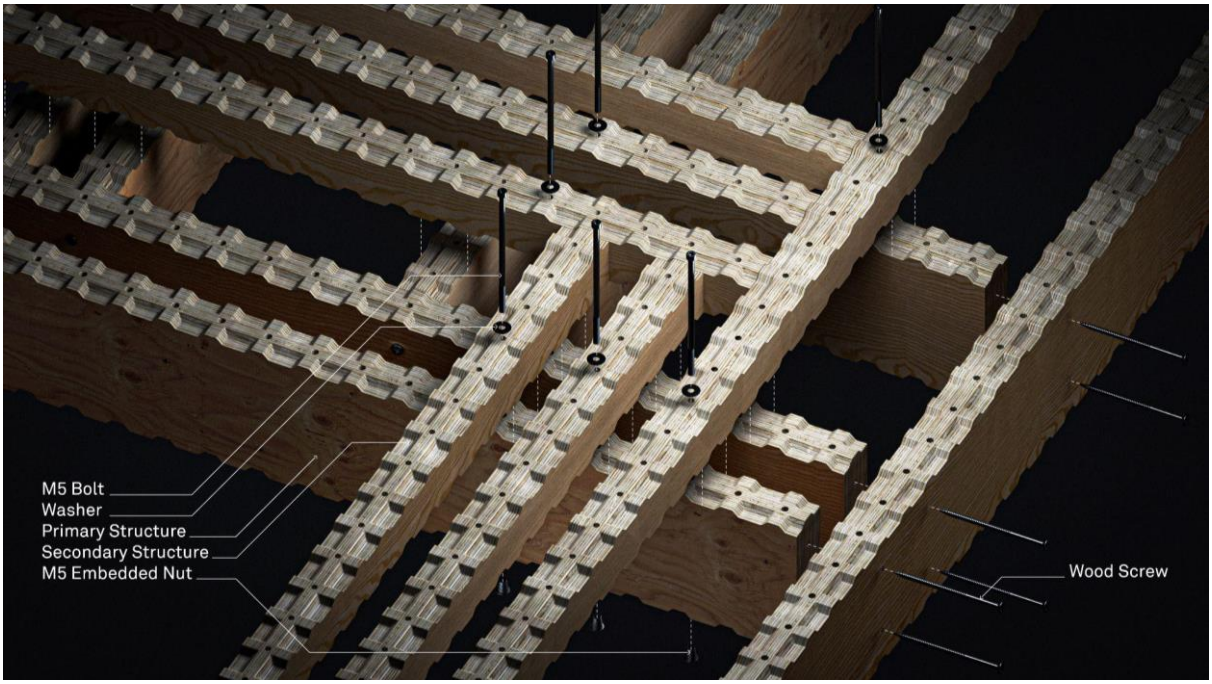

Figure 2. ReconWood construction system and joint types

3.2. Robotic fabrication of ReconWood beams

The ReconWood beams were robotically fabricated using a KUKA KR240 R3330 industrial robot arm that moves along a six-meter linear rail and is equipped with a 12 kW rotary spindle (Fig. 3). The building blocks of different lengths were nested into three-meter-long LVL beams which were clamped in front of the robot, parallel to the rail, and milled on the male side first, and female side afterwards.

Three milling tools were exchanged automatically during fabrication to produce the cross-shaped joints along the beam, and their respective Tool Centre Points (TCP) were defined in the toolpath programming algorithm. The 6 mm holes were drilled, providing additional space around the M5 bolts. This is desired both for facilitating the automated robotic assembly and disassembly [7] as well as for the mechanical performance of the joints [6]. Secondly, a V-shaped tool with a 45° inclined blade was

used to achieve oblique sides of the cross geometry in a single cut. Finally, a flat-end mill was employed to clear out the remaining material and even out all the horizontal sides of the joint.

Figure 3. (left) Robotic fabrication of a ReconWood beam; (right) Robotic milling toolpath of the male and female beam sides

3.3. Voxel-based computational design and structural optimization of ReconWood slabs

A computational workflow for the design and structural optimization of ReconWood slabs was developed through a voxel-based approach in Grasshopper for Rhino (Fig. 4). The voxelization method was used for computing the structural analysis, interpreting and discretizing its results and translating these into material layouts. The voxel size, and therefore the basic calculation unit, was based on the material unit itself, i.e., the length of the *ReconWood block*, significantly reducing computation time and allowing for a wide variety of design options. Implementing such an approach enables an easy and flexible iterative design process, where structurally optimized timber slabs are generated from simple user/designer inputs.

Karamba 3D [14] shell analysis was first performed to understand the slab deflection under given loading scenarios. The resulting data, such as the Principal shell forces and the Principal force directions, were discretized and used to determine the stress-driven material layout. The *Voxel* was a discretizing unit that stored self-pertaining structural data as design attributes. Thus the discretized Principal force direction was stored as a *direction* attribute and the Principal shell force as a *magnitude* attribute. A voxelized design space was generated from a given form or simply a set of inputs regarding structural boundary conditions. The corresponding materialized output was generated based on these, namely the *Maxel*.

Initially, a uniformly voxelized grid was computed, after which its *maxelized* counterpart was analyzed with Karamba3D beam analysis. If the beam displacement exceeded the targeted value (L/250), the voxels with larger *magnitude* attributes were subdivided. This procedure was repeated iteratively until

the maximum displacement conditions were met. Driven by the underlying voxel attributes, the optimized slab structure was characterized by a multi-resolution timber frame with a specific orientation of the primary beams and an optimized connectivity pattern between them.

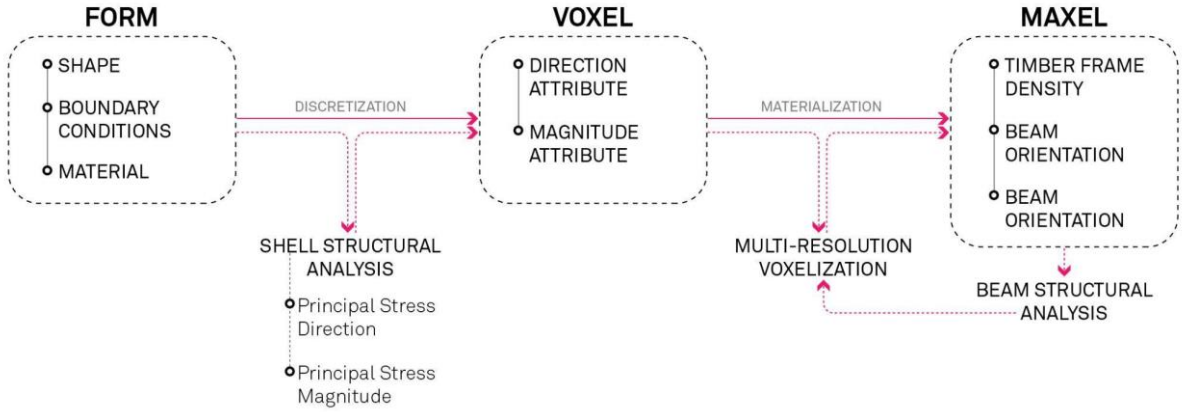

Figure 4. Computational workflow diagram for a stress-driven design and optimization of ReconWood slabs

3.4. Stress-based connectivity patterns

In the ReconWood slab, the reciprocal connectivity between the primary beams was crucial for the load transfer, while the secondary beams served as additional structural stiffeners. An algorithm that follows discretized Principal force directions and maximizes reciprocal connection points were implemented to optimize the force flow throughout the beams toward the supports.

In particular, a frame cell with a double beam was generated at each voxel's perimeter. The voxels with the same *direction* and *magnitude* attributes were joined into one frame cell. Considering the XY coordinate system to which the voxel grid was aligned, the beams of horizontal (along the X axis) and vertical (along the Y axis) were distinguished. Each beam was shortened or extended at both ends to meet its perpendicular neighbors most efficiently, allowing for a continuous and uninterrupted force flow. For each beam's endpoint, the algorithm first 1) checked the *direction* attribute of the voxel from which the specific beam is derived and 2) checked the *direction* attributes of the neighboring voxels. If the specific beam was oriented in the same direction as its correlated voxel and most neighboring voxels (e.g., vertical), it was extended until the first neighboring perpendicular beam. Else, if the beam was oriented in the opposite direction from its prevailing surroundings, it was shortened (Fig. 5). This control over the joinery layout was essential to ensure a stiff structure and maximize interconnectivity between the beams.

The secondary beams were consequently oriented perpendicular to their corresponding voxel's *directions.* Considering the span of the secondary beams and the number of primary beams upon which they lie, the number and positioning of the steel bolts were determined. The goal was to reduce the steel used while ensuring enough ties between the primary and secondary beams.

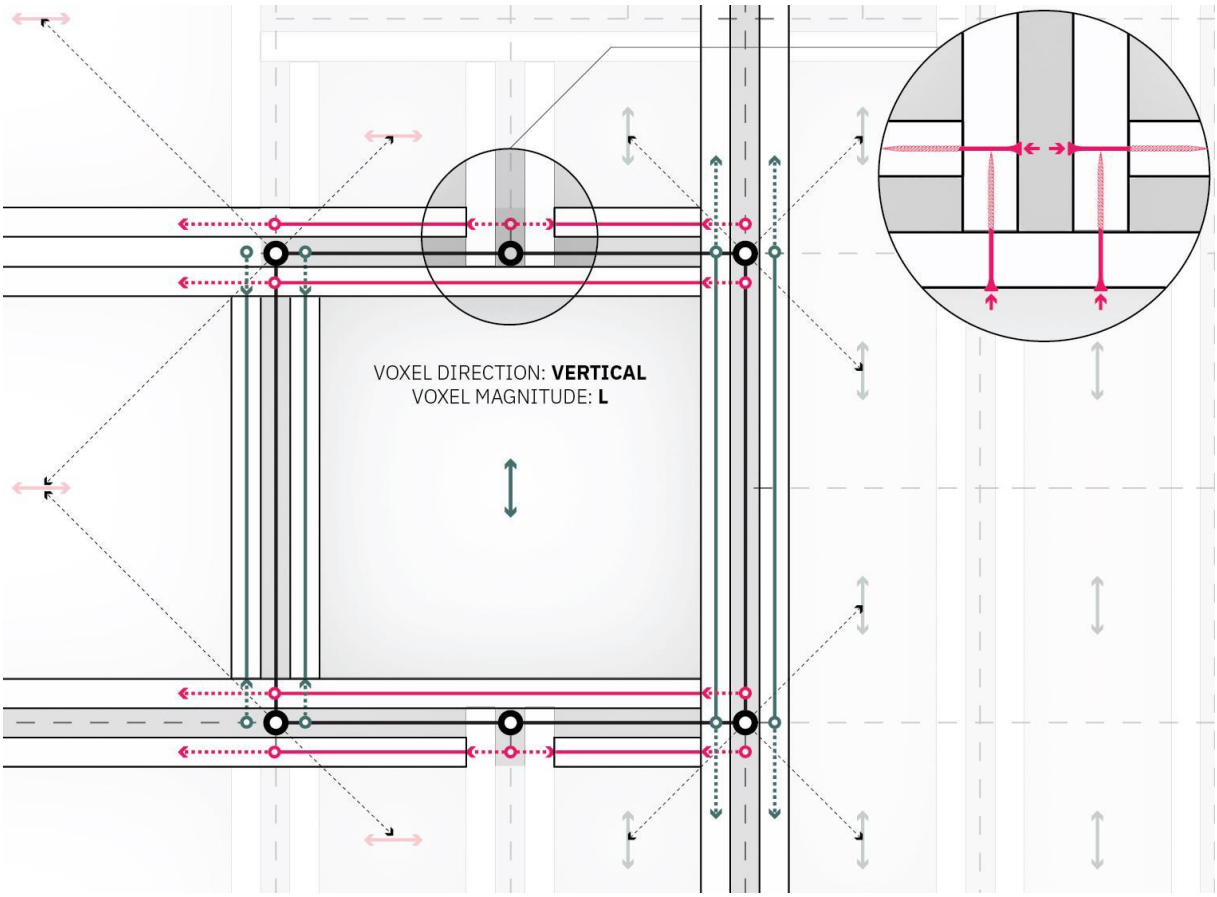

Figure 5. "Maxelization" process and connectivity optimization based on the stress-based Voxel attributes

4. Results

Design. Following the established workflow, a 3x2m ReconWood Slab was designed and structurally optimized. The slab was supported at four midpoints on each side, featuring cantilevering corners. The finite element model for the beam analysis (FEM) was developed, considering fixed supports and hinges at the connection points. To generate design iterations, a 200kg/m^2 distributed load and the self-weight of the structure were applied, and a maximum displacement limit was set. Considering the longest spanning beam of 1.5m starting from the support point on the longer side towards the cantilevered corner and following the Eurocode 5 [15] regulation for the instantaneous maximum deflection for cantilevering beams (W_{inst} = L/250), the value of 6mm was set as the optimization target. Different design options were generated and structurally simulated following a stress-driven multi-resolution voxelization, seeking an equilibrium between the material usage, maximum deflection, and stress distribution (Fig. 6).

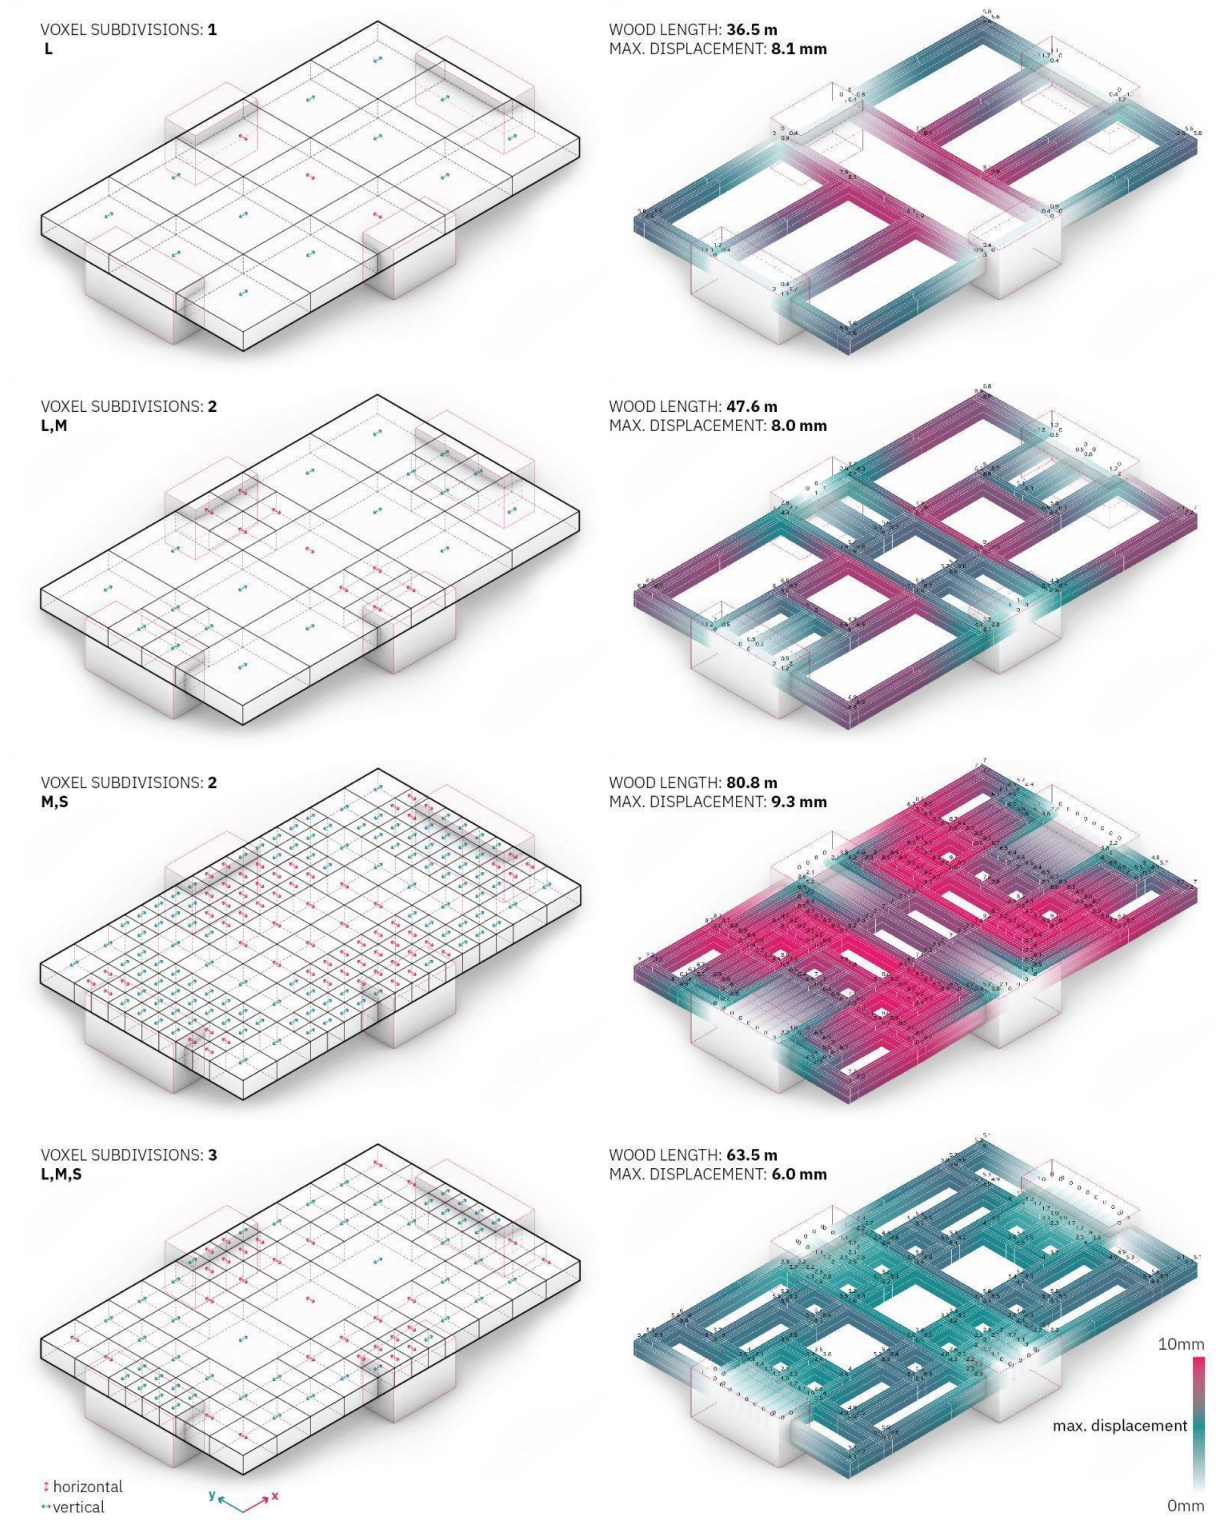

Figure 6. Iterative design and structural analysis of the ReconWood Slab prototype

The optimized slab resulted in 63.5 meters of wood for the primary beams and about 150 meters of wood for the secondary beams and a total weight of 210 kg. Since the goal of the ReconWood structures is reusability and reconfigurability, the structural layout with the most balanced stress distribution was selected, assuring that no joint or beam was overstressed and, therefore, unsuitable for use in further life cycles. Material redundancy and oversized safety factors are seen as an opportunity to provide long-lasting serviceability for each beam. Two semi-threaded structural wood screws were inserted at each connection between the primary and secondary beams. In contrast, the bolt-nut connections were minimized following the previously described principles (Fig. 7).

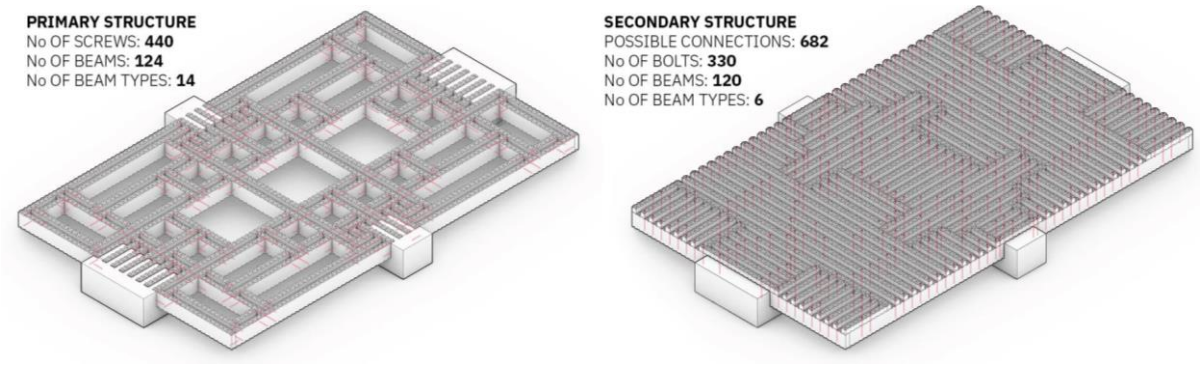

Figure 7. Final material configuration and optimized connections layout of the ReconWood Slab prototype

Workflow application. The flexibility of the established workflow was tested by applying the "calibrated" model for a specific loading condition to a wide range of design solutions that were generated to respond to different support layouts (Fig. 8A). For most of the generated slabs, the stress distribution and maximum deflection were already satisfying without the need for a further iterative optimization process (Fig. 8B). This means that the design optioneering and explorations can be done much faster. The iterative optimization can be done only at the beginning of the design process to calibrate the structural model and, in the end, refine the final design solution, thus saving much time.

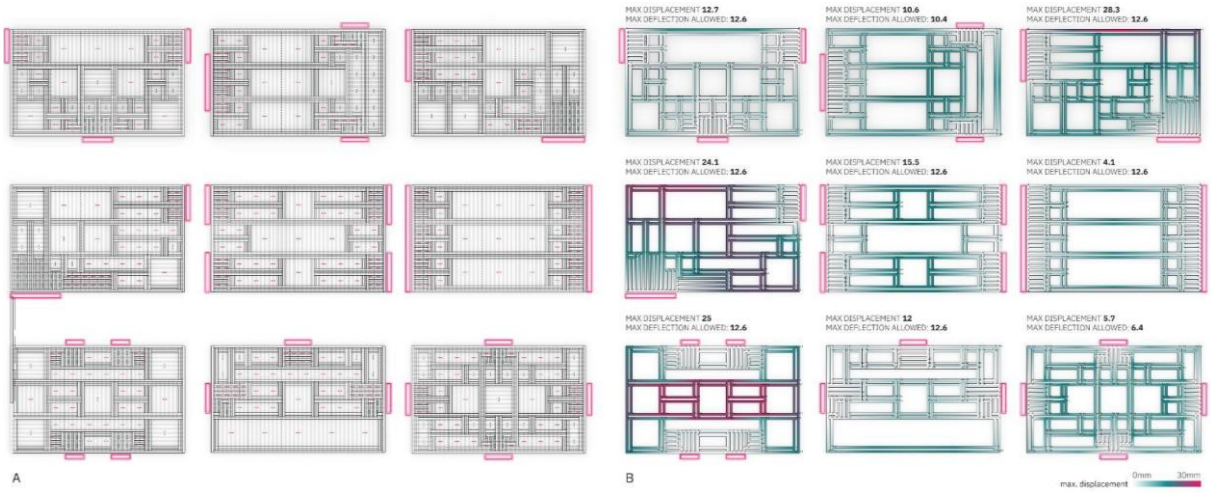

Figure 8. (left) Design optioneering of ReconWood slabs for a 200kg/m^2 + self-weight load and varying support locations; (right) Structural analysis outcomes based on a calibrated FE model

5. Conclusions and discussion

ReconWood is a system conceived for automated construction, de-construction, and re-construction of customized and data-informed prefabricated timber frame structures. This paper specifically described the computational design and structural optimization workflow for the generation of reconfigurable timber slabs using this system, following a stress-driven double-frame layout (Fig. 9). The process and constructed prototype results showed the possibility of obtaining structural layouts and controlling the stress distribution within the structure while ensuring the reusability of the building elements, thus extending the CO_2 capture within them. Disassembly and re-assembly of different configurations are made possible, enabled by closed data loops and a data-driven design approach. This construction system supports a more agile and transformable architecture without needing large and massive construction elements that limit spatial and operational flexibility and adaptation. Moving towards an application at a larger scale, the future work will further study and focus on mechanical characterization of the different joints, which will inform a new iteration of the FE modeling and simulation process. The ReconWood slab will be structurally benchmarked to CLT slabs to fully evaluate the potential of this construction concept. From an industrialization perspective, the fabrication process would require a redesign for parallel machining to reduce production time and costs.

Abstract

With the frequent occurrence of extreme ice and snow weather, engineering accidents such as the destruction and collapse of building structures have happened increasingly, resulting in huge economic losses and a large number of casualties. Due to functional requirements and building appearance, various forms of local obstructions are often arranged on long-span roofs. Such a structural form will exacerbate the uneven distribution of snow cover, which can more easily cause damage and destruction of the roof structures. Therefore, based on the wind-snow combined experiment facility and the similarity criteria based on snowfall, this paper systematically investigated the characteristics of snow distribution on long-span roofs with local obstructions under the effects of different inflow wind velocities, different lengths of the windward side of the obstructions, different heights of the obstructions, and different distances between obstruction center and long-span roof edge.

Keywords: long-span roofs, local obstructions, snow loads, wind-snow combined experiment

1. Introduction

In recent years, extreme ice and snow weather has occurred frequently worldwide, and the damage to building structures caused by snow disasters has become the focus of scholars [1]. With modern buildings in China becoming more and more diverse and complicated, long-span roofs are increasingly and widely used in civil, public, and industrial buildings. To satisfy the specific functional requirements and building appearance, it is often necessary to arrange various local obstructions on long-span roofs, such as daylighting and ventilation skylights, or air conditioning equipment. A long-span roof is a typical snow load sensitive structure due to the lightweight, complicated roof shape, huge roof area, and large proportion of snow load. Therefore, it is much more easily to form local snow accumulations on the roof, which is more likely to result in engineering accidents during snow disasters, causing more serious property losses and casualties. While the presence of local obstructions can exacerbate the uneven distribution of snow cover on the long-span roofs as shown in Figure 1, which will further increase the safety hazards of the structures and cause cracking and falling off of roof structural components, even resulting in severe engineering accidents such as structural overall collapse.

Currently, there is little research on snow distribution in long-span roofs with local obstructions, and the regulations on snow distribution coefficients for such roofs in the snow load codes lack sufficient data and empirical support. Therefore, based on wind-snow combined experiments, the important factors that affect the process of wind-induced snow drift on long-span roofs with local obstructions, such as the inflow wind velocity, the length of the windward side of the obstruction, the height of the obstruction,

and the distance between obstruction center and long-span roof edge were systematically investigated in this paper, and the laws of snow distribution patterns and coefficients were summarized, which could provide for future building code revisions and practical engineering applications with a reference.

Figure 1. Uneven snow distribution on long-span roofs with local obstructions

2. Wind-snow combined experiment

2.1. Experiment facility

The experiments were carried out in an outdoor wind-snow combined experiment facility which was independently developed by the research team at the Harbin Institute of Technology [2], as shown in Figure 2. The experiment facility consists of a power system (fan matrix, guide tube, honeycomb, and damping net), a vibration-seeding snowfall simulator, an experimental platform, and a measurement system (thermal anemometer, PC-4 automatic weather station, box-type snow flux trapper). The experimental section is 4.5m×3.0m×10m and equipped with a laser positioning system, which can simulate any experiment cases under different wind directions. The power system consists of a 2×3 fan matrix, which can generate a stable and continuous wind field from 0.5m/s~11.5m/s. The snowfall simulator can seed snow particles into the experiment section through vibration, and different snowfall intensities can be simulated by adjusting the vibration frequency and the size of the sieve aperture.

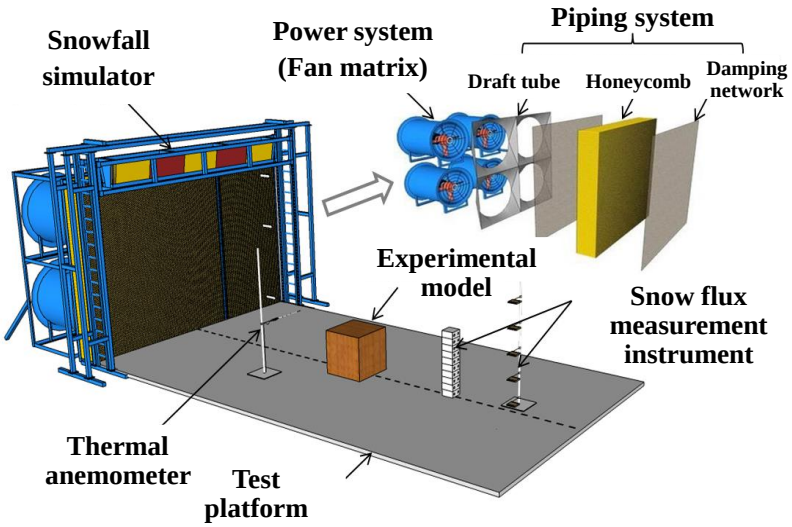

Figure 2. The design diagram of the wind-snow combined experiment facility

2.2. Validation of the experiment method

In order to validate the accuracy of the experiment method, the field observations of snow distribution around a standard cube model measured by Oikawa [3] (No. SN09) were selected as the prototype, and a comparative experiment was designed using the similarity criteria based on snowfall patterns [4]. The scale ratio of the experiment model was set as 1/5, the inflow wind velocity was set as 1.7m/s, the inflow

wind direction angle was set as 0 °, the snowfall rate was set as 25mm/h, and the experiment particles were artificial snow particles.

Figure 3 shows the comparison of SN09 measured results with those from different experimental results conducted by *Li et al*. Selecting the snow distribution in the standing vortex region at the front of the model of the windward direction as the focus to analyze, three essential characteristic points were divided: ① the peak value of snow deposition area on the windward side near the model; ② the minimum value of snow erosion area on the windward side of the model; ③ the peak value of snow deposition area on the windward side far away from the model. By comparing the snow distribution coefficients at three characteristic points obtained by different methods, the deviations among results of field observation and different experiments were shown in Table 1. It is obvious that the accuracy of snow distribution prediction using the wind-snow combined experiment method in this paper was higher than others, which validated the reliability of the experiment method.

3. Wind-snow combined experiments of the long-span roof with local obstructions

3.1. Experiment settings

Since this paper aimed at investigating the influence of local obstructions on the snow distribution on the long-span roof, the same long-span roof was set for each experiment case, to eliminate the interference from different roof features on the snow distribution. The dimension of the long-span roof model was set as 2.0m×2.0m×0.5m with a scale ratio of 1/20. Considering the numerous factors that affect the snow distribution on the long-span roof with local obstructions, the inflow wind velocity, the length of the windward side of the obstruction, the height of the obstruction, and the distance between the obstruction center and long-span roof edge were selected as the investigated objects in this paper. Referring to the provisions in engineering applications, for the experiments, the width of the obstruction was set as 0.1m, the length of the windward side of the obstructions l_0 was set as 0.1m, 0.2m, 0.3m; the

height of the obstructions h was set as 0.1m, 0.125m, 0.15m; the distance between obstruction center and long-span roof edge l_u was set as 1.0m, 0.6m, 0.3m, as shown in Figure 4. The inflow wind simulated the environmental conditions of the Class B landforms. The wind velocities for the prototype building were set as 4.7m/s, and 6.6m/s, and the corresponding experiment wind velocities were 2m/s, and 2.5m/s calculated by the snowfall similarity criteria.

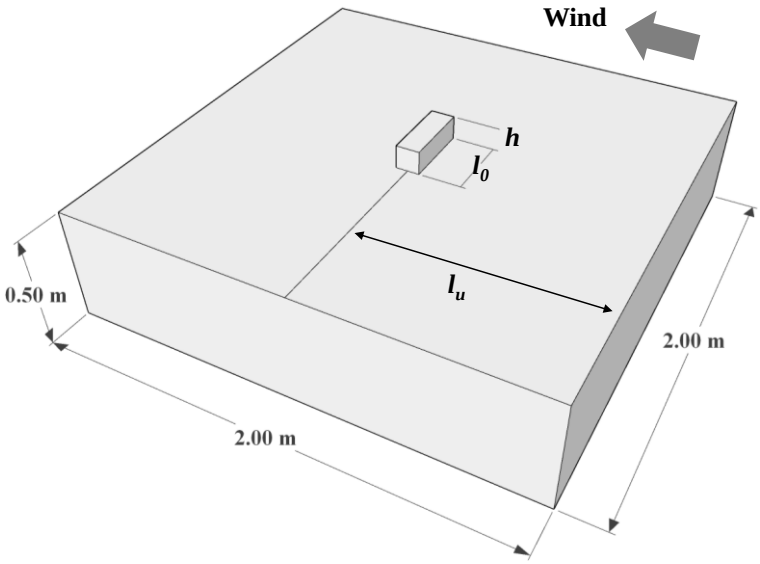

Figure 4. Experiment model

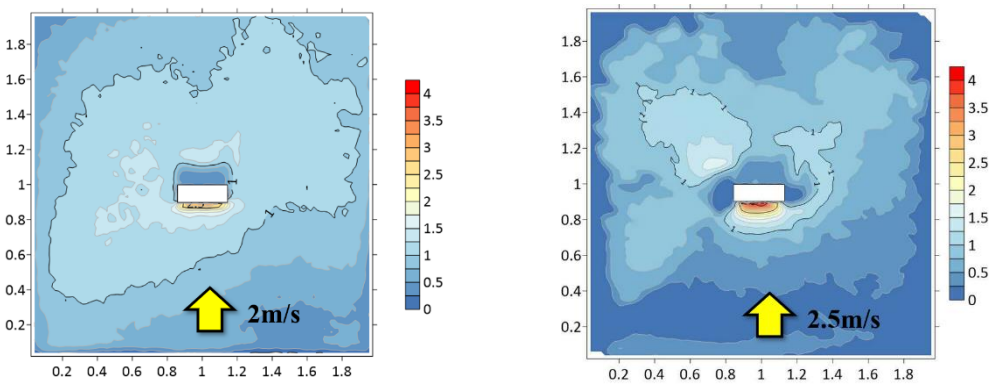
3.2. Experiment results

The experiment results were illustrated by the snow distribution coefficient, which was obtained by dividing the snow depth at any point by the mean snow depth on the ground without obstacles. Figure 5 shows the contours of the snow distribution coefficient under different wind velocities. It is illustrated that with the increase in wind velocity, the overall snow accumulation amount on the long-span roof decreases. However, an obvious snow deposition region appears on the windward side of the local obstruction, and the peak snow distribution coefficient increases, with a maximum of 3.8. In addition, there are two horseshoe-shaped snow erosion regions appearing on both sides of the local obstruction with wind velocity increasing, which exacerbates the uneven distribution of snow and causes a more adverse impact on the structure.



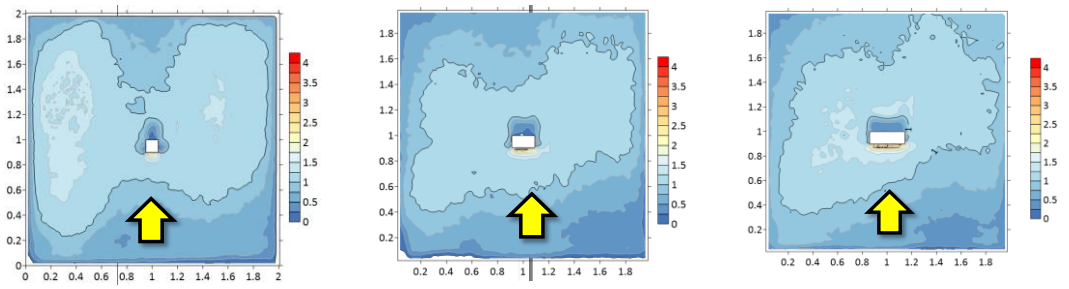


Figure 5. The contours of the snow distribution coefficient under different wind velocities

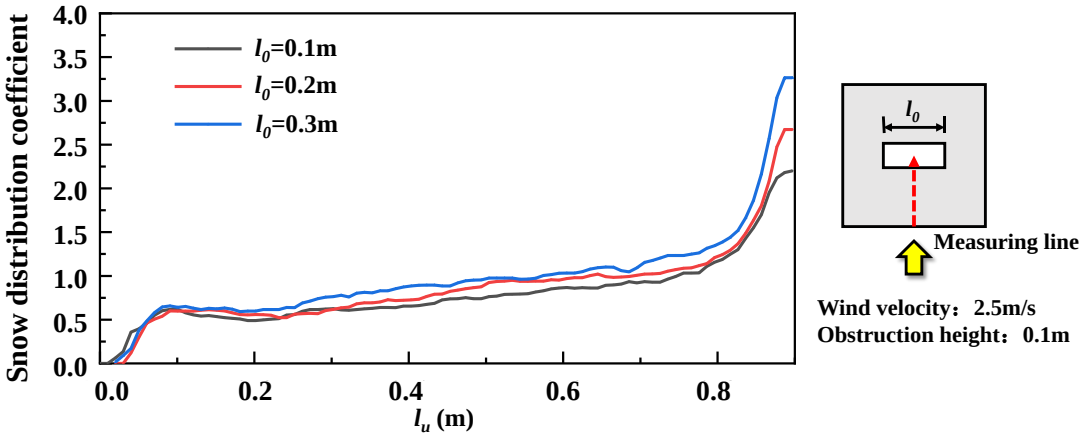
Figure 6 and Figure 7 show the contours and centerline values of the snow distribution coefficient under different lengths of the windward side of the obstructions. As the increase of the length of the local obstructions, the uneven snow distribution on the long-span roof on the windward side increases

gradually, and the maximum snow distribution coefficient could reach 3.3. Moreover, with the increase of the obstruction length, the obstructed cross-sectional area of inflow wind increases, which resulted in an increase of the overall snow accumulation amount in front of the obstruction at the windward side. Nevertheless, such influence on snow distribution only occurs within a certain range near the local obstruction, and there is nearly a change in the other area farther away from the local obstruction.

(a) l_0=0.1m (b) l_0=0.2m (c) l_0=0.3m

Figure 6. The contours of the snow distribution coefficient under different lengths at the windward side of the obstructions



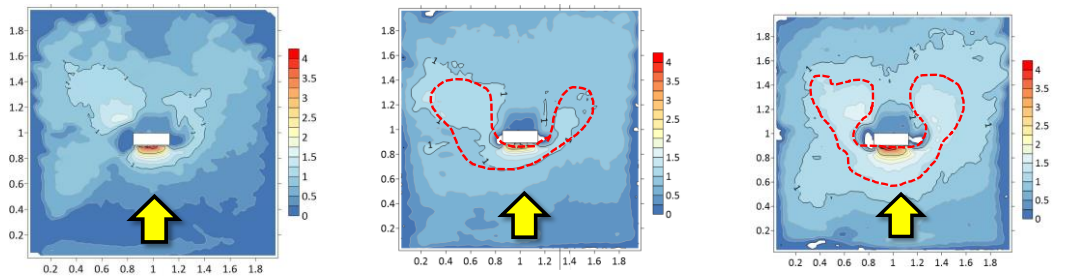


Figure 7. The centreline values of the snow distribution coefficient under different lengths at the windward side of the obstructions

Figure 8 and Figure 9 show the contours and centerline values of the snow distribution coefficient under different heights of the obstructions. It can be concluded that as the height increases, the area covered by snow particles increases, and two horseshoe-shaped erosion areas start to appear at both sides of the local obstruction, which are circled by red dotted lines in Figure 8. Besides, the range of uneven snow distribution grows with the increase of the obstruction height, and the peak snow distribution coefficient value could reach 4.2.

(a) h=0.1m (b) h=0.125m (c) h=0.15m

Figure 8. The contours of the snow distribution coefficient under different heights of the obstructions

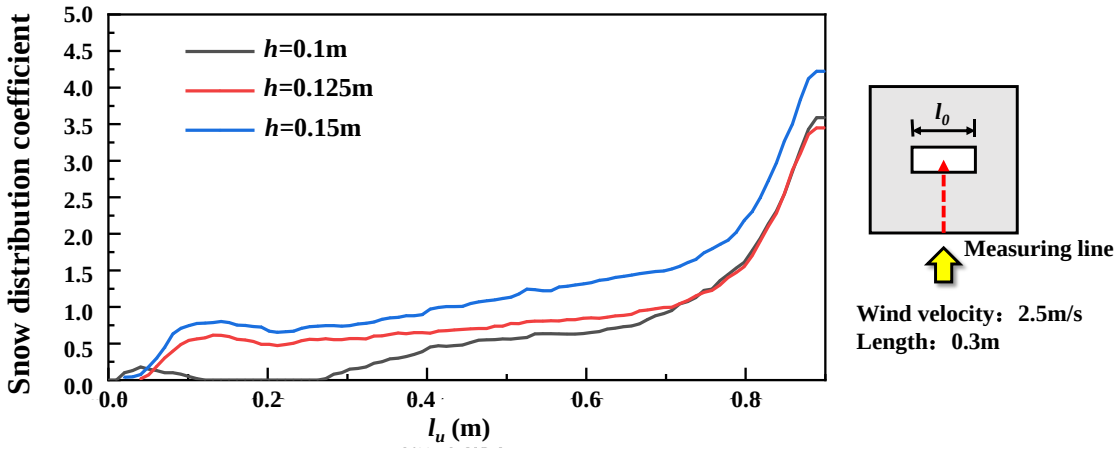

Figure 9. The centreline values of the snow distribution coefficient under different heights of the obstructions

Figure 10 shows the centerline values of the snow distribution coefficient under different distances between the obstruction center and long-span roof edge l_u. With the decrease of l_u, the amount of snow deposition in front of the local obstruction at the windward side also decreases. When l_u decreases to 0.6m, the peak value of the snow distribution coefficient decreases to 2.4; while when l_u decreases to 0.3m, there is a significant erosion region shown in front of the obstruction, with almost no accumulation of snow particles, and snow particles deposition occurs again at a distance from the obstruction. Through comparing different experiment cases, it can be found that when the l_u is $0.6l_u$~l_u (l_u=1.0m), with the increase of l_u, the area on the roof where snow particles can drift expands, and the peak value of snow distribution near the obstruction also increases; When l_u is within the range of 0.3 l_u to 0.6 l_u, due to the closer distance between the obstruction and the edge of the roof, the inflow wind field will generate vortices at the front of the obstruction at the windward, resulting in a significant erosion area at the windward side in front of the obstruction.

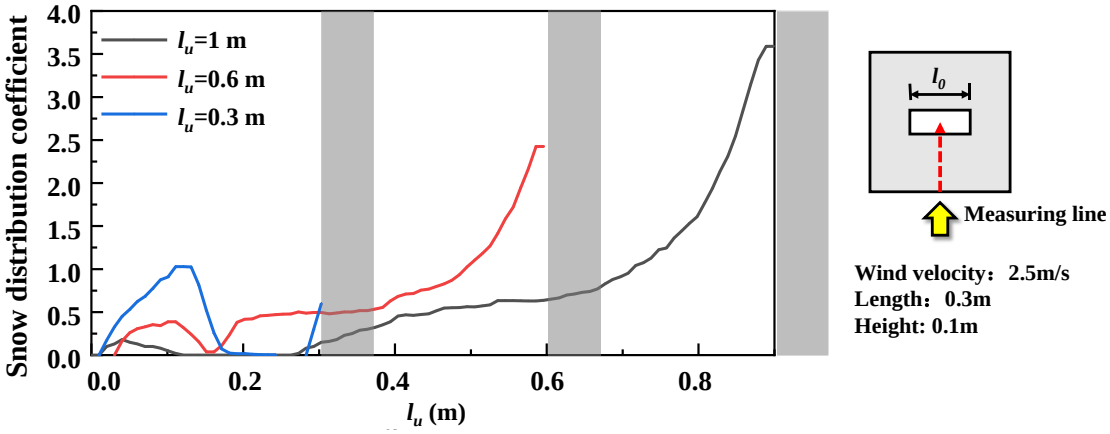

Figure 10. The centreline values of the snow distribution coefficient under different distances between the obstruction center and long-span roof edge

4. Conclusions

This paper systematically investigated the snow distribution characteristics on the long-span roof with local obstructions, the followings are the conclusions:

(1) The snow distribution on the long-span roof with local obstructions shows a typical pattern, with a horseshoe-shaped accumulation area around the center of the local obstruction. There is an obvious deposition area that appears on the windward side of the local obstruction, and erosion areas appear on

both sides of the obstruction. Such uneven snow distribution can result in adverse consequences for long-span roof structures.

(2) The snow distribution on the long-span roof with local obstructions is significantly affected by inflow wind velocity. Higher wind velocity can reduce the overall amount of snow particles on the roof, but it can exacerbate the uneven snow distribution on the long-span roof, with a maximum value of 3.8.

(3) For the long-span roof with local obstructions, the snow distribution coefficient on the roof is positively correlated with the height and length at the windward of the local obstruction. As the distance between the obstruction center and the long-span roof edge decreases, the snow distribution coefficient will also decrease, but there will be obvious erosion areas at the windward side of the local obstruction.

Abstract

RETHINK ROTOR, the reuse of rotor blades in the construction sector promotes the circular economy that works across industries, which not only enables significant CO2 reductions by keeping the giant blades in the anthroposphere, but also shows a way out of the recycling dilemma. Thanks to the aesthetic potential and material properties such as durability, corrosion resistance, lightness and stability, added value is gained for the construction industry.

Keywords: fiber composites, shells, energy turnaround, architecture, climate turnaround, circular economy, wind energy, waste management, construction industry, urban mining

1. Introduction

The European Union's goal, as set out in the "European Green Deal", to reduce net emissions of greenhouse gases to zero by 2050, or to offset all unavoidable emissions with suitable processes and thus become the first continent to become climate-neutral, requires the transformation of the economy to circular systems (Circular Economy). The European fiber composite industry is facing major challenges in this context. On the one hand, the demand for lightweight materials in energy-intensive value chains such as the wind energy industry will increase; on the other hand, fiber composites have so far been difficult to reuse or recycle because the available technologies such as high-temperature pyrolysis or shredding (for use as a filler) are either not environmentally friendly or economically unattractive. In addition, it is forecast that from 2025 onwards, around 80,000 tons of material will be produced annually from end-of-life composite components - in Germany alone, around 7,500 discarded rotor blades are removed from wind turbines every year.But what happens to the discarded, in some cases over 80 m long, custom-made epoxy resin-bonded fiber-reinforced plastics (FRP) after their approx. 20 years of use in the wind farm?

REHINK*ROTOR supports the way out of the recycling dilemma: leaving the huge blades in the anthroposphere enables a significant CO2 reduction. The reuse of the complete rotor blades is many times more sustainable than their material recycling.

Upcycling: the aesthetic potential of the blades, their durability, corrosion resistance, lightness and stability are an added value for the construction industry.

New life cycle: the reuse of rotor blades reduces the consumption of raw materials and energy and the amount of waste generated.

The resource-conserving use of materials, building products and processes makes a significant contribution to climate justice and cannot be reduced to individual sectors. The cross-sectoral linking of

Copyright © 2023 by Marcin ORAWIEC and Ina-Marie ORAWIEC. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

circular value creation is a significant prerequisite for the success of the climate, construction, mobility and energy transformation. In this context, the socio-economic potential of the creative industries in particular can enrich and dynamize cross-innovative collaboration and the conviction that this will result in projects that solve man-made problems and do not create further ones. The RETHINK*ROTOR technical session will thus become a "best practice" example and an initial spark for comparable, transdisciplinary projects.

Promotion of acceptance: due to its sustainability, REHINK*ROTOR stands for a visibly comprehensible, social added value and has a positive influence on the public perception of wind energy.

2. Background information

2.1 Background information on the construction industry

approx. 90% of all mineral raw materials used in Germany are used for the production of building materials. The construction industry is a major contributor to waste generation (approx. 54%). Buildings account for 40% of the total energy demand, so that resource-saving construction is of particular importance.

2.2 Background information Wind energy

With approx. 22% of the gross electricity in Germany, wind energy is a fast growing market, but wind turbines have to be dismantled after 20 years. In Germany alone, 7,500 decommissioned rotor blades are produced annually. Their plastic matrix cannot be deformed. The material cocktail of the blades can only be partially recycled by means of costly, environmentally harmful processes. This is not done residue-free, neither CO_2-neutral, nor sustainable! Some are therefore shredded and metal residues contained therein are separated. The remaining waste is used as fuel or substitute in the cement industry or burned in small quantities in waste incineration plants.

2.3 Background information on political and social framework conditions

In December 2015, at the World Climate Conference in Paris, a climate agreement was reached in which 195 countries pledged to curb climate change and to transform the global economy in a climate-friendly way. Specifically, the agreement states that the global temperature increase should be limited to 1.5 degrees Celsius if possible, and in any case to well below two degrees Celsius compared to the pre-industrial era.

To achieve this goal, no more climate-damaging gases may be emitted in the second half of this century than are removed from the atmosphere by so-called carbon sinks, such as forests.

One of the most important principles for our handling of these findings is: the gray energy contained in every building but also in every manufactured part (e.g. rotor blade) is irretrievably lost if we do not reuse it. In order to reduce further exploitation of the earth's resources, the preservation or recycling of urban warehouses represents an important economic objective.

For this reason, a team of experts has been working for some time within the RETHINK*ROTOR project on the possibilities of finding a reuse for the discarded rotor blades in the construction industry - in the spirit of circularity.

2.4 Background information Processing

because of the high-performance but exclusively duromer-based material cocktail, the rotor blades are only partially recyclable through costly, environmentally harmful processes. Once cured, the epoxy resin-based plastic matrix of the huge blade surfaces can no longer be deformed. Some are therefore shredded after dismantling and metal residues contained therein are separated. The remaining waste is thermally recycled as fuel and sand substitute in the cement industry or incinerated in small quantities in conventional waste incineration plants. This form of thermal recycling is not residue-free, neither

CO_2-neutral, nor sustainable. The complex geometry of the rotor blades and their material properties, such as durability, combined with low weight and high rigidity, offer the way out of the recycling dilemma. The shapeliness of the components and the efficiency of the composite material can be "profitably" exploited in new applications. The construction industry, with its large material consumption, is therefore particularly predestined for the use of end-of-life (EoL) components.

Recycling is accompanied by a loss of quality of the non-degradable materials, which eventually end up in the waste. Common practice is therefore to store the rotor blades indefinitely. Due to their sheer size, this triggers a steadily increasing demand for space.

2.5 Background information on existing recycling processes

according to the evaluation of the recycling processes of the discarded rotor blades considered in various studies, it can be assumed that these processes will not achieve sufficient capacities in the foreseeable future to recycle the forecast GRP waste volumes. In addition, a large number of materials with insufficient data on toxicological effects are installed in rotor blades. A concrete example is the glass fibers, which may or may not be classified as carcinogenic depending on their type. Since critical fiber fragments with WHO geometry can be released during processing, the more dangerous case must always be assumed according to the precautionary principle.

3. Design principles

3.1 Initial situation design

RETHINK*ROTOR provides high-quality yet simple solutions for the complex task of giving disused rotor blades a second life in the construction sector and integrating them into the architecture of buildings.

The "second life applications" of the complex geometries of the rotor blades are supported by the beauty of the parts, but in order to guarantee their use in new applications, a whole series of creative and constructive ideas are required. Only then can the aesthetic potential of the repaired, used and reclaimed be fully realized.

The complex geometry of rotor blades and the fact that cutting them up is costly and sometimes harmful to health makes it necessary, when reusing the discarded custom-made products, to "profitably" transform the shape into a new form - a challenge for creatives that the team of the RETHINK*ROTOR project has taken on.

The challenge, which results from the complexity and a long-lasting use of the parts once produced, whether these are rotor blades or parts of a building, illustrates the urgency of solving the individual critical aspects. Without this, the vision of the building turnaround and the sustainable built world is only an illusion.

3.2 Static and design qualities

the wind turbine rotor blades, which are made of glass fiber-reinforced plastic, are subjected to static stresses - due to their own weight and wind - and, above all, dynamic stresses - in the form of vibrations - throughout their entire service life during initial use. Unlike most metals, fiber composites exhibit very good fatigue properties. Even under frequent load changes, the fatigue strength remains only slightly below the static strength.

No reduction in strength or other mechanical properties is to be expected after initial use. For the rotor blades intended for reuse, material properties can be assumed to be the same as for a newly manufactured GRP component. The rotor blade is designed as a hollow body, which is kept dimensionally stable by various stiffening ribs. Due to the variable oval shape over the length, there are clearly different geometric stiffnesses in the main directions (surface moments of inertia). The fiber scrims, which are

quite uniform over the surface, have local reinforcement areas and are reinforced with some compact chords. The bending, torsional and elongation stiffness has to be determined based on a specific analysis of the geometry and fabric formation, but can be well captured using simplified assumptions.

The rotor blades can be used as bending-stressed, torsion-stressed or normal-force-stressed components.

The necessary connection and joining points are advantageously realized by laminating stainless steel sheet segments. In this way, structural steel connections can be used for joining.

3.3 Scalability of possible uses

as already mentioned, about 7,500 of the rotor blades are currently disposed of as waste each year in Germany. In the near future, a much larger number can be expected.

For this reason, the focus of the Rethink*Rotor project is on a broad spectrum of possible new applications for rotor blades in the construction sector. Starting with 30 to 60 pieces for an industrial hall or 600 for a noise barrier up to 2000 or more for a pontoon construction as a floating support structure for a floating village. These are only three selected examples of many topics that the Rethink*Rotor project deals with. An important aspect is to find a secondary use near the original location of the wind turbine in order to minimize the transport distances. To this end, work is also being done on processing concepts that enable on-site feasibility. One of the prerequisites is that the joints for the components can be realized with low-tach methods.

Thanks to the prospects shown for subsequent use for the rotor blades, acceptance of the wind turbines in an urban context will also be increased.

3.4 General design starting point: the rotor blades of the wind turbines, which are made of glass fiber-reinforced plastic, are subjected to static stress - due to their own weight and wind - and, above all, dynamic stress - in the form of vibrations - throughout their entire service life during initial use. Unlike most metals, fiber composites exhibit very good fatigue properties. Even under frequent load changes, the fatigue strength remains only slightly below the static strength. No reduction in strength or other mechanical properties is to be expected after initial use. For the rotor blades intended for reuse, material properties can be assumed to be the same as for a newly manufactured GRP component. Of course, each component will have to be subjected to close inspection to determine that no mechanical damage such as localized fracture, delamination, etc. is present. The rotor blade is designed as a hollow body, which is held dimensionally stable by various stiffening ribs. Due to the variable oval shape over the length, there are clearly different geometric stiffnesses in the main directions (surface moments of inertia). The fiber scrims, which are quite uniform over the surface, have local reinforcement areas and are reinforced with some compact chords. The bending, torsional and elongation stiffness has to be determined based on a specific analysis of the geometry and fabric formation, but can be well captured using simplified assumptions. The rotor blades can be used as bending-stressed, torsion-stressed or normal-force-stressed components. The necessary connection and joining points are advantageously realized by laminating stainless steel sheet segments. In this way, structural steel connections can be used for joining.

4 Fields of application

An important aspect when deciding where to use the discarded rotor blades is the proximity to the site of the wind farm that is to be dismantled. This guarantees short transport distances.

For this reason, the applications are divided into onshore and offshore applications.

4.1 Onshore applications include:

4.1.1 Noise barriers

Similar to the initial application in the wind turbine, the rotor blades, which are set up in a row, are primarily loaded by wind transverse to the longitudinal axis. Therefore, no reinforcements to a significant extent should be necessary.

Figure 1. Noise barriers

4.1.2 Schuchow tower

The rotor blades are used as vertical members mainly transferring gravitational loads. The inner structural layer effectively stiffens the structure.

In this variant, the rotor blade segments are mainly subjected to normal force loads.

Depending on the specific design of the structure, longitudinally laminated GRP or CfK webbing supports the load transfer. Tie points to the inner cable structure can be designed as anchor points laminated to the inner belt layer.

Figure 2. Schuchow tower

4.1.3 Cantilever beams - Rotating roof support structure

The horizontal segments are mainly subjected to normal force (compression) and secondarily to bending due to the attached roof cladding. The chord reinforcement required for bending and normal force is combined in one element.

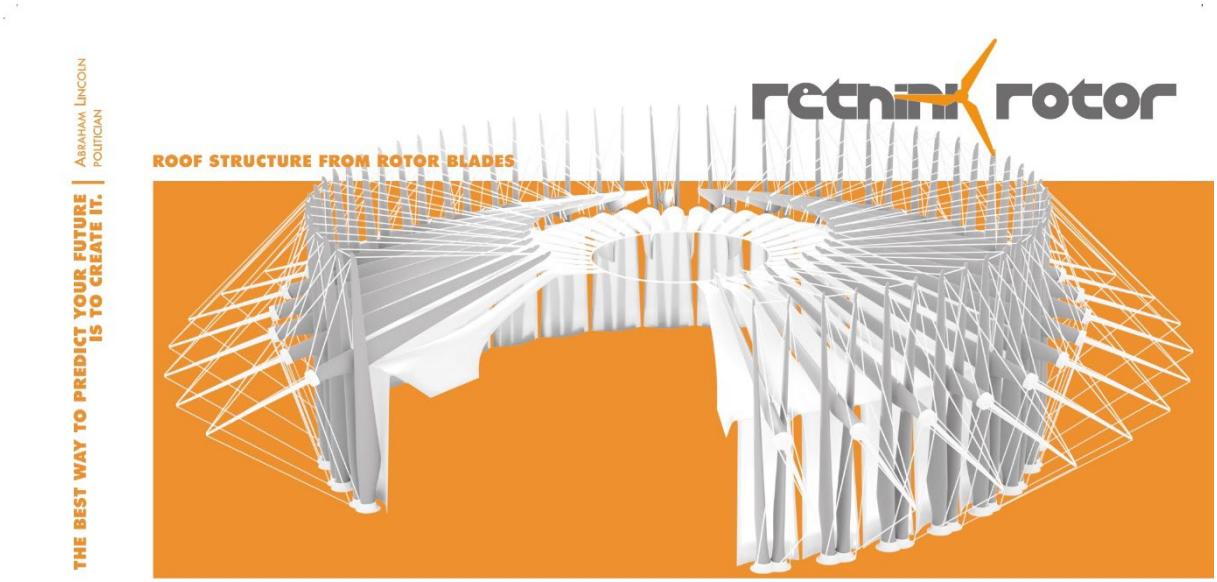

Figure 3. Cantilever beams - Rotating roof support structure

4.1.4 Saddle roof beam

Figure 4. Saddle roof beam

4.1.3 Cantilever beams - Parallel structure

The horizontal segments are mainly subjected to normal force (compression) and secondarily to bending due to the attached roof cladding. The chord reinforcement required for bending and normal force is combined in one element.

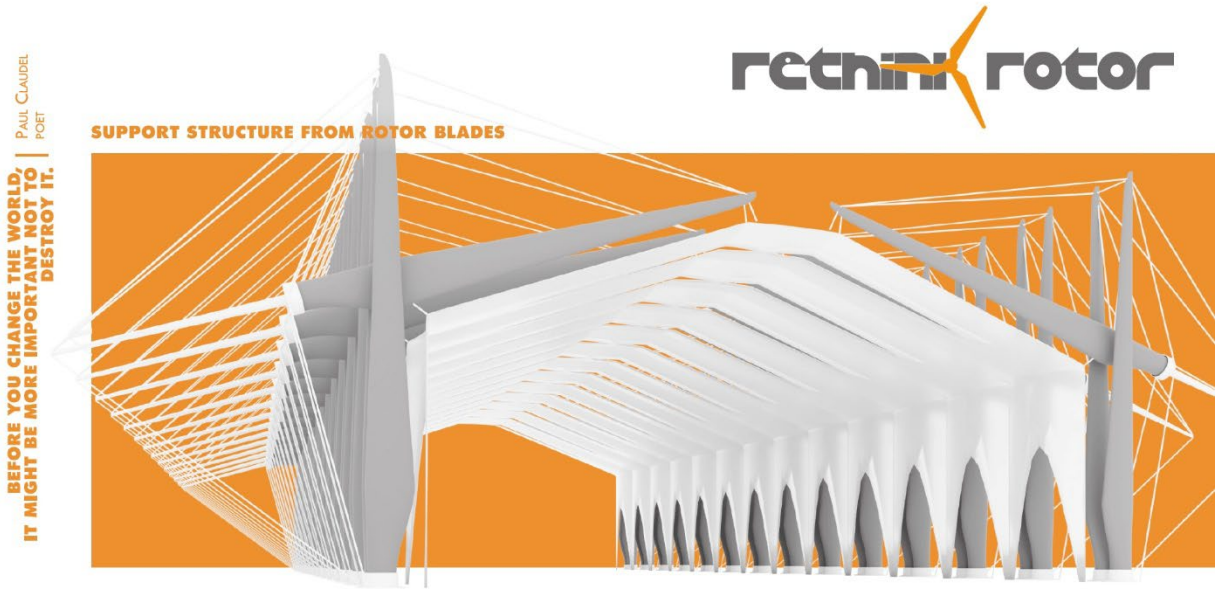

Figure 5. Cantilever beams - Parallel structure

4.1.5 Stadium roof

The cantilever beams are clamped at the base into the circumferential ring and carry only wind loads and the small dead loads. Reinforcement by laminated chord strips will only be necessary near the restraint in the bending compression and tension areas.

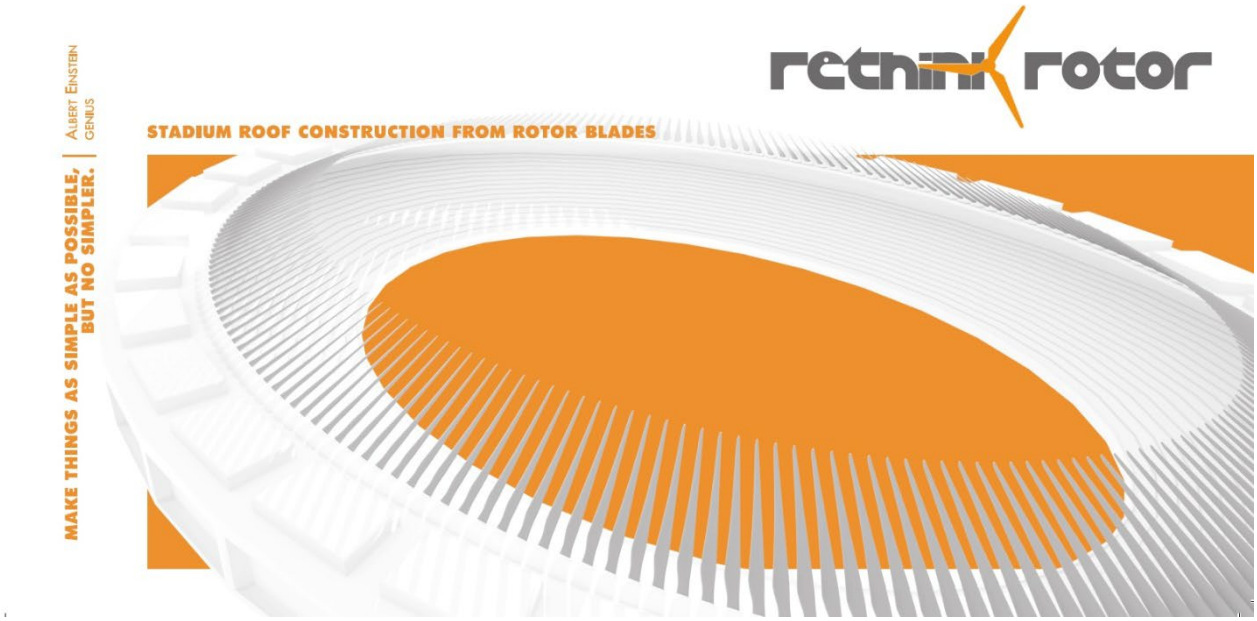

Figure 6. Stadium roof

4.2 Offshore applications include:

4.2.1 Coastal protection and retaining walls.

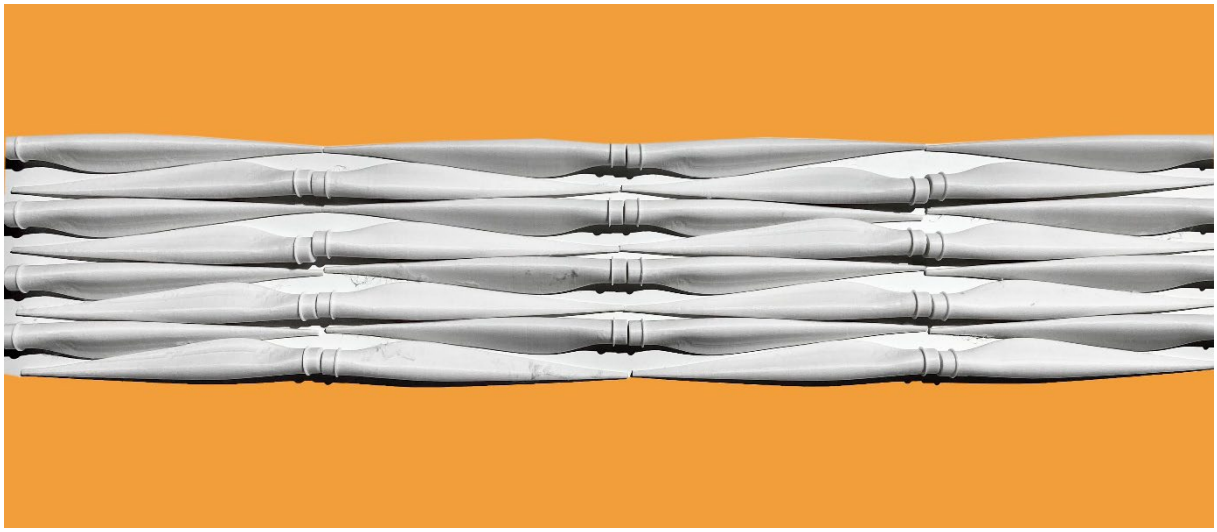

Figure 7. Coastal protection and retaining walls

4.2.2 Pontoons for floating islands

The calculation of the lift force is based on the rotor blade Enercon E66. The rotor blade type was installed in wind turbines between 1995 and 2005 and currently belongs to the type generation affected by decommissioning in Europe. The rotor blades are each 31m long. More recent models are sometimes 34m long. The 31 m long blade has a volume of 98.8 m3. The lift force, and thus the possible load capacity, is 94 tons after deducting the dead weight.

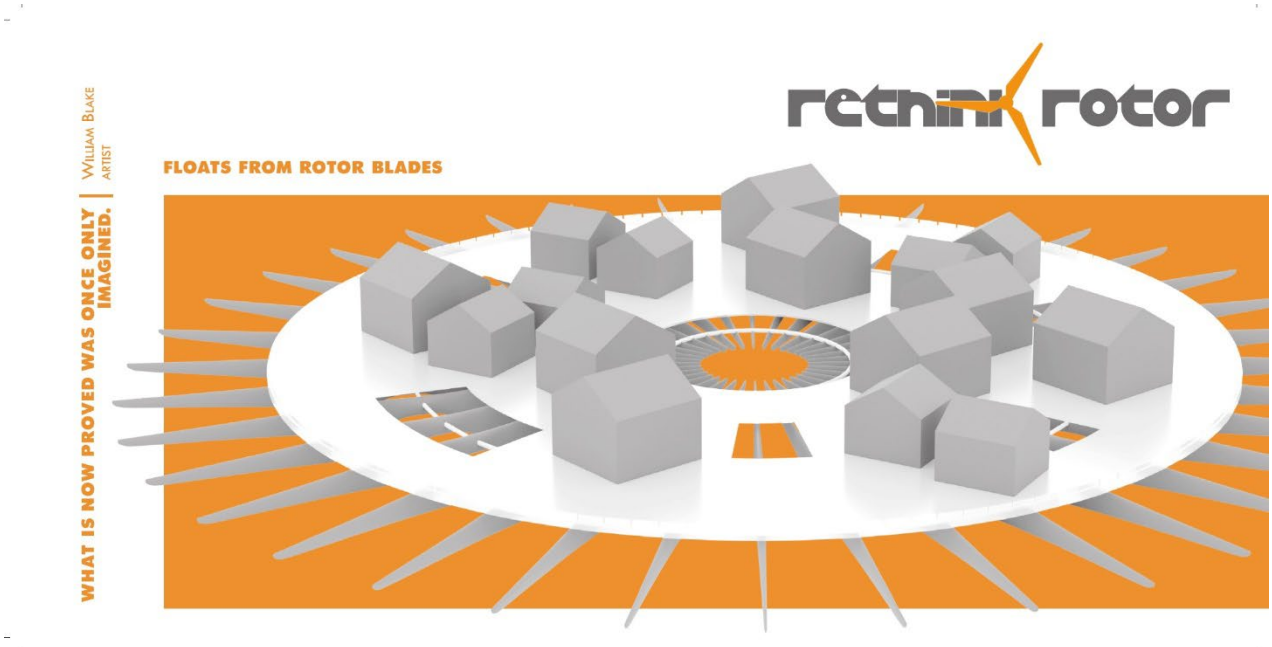

Figure 8. Pontoons for floating islands

Based on these fixed sizes, concepts for floating islands are being developed in the RETHINK*ROTOR project.

One of the possible uses is to provide a land substitute where natural islands are in danger of sinking due to rising sea levels. Tuvalu, for example, is affected. As early as 1989, the United Nations placed the country on a list of several island groups that are in danger of sinking into the sea in the 21st century due to global warming. Already today, two of Tuvalu's nine atolls are almost completely submerged. Because of its remote location in Oceania, the South Pacific island nation of Tuvalu is difficult to reach and massively threatened by rising sea levels. Only 11,500 people live on Tuvalu's nine islands - comparable to a small Central European town. On the densely populated atoll of Funafuti, which is one of the nine inhabited island groups of Tuvalu, live just over 6,000 inhabitants, about 60% of the total population. The atoll's 33 islands surround TeNamo Lagoon, which is also the largest lagoon in Tuvalu, covering 275 square kilometers.

The RETHINK*ROTOR project is now looking into the possibilities of creating a perspective for the future for the approximately 12 thousand inhabitants.

5. Conclusion

Using EoL wind power rotor blades as an example, RETHINK*ROTOR demonstrates that it is possible to create a closed loop of materials and further use EoL rotor blades in construction and give the process prominent visibility. The whole chain from the condition assessment of the EoL rotor blades: the logistics and the reprocessing, the planning of the recycling, the statics and implementation, must and will be profitably considered taking advantage of their aesthetic potentials. The knowledge and grey energy bound in each wind rotor blade will be definitively lost if it is not reused. With its project ideas, RETHINK*ROTOR aims to link a cross-sector repurpose of the blades, creative energy, new technologies and sustainability goals.

Structural design of a gymnasium with warren trusses in a grid arrangement supported by thin columns and damping braces

Eisuke MITSUDA[a,* (**)]

mitsuda@kit.ac.jp

Abstract

This paper describes the structural design of a gymnasium for a famous badminton team practice with a 36.36m x 36.36m sq. arena. The building is located in Kumamoto Prefecture, where a major earthquake occurred in 2016, and the structural design of the roof with long span as well as its seismic design was carefully considered. The ceiling height of this arena is 10.5 m to meet the standards for international badminton matches. A unique feature of this gymnasium project is that half of the arena's height is buried underground as a basement floor. On the ground floor, 5.5 m high steel columns are erected, on top of which the roof structure is placed. The roof structure consists of giridded warren trusses. The grid size is set at 6.06m, divided into six equal parts per side of the arena. All truss's sections were unified with H-beams of the 150-width series. φ165.2 steel pipes were used for the columns to match the H-beam trusses. In addition, buckling-restrained braces are used in order to grant a high energy absorption efficiency and toughness. The size of the brace core members was determined so that the stiffening tubes for buckling restraint were the same diameter as the columns, φ 165.2, and the total number of braces was determined backwards from the required bearing capacity of the building. In this gymnasium, all structural elements - trusses, columns and braces - are holistically designed.

1. Introduction

This building is a corporate's gymnasium in Kumamoto Prefecture, JAPAN. The company has a well-known women's badminton team with a World Championship winner, and this is their training base. The office and facotry of this company are located on a small hill near Kumamoto Airport. The company has spent a long time developing a beutiful green hill and the hill has become a favourite place for local people. This gymnasium was planned on the hillside.

The required effective ceiling height of 10.5 m was required for the arena. If a huge building were to be placed on top of the hill, it would destroy the beautiful site landscape that had been nurtured over the years, so the plan was to dig the ground to a certain depth and bury part of the building.

The basement floor of the building consists of a square arena measuring 36.36m x 36.36m, surrounded by changing rooms, lounges, equipment and machinery rooms in an L shape, which together form a rectangular shape measuring 48.48m x 42.42m. The ground floor consists of an atrium above the arena, as well as an entrance, a multi-purpose space, a gym and a viewing terrace. It is covered by a single large 54.54 m x 48.48 m truss roof that also serves as a cantilevered eave over the whole of the building.

3. Structural scheme

General information about the structural planning

Structure of basement floor: Reinforced Concrete construction

Structure of ground floor: Steel frame construction with buckling-restrained braces

Foundation type: spread foundation (mat foundation)

Construction period: October 2016 to June 2017 (9 months)

3.1. Roof structure

To cover the 36.36m x 36.36m square arena, the roof has a grid of warren trusses in the form of lattice beams. The grid size is 6.06m x 6.06m to ensure that shuttles and balls do not hit the trusses as far as possible if they rise higher than the required ceiling height of 10.5m.

3.1.1. The configuration of the trusses

The truss cross-section was previously defined as 2.35 m externally, taking into account the transport unit from the factory to the site. The upper chords, which are subject to bending due to roof loads, are H-300x150x6.5x9, while the lower chords and diagonals, which are not subject to bending, are H-150x150x7x10. All H-beams in 150-width series are used.

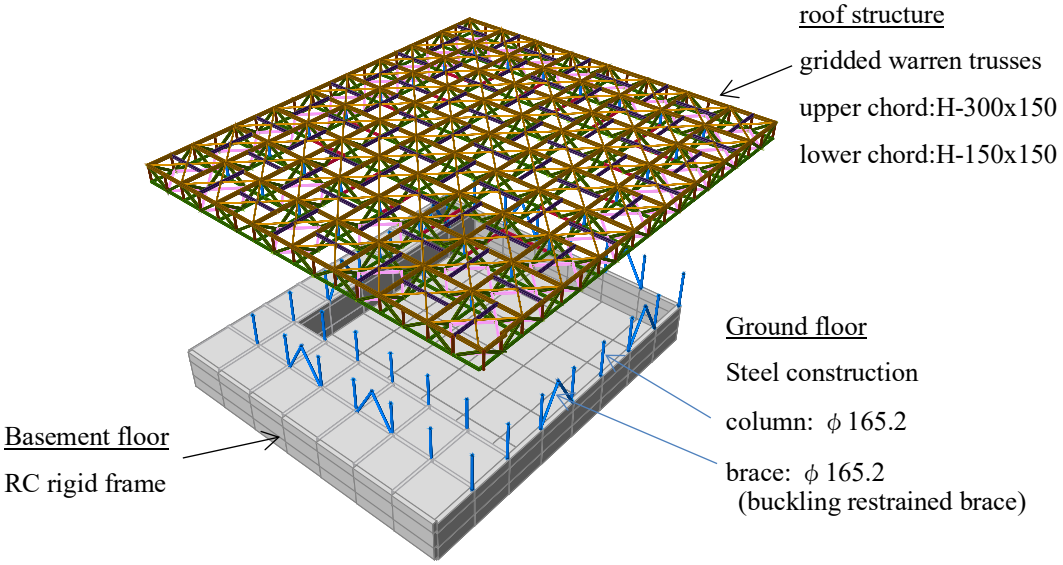

Figure 6. Building composition

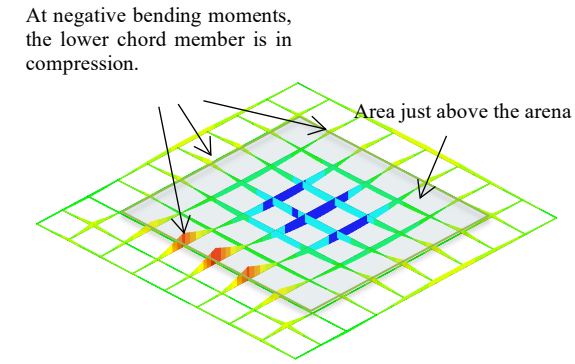

Figure 7. Moment diagram for grid beam model

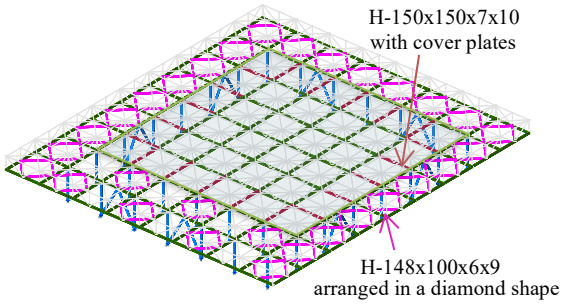

Figure 8. Buckling stiffening of truss lower chords

Figure 9. Specific examples of anti-buckling measures

Figure 10. Connect to the top of the seismic brace

3.1.2. Anti-buckling measures for truss members

The in-plane stiffness of the whole roof is ensured by in-plane bracing at the upper string level. Braces and beams reduce the buckling length of the upper chord by half to 3.03 m. During gravity action, compressive forces are also generated in the lower string members near the support point (Figure 7), which means that anti-buckling measures are also required for the lower string members. Outside the upper part of the arena, such as in gym and multipurpose spaces, the centres of the four sides of the grid are connected in a diamond shape with H-148x100x6x9 to reduce their buckling length by half (Figure 8,9). On the other hand, inside the arena, the arrangement of the diamond-shaped components is obstructed by the lighting, so the weak axis is supplemented by a cover plate (Figure 8,9). In addition, the diamond-shaped in-plane brace also serves to restrain the out-of-plane deformation of the head of the buckling-restrained braces, which are the elements that bear the seismic forces (Figure 10).

3.2. Supporting structure - column and brace

To give the impression of light, floating roof trusses, the columns and braces were designed to be moderately slender but with strong seismic performance.

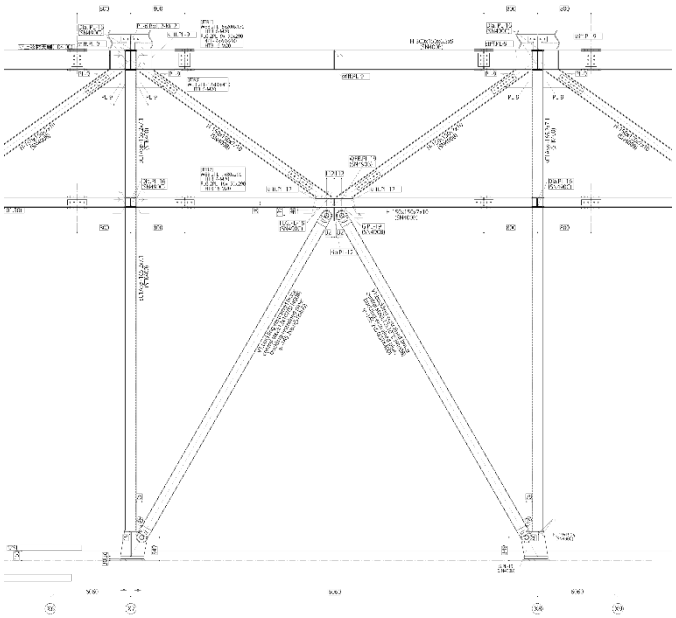

Figure 11. Detailed diagram of the steel frame structure

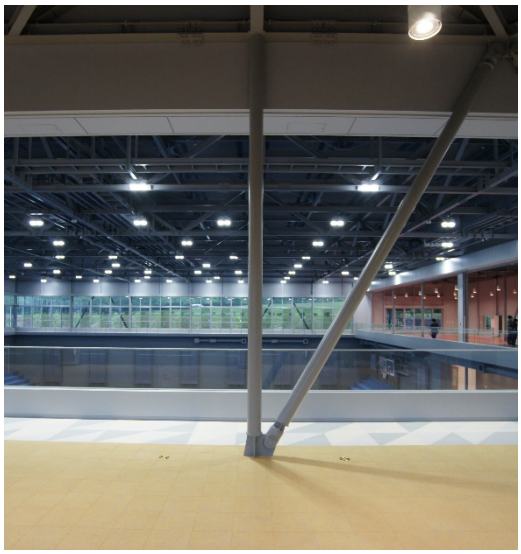

Figure 12. Column and buckling-restrained brace

3.2.1. Steel pipe columns with φ165.2 series

Where H-beam trusses with a unified 150 width join the columns, steel pipe columns of the φ 165.2 series are used to ensure that the diaphragm is of a suitable size to support the 150-width member (Figure 11). Steel pipe columns are erected at a pitch of 6.06m to support all the trusses covering the arena (Figure 13). Differences in the configuration of the outer side of the arena cause slight differences in axial forces in the columns. The thickness of some steel pipe columns is changed accordingly (standard thickness 7.1 mm, some 9.3 mm). The thickness of the steel pipes does not affect the truss-to-column joint details, so they all have a uniform detail.

3.2.2. Buckling-restrained bracing in a K-shaped arrangement

The seismic structure type of this building is braced, but with buckling-constrained bracing, which makes it a tough structure with high energy absorption efficiency. The buckling-restrained braces are selected in combination with a central steel member whose buckling-restrained pipe size is the same diameter as that of the columns, φ 165.2. The total number of braces is determined backwards from the required bearing capacity of the building (Figure 14). For design reasons, pin-type details are used at the ends of the braces instead of the high-strength bolt type (Figure 12).

The K-shaped arrangement of the braces allows horizontal forces during earthquakes to flow directly to the braces, resulting in almost no variable axial forces on the columns. Therefore, the φ165.2 columns, whose cross-sections are defined by long-term axial forces, are not affected. Furthermore, in the case of K-shaped arrangement bracing, the braces do not intersect at the truss-to-column joints, thus maintaining a uniform truss-to-column joint detailing.

An advantage of using buckling-restrained braces with K-shaped arrangement is that the pull-out and shear forces in the legs are determined by the brace yield axial force, thus reducing the need for complicated anchor bolts. Similarly, the design of the members in the brace frame is easier because the upper limit of the forces gathered at the connection between the brace and the truss is determined.

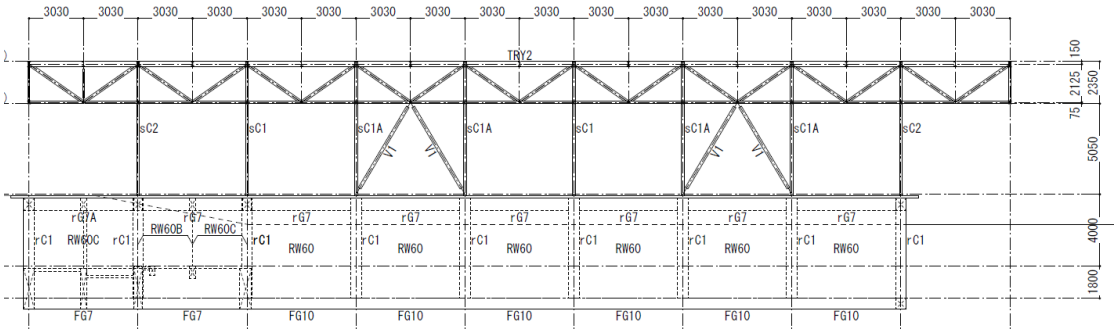

Figure 13. Framing elevation including K-shaped braces

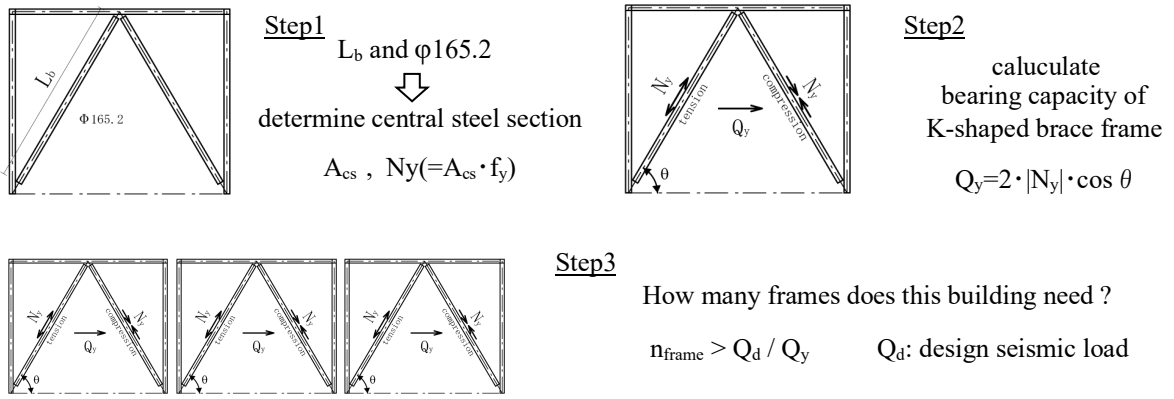

Figure 14. Design process of K-shaped buckling-restrained brace frame

3.3. Reinforcement concrete structure for basement floor

The basement floor is subject to soil pressure around the outside, and is therefore of RC construction. The 60 cm thick retaining wall circles the entire basement floor. The structure, including the retaining walls, is a rigid frame with columns and girders and earthquake-resistant walls (Figure 17), which is sufficiently rigid and strong. Two of the four sides surrounding the arena are directly in contact with the soil, and to prevent the retaining wall from being cantilevered, the top of the wall has a continuous strip of 2m to 2.5m wide slabs that also serve as a maintenance walkway.

3.4. Foundation structure

Although the site had soft ground, the weight of the soil removed by excavation was far heavier than the weight of the new building to be placed on it(Figure 18), so a direct foundation with mat slabs was applied. Due to the large size of the site, excavation was done by open cut and the surrounding area was backfilled after the retaining walls were constructed (Figure 15,16).

Figure 15. open cut excavation

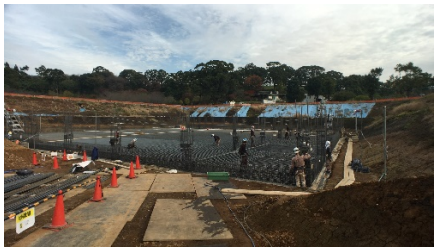

Figure 16. rebar construction of mat slab

Figure 17. RC skeleton in BF

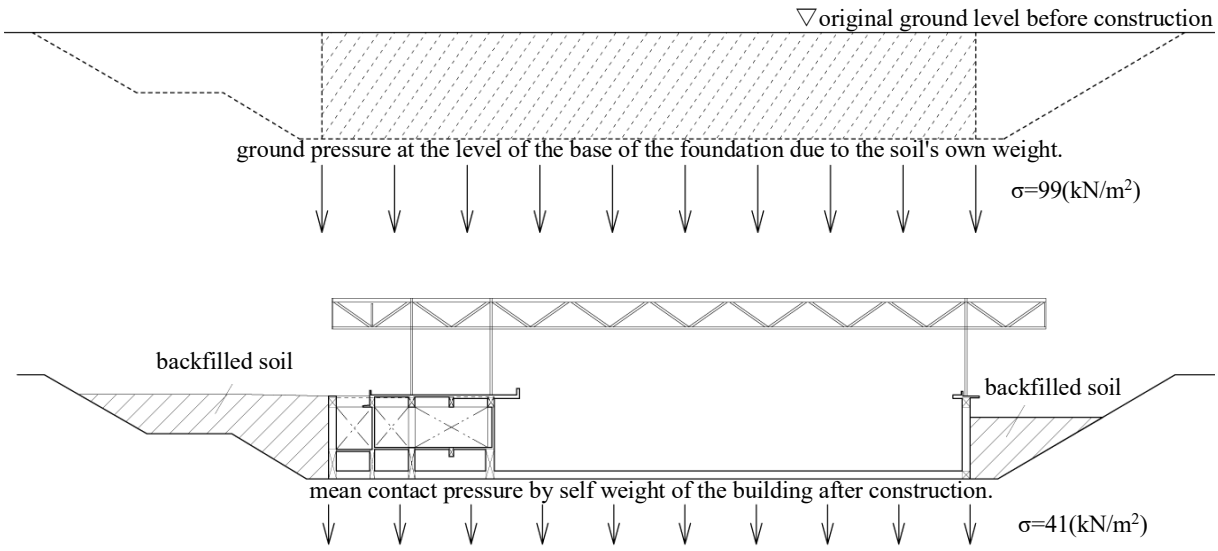

Figure 18. Comparison of contact pressure before and after construction

4. Construction plan of the roof structure

As noted in section 3.1.1, the external dimensions of the trusses were determined first so that a special permit under the Japanese Road Traffic Act would not be required. This allows the upper and lower string members to be transported as one unit, although they need to be divided in the longitudinal direction. The trusses were arranged in a grid pattern with the intention of distributing the stresses evenly.

Figure 19. Construction process of the warren truss. (a) transported by standard truck, (b) field assembling, (c) hanging the 36m long truss

Figure 20. Construction process with using four temporary support columns. (a) four temporary columns, (b) during the construction process, (c) after jacking-down

If longer trusses were installed first without support, they would become keel trusses and bear excessive stresses. Therefore, the use of four temporary columns was included in the design (Figure 20).

Two of the trusses delivered to the site were united in 36m lengths before being hoisted and hung in a position to be supported by temporary posts erected every 12m (Figure 19,20). The remaining trusses were installed in a sequential grid based on the two trusses supported by the temporary columns. After all trusses had been installed, the support columns were removed. Secondary components such as roof decking were installed after the removal of temporary columns.

5. Conclusion

This paper describes the structural design of a gymnasium with a 36mx36m square arena. It showed that the structural frame itself can make a high contribution to the design by making thorough and logical decisions.

・For roofs over square shapes, using grid trusses is effective in obtaining a homogeneous and smaller stress state.

・The overall size of the truss beams was determined in consideration of the transport size, and the components of the trusses were unified using H-beams of the 150-width series.

・In the compression zone of truss members, the buckling stiffening method can be switched according to the characteristics of the location, so that both design and structural performance can be achieved.

・Buckling-restrained braces were adopted so that the columns do not bear the seismic forces, and all the lattice trusses are supported by columns, so that a large roof can be supported by a thin column of Φ165, giving the design a light impression.

・A light and uniform design can be achieved by using column sizes according to the width of the truss members and sizing the buckling-restrained braces to match the column sizes.

・The design approach was to adjust the seismic performance by the number of braces by adopting braces that matched the column size, but this did not compromise the design quality compared to the conventional approach of determining the brace location first and then the performance required for the braces.

・By using excavation methods appropriate to the site's characteristics and efficient use of temporary columns, attractive internal spaces and an exterior appearance that is considerate of the surroundings were achieved without incurring extra costs.

It is important to develop the above logical thinking in a holistic way, which is also effective structural design as design.

Abstract

The paper presents some proposals for the shaping of support nodes that can be an important part of the structural systems of foundations for buildings located in the seismically active areas. The proposed forms of such nodes are shown on examples of their use as not only the auxiliary but indeed the integral components of the system of composite foundation, however, they can also be applied in other commonly used types of the foundation structures. The structural system of the foundation of a building located in a seismically active area should ensure horizontal dilatation of this building from the ground and at the same time enable safe movement of the building in the horizontal and vertical directions, of course within an appropriate range of such displacements. The proposed forms of support nodes make possible to meet these requirements by using an appropriate arrangement of metal vertical ribs permanently connected to the metal main bodies of these nodes. These single ribs contain circular rollers with eccentrically placed holes where cylindrical pivots are located, due to which the load forces are transmitted to the adjacent body of the foundation node. Moreover suitable application of the proposed support nodes in the structures of floating platforms, where they can be appropriately connected with electricity generators, can contribute to obtaining the emission-free energy from the movement of sea waves.

1. Introduction

There are numerous structural systems of foundation applied in the practice for a long time, which are permanently modified and gradually improved. They may be subdivided generally into two main groups of the shallow and the deep foundation systems. Systems of the shallow foundations are mostly applied when the passive earth pressure beneath the bottom surface of the foundation is also within the range of load carrying ability of the ground and usually these systems are not complex due to simplicity of their structural forms. Complexity of the deep foundations makes them often difficult to construct that is why

Copyright © 2023 by Janusz RĘBIELAK. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

they are the expensive technical solutions. In buildings erected in seismic areas, it is recommended to horizontally separate the load-bearing structures of the building from the ground, in order to enable appropriate horizontal displacements of the buildings [1 - 11]. The structural systems of support nodes presented in this paper are the results of the author's efforts to enlarge the range of possible applications of the system of composite foundation invented by him some time ago [12,13].

2. Structural concept of the system of composite foundation

The essential point of this system is to arrange the most important support nodes uniformly along the neutral axes of the main beams (1) placed on common base slab (BS), see Figure 2 and Figure 3. In a narrow space between two main beams, an intermediate system of straight structural members is arranged, while only its nodes situated along the neutral axis are connected to the main bodies of the horizontal beams. An outer concentrated force (F) is applied to an upper node (A) of a short vertical member put in vertical guides and having possibility to move only along the vertical direction. An intermediate system is built of two subsystems, the first one is called a cable system, see Figure 2(a) and Figure 1(d), while the second one is called an arch system, see Figure 2(b) and Figure 2(e). When these both subsystems are symmetrical arranged towards the neutral axes of the beams and they are combined together, see Figure 2(c) and Figure 2(f), then in the external central nodes act only vertical components of reactions, which in this case are directed down.

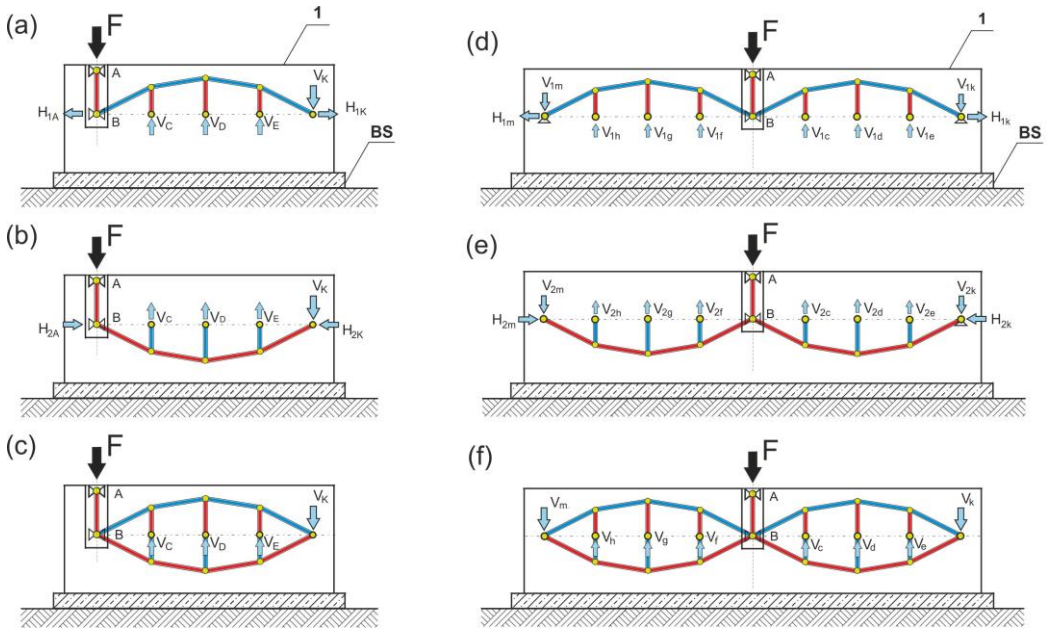

Figure 2. Structural analytic schemes of system of composite foundation

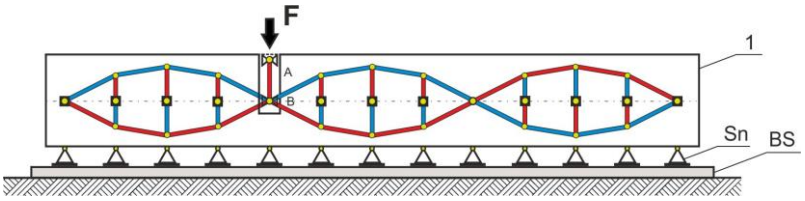

Figure 3. General scheme of an exemplary form of the more complex shape of system of the composite foundation with the way of arrangement of the proposed support nodes.

A lenticular set of two subtypes of the intermediate system, see Figure 2(c), is considered as a modular unit of this structural foundation system and it can be duplicated, see Figure 2(f). Number of its replications is optional, see Figure 3, what means that it can be replicated endlessly along the horizontal direction what further implies, that surface of this type of foundation structure can be theoretically unlimited. The application of the system of composite foundation makes possible to construct the very heavily loaded buildings, including the tall buildings, on the ground of very small load carrying ability on the main condition, that the available free terrain around the building is large enough. Due to the specific arrangement of components into the inner space the system of composite foundation is able to absorb a part of energy induced in the building structure by the earthquake. This ability can be enhanced e.g. by suitable application of computer controlled hydraulic actuators or for instance by application of system of appropriately designed support nodes.

3. Basic structural assumptions of the foundation supporting node

The structure of a building located in a seismically active area should be horizontally separated from the ground, and the foundation system under the influence of seismic loads should allow safe movement of the building structure in the horizontal and vertical directions, of course within the appropriate assumed ranges of such displacements. Currently, there are many types of construction solutions for foundations that make it possible to meet the above-mentioned requirements.

In all the presented proposals of shaping the new types of structures of such nodes, a structural configuration of a connector is used, which consists of a single vertical rib (R1), Figure 4(a), and a set of two vertical ribs (R2), Figure 4(b), which are connected together as it is shown in Figure 4(c). Inside the matter of a single rib, there is a relatively large cylindrical hole (2) inside which a circular roller (3) is placed in a tight manner and is freely rotatable around the horizontal axis X1. Moreover in the matter of this circular roller there is a much smaller cylindrical hole (4) intended for location a cylindrical pin (5), having the freedom of full rotation around the X2 axis parallel to the X1 axis, and applied to articulate connection of a single vertical rib with a set of two vertical ribs, also by help of similar holes (6), which are of the same diameter and present in each rib in the set of the two vertical ribs (R2) [14].

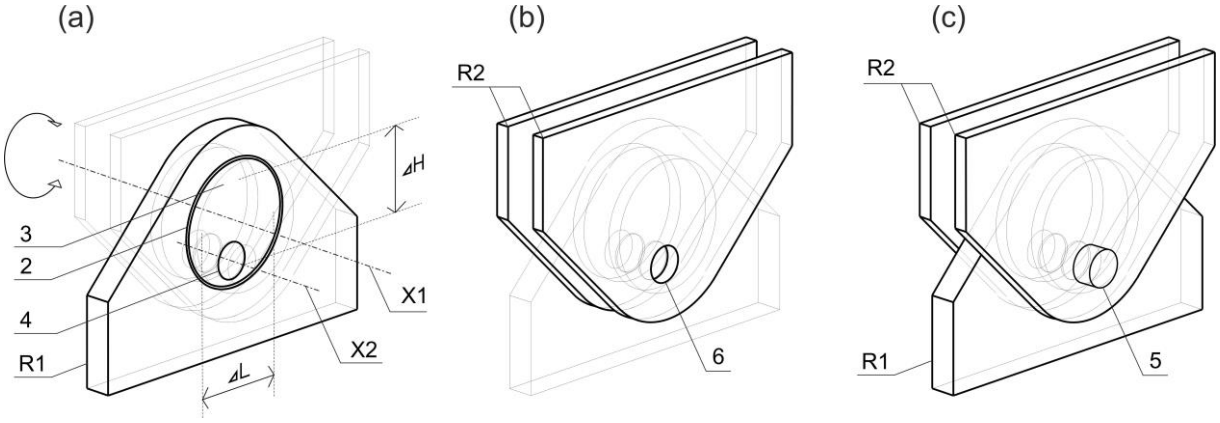

Figure 4. Structural configuration of basic component parts of a connector applied in all types of the proposed structures of the foundation support nodes.

All components of the basic structural set should be quite closely matched to each other, and their mutual contact surfaces should be covered with layers of e.g. Teflon or separated from each other with Kevlar spacers to facilitate their movements. The modular range of possible horizontal (ΔL) and vertical displacements (ΔH) is conditioned by the mutual relations of the geometric dimensions of the circular roller (3) and the distance between the axes X1 and Z2, however total range of the horizontal

displacement (ΔL) of the foundation can be enlarged by combining this basic structural configuration with suitably formed main bodies of the foundation node.

4. Support node with a conical form of the main body

From numerous observations of the effects of earthquakes follows that the greatest damages are usually caused by the action of horizontal seismic waves. Therefore, the structures of foundations called anti-seismic should enable the buildings to have the greatest value of safe displacements in the horizontal direction. The conical form and structure of the main body of the first of the proposed systems of support nodes, shown in Figure 5, enables such type of the displacements.

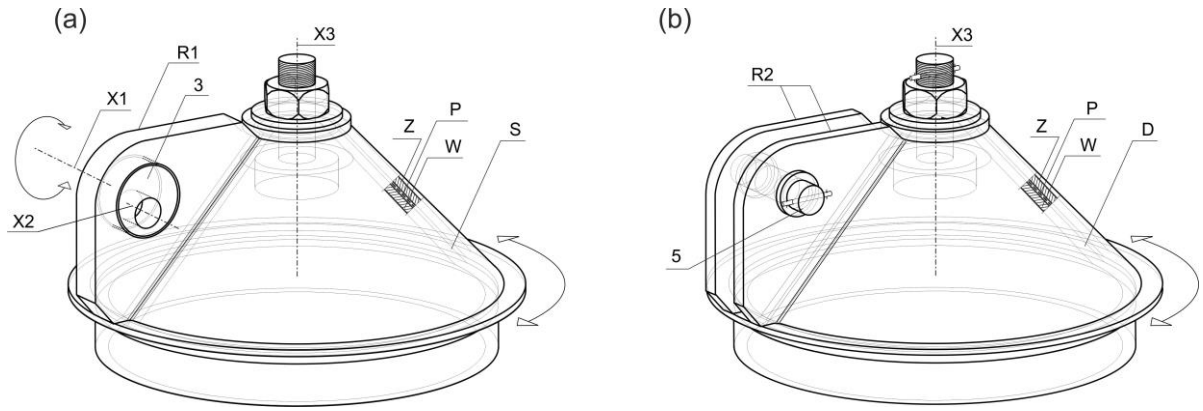

Figure 5. Conical form of main body of the support node with, (a) a single rib, (b) a set of two ribs.

In this case, an external conical structure (Z) is mounted on the internal conical structure (W), and between them there is, for example, a Teflon conical spacer (P) facilitating full rotation of the both main shells around the vertical axis X3. The outer conical structure (Z) is rigidly connected to a single rib (R1) or to a set of two ribs (R2). The main body with single rib (S) is connected to the main body with two rib set (D) by a cylindrical pin (5) as shown in Figure 6.

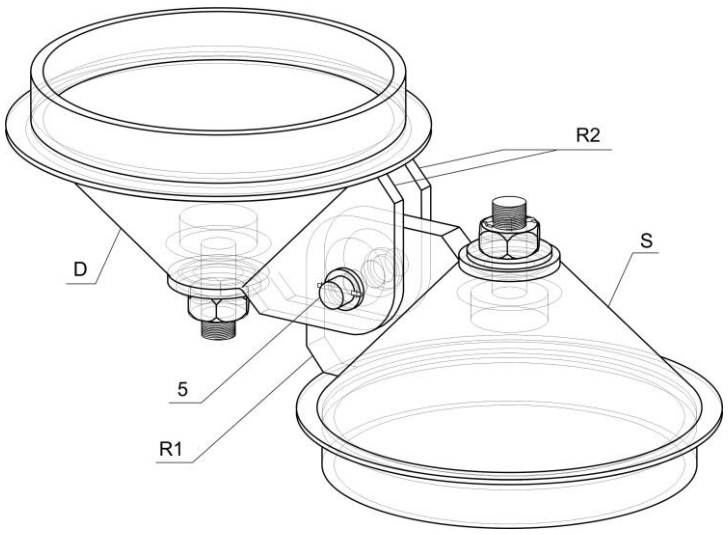

Figure 6. General view of the whole structure of the support node with conical forms of the main bodies.

In the configuration shown in Figure 6, Figure 7 and in Figure 8, the main body with a single rib (S) is fixed in the lower building structure (L) and the main body with a set of two ribs (D) is fixed in the upper building structure (U). The opposite configuration is equally valid, i.e. when the main body with a single rib (S) is fixed to the upper building structure (U) located above, and the main body with a set of two ribs (D) is fixed in the lower building structure (L) located below.

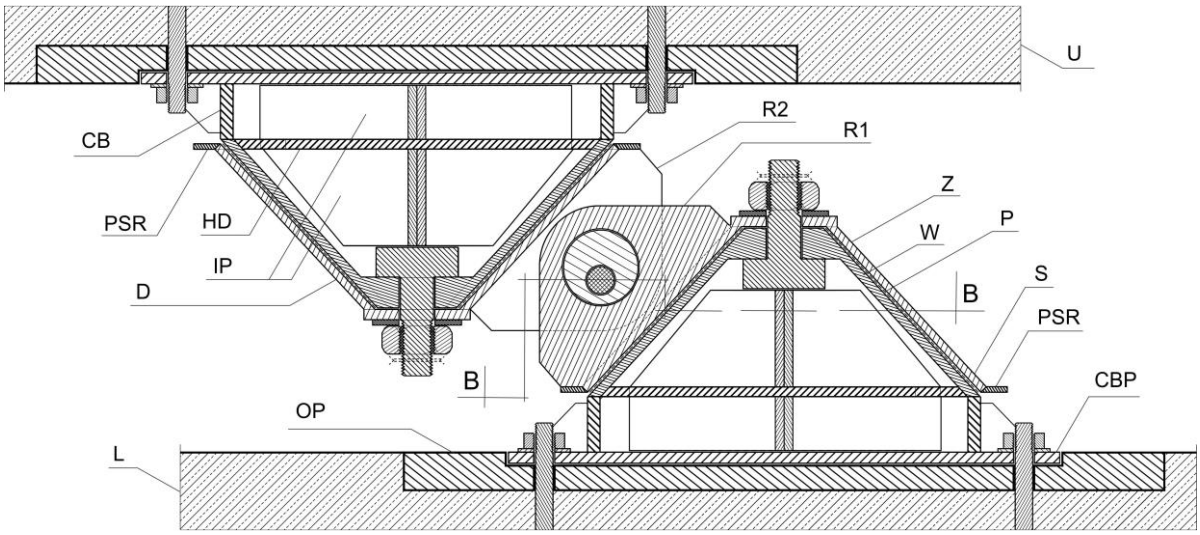

Figure 7. Vertical cross-section A-A of the whole support node with conical forms of the main bodies.

If the geometrical dimensions of the support node are significant, inside each body should be a horizontal disk (HD) and outside a peripheral stabilization ring (PSR), which is permanently connected to the lower edge of the external conical structure (Z). In the inner space there are located internal partitions (IP), see Figure 7, Figure 8, evenly spaced inside the conical structure, whose ends (IPE), see Figure 8(a), are permanently connected to the cylindrical base (CB), what base is also permanently connected to the metal, circular base plate (CBP), which is placed in a circular cavity of a metal outer plate (OP), while the last one can be of any shape. External plates (CBP) and (OP) are also permanently attached to the lower structure (L) or to the above-ground structure of the facility (U).

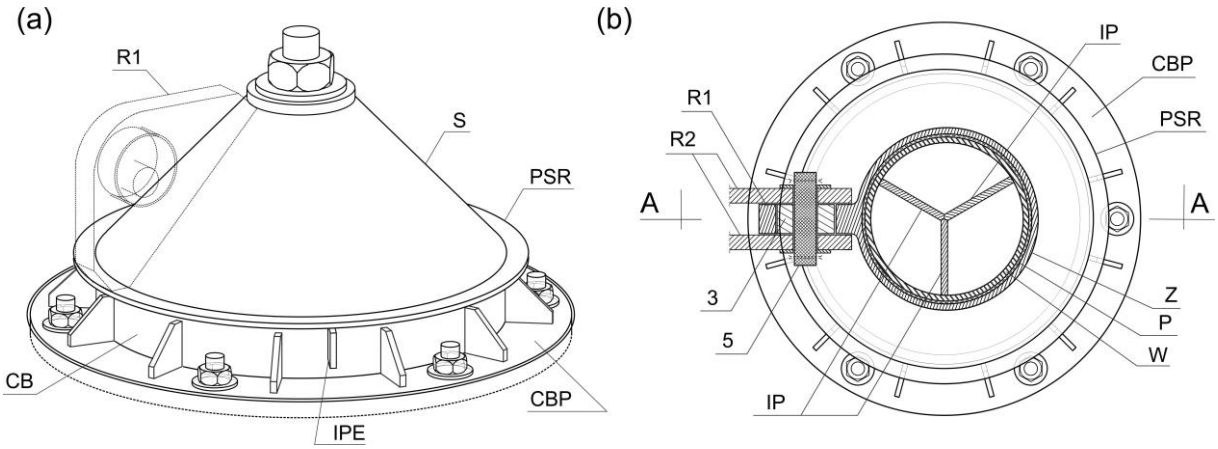

Figure 8. Support node with conical forms of the main bodies, (a) view of selected type the main body, (b) the horizontal offset cross-section B-B of the lower main body of the foundation support node structure.

One of the types of connectors joining these boards are fastening bolts located between circumferential ribs, and the fastening bolts are rigidly anchored in the structure of the lower object (L) or rigidly connected to the structure of the upper object (U). It is also possible to directly anchor cylindrical bases in the solid matters of the building structures located above or below the structure of the support node.

4.1. Example of possible applications

The main task of the structure of the support nodes made of conical bodies is to effectively suppress vibration energy caused by dynamic load applied from any direction through controlled movement of the lower and upper parts of the object connected with each other by a set of such nodes. If the values of dynamic loads are very large, then these displacements, mainly in the horizontal plane, consisting in the mutual rotation of conical solids relative to the vertical axes of the X3 type, see Figure 9, can sometimes be very fast.

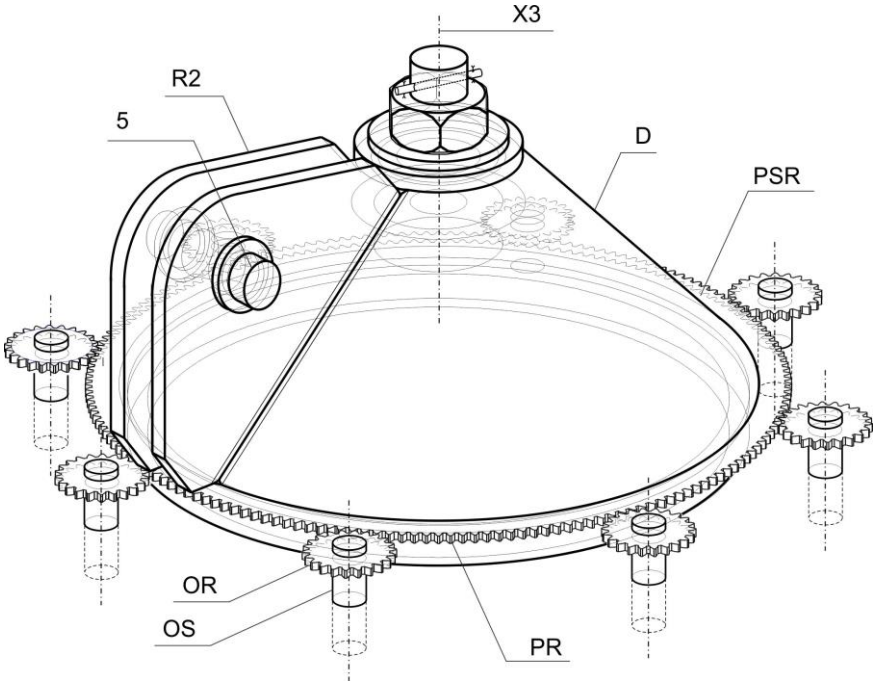

Figure 9. View of the conical body of the support node with a peripheral gear wheel and a set of external gears.

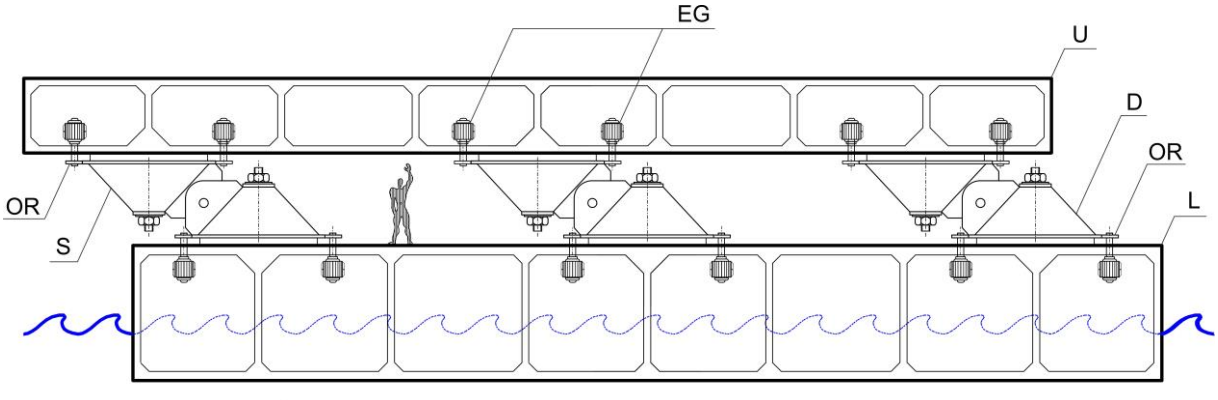

Figure 10. Scheme of a vertical cross-section of a dynamically loaded object built in the form of a floating platform consisting of the upper and lower parts of the object connected with each other by a system of the conical support nodes with the peripheral gears.

This may be hazardous, especially if the object has significant geometric dimensions. In this case, the geometrical dimensions of the support nodes and the conical solids constituting them can also be large. In order to make the vibration energy damping processes more effective, it will be beneficial to transfer the rotational energy of each of the conical bodies to the largest possible number of devices that can absorb this energy in a controlled and safely manner. This can be achieved, for example, by making a peripheral stabilization ring (PSR) in the form of a toothed wheel cooperating with external racks (OR) suitably located along the circumference of this wheel, see Figure 9. Each of these racks (OR) is mounted on an outer sleeve (OS), which in turn can be connected e.g. to friction discs, and these by controlled pressure force to similar discs mounted in the lower (L) and upper (U) structure of the object, what will enable more efficient dissipation of the vibration energy caused by the dynamic load [14].

A set of such support nodes can be a very efficient horizontal dilation of the upper part of the structure from its lower part. If the object constructed in this way is made as a floating horizontal platform, see Figure 10, then under the influence of the sea waves energy its lower (L) and upper (U) parts will move mutually. In this case, the receivers of the rotation energy of the conical bodies can be electric current generators (EG), then the electric energy generated in this way can be stored e.g. in battery packs located in the internal spaces of the lower (L) and upper (U) parts of the platform structure or this energy can be transmitted outside by special electric cables. This will enable emission-free production of ecologically clean electricity. The sizes of a single platform can vary and the number of platforms can be very large. The single platform itself can be anchored in the coastal zone or in the open sea, it can also be able to change its position on the surface of a lake, a sea or an ocean.

5. Support node with a cylindrical form of the main bodies

In the next presented type of the structural system of the support node the way of transmitting forces between the main bodies remains the same, it means they are transmitted from the single rib (R1) to the set of two ribs (R2) by means of horizontally located cylindrical pin (5), but now the upper part of the main body with a single rib is cylindrical (C1), Figure 11, likewise the upper part of the cylindrical main body with a set of two ribs (C2), and they are mounted on their lower parts in a way that allows the upper parts to rotate around the vertical axis X3, which is also the axis of the main vertical screw.

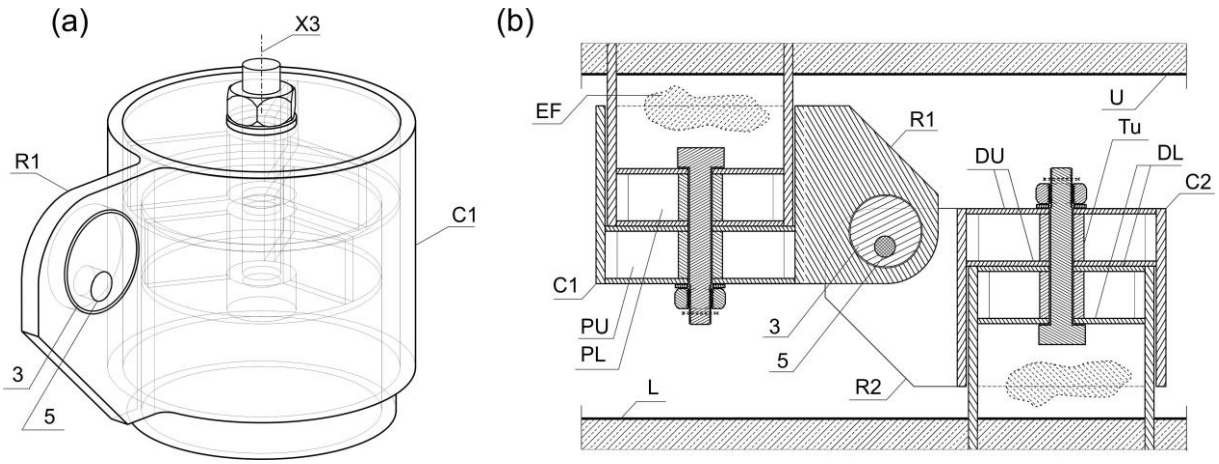

Figure 11. Support node with cylindrical forms of the main bodies, (a) general view of the main body with single rib, (b) vertical cross-section section of the support node with cylindrical forms of the main bodies.

Each of these main parts has its upper zone, and so the upper part of the cylindrical main body with a single rib (C1) has two circular horizontal discs (DU) vertically spaced apart by the value of the height of the stiffening ribs (PU), located between the vertical wall of the upper cylindrical component with

the single rib main body (C1), and the central sleeve (Tu). All these elements of the upper part are permanently connected to each other. The lower part of each main body is in this example rigidly fixed in the lower part of the object (L) or in the upper structure of the object (U). The upper zone of a single body is built in a similar way, i.e. it has two circular horizontal discs (DL) of a suitably smaller diameter than the horizontal discs (DU) and, as previously, are they are vertically spaced apart by the height of the stiffening ribs of the lower zone (PL) located between the vertical cylinder wall of the lower part of the cylindrical main body and the central sleeve (Tu). Empty spaces of lower parts of each main body of the foundation node can be also initially fulfilled e.g. by application of a cement mortar (EF).

6. Support node with a modular form of the main body

In the third proposed type of the structural system, the same form of a single vertical flat rib (R1) is used, see Figure 4(a), but now it is supplemented with two rectangular ribs (RR) located perpendicularly to its middle plane and permanently connected to it on both at its ends, Figure 12(a), the mirror image of which relative to its base and rotated by a right angle, then supplemented by a central horizontal plate

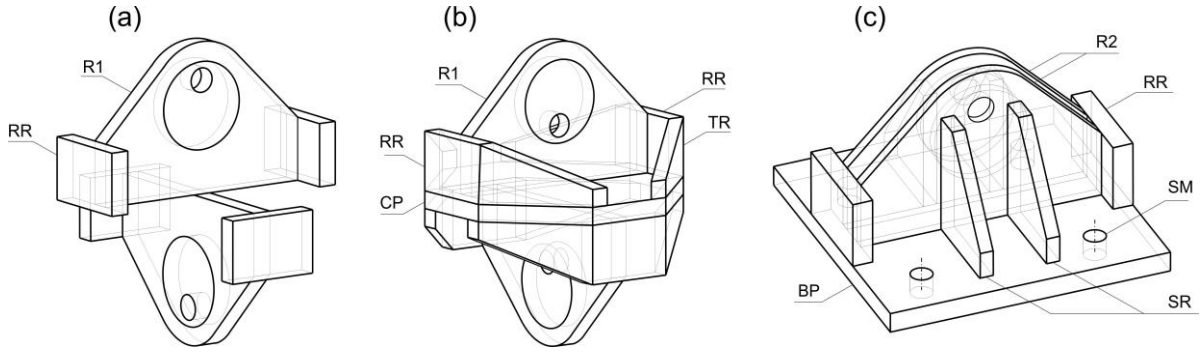

Figure 12. Component parts of third type of the support node, (a) basic modular configuration, (b) view of the central part, (c) shape of the border module of the support node.

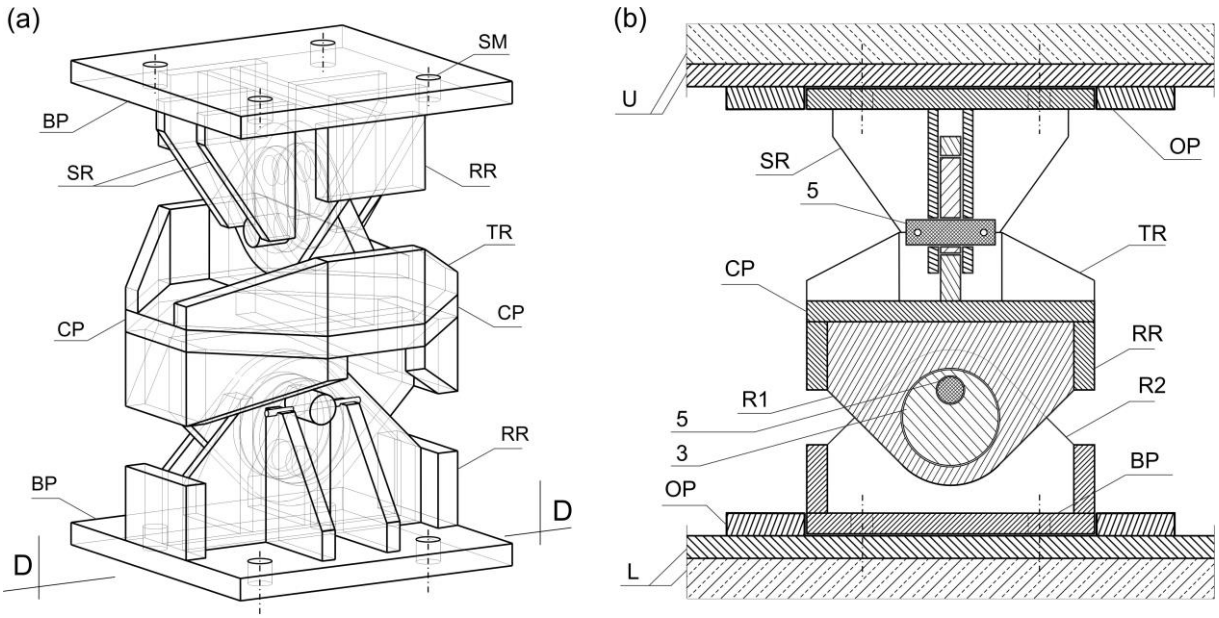

Figure 13. Modular support node, (a) general view, (b) vertical cross-section D-D.

(CP) and also suitably arranged trapezoidal ribs (TR), what together constitutes the structural module of the central part, see Figure 12(b), of this variant of the support node.

A set of two vertical ribs (R2) supplemented on each of its side sides with stabilizing ribs (SR) and front rectangular ribs (RR) located on a common base plate (BP) being with it and mutually between rigidly connected, form a border module, Figure 12(c), for the structure of such type of the support node, which is connected to the lower object structure (L) or to the upper structure of the object (U) by means of several anchor bolts placed in the screw holes (SM) with vertical axes, see Figure 13.

All the main components of this third and as well as the two previously presented types of the support node structure are made of metal, preferably of high-strength and corrosion-resistant steel. The range of vertical displacements possible to obtain with the use of the last presented form of the node is much larger than with the application of the two previously presented types of the support node structure, however range of horizontal displacements is relatively small. In addition, for the last described type of structural system, the mutual location of successive nodes need not be so precisely coordinated with each other, as it is required for nodes having structural systems presented in Chapter 4 and Chapter 5.

7. Conclusions

The presented structural systems of the support nodes are the results of the last stage of research undertaken in the past by the author through the development of system of the composite foundation. These types of nodes should be relatively close to each other and due to the recommended large number, they can be, e.g. horizontal dilatation of the building from the ground. Each of the developed variants of the structure of such the node has the ability to move within a certain range in the horizontal direction and at the same time in the vertical direction, which allows for the effective absorption of all or a significant part of the energy of vibrations, which in turn enables the safe operation of the building structure during an earthquake. The proposed forms of support nodes can be applied for almost all types of foundations for buildings located in seismically active areas. Initial studies of the forms of these nodes were carried out thanks to the analysis of their numerical models defined in the Formian programming language [15]. Important tasks in the next stages of research will include, among others: determining the optimal dimensions and geometric proportions of the movable components of the structural system of each of the proposed types of support nodes.

It seems that the support node with the conical form of the main bodies has the most advantageous structural, technological and utility features. The construction of the articulated joint placed along the inclined line, i.e. along the generatrix of the cone, makes the conical shape of the basic structure the most effective kind of this type of technical solution, since dynamic loads applied from each direction will cause rotation of the lower and upper part of the whole building structure about the vertical axes X3. The support node made of cylindrical bodies is similarly effective, the operational reliability of which is ensured mainly by the possibility of efficient rotation of the circular roller (3) relative to the horizontal axis X1. Conical or cylindrical joint bodies must be oriented in the same way between the lower part of the structure (L) and the upper part of the structure (U) in the entire area of the integral support field. On the other hand, the plate, metal bodies of the modular node can be freely oriented between the lower part of the structure (L) and the upper part of the object structure (U) in the area of the integral support field, but only in relation to the orthogonal axis system of such a support field.

The support nodes, especially those with a conical shape of the main bodies, can be applied in structures of floating platforms of various sizes designed as a kind of artificial islands, and in connections with appropriate power generators, the proposed support nodes should contribute to get of the emission-free electric energy. In addition, the upper surfaces of this type of platforms can be adapted to the cultivation of appropriate plant species. Moreover they can form the basis for photovoltaic panels or windmills, thus increasing the scope of the emission-free electricity production.

All the proposed types of foundation support nodes must be subjected to thorough and comprehensive static, dynamic and strength analyses, including tests of objects on a natural scale, in order to assess their practical suitability for the proposed purposes.

Abstract

The Sydney Football Stadium (SFS) is an $828m AUD state-of-the-art stadium near Sydney's CBD. This paper focuses on the collaborative approach to design, fabrication and erection that enabled the complex 2,000 tonne synclastic diagrid shell roof to be successfully brought to life in a fast-tracked design and construction programme whilst overcoming supply chain and lockdown challenges associated with COVID-19. The unique 25,000m^2 roof is constructed with inner arched trusses that span approximately 140m and 90m in length, a 680m long perimeter tension ring and a diagrid shell structure that includes arched sections spanning between the inner truss chord and tension ring. This structural behaviour and form-found geometry allow for an efficient and lightweight design for the roof. Prefabrication and modular construction techniques were adopted to limit working at heights and improve the erection efficiency on site, it enabled over 85% of steelwork installation to be undertaken at ground level. The roof consists of 5,000 individual pieces of steel, each with an associated pre-set length and geometry which required precise coordination, fabrication and planning through each stage of design and construction, a novel digital workflow was developed to enable the seamless translation of data between each sub-consultant. The connections of the roof are also some of the most intricate in Australia, the adoption of bi-directional digital workflows between structural engineers and steel detailers were essential to save time and improve quality assurance.

1. Project background and vision

Sydney Football Stadium (SFS), also known as Allianz Stadium is a state-of-the-art stadium, near Sydney's CBD. Designed to create a vibrant atmosphere with steep seating to bring 42,500 fans closer to the action, the world-class, multi-use rectangular stadium opened in August 2022 and has hosted football, rugby league, rugby union matches and concerts, as well as community and cultural events. The new stadium is a key component of the NSW Government's stadia strategy to promote a strong cultural and sporting sector by delivering a world-class venue within a parkland precinct for the state and Australia as a whole.

The previous Allianz Stadium on the same site was nearing the end of its economic and functional life and would not meet future safety and access requirements. Bringing the new $828 AUD million stadia to life were project partners Aurecon, as structural and civil engineers, John Holland Group, Cox Architecture and Schlaich Bergermann Partner (SBP), for the New South Wales (NSW) Government. The vision was to blend engineering and art through a 'sculpture', featuring a sweeping roof that covers 100 per cent of seats and a colosseum-like seating bowl that creates an electrifying atmosphere.
The stadium has been designed to achieve a US Green Building Council LEED gold rating. It features design for disassembly principles, a strong connection to the indigenous people of the land and involved

the recycling of over 85% of construction and demolition materials from the former Sydney Football Stadium to construct the new stadium.

The new stadium for Sydney allows Australia to continue offering fans some of the most memorable moments in Australian sports history. It is a stadium that strengthens Sydney as a destination for major sporting and entertainment events while enhancing the surrounding precinct with public places and spaces year-round. It has been delivered on time and on budget by the more than 7,000 personnel who contributed to the project despite disruptions to procurement and construction due to COVID-19, a proud achievement for the entire design and construction team.

2. Structural philosophy

Various stadia across Australia and the world have inspired the chosen design features in the redevelopment of SFS. The structural philosophy of this roof is based on the roof-ring principle. One of the first applications of this principle in large sporting arenas was in the redevelopment of the Stuttgart – Mercedes Benz Arena which paved the way for a new generation of stadia roof [2]. Relatedly, the roof of SFS utilises a tension ring and compression arch as an efficient global load path for the structure. The SFS roof is supported by four corner structures termed 'derricks' which are braced Circular Hollow Sections (CHS) that cantilever to support the arched trusses, this element was inspired from Suncorp Stadium in Brisbane [3]. The adoption of a diagrid shell structure contributes to the visual identify of the SFS roof, provides lateral stability and a secondary load path for the roof. Diagrid shell structures are prevalent in sports arenas globally and locally such as Adelaide Oval Western Grandstand redevelopment [4].

3. Adopted roof

The 25,000m^2 SFS roof transfers loads via axial forces with the use of arches and tensile mechanisms. The diagrid is supported on the inner chord via arched trusses that span 140m and 90m in length between the four corner 'derricks'. The trusses are arched in plan and elevation to efficiently transfer vertical and lateral loading. A 680m long perimeter tension ring is used to provide restraint to the diagrid, utilising the axial stiffness of the ring to prevent the diagrid from moving outwards. The diagrid shell adopts radial arched sections spanning between the inner compression arched truss and tension ring, with diagonal CHS members providing stability and support. The derrick's are braced CHS members which transfer approximately 50% of the roof vertical loads and 100% of the lateral loads to the superstructure.

Structural shells require stiff and, in this case, continuous edge elements in tension and compression. For SFS the outer boundary element is continuous and curved against the thrust forces from gravitational loads of the diagrid shell constituting a Tension Ring. The inner boundary element is curved in the same direction as the thrust constituting a Compression Arched Truss, see *Figure 2*. The primary structure of

the roof utilised mild steel CHS and Rectangular Hollow Sections (RHS). These hollow steel sections offer high strength-to-weight ratios and versatility, enabling Aurecon, SBP and Cox Architecture to devise an innovative and visually striking roof configuration that not only met the demands of a modern stadium design but also ensured long-lasting performance in an adverse coastal environment.

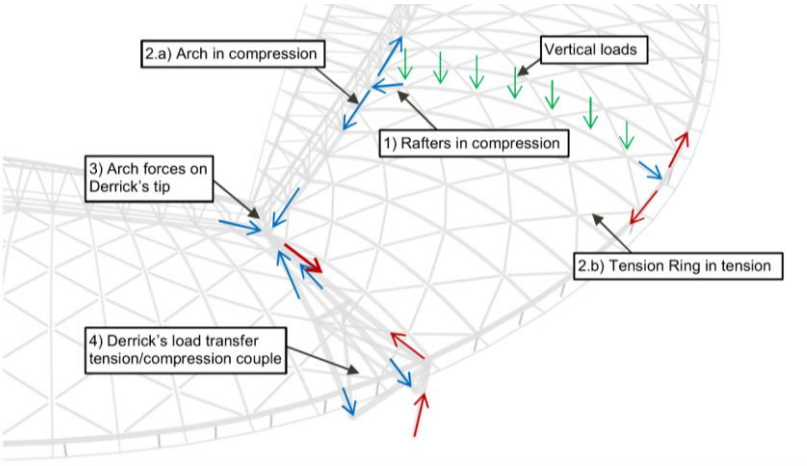

Figure 2. Structural load path of the Sydney Football Stadium Roof.

The extensive use of faceted steel sections for the 'arched' trusses and 'elliptical' tension ring created an efficient structural form compared to the traditional stadia roof philosophy such as deep flexural trusses. This structural behaviour allowed for an efficient and lightweight design for the adopted roof and the facetted geometry simplified fabrication without compromising the visual perception of curved elegant elements.

4. Form finding

In the world of architecture and structural engineering, form-finding is an important methodology to improve efficiency, dematerialisation and unlock complex and organic shapes. Historical figures like Catalan architect Antoni Gaudí paved the way for modern form-finding. Gaudí's designs, which employ organic and biomimetic principles, demonstrate both visual appeal and structural efficiency. To study these forms, Gaudí often employed the use of hanging chain models, by suspending chains from points that represented the supports and applying weights to mimic loads, Gaudí could visualise the natural equilibrium shape for particular structures. He would then photograph the models, invert the images, and use them as a basis for his design [1]. Gaudi's form-finding techniques date back to the 1880s, but the principles he developed and demonstrated on projects such as Casa Vicens and Sagrada Familia form the basis of the form-finding implemented for the roof of Sydney Football Stadium.

The roof of Sydney Football Stadium adopted multiple methods of form-finding in the early geometry definition of elements and the overall structure. The *Stiffness Matrix form-finding* technique was one of the primary methods used and involved the following steps:

1. Define the initial geometry, including the position of nodes, the connectivity between nodes (any translational, rotation releases or offsets), and the structural elements such as beams or cables, for Sydney Football Stadium this was defined using Rhino and Grasshopper (a parametric modelling software) which enabled rapid geometry and design iterations.
2. Assign material properties, Elastic modulus and the cross-sectional areas of each element.
3. Define loads and boundary conditions which describe the constraints on the structure, for Sydney Football Stadium there was a maximum height limitation to respect the heritage Sydney Cricket Ground which is adjacent to the stadium as one example.
4. Develop the form-finding criteria, for Sydney Football Stadium, the six criteria were:
    I. Minimise bending actions to improve the efficiency of members
    II. Balance the forces of the trusses to align with the orientation of the derricks,
    III. Minimise the mass of the structure
    IV. Ensure the structure is stable and the global buckling behaviour is sufficient
    V. Create a structure with 2 axes of Symmetry
    VI. Minimise dead load displacements to span/500
5. Assemble the global stiffness matrix, in the case of Sydney Football Stadium this was undertaken using Strand7 Finite Element Analysis (Aurecon) and Oasys GSA (SBP).
6. Solve for nodal displacements, i.e. changes in the nodal coordinates after the loads are applied and the analysis is undertaken. This step results in the new positions of the nodes, which define the equilibrium shape of the structure.
7. Once the equilibrium shape was found, analyse the structural performance (stresses, deflections, and stability) and optimise the design, if necessary, by adjusting the geometry, member sizes, or material properties.
8. Iterate, if the optimised structure did not meet the desired objectives, then the initial geometry, or boundary conditions were adjusted, and steps 5 to 7 were repeated until the desired accuracy was achieved.

The form finding undertaken allowed for the efficient and accurate determination of equilibrium shapes under various load conditions, it resulted in a roof that is approximately 40% lighter than traditional long-span flexural systems, reducing cost and improving sustainability through dematerialisation.

5. Structural analysis and design

Due to the geometrical and loading complexity of the roof, the analysis and design required advanced engineering assessments and various sensitivity studies to ensure the roof was not only structural adequate but that sufficient fabrication and erection tolerances were allowed for. Due to the extensive number of load cases associated with wind tunnel testing and the fast-tracked procurement and erection program, a novel digital workflow was adopted. The analysis and design approach adopted for the design of the SFS roof is detailed below.

5.1 Global analysis

The structural analysis was partially completed in Strand 7 with a standalone roof model that had spring stiffness boundary constraints to represent the abutment cores and bored pile system supporting the roof. This more time-efficient model was used to inform the initial member selections and was validated with

a more detailed global analysis model in the detailed design which captured both the super and sub-structure behaviour of the stadium. Due to the 'arching' structural behaviour, the structure was sensitive to non-linear geometric analyses and softer boundary conditions which results in the compression arch flattening which induced higher axial loads. The design considered both upper-bound and lower-bound pile spring and concrete superstructure stiffnesses based on the available geological information. To optimise the applied loading, wind tunnel testing was conducted to provide more precise wind pressures and distributions. The wind tunnel test results were translated to the global and roof standalone models.

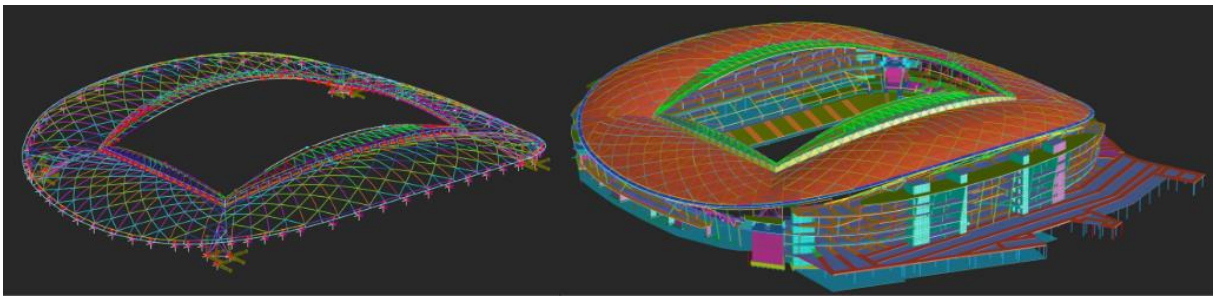

Figure 4. Analysis Models: (a) roof standalone model, (b) global model.

5.2 Digital workflow

The Stadium was designed and constructed within a two-and-a-half (2.5) year period. To meet this fast-tracked programme Aurecon developed a novel digital workflow that enabled exceptional collaboration, coordination and traceability on a level far beyond Federated Building Information Models. This digital workflow involved a 'single source of truth' database and computational design to produce models with 'smart' attributes and all relevant metadata in each of the preferred modelling software used by engineers, consultants, architects, builders, fabricators and shop detailers, this ensured rapid coordination and high quality assurance due to the common database, refer *Figure 5* below.

To ensure the full benefits of the workflow were realised, a unique, consistent and meaningful node and member numbering system was implemented for the traceability between all software (Rhino, Strand7, GSA, Revit, Tekla etc). Key building information attributes were also 'baked' into elements of every model ranging from the structural analysis, architectural and steel shop detailers model. Examples include the radii for the roof rafters or the translation from the fabrication geometry to the final installed geometry (which varied up to 300mm). This is estimated to have saved the project up to eight weeks as models could be updated and coordinated in a matter of hours, not days/weeks and helped automate the design, shop drawing review and verification process.

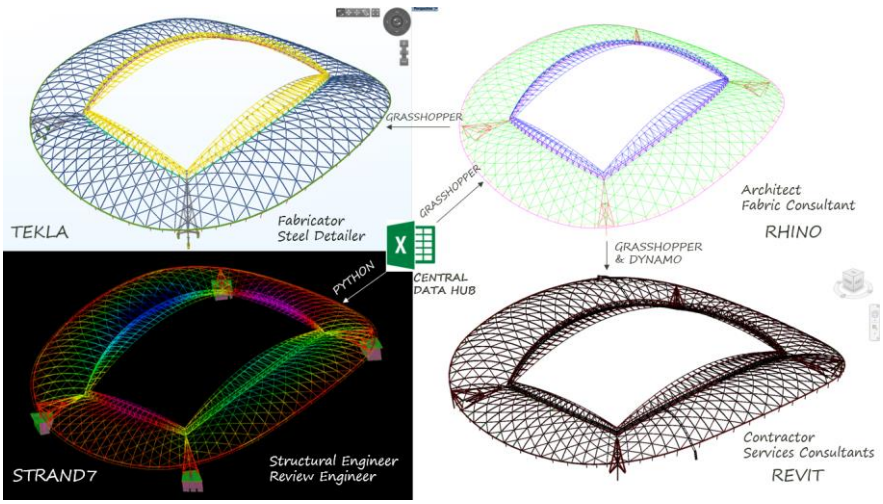

Figure 5. Digital workflow showing model interoperability.

5.3 Member design

The roof model consisted of approx. 5,000 beam elements and over 600 load cases. 10 data points per load case for each beam which were required to undertake the member design checks. Therefore approximately 30 million data points were required for each design iteration. In addition, the global analysis model required over 24 hours for analysis to be completed. The member design had two workflows adopted in the design process, the first of which was completed through excel via extracting the design actions and member properties from Strand 7. Data cleaning was conducted through queries in Excel to process the Strand 7 data into a suitable format for input into the VBA design scripts which were used to check each member for all load cases. The output summarised member utilisations, governing load case and output file which could be imported into Strand 7 to show design utilisations visually.

The second workflow used Python scripts, which were created with a variety of additional toolsets (pandas, jupyter, etc). The scripts were created to complete each task in the design process (data cleaning, member design, output files etc) independently during the debugging stage. This workflow had a significantly faster processing speed and was used in conjunction with the first workflow. Processing the two independent workflows allowed for internal validation of the design results.

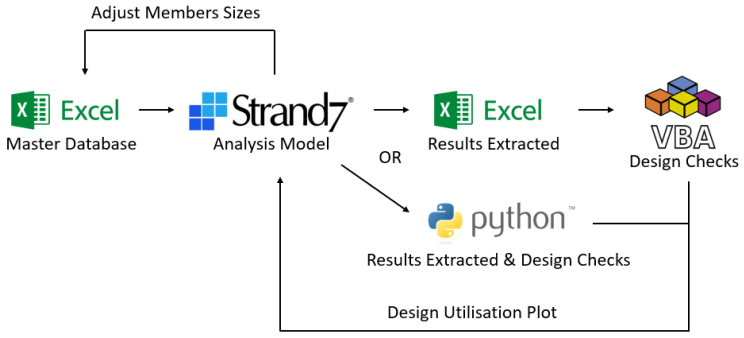

Figure 6. Member design workflow.

5.4 Connections

Due to the geometrical complexities of the roof, the steel connections are some of the most complex in Australian stadia. Large tubular, multi-noded connections exist throughout the roof package that required complex design and detailing. Aurecon and the DBM Vircon developed a bi-directional model workflow, enabling the design and shop detailing to work in parallel. The shop detailer worked with the structural engineers to help form connections suitable for the fabricator while incorporating the structural intent at an early stage. The shop detailer's model was then translated into analysis and design software to ensure design integrity.

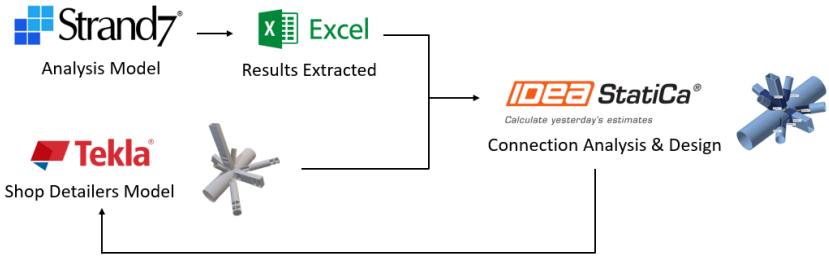

Figure 7. Typical connection design workflow.

The connections adopted were architecturally compact, avoiding bolts outside the cross-section of each member. This resulted in cruciform and bolted flange connections kept within the cross-section being

extensively used. Site welding was minimised as far as practically possible, for constructability and disassembly reasons, with 99% of all connections bolted. This enabled the erection of truss modules and diagrid segments to be installed with ease (refer to *Section 7. Erection and buildability* for more details on the erection staging of the roof).

Following the philosophy of the member design process, design actions and member properties were extracted from the global analysis and queried in Excel to have a suitable format for input into the connection analysis and design software. IDEA Statica was typically used for the majority of the roof connections, the associated design was accurate, and documentation was streamlined. The most critical and multi-elemental connections at the derricks were analysed through sub-modelling in Strand7 or local high-detail modelling within the global analysis model itself. Submodelling is a process which extracts a section of the global analysis model of interest to analyse in more detail. As global models typically make simplifications with the stiffness of connections, sub-modelling is an effective tool to validate the integrity of critical connections. Additionally, it removes any potential errors in translation between design software and provides greater confidence in the design. The design workflow for these connections is shown in the figure below.

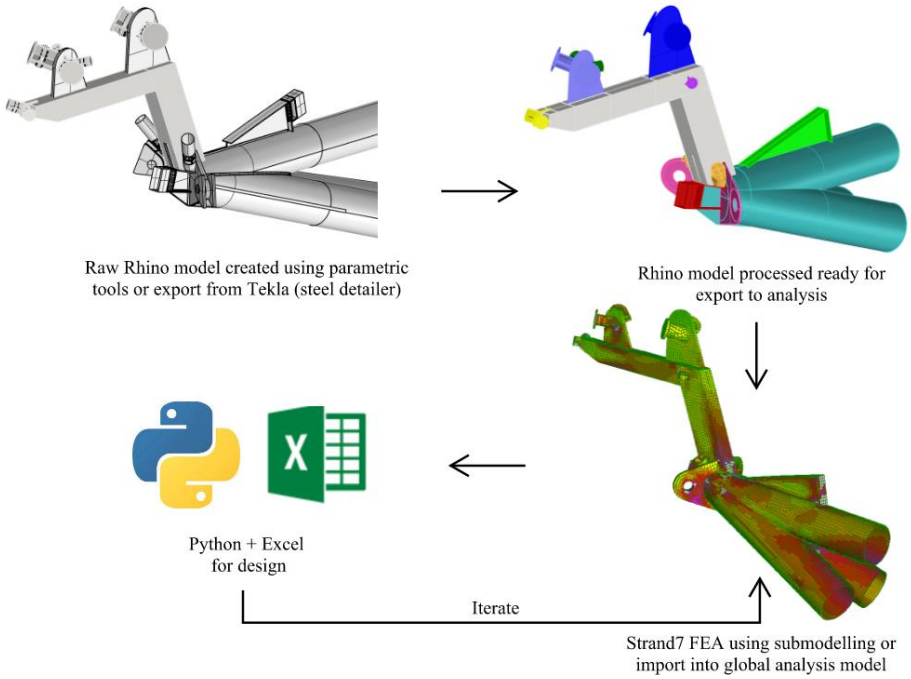

Figure 8. Connection design workflow for complex and stiffness sensitive connections.

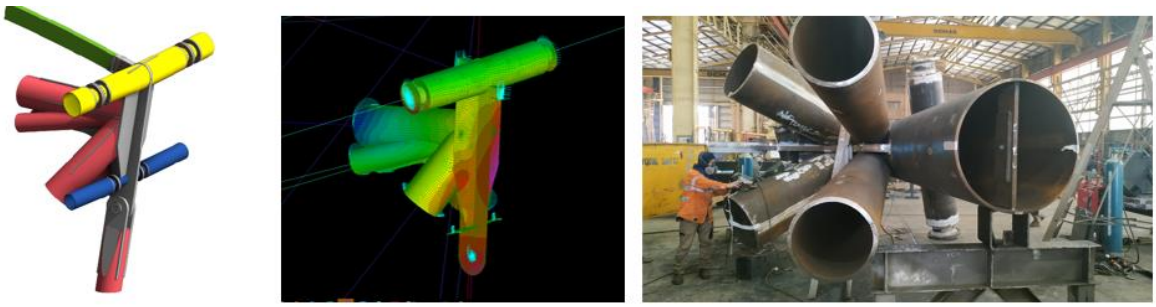

Figure 9. Derrick Rear Connections: (a) Tekla Model, (b) Finite Element Analysis Model, (c) Fabrication.

The digital workflow and bi-directional workflow between the structural engineer and the steel detailer (DBM Vircon) reduced iterations and ensured a very high standard of quality assurance, with over 95% of the shop drawings produced having no comments and proceeding straight to fabrication.

5.5 Buckling study

Long-span stadium roof structures can have trusses that exceed 100m in length, often fabricated in several segments which are erected and installed at elevated heights on site, creating a challenge for contractors to meet precise tolerances. The longest trusses in SFS span 140m and were erected in 3 segments with a nominated positional tolerance of 100mm. Typically when designing more standard structures, geometrical imperfections are captured in the design code buckling curves, (Some codes exclude the resistance, and are captured analytically through applied imperfections or notional loads). For key design elements, understanding sensitivity to tolerable geometrical imperfections may be necessary to provide confidence in the design for fabrication erection tolerances.
A study was undertaken at various design stages to assess the sensitivity of the SFS roof to geometrical imperfections. The workflow adopted is summarised below:

1. Using the base design geometry model, the Strand7 Application Programming Interface (API) was used to conduct a linear buckling analysis on all ULS load cases.
2. A Python script was run that extracted the buckling load factors for each load case.
3. The critical modes of interest were identified which related to the global buckling modes.
4. Geometrical imperfect models were created by adjusting the base design geometry to the shape of the global buckling modes. These models were created at 50mm, 100mm and 150mm imperfection magnitudes. Non-linear buckling analysis was run for each of these models.
5. A detailed assessment was undertaken to analyse the impact and sensitivity of geometric imperfections on the performance of the structure. This evaluation determined whether the roof was prone to buckling before yielding. This evaluation involved non-linear material and geometrical analyses to calculate the buckling load factors of the structure. Refer to *Figure 10*.

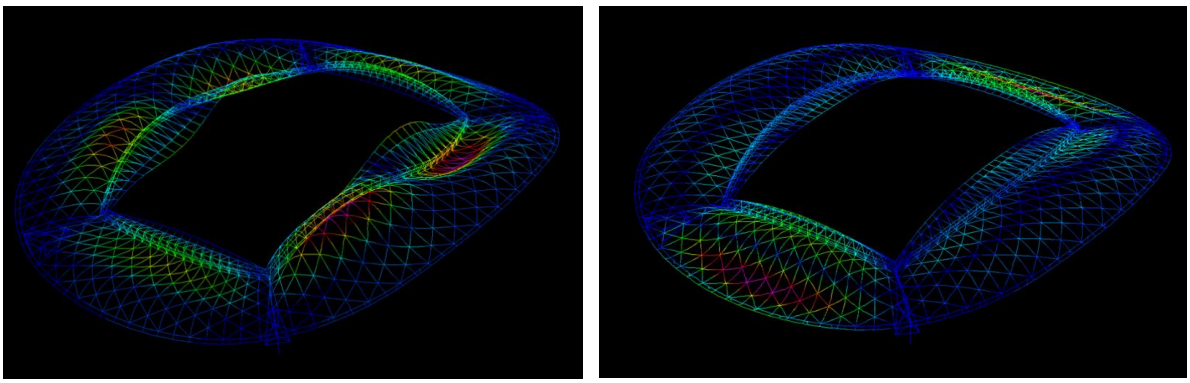

Figure 10. Roof buckling modes (a) Global buckling mode, (b) North-South diagrid buckling mode.

The buckling study indicated that the roof yielded before the first buckling mode occurred, exhibiting the desired structural behaviour, additionally the buckling load factors were within an acceptable range. The North-south bays, due to their pronounced curvature had a particular sensitivity to non-linear geometrical analysis and buckled via ‘snap-through buckling’. This form of buckling occurs when an arch is initially stable in compression, but as the vertical load progressively increases the arch flattens, which in turn increases the axial load in the arch due to the less optimal angle of the arch. The arch withstands the vertical load until buckling capacity is reached and ‘snaps-through’ as it reaches an inversed state that acts as a catenary.

6. Fabrication

The roof fabrication process for Sydney Football Stadium showcased cutting-edge techniques and exceptional collaboration among industry experts, resulting in a state-of-the-art stadium. A key focus during fabrication and procurement was to ensure precision and quality while adhering to the strict geometric tolerances of a form-found structural system. For the complex roof structure, steel fabricator S&L employed advanced processing methods for CHS members up to 762mm in diameter and the 400x200mm RHS members. Approximately 18 kilometres of steel members were sourced for the 2,000 tonne steel roof structure. The process of procurement took over 12 months and was staged to align with the lead times and critical path for erection, for example the structural design had to align with the procurement programme, particularly for the large diameter CHS members which were procured from South-East Asia, this fast-tracked programme enabled the first bulk order of steel to be made within three months of the commencement of design. The design and steel detailing of the members and connections aimed to standardise and simplify the complex geometry of the structure into an understandable and repeatable form, reducing material wastage while streamlining the shop detailing and fabrication process and improving the speed of erection within the confined site. The use of bolted connections allowed for simpler modifications or demountability in the future should the need arise, with over 99% of all steel site connections being bolted.

As with most form-found structures, the behaviour of the structure is sensitive to the geometry of the structure. The implementation of full-scale pre-assemblies of critical elements in the workshop validated the sensitive geometry and enabled any adjustments to be made before arriving on-site, improving the speed of assembly and installation on-site. This was critical to ensure all delivered steel was installed without the need for site modifications and enabled efficient use of the laydown and working areas on-site. The elements that were pre-assembled in the fabricator's workshop include; the Derricks, the Inner Arched Trusses, the Tension Ring and the Radial Arched Rafters.

Figure 11. Fabrication workshop (a) Roof truss pre-assembled, (b) Roof derrick pre-assembled.

Fabrication geometry requiring particularly high precision was the total length of each truss chord which was required to be within +/-10mm from derrick to derrick (up to 140m length), and similarly, the total length of the tension ring from derrick to derrick (up to 195m length) which was to be +/-10mm. This precision was defined based on sensitivity studies undertaken for the structure. This was a challenge to achieve as each element had multiple full strength butt welds with the potential for considerable weld contraction associated with heat and cooling cycles during the welding process. The cumulative effect of weld contraction could result in a significant change in the overall length or alignment. Therefore, multiple splice end plates were left unwelded until the final survey of the pre-assembled element was undertaken to enable adjustments in the root gaps of the welds, providing a method to compensate for any fabrication tolerances or weld contraction that may have occurred.

7. Erection and buildability

Prefabrication and modular construction techniques were adopted to limit the working at heights required and improve the erection efficiency on site, it also enabled multiple work fronts to progress on the pitch (working area) simultaneously without the use of a substantial tower or crawler cranes. The heaviest preassembled module was 130 tonnes which was assembled on the pitch and lifted onto temporary towers supporting the roof structure. The preassembled roof installation strategy enabled over 85 per cent of the roof steelwork installation to be undertaken at ground level, leading to substantial programme and safety benefits. The workshop modularisation or constructability extremities were governed by the overall transportation width and lengths. Each fabrication assembly was studied to ensure all structural members, assemblies and secondary items such as gutters, bull noses, gantries etc. could be installed in the fabricator's yard before transportation and to avoid overuse of the laydown areas on site.

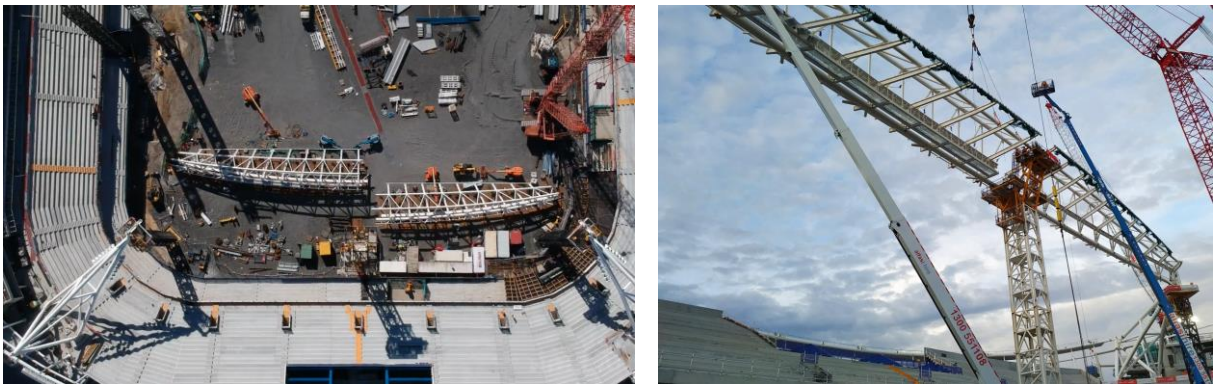

Figure 12. Roof truss erection (a) North truss preassembled on the pitch, (b) North truss installation of segment 2.

Early and collaborative involvement with the engineer, architect, contractor, fabricator and steel detailer was instrumental in achieving the tight design and construction timeframe of only two and a half years with the first steel ordered in less than three months from the commencement of the project. In contrast to many projects, direct relationships were formed through weekly design workshops with all stakeholders from the onset of the project. This is atypical as normally this type of feedback is only received once Issued Tender documentation is complete (i.e. 70% of the design). This early and crucial feedback ensured buildability and speed in fabrication and on-site assembly were at the centre of the design and modelling process.

7.1 Fabrication and design geometry

The design geometry is the agreed final architectural form. This geometry is achieved once all members are unpropped and all gravity loads from the permanent structure including superimposed loads from services, fabric and secondary steel are applied, this is the form-found structural geometry.

The fabrication geometry is the geometry for which the steel is fabricated and assembled in a stress-free state. It is established in such a manner, that the design geometry is achieved under permanent loads with as little deviation as possible.

To determine the fabrication geometry the following is undertaken for each element:

1. Lengthening of members to compensate for shortening through compression forces,
2. Shortening of members to compensate for lengthening through tension forces.

The force distribution in the roof structure follows this approach: The derricks, trusses and tension ring form the frame for the diagrid structure. The thrust from the curvature and intentional lengthening of the diagrid fabrication geometry ensures the tension ring and compression arched trusses are engaged and creates the desired load path. This pre-set geometry is not force-free contrary to an inversed gravity

approach that would be force free during installation but would not engage the derricks, trusses and tension ring as efficiently. The design geometry varies from the fabrication geometry by up to 300mm.

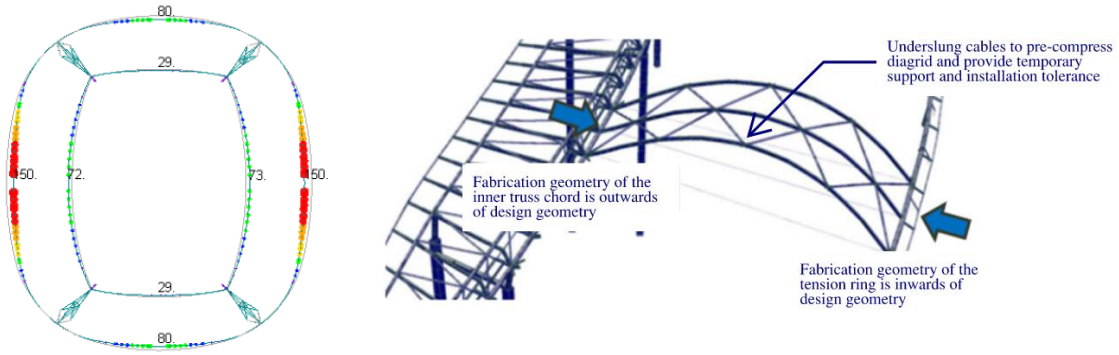

Figure 13. Design geometry and fabrication geometry for tension ring and inner truss chord.

7.2 Erection sequence

The main phases of roof construction were as follows:

1. Abutment cores and superstructure were constructed with associated cast-in anchors for the roof
2. The derrick structures were lifted into their pre-defined positions on the temporary tower at the tip and connected to the abutment cores at three points. The base points were grouted after a survey confirms the correct positions, refer to (a) of *Figure 14*.
3. Columns were installed and stabilised, the tension ring segments are installed and connected.
4. The Truss segments were lifted and connected to the derricks before being placed on temporary towers. As the lower truss chord is a highly compressed element (inner edge of the diagrid shell), the fabricated geometry is longer than the final geometry under force (refer to *Figure 13*). Therefore, to make the trusses fit and able to close the splice connections, vertical jacking operations were undertaken at the top of the towers to open and close the gaps of the end plates.
5. The diagrids were lifted into their positions in pre-assembled double bays. The curved radial arches were stabilised by temporary ties spanning between their ends. The lifted modules were connected by infill diagonals forming the shell structure.
6. Once the diagrid is completed, the radial cables were removed to activate the Tension Ring. Then the de-propping from the towers started by lowering the support to engage the Derricks and the trusses until the roof structure was self-standing and the towers could be dismantled.

The key erection stages are explained and illustrated below in *Figure 14*.

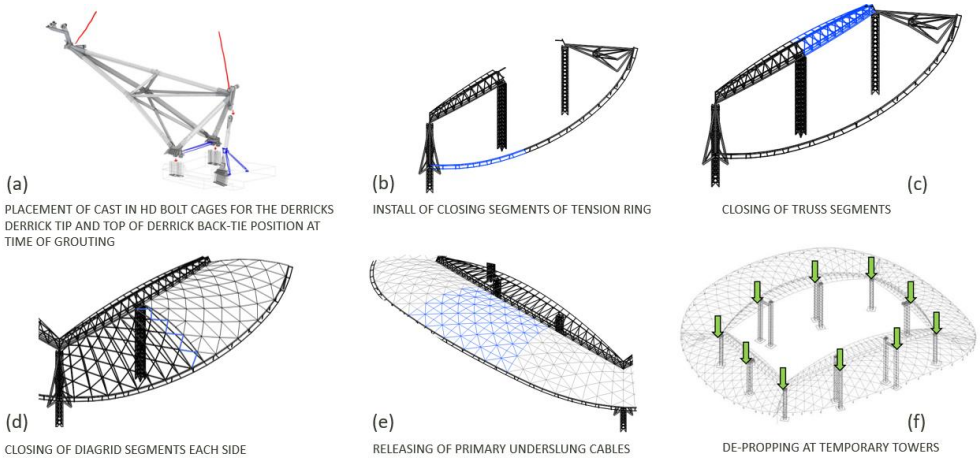

Figure 14. Key stages of erection.

Installing this complex roof with large spanning structures was a challenging task. Difficult access at height and a desire to preassemble as much as possible on the ground added a layer of complexity. Aurecon and Schlaich Bergermann Partner led the erection engineering, testing hundreds of possible deviations in sequence, temperature, geometry, jacking, de-jacking, site and fabrication tolerances, all of which were distilled into a series of simple 'rule books', which clearly outlined the procedures and bounds of what deviations are possible for each key erection stage. This provided substantial flexibility and ensured the roof was able to be fabricated and erected on programme. A key achievement, particularly considering the procurement and work constraints due to COVID-19.

8. Conclusion

Sydney Football Stadium stands as a testament to the power of collaboration, innovative design, and efficient construction techniques in the face of logistical and pandemic-related challenges. The state-of-the-art 2,000 tonne synclastic diagrid shell roof, with its unique geometry and intricate connections, was made possible through a combination of prefabrication, modular construction, and advanced erection engineering. The extensive use of bolted connections and ground-level assembly not only facilitated construction but also enabled future disassembly, adding to the structure's sustainability. The development of a novel digital workflow allowed seamless communication and coordination between various stakeholders, ensuring the successful integration of the roof's 5,000 individual steel pieces. The completion of the Sydney Football Stadium demonstrates the potential of modern engineering and construction techniques when they are employed within a cooperative and adaptive framework.

Abstract

In the ever so prevalent drive to reduce the environmental impacts of the construction industry, the (re)emergence of opting for a circular economy through repurposing of structural elements is gaining traction [1]. Methodologies and tools are currently being established for more efficient inventory processing coupled with structural optimisation and cost evaluation to design structures entirely of reused components [2]. This paper builds off this past research and supplementarily explores an approach to develop modular systems that could be assembled and reassembled in a vast array of options thus further extending the lifespan of existing structural elements. The project consists of four individual modules (footing module, wall module, wall to roof module and a roof module) that were designed with a self-assembly process in mind that solely relies on the utilisation of bolted connections. This paper outlines the digital workflow working with inventories of reclaimed stock material to design the modules and methodologies to populate them in a three-dimensional framework. A live feedback loop was established to evaluate the structural integrity of the entire system in the various design iterations. The project demonstrates a viable solution for further investigation into the circular economy of our built environment.

1. Introduction

We no longer have the luxury to design and construct structures of the same calibre that we do today. The construction sector itself has the strongest impact on the environment, accounting for 40% of global carbon dioxide emissions alone [3]. According to the National Waste Report, Australia generated 29 million tonnes (Mt) of construction and demolition waste in the financial year of 2020-2021, 38% of total waste in the country [4]. A building's operation has a major influence on its total carbon emissions, but its materials and construction are expected to be responsible for up to 80% of its cumulative carbon emissions by 2050 [5]. In an effort the environmental impact, the (re)emergence of opting for a circular economy in the construction industry through repurposing of structural elements is gaining traction [6].

This paper explores a circular design methodology from concept through to the construction of a temporary pavilion for Summer Place, an annual event located in Albury, NSW Australia (Fig. 1). The "Re/place Pavilion" for the 2022-2023 edition was collaboratively designed by Studio Chris Fox (based in Sydney), Bollinger+Grohmann (based in Melbourne), the University of Sydney and Swinburne University of Technology, Melbourne, combining the expertise of architects, artists, students, engineers, and contractors. This paper outlines the design procedure from working with an existing material inventory through to developing discrete modular units to assemble as a global structure. The project demonstrates a viable solution for further investigation into the circular economy of our built environment.

2. Working with existing material stock

The main goal of a circular economy is to maximize the lifespan of existing products by ensuring they remain in use for as long as possible representing an alternate approach to recycling and simply using recycled materials. By repurposing building elements for new use, one can prolong the original intended lifespan of that element and significantly reduce waste and carbon emissions in the construction industry. Methodologies and tools have already been established for more efficient inventory processing coupled with structural optimisation and cost evaluation to design structures entirely of reused components [2]. With computational design, it is also possible to enhance the procedure to develop methods of optimising the reused stock for the design of frame structures subject to ultimate and serviceability limit states [7]. These new structures take on a totally new identity, building up upon the history of the repurposed elements which each of them has their own individual story to tell.

The re-use of building elements from an existing inventory is not a novel idea, being intensively implemented prior to the industrial revolution [8]. The Romans, for example, famously reused materials from conquered territories to construct their expansive empire [9]. The inherent material properties of the building elements play a significant role on its suitability for reuse. A common approach for concrete is to simply crush demolished concrete which, at best, can be recycled as an aggregate for new concrete. This process reduces construction waste but is itself very energy intensive [10]. Current trends focus on utilising entire elements such as reused precast concrete structures [11], salvaged timber beams as well as unconventional materials [12] or even parts of an element such as extracted concrete blocks from demolished concrete structures for a footbridge design [13].

In order to maintain a minimal carbon footprint, the entirety of the timber elements for the pavilion were sourced from existing and used materials. Salvaged timber (Fig. 2) from across multiple locations around Sydney and Melbourne as well as reclaimed elements from previous deconstructed pavilions of the Summer Place were collected, and their suitability for structural, footing and cladding capacity evaluated.

Figure 2. Materials from various locations: (a) salvaged timber from a racecourse in Sydney, (b) structural timber from Timber Zoo, (c) timber beams from Albury City Council, (d) screw piles from previous pavilions.

3. Modular systems

Typically, the standard procedure when handling the reuse of building elements is often limited to its second life cycle. It was essential to extend the research to focus on how the elements could be reused in multiple lifecycles. In the process of DfDR (design for deconstruction and reuse) [14] a building is designed in a way that its parts can be easily dismantled and separated from each other for reuse or recycling. The research explored an approach to develop modular systems that could be assembled and reassembled in a vast array of options thus further extending the lifespan of existing elements.

With the city of Albury located at least three hours driving distance from Melbourne, and significantly longer from Sydney, it was essential to use prefabricated elements to minimize time on-site. The use of modular systems significantly reduces construction time on site, with most of the fabrication and assembly work largely completed off-site. They also offer increased flexibility in design: the components can be easily reconfigured or modified to accommodate changes in function or overall form.

Wasp is a plugin for Grasshopper that allows for "representing and designing with discrete elements" [15]. The toolkit allows for both the geometrical and topological description for each unit, as well as its inter-connectivity rules, to be defined. Researchers at the Frankfurt University of Applied Sciences used a similar approach to design a temporary pavilion with modular elements composed of discarded wire hangers, investigating the balance of achieving an "articulated morphological variation and a sufficient a level of design flexibility" [16]. Stochastic aggregation and field-driven aggregation methods in Wasp define instructions for the computational procedure to orient elements based on a set of connectivity rules [17] enabling the possibility to generate a vast array of design iterations in a short amount of time. Fig. 3 shows initial studies which looked at these aggregation methods based on the design of the individual discrete unit which themselves were designed based off stock material inventory.

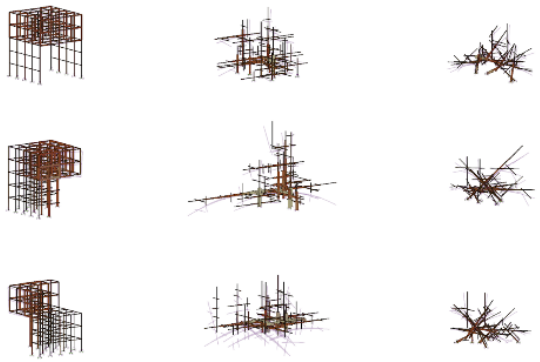

Figure 3. Design iterations using a discrete modular approach.

4. Identification of potential reusable elements

Bespoke computational workflows were developed in an initial case study that was presented at CAADRIA 2022. The workshop titled "Manipulating the VR space for the design of repurposed timber structures" set out to utilise the digital workflow working with inventories of reclaimed stock material to design the discrete units and methodologies to populate them in a three-dimensional framework. Techniques to 3d scan, archive, and document elements suitable for reuse were investigated during this workshop as depicted (Fig. 4). By studying several existing structures scheduled for demolition, it was possible to first identify and categorise specific elements to create a preliminary material database.

Figure 4. 3d scanning existing structure to create a digital archive and 3d model.

For the design of the new pavilion design, and its inherent structural properties and accessibility, timber was selected as the material of choice. There is an often-tedious process that involves analysing the salvaged timber elements for nails or foreign objects that need to be removed before processed with woodworking machinery. Initial prototyping, evaluation and processing of select timber beams that were over 100 years old were done at the University of Sydney. Due to time and resource limitations, an alternative approach was chosen were elements that were already dismantled and pre-processed were selected for the main structural elements, with those of less processing were used for non-structural elements such as the façade.

There was still a process to assess the acquired elements even if they are pre-processed beforehand. A surface assessment of the quality and defects of the timber helped to determine which elements could be used, which of them could be cut, where exactly it was appropriate to cut. This included a quite labour-intensive approach to manually evaluate whether there was warping, cracking, or bowing in the timber (Fig. 5). Any holes from nails and additional features were all entered in a Google Form which created an extensive Google Sheet of the sourced material (Fig. 6).

Figure 5. Identifying all the surface issues in the sourced timber.

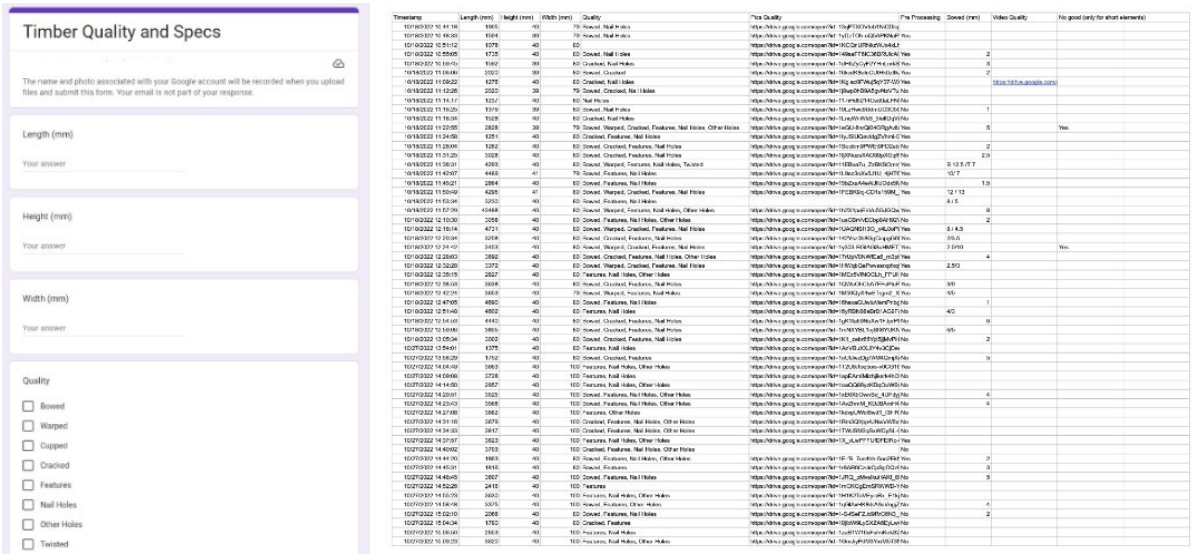

Figure 6. Google Form and Sheet to document the assessment of the timber quality.

5. Digital workflows

Setting up a computation workflow based on the findings from the CAADRIA workshop allow for quick sketches and 3d iterations based on the material database to be conceptualised. Simply adapting the starting input module and adjusting its connectivity rules, it was possible to generate many design iterations as depicted in Fig. 6. It was important to establish a dialogue with the new structure in its extended lifespan and its first intended function. Fig. 7 shows how elements from the digital model are able to be connected back its original position, allowing visitors to read the transition from old to new. The team of researchers led by Catherine De Wolf at the ETH Zurich explain that engraving QR codes on all repurposed elements "help people learn more about that building's history" [18].

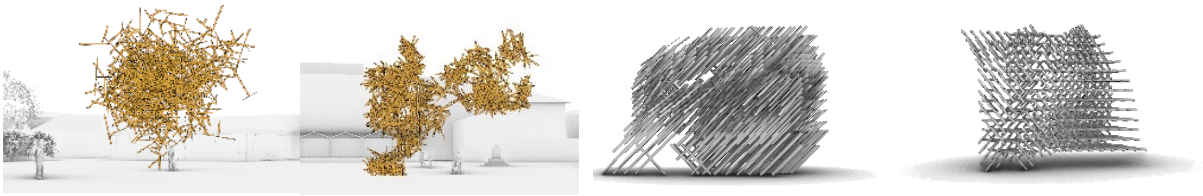

Figure 7. Early design iterations of the pavilions.

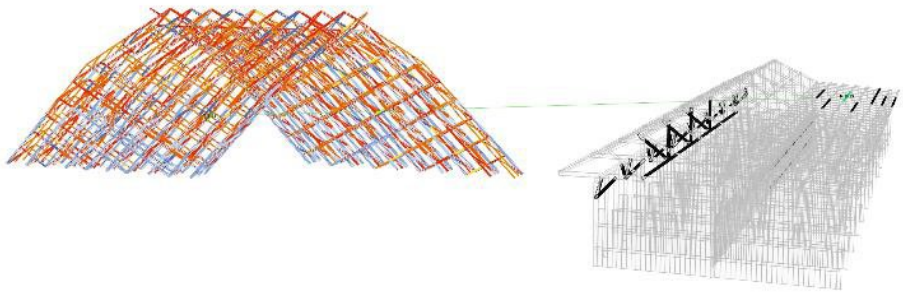

Figure 8. Design iteration relating to stock material.

5.1. Discrete modular elements

Several factors were at play in the design of the individual modules themselves (Fig. 8). They should be able to be lifted by hand by either one or two people without additional machinery, they needed to be transportable in the back of a small truck, the number of offcuts and material wastage should be minimized, and they needed to be self-supporting - able to carry its own weight and as well as other elements attached to it. With this design intent in mind, the team went through vigorous investigations of formal studies (Fig. 9) that coupled well with the modular design and to situate the pavilion within the context of the site of QE Square in the centre of Albury. Finally, a scheme depicting a deconstructed shed with a gable roof was chosen as point of inspiration.

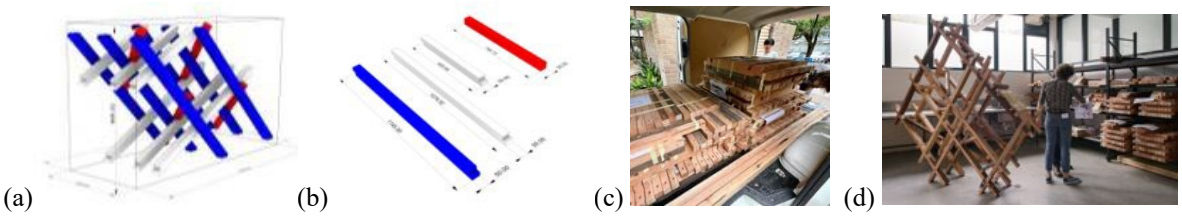

Figure 9. Module parameters: (a) Setting a module size, (b) Controlling the lengths and cuts, (c) Compact transportation of the elements, (d) Self-supporting modules lifted by hand.

Figure 10. Design iterations involving various predefined modular elements.

Enhancing the capabilities of a parametric design environment it was crucial to develop the geometry for the discrete units coupled with information about its structural axes that could be fed into a live analysis. Structural information in regard to cross sections and materials were also embedded to provide an accurate simulation of the structural integrity of the modules (Fig. 10). Any transformations to the starting module design would be immediately evaluated to provide quick live feedback.

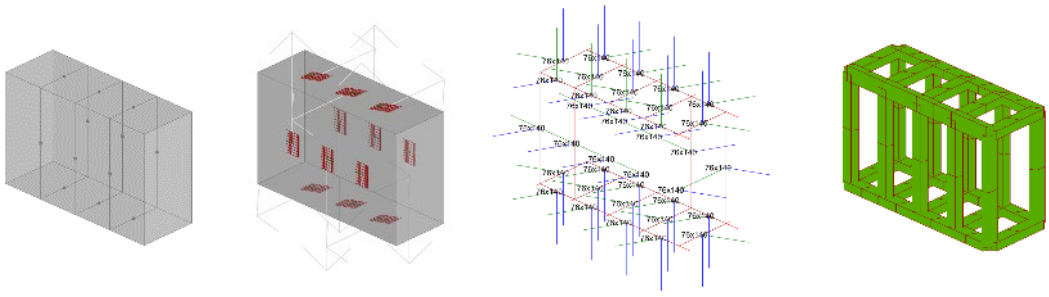

Figure 11. Modules embedded with geometry and structural information with live structural analysis.

Final design iterations resulted in individual modules for the pavilion design (footing module, wall module, wall to roof module and a roof module) that were designed with a self-assembly process in mind that solely relies on the utilisation of bolted connections. 20 wall modules, 12 roof modules, 10 footing modules, 6 wall to roof modules (Fig. 11). This would form the core structure of the pavilion, all elements self-supporting, and able to carry those adjacent to each other. Reclaimed timber strips from the previous pavilions were used as a final cladding element that helped to accentuate early key themes

of movement, dynamism, and texture, and also alleviate climbing potentials of the envisaged structure (Fig. 12).

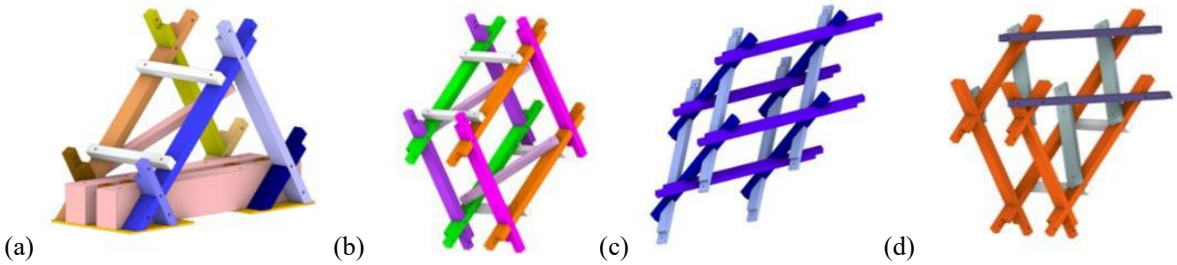

Figure 12. Final Modules (a) Footing, (b) Wall, (c) Roof, (d) Wall to Roof.

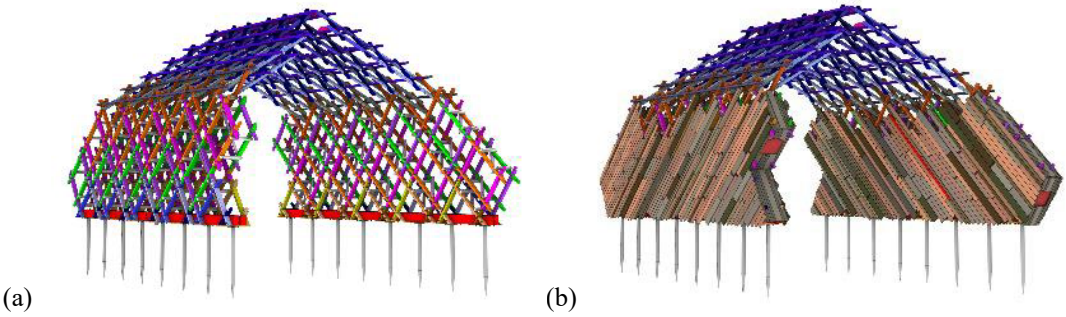

Figure 13. Final Pavilion (a) structural components, (b) with cladding.

5.2. Integrated structural analysis

The pavilion should provide some form of shelter, a portal where visitors could enter and experience the pavilion close up. With a clearly defined design concept, a grasshopper script was created to establish a live feedback loop to evaluate the structural integrity of the entire system in the various design iterations. The general form and silhouette of the project should remain consistent, but several parameters could be altered. The script allowed the size, angle, depth of the modules to be parametrically controlled (Fig. 13). Slight adjustments in the module design would have drastic effects on the global design as well as the overall structural capacity. It was crucial to be able to understand how the impact of the position and orientation of specific modules could affect the global structural behaviour (Fig. 14). During the structural design procedure, an optimisation was created to allow the algorithm to pick from the material database for a suitable cross section depending on its availability. The total amount of material could be easily extracted.

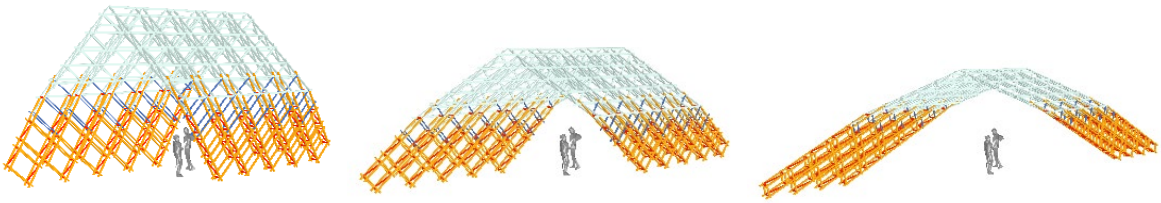

Figure 14. Parameters in the script-controlled size, angle of the module which affected the global shape.

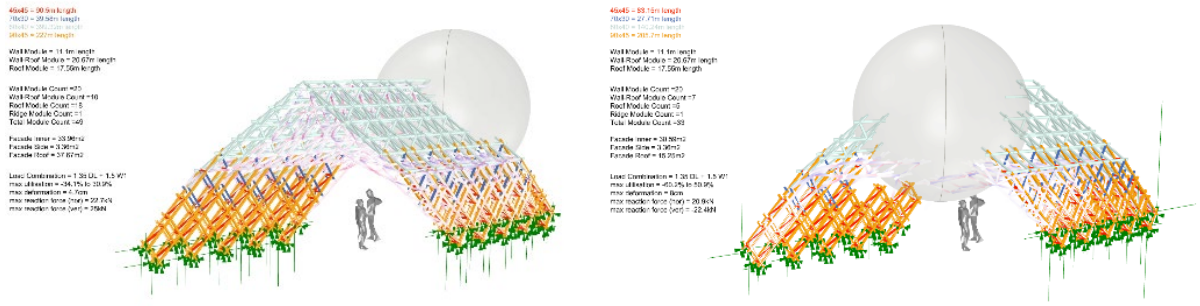

Figure 15. Design Iterations and their effect on the structural performance.

The pavilion measures 4.2m wide, 9.7m long and 4.2m high. Recycled screw piles were selected – 16 in total, 2 for each footing module. Calculations showed reaction forces of up to 4.65kN at the support positions meaning that the screw piles of 1.2m depth would be suitable. A timber base plate was attached onto the top of the screw piles where two recycled Kauri softwood beams (180x122mm) were fixed, onto which the footing modules would attach to. The roof and wall to roof modules are entirely constructed of 40x80mm hardwood members and the wall modules are composed of mainly 90x45mm softwood members with 45x45mm elements for bracing elements. Detailed structural calculations showed critical moments at the roof pitch junctions (Fig. 15).

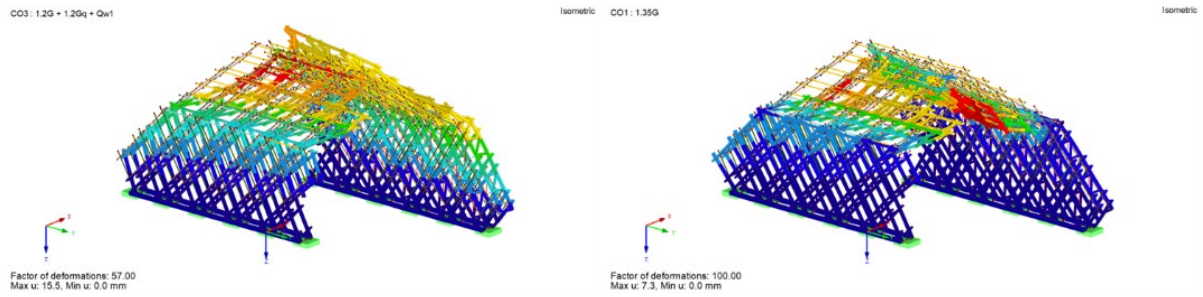

Figure 16. Structural analysis of the pavilion showing deformations under SLS loads.

6. Fabrication

The digital fabrication of the elements for the core structure was entirely done with a 3 axis CNC by the DMaF Lab in University of Sydney and Protolab in Swinburne University of Technology. For ease of assembly and fabrication, it was decided early on to use simple bolts and nuts to attach elements and modules to one another. Jigs were created to establish a seamless and efficient manufacturing line to cut, process and drill all the necessary components (Fig. 16). A distributed workflow allowed the separate universities to produce their subsequent modules, base and wall in Sydney and wall-roof and roof in Swinburne, and everything came together relatively easy on site even when they were fabricated in different locations.

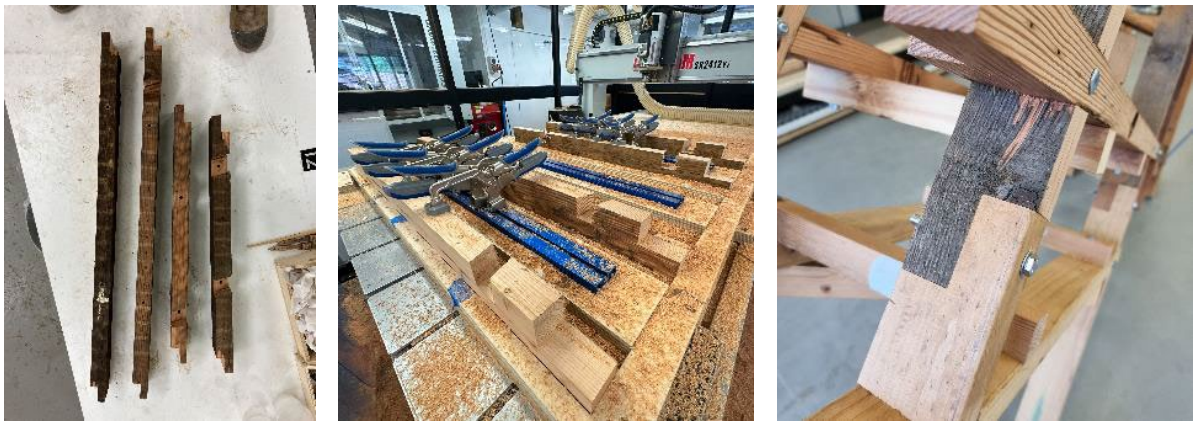

Figure 17. Fabrication of individual elements.

The individual elements were then transported in a small truck to Albury where all the modules were initially preassembled. A detailed assembly process was established in the planning process to allow the pavilion to be constructed from both walls simultaneously from the base. The wall-roof and roof modules would then be attached where the roof would eventually meet at its pitch. Individual elements were then used to join both sides of the pavilion together. This meant that no additional scaffolding was needed and only a mobile scissor lift was required to lift the uppermost modules into position. Fig. 18 shows the assembly process on site.

Figure 18. Assembly Process.

7. Sustainability aspects

The core structure of the pavilion has been built from entirely repurposed construction timber elements from various construction sites sourced by Among The Trees in Sydney and Timber Zoo in Melbourne. Oregon and Pine were used for the wall modules, originally sourced from USA, as was typical in the early 1900s. Messmate was used for the roof modules. The Oregon and Pine timber have been collected from different buildings built between 1920s and 1950s across the Sydney area. The Pavilion façade is composed of repurposed timber from Albury including reclaimed elements taken from the previous iteration of the Summer Place Pavilion. These timber boards were also originally salvaged from the Black Summer bushfires near Corryong in 2019-2020, blackened using an oxidizing process (Fig. 19).

Figure 19. "See the forest" by Akimbo Architecture, © Jeremy Weihrauch

With a life cycle analysis, it is possible to identify the environmental impact should have the structure been constructed of entirely new elements. Out of all the material used for the pavilion, the base plates, bolts and nuts were the only elements that were not sourced from an existing site, but rather purchased and are the only contributing value to the total embodied carbon of the structure. Table 1 outlines a comparison of all the materials and their embodied carbon or equivalent should they have had been newly sourced. All timber and screw piles were reclaimed from existing sites, and therefore do not contribute to the impact of this project. Only 14% of the total embodied carbon came from newly sourced materials (bolts, nuts, washers and base plates). Values are based on the ICE Database for Cradle to Gate Life cycle stages (A1-A3, C3+C4) [19].

Table 1. Values from Embodied Carbon - The ICE Database [19] and EPD-V/S/B [20]

Typology	New/Reclaimed	Material	Weight kg	CO_2 Emissions kg $C0_2e$/kg	Total CO_2 Emissions kg $C0_2e$
Timber Beams	Reclaimed	Softwood	220,5	0.263	57.99
Footing	Reclaimed	Softwood	126	0.263	33.14
Wall	Reclaimed	Softwood	328,5	0.263	86.40
Wall-Roof	Reclaimed	Hardwood	223,3	0.306	68.33
Roof	Reclaimed	Hardwood	408,1	0.306	124.88
Facade	Reclaimed	Softwood	454,5	0.263	119.53
Screw Piles	Reclaimed	Existing	62,8	3.75	235.50
				Subtotal	**725.77**
Base Plate	New	Steel	23,55	2.46	57,93
Bolts & Nuts	New	Steel	15,7	3.75	58.88
				Subtotal	**116.81**

Timber, when handled and treated properly, has great potential and durability, as seen in its ease when selecting it for repurposing. The dressing, cutting and drilling into the timber elements can affect its durability and continued processing can reduce its structural capacity. When addressing the idea of designing for a circular economy, it was therefore important to consider further potential for reuse where the pavilion could be disassembled into its separate modules and reassembled in different configurations (Fig. 20).

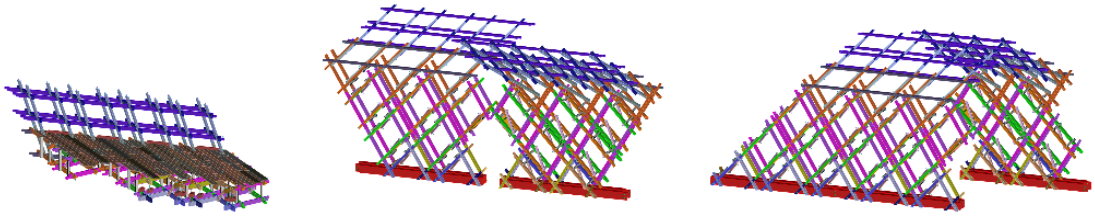

Fig. 20: Reconfigured elements.

8. Reflection & conclusion

Figure 21. Completed Structure © Jeremy Weihrauch.

The utilization of reclaimed timber for the construction industry is still challenging. Especially if it comes to liability clients and builders are concerned to use reclaimed timber since there are currently no standards or guidelines of how to proceed and design with this type of timber. Every source where the potential timber might come from has its own challenges whether it is accessibility, project management or lack of expertise. Most reclaimed timber elements are regarded not usable and classified as non-structural material and only fit for furniture making.

During the project development and the sourcing of the material, it became paramount to have one or in this case two reliable sources to purchase the material from. With a steady source of the material, a workflow was established that verified the quality of the timber delivered and its allocation in the design was assigned. This process is crucial and needs more research to improve on. For example, with vision control and AI technology smarter and faster ways of categorizing the material samples could be achieved in the future.

The design principles and the logic of reconfigurable modules will be further tested with the pavilion once it's reached its end of life at the current location. The idea is to relocate the pavilion and to give it a new life in a reconfigured way to extend the use of the pavilion and to showcase the next level of circular economy.

New master's education: innovative teaching of sustainable design approaches for handling uncertainty

olga.larsen@kglakademi.dk

Abstract

The climate emergency requires all sectors of Society to work together in seeking less polluting, better functioning, and more sustainable solutions. The building sector with a huge negative environmental impact currently is a segmented industry - with responsibilities, but also visions, values, and approaches that are fragmented. In the search for more holistic approaches/solutions that will reduce/revert the negative impacts of the building sector collaboration across disciplines is essential. This is both the vision, starting point and main aim of the new master's education at the Royal Danish Academy in Copenhagen - *Architectural Technology*. Designed as a two-year professional master's program for constructing architects, it started with new students in September 2021/22. Through the innovative teaching of sustainable design approaches, the graduates are better positioned to handling design uncertainty including scarcity of materials, structural robustness, adaptability, new design requirements etc. The paper presents the aims and vision for the program, the Nordic educational context, course structure and modules descriptions, project examples as well as a reflection for further developments.

Keywords: new education, teaching methods, sustainable approaches, holistic thinking, design uncertainty, materials reuse, structural robustness, adaptability

1. Introduction

Historic building design has created architectural masterpieces through a holistic approach. The glory of the Master builders and the embodiment of single leader- master in charge the project – dealing with aspects from technical to artistic, geometry, detailing, considerations about economy, planning and organising the construction process, as well as defining material choices, qualities and quantities manifests itself in the beautiful architectural examples. Whilst the huge development of technical knowledge and technology, made this was impossible to sustain, it is still the case that the collaboration in the design/construction team is what often "makes" or "breaks" a project. In more current projects facilitated by new collaborative tools and methods of working we can clearly follow the quality of outcome through the lenses of the quality and level of collaboration.

In the past collaboration was important for achieving good value building design and construction, which, to a large extent was relating to safety and durability. Today, building design and construction have additional requirements to fulfill. Yet, collaboration remains essential in seeking approaches that can address climate crisis we are facing [1]. The high level of uncertainty, lack of resources, complexity in design and huge environmental impacts of the building sector, are only some of the challenges we are encountering. On the one hand there is a need for a creative approach and thinking out of the box, on the another – high level of technical knowledge is required to fully foresee the consequences as well as opportunities. Perhaps the most important of all is to possess the ability for critical reflection and evaluation as well as holistic approach across all building design and construction phases. It is exactly out of these needs the idea for establishing the new master's education – Architectural Technology (AT) at the Royal Danish Academy was born.

2. The vision for the new program – architectural technology (AT)

The following two statements encapsulate the AT's main aim:

from normative to critical

from convention to vision

Globally, the building sector is fully regulated to ensure quality and safety. As a result, most technical educations worldwide educate about how to work well within current regulations. AT as a master's program, is aimed for applicants who have already completed a 3.5 years' professional bachelor's degree with the title of "constructing architects". This education provides the graduates with a technical foundation and practical skills for working within the building sector. Constructing architects are a very respected profession in Denmark. They are highly employable and skilled in working with BIM, designing and drawing of technical details, supporting architectural design work in architectural practices, supporting engineering work in consultancies, also working as contractors and developers. They are highly skilled in many very relevant aspects needed in the building design and construction practice. Perhaps, one very important skill they come with is that they fully understand current and coming up building regulations and how to operate within them.

One of the main aims for the AT education is to work further with the normative aspects, to evaluate and challenge them. We would like the graduates, through the AT education to develop skills that enable them to move from the normative to the visionary. During the two years master's program we work with critical evaluation, analysis and critical thinking to develop the current conventions into new visions. The core of the AT aims is to develop critical and reflective practitioners who will be able in building design practice to support architectural quality and develop new ways of working that will address the climate crisis.

2.1. The Danish/Nordic educational context

It is evident that educational systems differ globally, yet these differences are greater within architectural education when compared to more technical educations within the building sector. That *"There are many ways of becoming an architect"* comes from the fact that an architectural education builds on design traditions, local building culture, context, by bridging artistic, practice-based and scientific knowledge creation methods.

The Danish/Nordic context typically builds upon the artistic tradition within architectural education. This has established Danish architecture globally with buildings that embrace building form, materiality and craftsmanship growing out of the context resulting in beautiful architectural masterpieces. Widely renown are buildings as the historic Kronborg Castle, Utzon's Sydney Opera House, Housing projects by BIG, Dorthe Mandrups's Wadden Sea Centre and many others.

Within the building sector globally, but also in Denmark/Nordic region we experience increasing need for documenting safety, performance, complying with new building regulation requirements, many of these challenging architectural quality. Many of the requirements are dealt with separately making it very difficult to retain the holistic approaches required for remaining true to the architect's design vision, but also, addressing the climate crisis. These aspects are exactly what AT graduates are educated to support: architectural quality and sustainable approaches within a circular context.

2.2. AT's programme structure, semester themes and module content

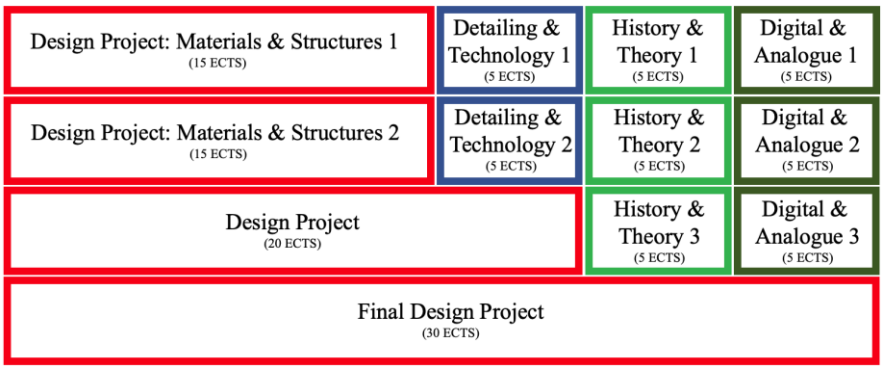
The education is organised in 4 semesters of 30 ECTS points each. Each semester is a mix of taught modules – so called "*shoulder modules*" that provide the knowledge basis for the project work. There is a clear progression with increased complexity from one semester to the next with each semester organised around a specific theme:

1. *Learning from history* – is the theme for the first semester. The taught modules offer lecture courses

that give insight into past examples of Danish and Nordic architecture and discuss the lessons to be learned. The 1st semester project is a study of a recognised historic building project where after learning about the history, period, context and architecture, the students take some aspects that are especially valuable and try to bring them into a current context. Some of these, due to current building regulations or because of current building practices would be impossible to build. Alternatives are investigated that achieve the same level of quality.

2. *Sustainable renovation* – is the theme of the second semester. Courses are offered to support the project that typically deals with a large renovation project. Strategies and approaches are investigated that challenge current practice, such as renovating with as much as possible reclaimed material harvested from the renovation project itself, or working with biodegradable materials, or seeking ways to have the lowest possible renovation footprint whilst supporting biodiversity. The specific projects that come as a result of these strategies, are then developed to detail level and represented through digital models and physical prototypes.

3. *From relative to absolute sustainability* – with this theme, the third semester is organised through seminars about how to design and stay within the planetary boundaries. The main design project and investigations are closely related to the themes that the faculty – teachers are working within their research, practice, or artistic development work, broadly addressing aspects of sustainability.



4. *Final project* – the final forth semester is used for a large independent project that will embrace all that has been learned in the previous three semesters. As a culmination the final project deals with a theme with substantial complexity and high level of development. Typically, the final project deals with a design or a research investigation that is relevant for current/future sustainable building practice where the student can show their critical thinking skills, investigation, and design skills. It is a crown - the finale of the two-year master's education.

In parallel with the taught modules and project work supervision, various workshops, including skill-building teaching is offered. These include:

- hands-on workshop skills building - working with wood, metal, concrete, glass, clay, etc.
- computation workshops: parametric tools, CFD modelling, acoustic and lighting modelling software, etc.
- hand sketching, artistic work, working with prints and paint, etc.

During the four semesters typically there are two trips, one in Denmark and one abroad as well as multiple visits to building projects under construction as well as completed ones, producers of materials, experimental practice offices etc.

Table 1. Architectural Technology – Course structure with modules overview

3. Project examples

First semester project, fall 2021: Islev church

At the very first semester, in the fall of 2021, students were divided into groups of four. Each group were assigned an existing building in the greater area of Copenhagen, where the main material consisted of either masonry, concrete, timber, or steel, which are frequently used materials for construction in Denmark. Typically, the buildings chosen were listed because of their recognised architectural qualities. The assignment was about analysing material use and construction, tendencies in contemporary architecture from when it was built, and then relate the acquired knowledge to today's construction methods, and technical requirements. It was about *learning from the past*.

One group was assigned Islev Church, a classic modern movement cubic church from 1970, with load-bearing masonry facades, and a long-span timber ceiling truss, spanning approx. eighteen meters (Figure 1). Compared to today's energy requirements in Denmark, the facades U-value (W/m^2K) would be inadequate, and even though the bonded ties with cavities require less bricks, compared to a massive masonry wall, a lot of bricks would still be needed. Therefore, theoretically, an alternative masonry wall was suggested: the diaphragm wall (Figure 2). Diaphragm wall, which means partition, separation, or division, is a form of traditionally known loadbearing masonry wall, where the inner- and outer walls are connected by bonded cross-ribs. The wall is a 2 – 2 ½ thick brick wall, between 466 – 570 mm. The cross-ribs, with a space distance between 800-1200 mm, give the wall an increased bending stiffness, dividing the wall into sections. The deeper the wall gets - the more load it can take, and more insulation can be added in the cavity. This makes it suitable for tall, single-storey buildings, such as Islev Church. Because of the length of the cross-ribs, the thermal loss through the ribs is limited and is generally assumed to have an 10% higher U-value than conventionally brick cavity walls [2], [3], which, theoretically, makes it possible to perform within the minimum U-value requirements in the Danish building regulations [4].

The roof loadbearing structure consists of four timber trusses in each direction. Because of the trusses being connected in both top and bottom in two directions, the calculated effective length of each member working in compression is halved [5]. This results in relatively slender timber members, forming a long span timber structure with relatively little material use.

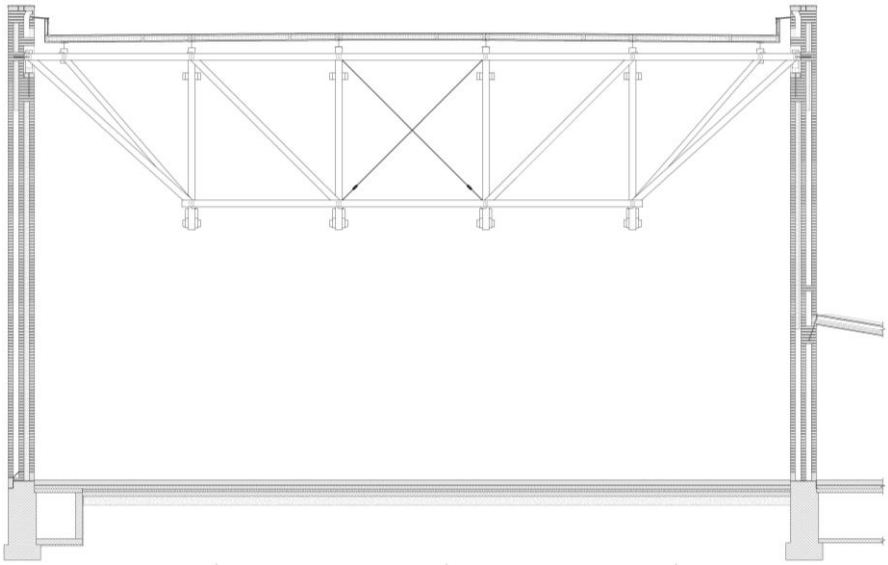


Figure 1. Cross section of Islev Church, with the original three-layer masonry walls. The masonry walls consist of three bonded layers of brick walls and two cavity spaces. The timber roof loadbearing structure, transferred the load onto the masonry walls, consists of four timber trusses in each direction that are connected. This increases the bending stiffness of the trusses.

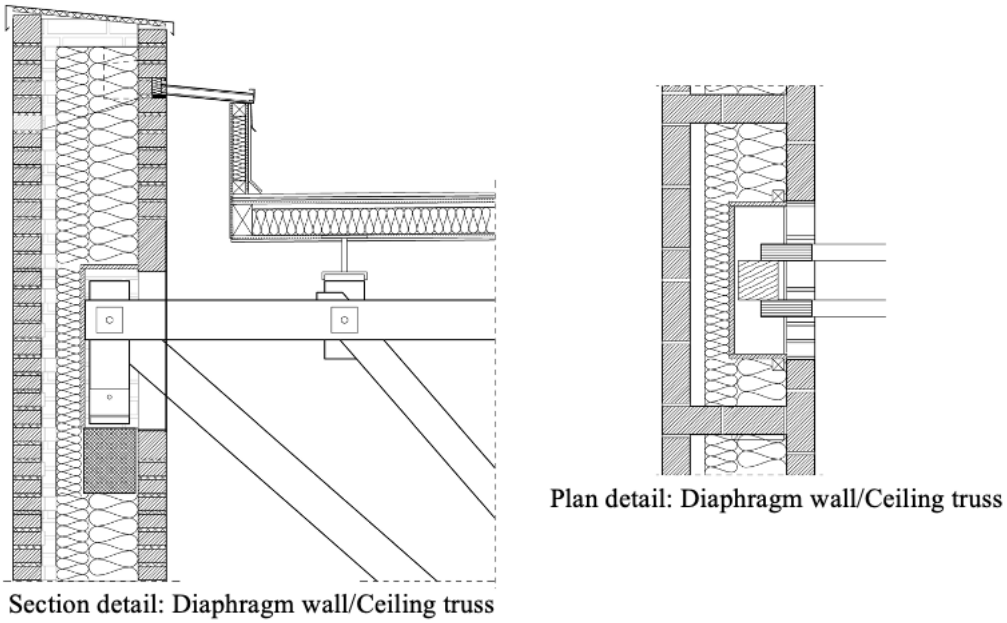

Figure 2. Connection and placement of a roof truss, with the diaphragm wall. Left: vertical detail section, showing the roof truss foot placed on a beam inside the diaphragm wall, supported by the cross ribs. Right: Horizontal detail view, showing the inner- and outer brick walls and the bonded cross ribs with insulation in the cavity.

Second semester project, spring 2022: The scarce & the reversible

In the second semester, the main theme was *sustainable renovation* and circular design approaches. The students were divided in groups, each group focusing on an existing building from between late 1940's and mid 1970's in, or near, Copenhagen, with different needs for renovation. The assignment was divided into two phases. The first was to investigate the needs for renovation, concerning poor insulation values, thermal bridges, and the general condition of the building; but also learning about architectural qualities and characteristics in the time when the buildings were constructed. The second phase was to make a renovation strategy, incorporating circular solutions. One group was assigned a two-story social housing area, build in 1948, called *Ved Kirken*.

After the second world war, in the second half of the 1940's and in the 1950's, there was a great need for social housing in Denmark. In this period a substantial number of apartment buildings were constructed, accounting for around 10% of all apartment buildings in Denmark in 2015. The 1940s and 1950s were a time with scarcity of energy and materials, which called for an optimization of traditional construction methods, where more could be obtained with less. The main characteristics for apartment buildings, from this period, are homogenic use of materials with masonry facades, and sloped roofs covered with tiles. Wall cavities were introduced in the masonry facades, reducing both material use, and construction time, as well as providing insulation properties to the wall, thus reducing the thermal loss. The façade now consisted of two brick walls connected with bonded bricks, making the wall 1 ½ brick thick, equivalent to 348 mm (Figure 3). Living rooms were often oriented towards south-west, often with a balcony, or there was a bay window, made from concrete. This period in Danish architecture, is known to have contributed with great architectural/aesthetic and cultural values, and therefore there is a wish for the architecture to be preserved. However, the buildings have issues with thermal bridges, also poor U-values (W/m^2K), mainly due to concrete in the walls crossing from the inside to the outside, also because of lack of insulation. This causes significant loss of energy, sometimes humidity with indoor mould growth, damaging the indoor climate. In many cases insulation has been added - blown into the cavity, but because of the relatively short length of the bonded ties, it is often an inadequate solution concerning thermal bridges and mould development [6], [7].

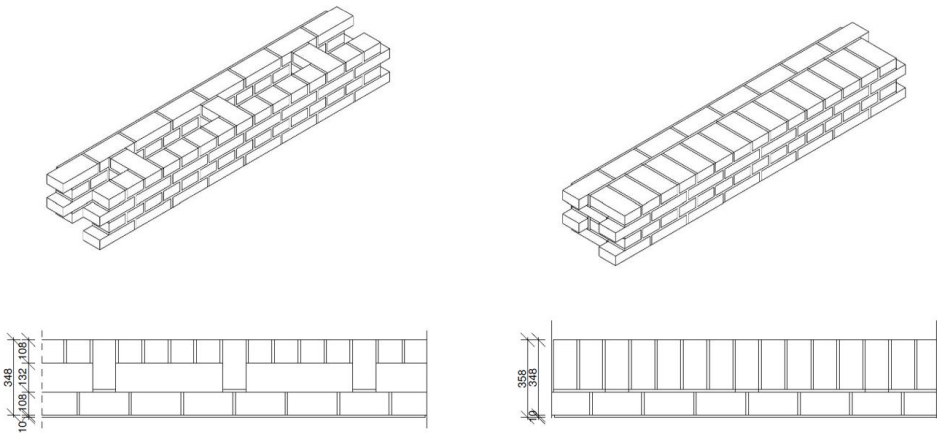

Figure 3. Left: The masonry wall, consisting of an inner- and outer brick wall, bonded together with brick ties, creating cavities inside the wall. Right: Where it was not possible to make the cavity due to structural reasons, a massive masonry wall was used instead, which is traditional in Denmark and a well-known solution

The group's main aim was to handle the poor insulation values, and cold bridges, while keeping the architectural characteristics and qualities, and to do so by adding as few new materials as possible. Danish studies have shown a short break-even time, for energy optimizing buildings from this Danish building period [8]. One aspect of the renovation strategy was to break down the outer brick layer, which, theoretically, would be possible due to the use of lime mortar used in this period [6], and "moving" the outer wall 30 mm out (because of the wish for using the existing foundation), cutting the bonded ties and eliminating the direct thermal bridges, and filling the cavity with insulation. The outer wall should then be built up again re-using the existing bricks, connected to the inner wall with mechanical mounted steel ties (Figure 4). A relevant discussion in terms of this solution was the long time -man hours needed for executing this approach. However, there is a successful precedent of a Danish demonstration project, using the same method of demolishing, insulating, and building up the wall again reusing the bricks, has been done. The results were positive both aesthetically, economically, and environmentally [9].

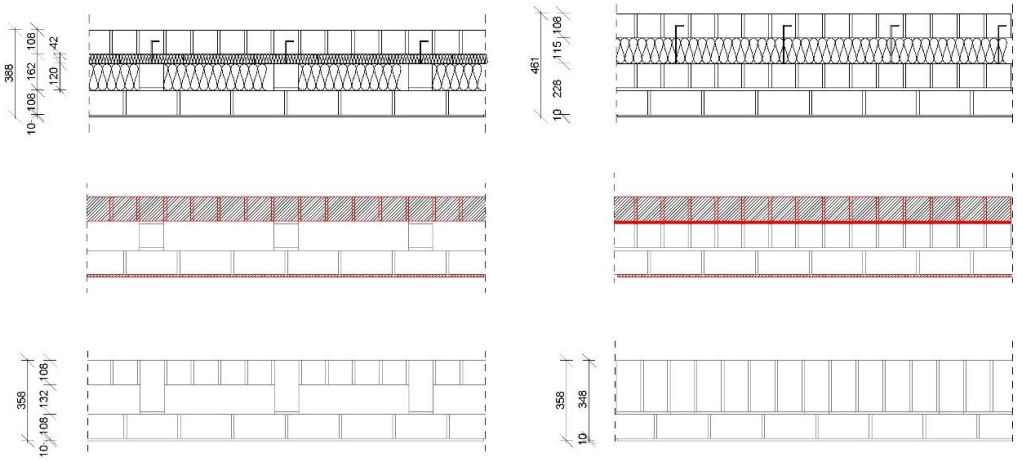

Figure 4. The process for demolishing the outer wall, insulating it, and building it up again connecting it with the inner wall using steel ties. Where there were no cavities, the students found the amount of insulation inadequate. They proposed the outer wall to be moved 30 mm. This however required further action and alterations to the foundation to be taken.

Third semester project, fall 2022: tectonics in industrialized timber structures

During the third semester, that addressed the theme *from relative to absolute sustainability*, the students were free to choose the topic of their project if it broadly related to sustainability in the building industry. One group focused on the opportunities and challenges of loadbearing timber structures between 5-8 storeys, for urban areas in Denmark. Their aim was to address local fire and acoustic regulations, deforestation tendencies globally, and carbon emissions from the building industry. In addition, the project investigated the potential for implementing re-used timber and enabling building transformations. The 5-8 storeys building height was chosen because of two main considerations:

(1) Based on studies investigating resource efficiency in different building typologies – including a 2-storey single-family house, 4 and 6-storey apartment buildings and 20 and 40-storey high-rise buildings - and various urban densities, it was identified as trend that there was higher resource efficiency in urban areas with higher density. The study identified the 4 and 6-storey apartment buildings with the lowest use of resources within the different building typologies that were studies. This was due to, among other things, a relatively low weight pr. m^2, and the greater number of people using common access ways [10].

(2) The second reason was relating to the Danish fire regulations. In Denmark, concerning fire, there are various prescriptive solutions for designing different building typologies. Here, there are two essential aspects: the calculated time for fire resistance, and the size of exposed area of wooden surfaces. Therefore, one aim for the project was to reduce the complexity of the building, by limiting the total area of exposed wooden surfaces to a maximum of 20 % of the indoor surface areas (excl. flooring). This, according to the prescriptive-accepted solutions, should not exceed 22 meters to the top floor which is the limit for the fire departments ladders in Denmark, and also, to limiting fire sections up to a maximum of 600 m^2 [11].The students choose to create an 8-storey case, consisting of a loadbearing glulam beam- and column structure considering the building's overall longevity [12]. The loadbearing parts in open plan structures, such as beam-column and beam-slab systems, don't partition the spaces, increasing the adaptability and building transformation potential.

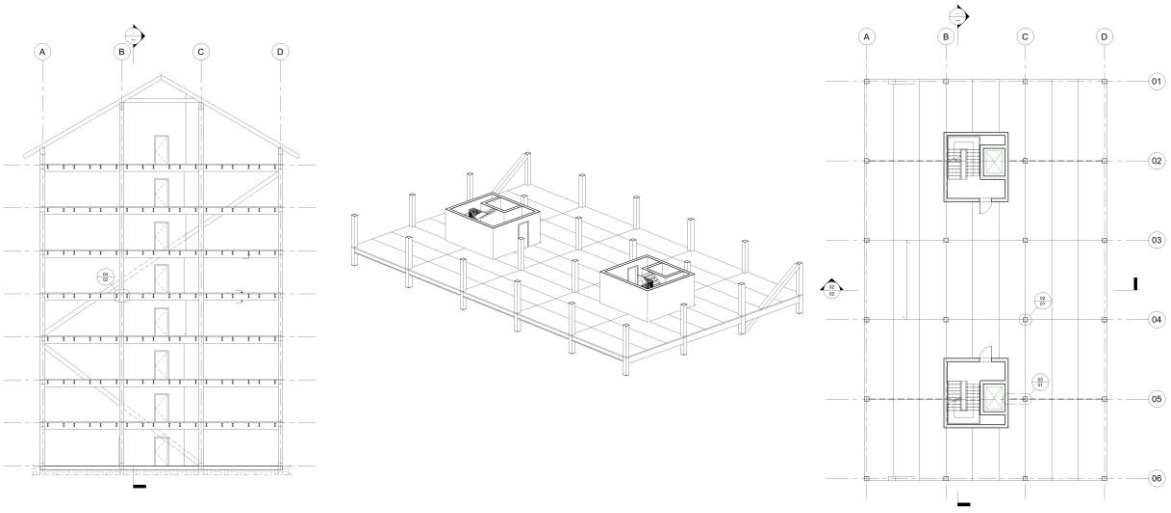

Figure 5. The students generated case. An 8-storey generic timber structure, consisting of glulam beams and columns with rib elements as slabs. The forces are transferred through the slab-elements and into loadbearing CLT-element cores. Bracing is achieved through diagonal members in the gables.

A proposal to substitute conventionally used CLT-slabs with glue less re-used timber components were introduced. For this there were several reasons. One was the environmental aspect where, regarding energy use from the production of timber products, the significantly higher consumption comes from the drying of green wood, and after that the adhesives used in e.g., glulam, plywood, and LVL [13]. Here, a large part of the total volume of materials used is related to the slabs, in the loadbearing structure. An overall wish for the case, was to articulate the loadbearing structure, keeping the beams and columns exposed, and with the assumption of difficulty in documenting re-used timber components properties concerning fire, the re-used timber could be protected by clay- or plasterboards. Here, it made sense to use re-used wood as slabs, because the ceilings would need to be covered anyway due to the 20% fire-related rule (Figure 4). The slabs used in this project case were inspired by already ongoing research projects with loadbearing, glue less, and waste wood components. The up-cycled floor-slabs consisted of structural waste wood beams, developed by PhD-student Xan Browne and the first author, which is inspired by a long-span beam system developed by Swedish Engineer Hilding Brosenius. Here, short members of reclaimed wood are put together in such a way that load is shared and transferred by each wood member. The beam members are screwed together without glue, making it suitable for disassembly and therefore each wooden peace reversable, thus reusable for further applications [14].The floor deck is a short-span re-used timber deck developed by the students themselves and inspired by a massive wood board element without glue, more suitable for longer spans, developed by Hüseyin Emre Ilgin and Markku Karjalainen [15].

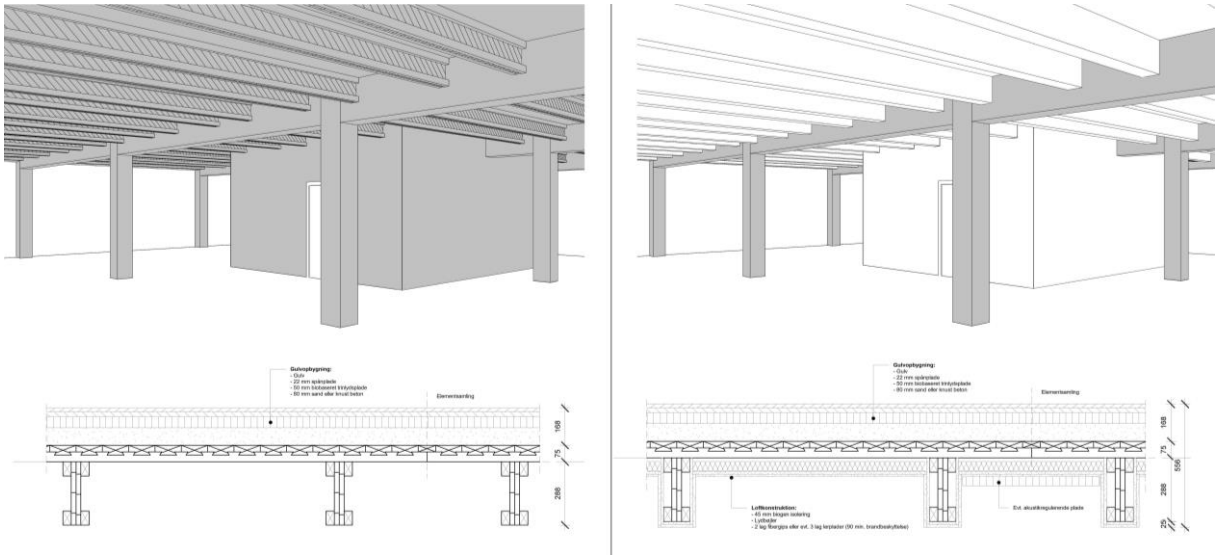

Figure 6. Top left: grey surfaces indicate exposed wooden surfaces in the case. Bottom left: section view of re-used slab-elements, with floor construction on top to reduce noise through different floor layers. A high-density aggregate was needed to reduce low transmission noise. Top right: a proposal that limiting the area of exposed wooden surfaces, by covering walls and ceilings with fire protecting clay- or plasterboards. This proposal left the glulam beams and columns exposed, articulating the loadbearing structure, while protecting the waste wood components from fire according to current Danish fire regulations.

4. AT within the Nordic, European and global educational environments

When one creates something new- it is never completely new as it has a context that it has grown out of. In creating AT it has always been a question of how this education compares with other educations within the Nordic, European and the global landscape. For us it is important what we can offer to other educational environments, but also, what can we learn from others. In that sense AT is fully new within

the Nordic context, that as described is very specific with the large knowledge/skills distance between the technical and artistic aspects within the building design professions. The evaluations of how we address the needs of the Nordic building design will show in time how we need to develop further and adjust the curriculum.

Within Europe and internationally the context is different. Even though this is true, we strongly believe that there are many good lessons to be learnt from other educations within Europe and more broadly. This is indeed our aim for the years to come to map the landscape of educations that we can compare with and offer and gain from each other's experiences that can inspire further developments for us and others, too.

5. Conclusion: submission of contributions

The paper presented the aims, vision, and program development of the new two- year master's education "Architectural Technology" at the Royal Danish Academy in Copenhagen. By outlining the module structure and module contents as well as describing some of the design projects, it is hoped that the reader will get a flavour of what the education offers. It is for the first time that we will have graduates finishing the program and graduating in the end of June 2023. It is a question time and following the graduates to see if they become the ones who integrate the building sector, support architectural quality and sustainable approaches. The fantastic project results we have seen so far give us faith that the coming up AT graduates are the ones who will challenge the normative and work further with the visionary, helping us build better and with more sustainable approaches in mind. We are looking forward to learning from other similar and different educations internationally.

Acknowledgements

Many have a great contribution in establishing and developing the Architectural Technology new education. The AT program would have not been possible without Natalie Mossin, architect and Institute leader at IBT, The Royal Danish Academy, Kirsten Nielsen chair and Jette Leth Djælund deputy chair of the Danish professional association of Architectural Technologists, Peter Hinsby – philosopher and PhD candidate at The Royal Danish Academy, Frans Drewniak, Architect and Associate Professor at The Royal Danish Academy, to name just a few. A huge thank you goes to the AT teaching team as well as the AT master's students for the great engagement, trust and input.

Abstract

This paper presents a theoretical framework and pedagogical principles for performance-based design education focusing on acoustics and structural behaviour within the architectural context of the Melbourne School of Design of The University of Melbourne. Our architecture students have limited exposure to acoustics and structures, and both can be mistakenly perceived as engineering disciplines confined to specialists, taking place after a design idea is formalised. A design studio, *CDE Studio 45* [1], developed and taught by the authors for the past three years within the Master of Architecture Course of the Melbourne School of Design, is showcased in this paper to illustrate how structural behaviour, acoustics and music can drive design education and engage students intellectually and creatively, shifting between analytic, synthetic, and evaluative modes of design thinking (performance-based, model-making, computational design). Physical models of shell-like structures are developed and recursively tested through critical listening exercises and analogue acoustic simulations to visualise sound propagation (Figure 1). Proposals undergo acoustic analysis and optimisation via geometric acoustics methods and Multi-Objective Genetic Algorithms (MOGA) to evaluate and improve the final design's acoustic performance, allowing students to verify their design processes. Students' final designs demonstrate a capacity for critical design thinking driven by landscape, acoustics, structural and material systems, and detail considerations.

Keywords: Design studio pedagogy, shells, acoustics, structural behaviours, communication, design education, design research, research methods.

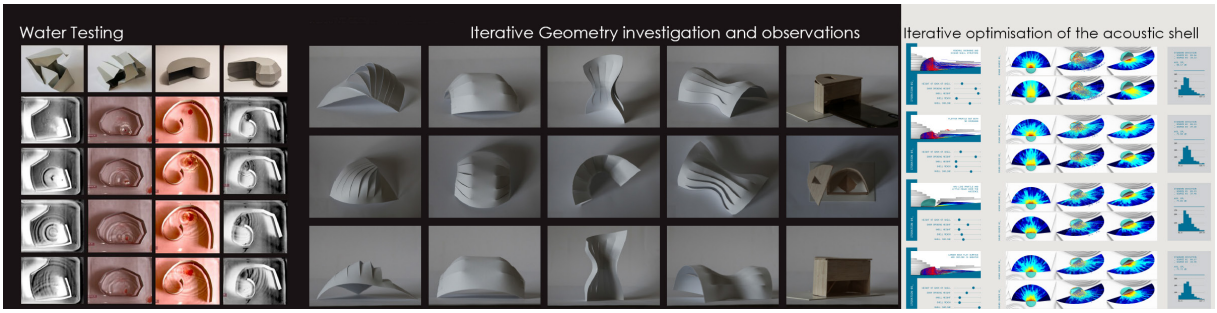

Figure 1. Amplify Your Phone exercise by Jeremy Bonwick. The physical models and listening tests informed the creation of digital models, run through a ray tracing simulation program to acoustically optimise the shells' final shape (reproduced by permission).

1. Context and background

The University of Melbourne adopted the *Melbourne Model* in 2008 to replace its 96 undergraduate courses; it involves seven undergraduate degrees supporting depth and breadth of knowledge. One of

Copyright © 2023 by Sofia COLABELLA and Michael MACK. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

the main aims is to develop a student's broad understanding across a range of disciplines. Introducing flexibility meant, specifically for a faculty of architecture, focusing on a wide range of disciplines instead of providing students with a strong technical background. On this aspect, teaching structures and acoustics within an architectural/design context poses a range of challenges in fine-tuning the way the technical content is conveyed in an appealing and meaningful manner. As Popovic described in 2015, "an engineer will spend a large proportion of their time studying how to minimise and optimise structural sections to achieve material economy through structural efficiency; these aspects of the structural concept design, for an architect, although relevant, may be secondary to other "more relevant" design aspects" [7].

This difference in values and approaches becomes even more delicate and complex when teaching acoustics, as vision dominates our relationship with architecture, both as users and designers. As prompted by Juhani Pallasmaa, in "Western culture, sight has historically been regarded as the noblest of the senses and thinking itself thought of in terms of seeing". According to the Finnish architect, that has long been entrenched in our culture as he quotes, "the eyes are more exact witnesses than the ears" [5]. The process of design and how we represent architecture through renders, diagrams, and drawings are all inherently visual exercises.

In response to this ocular-centric approach, we developed and taught a design studio (*CDE Studio 45*) within the *CDE Design Studios* coordinated by Professor Donald Bates in the Master of Architecture Course at the Melbourne School of Design for the past three years, based on the concept that structural behaviour and acoustics can drive design education and engage students intellectually from the early stages of design concepts. We aimed to expose our students to acoustics and structures not as engineering disciplines confined to specialists taking place after a design idea is formalised, but as creative tools to generate ideas at the inception of the design process. We purposely flipped the creative process to scaffold students' critical reflections and design thinking through tectonics, material, and performative investigations while enquiring "how to make the technical teaching content relevant, interesting and applicable" [10] [11].

Introducing students to acoustics seemed an obvious choice also because, despite the acoustic quality of buildings being vital to well-being, room acoustics are often the forgotten variable [5] of architectural design, resulting in an individualistic (and late) effort of acoustic engineers to correct or improve the acoustics of spaces. As recording and microphone technology, the arts of music, drama and public discourse have influenced and been influenced by the acoustics and architecture of their presentation environments [7] [1], we introduced basic concepts of music education to remove the instinctive relegation of acoustics to a pure engineering discipline.

2. Music and acoustics in architectural design education

CDE Studio 45 [1], is based on a recursive approach to design thinking through structural behaviour and acoustics as creative tools enabling design education and engaging students intellectually and shifting between analytic, synthetic, and evaluative modes of design thinking (performance-based, model-making, computational design). This design studio was conceived to expose students to a holistic understanding of architectural form, acoustics, and structural design, while considering the behaviour of materials to make informed design decisions that consider the technical and functional requirements of a building, along with its aesthetic qualities. Exposing students to engineering principles (both structures and acoustics) allows them to face opportunities, limitations, and implications of their design decisions; having this set of skills is meant to prepare them to collaborate with specialists and be more effective and well-rounded professionals in their field.

Despite the challenges of integrating technical aspects into the architectural design context, teaching structures in a design studio has long been trialled worldwide [10]. While we can learn from this integration, teaching architectural acoustics in a design studio has additional complications: (1) sound is invisible, and soundscape can change at any moment [12]; (2) how we experience and perceive sound

is a subjective process, and how, as architects, we design through it is still based on the intuitive approach and the trial-and-error experience on which knowledge about acoustic design is currently based [2]; (3) though computer simulations enabling the rapid testing of what-if scenarios alongside acoustic analysis and visualisation have been developed and made broadly available, there is a level of abstraction and understanding to overcome.

CDE Studio 45 is structured around these aspects, the outcomes of which are discussed and shown in section 4. A key element of the studio pedagogy is the intention to teach students to approach and understand sound and structural behaviour intuitively through the exercise *Amplify Your Phone* presented in section 3.

Introducing basic principles of music to design studio education acts to remove the distinction of acoustics as a purely engineering discipline. Alongside instruction in the physics of sound, acoustic, and lighting design, students receive a lecture on music performance and instrumentation, which ties acoustic principles and measures to aural effects. Some examples of this include acoustic measurements of reverberation time and initial time delay gap, which are chained to principles of clarity and articulation, and diffusion spacing in panels linked to harmonic and overtone frequencies.

Instruction on the relationship between music listening and acoustic outputs introduces students to the vocabulary needed to assess acoustic outcomes, providing them with the necessary skills to communicate with acoustic consultants and musicians. Through practical demonstration, key difficulties in designing performance venues can be more easily demonstrated. The level of subjectivity resulting from listening and observing music is also encouraged and discussed, softening the learning curve into approaching acoustics. This is a critical educative point, as students are demonstrated the importance of balancing visual intent with the acoustic outcome. Combined with prototyping and model-making, these initial observations become an essential method of design validation (Figure 1).

Prompted by David Byrne's exploration of the history of how context has led musical innovation [3], we have developed an all-rounded set of tools and workflow to allow students to shift between analytic, synthetic, and evaluative modes of design thinking through (1) model-making and grammar of sound; (2) digital models and performance-based design; (3) optimisation through MOGA and reflections on the final outcomes; (4) detailing of the main stage, both structurally and acoustically; final review of the festival program and design outcomes.

3. Theoretical framework and pedagogical principles

During the first three weeks of the semester, students investigate the basic concepts of acoustic and lighting design to explore the relationship between form and acoustic performance through physical models of acoustic shells. Students familiarise themselves with the reciprocal determinations between architectural forms and acoustic performance through the design group exercise, *Amplify Your Phone (AYP)*, to become aware of the geometric relationship between architectural form and acoustic performance. The AYP recursive exercise is based on a sequence of tasks: **listening** (A); **making physical models** (B); **evaluating acoustic qualities** (C); **making digital models through parametrisation** (D); **comparing the winning solutions and reflecting on the design thinking process** (E).

During this initial phase, each group of students is required to select three songs, varying in genre, instrumentation, and textures; students listening awareness is tested through their capacity to skilfully describe their listening experience using specialist terminology, the existence of which is unknown for the majority of them (A). Simultaneously, students are tasked with iteratively **making physical models** (B) to find a persuasive design and optimal acoustic shell geometry to amplify their phones. Listening to the chosen three songs with and without the acoustic shells allows them to test the amplification of their smartphones while refining their listening awareness. Figure 2 shows Alba's reflections on four iterative scale models based on the use of three different material systems and four shape variations.

Students usually focus on clarity and amount of amplification because detecting other parameters, such as reverberation, would be almost impossible at such a small scale. By using different materials, students learn to identify the unique qualities of each material and how they affect the overall performance of a given shape.

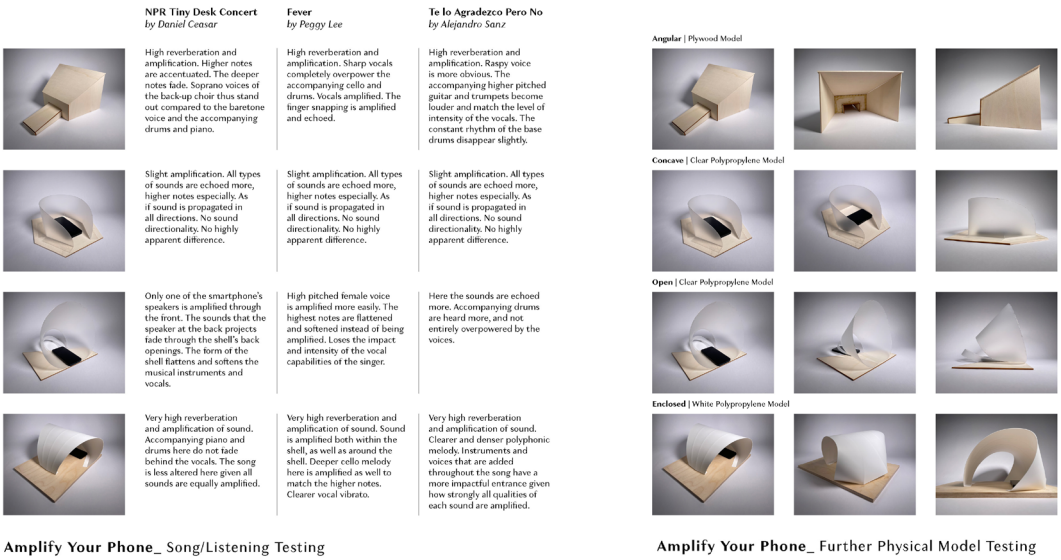

Figure 2. AYP, scale model studies and listening tests by Alba Moncau Munio and Michael Ming Park (reproduced by permission).

Alongside the listening exercises, students are introduced to **analogue evaluation techniques** (C) involving light and water, which simulate the ray and wave effects of sound. These tests consolidate students' understanding of sound interactions with geometry through visualisation. Students insert lights or a laser pointer into a reflective card or aluminium model for the lighting tests (based on those done by Alvar Aalto for the Municipal Library of Viipuri). To perform the water tests (based on the experiments by Jørn Utzon for the *Bagsværd Church*), students develop the shell profiles in sections out of aluminium or plexiglass and place them in a small pool of water. Coloured droplets generate waves, and a video is recorded in slow motion. Frames at consistent time periods can be extracted to compare the effects of different sections and annotate their observations. As shown in Figure 3, students fine-tune the shell profiles by adjusting them consistently as they repeat the tests.

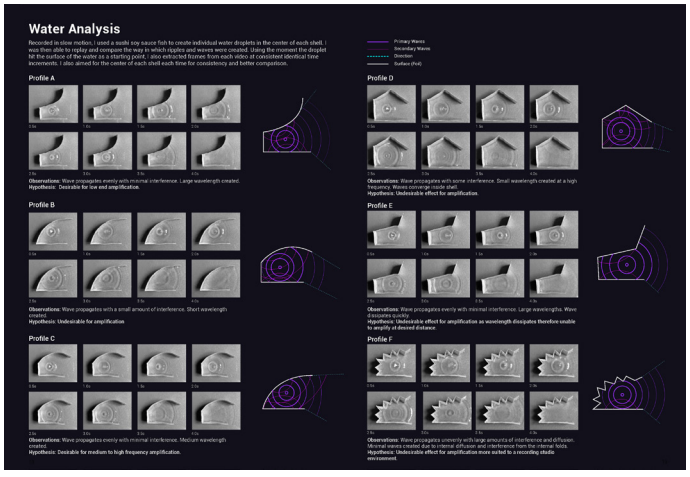

Figure 3. Observing sound through the water and light tests by Isabel Solin (reproduced by permission).

From these initial prototypes, students select and transform the best-performing shells, based on their observations, into a set of **digital models** by expressing their winning solutions as a function of specific quantities or parameters; they also select one or more invariances as the guiding principle of their design. Both invariances and parameters are essential to determine the next set of tests (D) through two acoustic simulators, *Pachyderm* 2020 and *Aeolus* 2021 and 2022, to compute the sound reflection paths and associated sound pressure levels (SPLs) at one or multiple target locations [8].

The final stage of this first assessment task is **comparing** the acoustic analyses and observations gathered from the physical models listening and testing phase for verification and validation (E). By comparing the two data sets, students can identify any discrepancies or inconsistencies between the objective and subjective observations. This analysis can also help students understand the relationship between the measurable qualities of acoustics and the subjective experiences of sound while developing a more nuanced understanding of the complexity of acoustics and how the human ear perceives it.

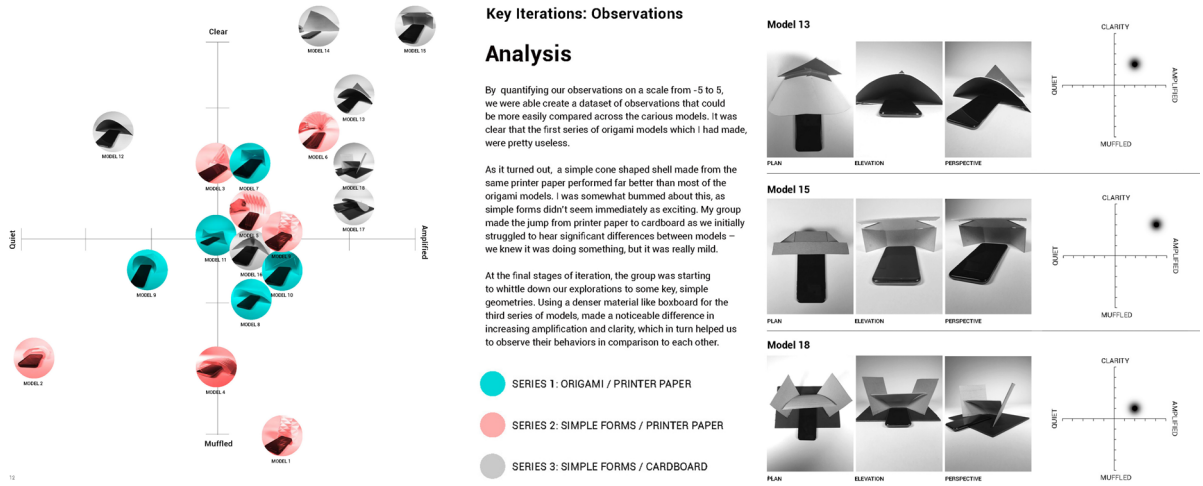

Figure 4. Dataset of listening observations by Isabel Solin, Michael Gentile, and Alessandro Antoci (reproduced by permission).

After the first three weeks, students apply their new knowledge to the given brief related to the requalification of an abandoned quarry in regional Victoria (AU) through the activation of a Music and Art Precinct comprising different programs. Performing Art Centres can contribute to community development in many ways, and students are also tasked with the redevelopment from a social and environmental standpoint. The design brief comprises 50% of the site to be revegetated for environmental sustainability and 50% for temporary activities for a range of community events linked with the Art Precinct and the Music Festival programs.

By the end of week 12, students will demonstrate to be able to: [1] develop the brief and the planning of a live art performance and events venue for a Music Festival; [2] simulate acoustic performance and lighting phenomena; [3] define and improve the acoustic and lighting qualities of their architectures; [4] communicate design ideas and propositions through a variety of media; [5] present their work verbally to an external panel of architects and engineers; [6] design a live-performing venue at different scales (1:1000 to 1:5). Overall, students will have learnt to use computational tools for acoustic analysis (the graphical algorithm editor *Grasshopper*® within *Rhinoceros*®) to evaluate and improve the acoustic performance of their design. The geometric acoustic analysis consolidates students' acquisition of how each variable impacts the shell performance, which in turn will generate a review and further refinement of their design, which includes all the BoH (Back-of-House) and FoH (Front-of-House) facilities of a performance venue (e.g. foyer, box office, food and toilet services, backstage facilities, car parking, etc.), and the ticket and audience area, which are discussed as a consequence of the effective audience

sight-lines to the stage and predicted acoustic qualities. The final challenge is balancing the architectural intent and aesthetics with the optimisation and performance of the acoustic shell. While the aesthetic aspects of a performance space are crucial for a visually appealing and immersive experience, its acoustic properties will massively impact its fruition and success. To strike this balance, students must consider the performance space's form and function, acknowledging that even if it is a common belief that acoustics can always be adjusted later, the best performance venues are the ones that prioritise acoustics at the early stages of the design process.

4. Acoustic design framework: in practice (CDE Studio 45)

The *CDE Studio 45* pedagogical framework is designed to encourage students to explore the multifaceted correlations between music, acoustics, structural design, and architectural design through 12-week activities. For the scope of this paper, we primarily focus on the outcomes of the first three-week exercise, *Amplify Your Phone*, based on the five tasks (A-E) explained in section 3 and how this exercise informed the translation into an architectural proposal. Over the last three iterations of this design studio activities, students have demonstrated and developed an affinity for specific aspects of the exercise, favouring parts of the acoustic testing methods over others, mostly based on their specific interests or passions and previous knowledge. Each student highlights different approaches to acoustic design thinking developed through the teaching framework.

Incorporating maker pedagogy into design studio education is a well-known tool to empower students to experiment, explore, and express themselves while developing critical thinking and problem-solving abilities [5]. In *CDE Studio 45*, the consequences of making and material choices are explored through the listening exercise in a recursive loop: students reproduce the same shell geometry with different materials to develop a more nuanced understanding of the properties (and possible uses) of acoustic materials. Given the small scale of the prototypes, echoes, reverberation, resonance, and reflection cannot be observed. Still, students generally get an initial understanding of the different capacities to absorb or reflect sound and noise due to the high and low density of materials. The exercise AYP doesn't provide a rigorous listening method for assessing acoustic performance, given the scale issues and external considerations such as surrounding objects and their materials. However, even with these constraints, prototypes still show noticeable differences. Repeating the listening exercise under the same conditions allows students to detect and identify the differences through aural observation.

The way students approach the given architectural design brief is illustrated below through a set of selected works produced by students within *CDE Studio 45.*

The first example (Figure 1) shows an initial workflow based on the rapid prototyping of structural forms. Hann Lynn Chan focused on broadly experimenting with a variety of structural configurations via a range of folded geometry. Qualitative analysis via listening and lighting tests was used to perform an initial survey to provide immediate feedback on the design iteration process. Trends between positive listening tests and lighting conditions were established through this prototyping process and used for further design iterations and narrowing of the design space. Eventually, a preliminary set of parameters for the shell's overall dimensions and form was developed.

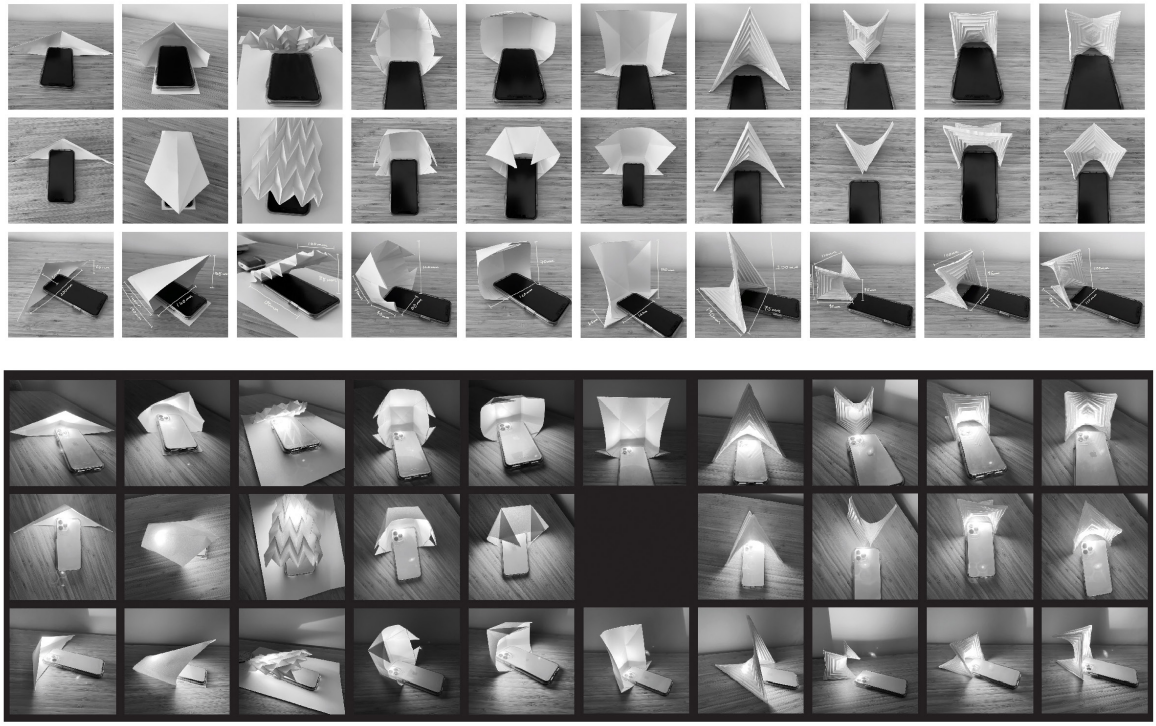

Figure 5. AYP, scale model prototyping and lighting testing by Hann Lynn Chan (reproduced by permission).

The best-performing examples based on Hann Lynn's qualitative evaluations are then converted to parametric models for acoustic analysis and optimisation, shown in Figure 6. This workflow proved useful for students less proficient with digital skills and parametric design tools: focusing on the model-making process provides them with a shortcut to iterate and optimise their designs through analogue methods before moving into the multi-objective optimisation process.

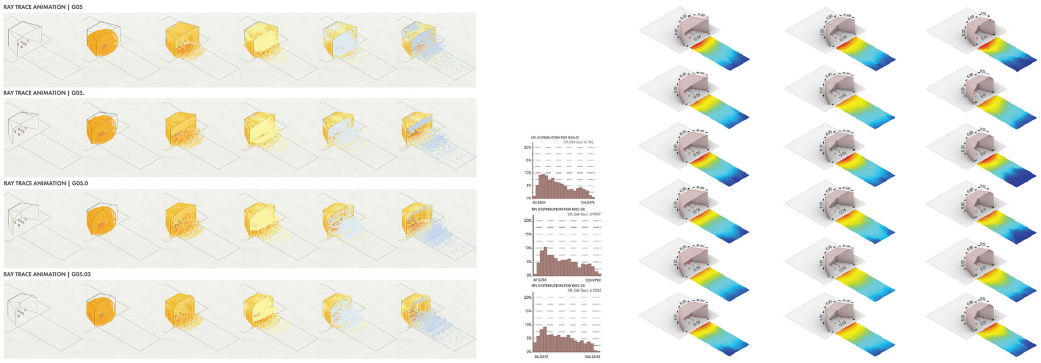

Figure 6. AYP, multi-objective optimisation of shortlisted designs by Hann Lynn Chan (reproduced by permission).

Figure 1 (page 1) shows Jeremy Bonwick's approach to the task, initially focused on the qualities of abstract architectural and sculptural forms: a wide variety of initial prototypes were tested and qualitatively ranked based on the initial impressions of their acoustic performance. Parallel to this, favourable samples were modelled in section using aluminium, placed in a shallow tub of water, and dropped with red food dye to visualise the wave propagation in each form (Figure 1, left). The flexibility of the aluminium models meant that several sections could be easily tested through adjustments in the model and repeating the test.

The outcomes of these analogue water tests from the AYP exercise informed Jeremy's approach to the architectural form in the following stage of the design process. He recognised that after scaling up the geometry to an architectural scale, the opening of the model's section where the projection of the waves occurred had to be developed geometrically and architecturally. By revolving the section around an axis, Jeremy could incorporate structural considerations into the shell-like structure. This process led to the development of the parametric model and optimisation process for the final acoustic shell structure shown in Figure 7.

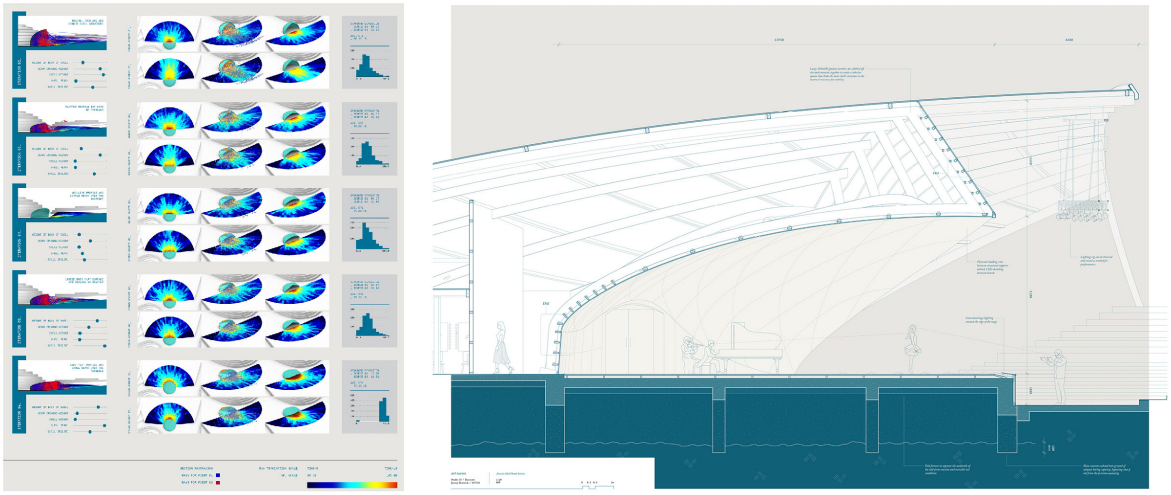

Figure 7. Translation of sectional model testing into an architectural proposal for an acoustic shell by Jeremy Bonwick (reproduced by permission).

Figure 8 shows a workflow largely based on material exploration: Alba and Michael's prototypes were constructed from cardboard, polypropylene, plywood, solid timber, and 3D-printed clay to explore the material impact on acoustic quality. Though the students acknowledged the materials were not necessarily translating full-scale acoustic properties, they observed a noticeable difference between the prototypes demonstrating their understanding of the relationship between material density and observed musical outcome.

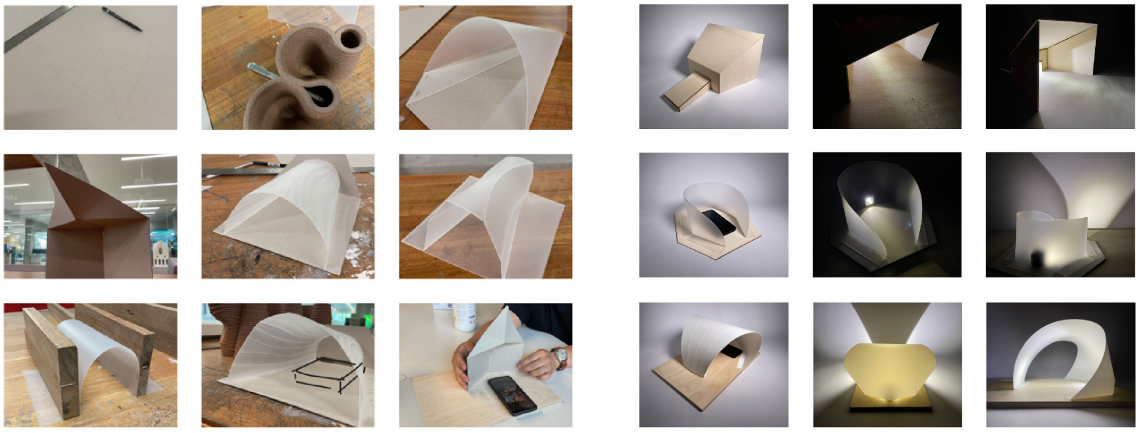

Figure 8. AYP material exploration and prototyping by Alba Moncau Munio and Michael Ming Park (reproduced by permission).

Michael and Alba selected the prototype to develop further based on the potentially novel architectural conditions of a laterally open audience area. The selected design shown in Figure 9 included strong rear reflections but necessitated an acoustic reflection strategy that improved the lateral distribution of sound.

The students recognised they could utilise the folding strategy developed in the AYP prototyping to accomplish and establish a discretisation approach that included both the acoustic and structural considerations for the ribs.

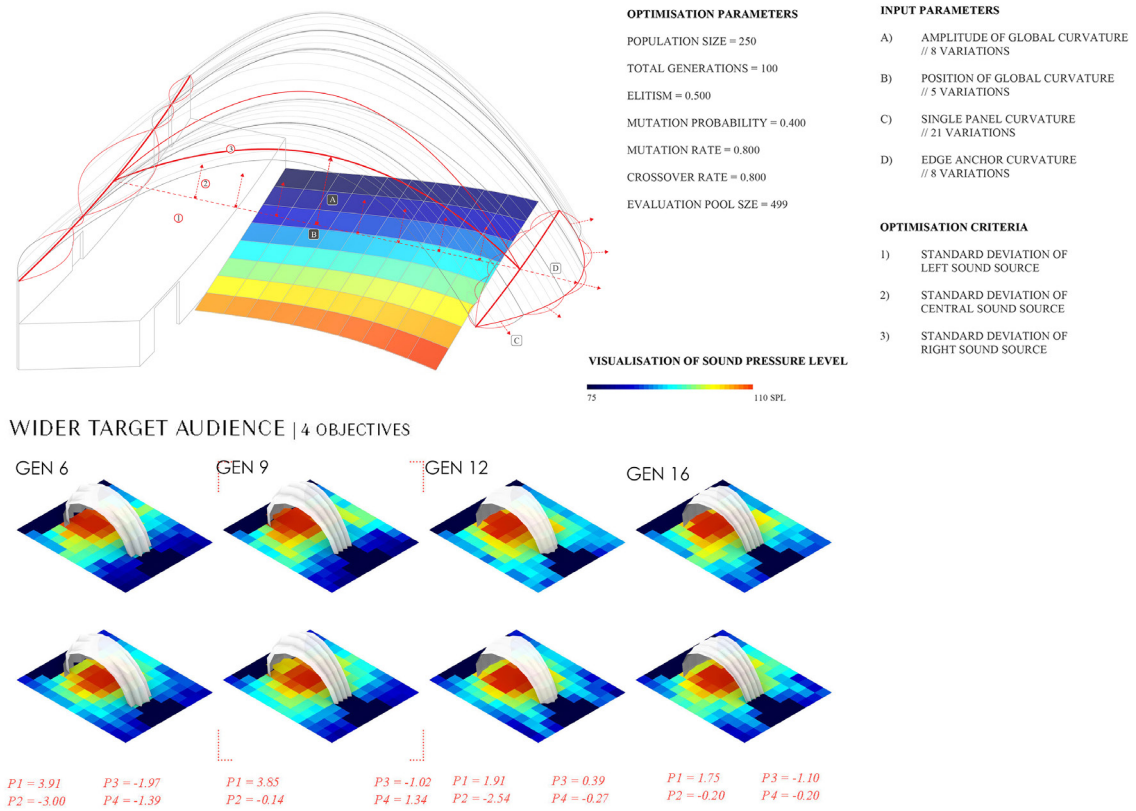

Figure 9. AYP material exploration and prototyping by Alba Moncau Munio and Michael Ming Park (reproduced by permission).

Unlike previous examples that developed the project formally or through the verification process, Vincent Heru's work (Figure 10) illustrates the development of an architectural proposal through an interest in acoustic principles. In his AYP exercise, Vincent prototyped a few panelised and folded geometries to attempt to observe the acoustic scattering effects. Unfortunately, this was largely unsuccessful as these effects could not be analysed at the scale at which the tests were being formed. Nonetheless, Vincent utilised learned principles of geometric acoustics to demonstrate a fundamental understanding of the acoustic ray tracing method through photos and sketches.

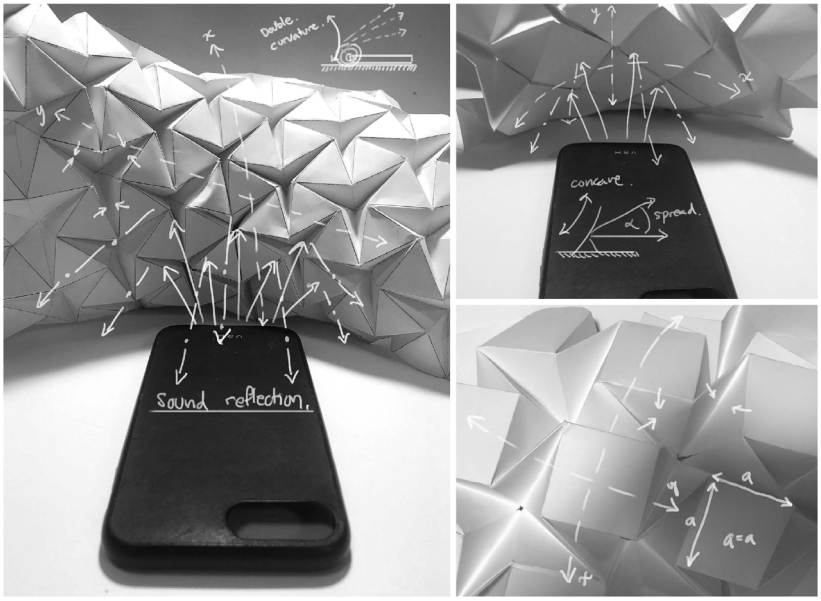

Figure 10. Preliminary sketches of ray tracing analysis of folded structures by Vincent Heru (reproduced by permission).

The models relied largely on three-dimensional representations and flexible materials for the scale of construction, making other analogue tests difficult to perform. However, an abstracted sectional model and water testing validated Vincent's understanding of the scattering effects (Figure 11). The analysis and diagramming of these tests further illustrate the development and consolidation of the relationship between acoustic principles and form.

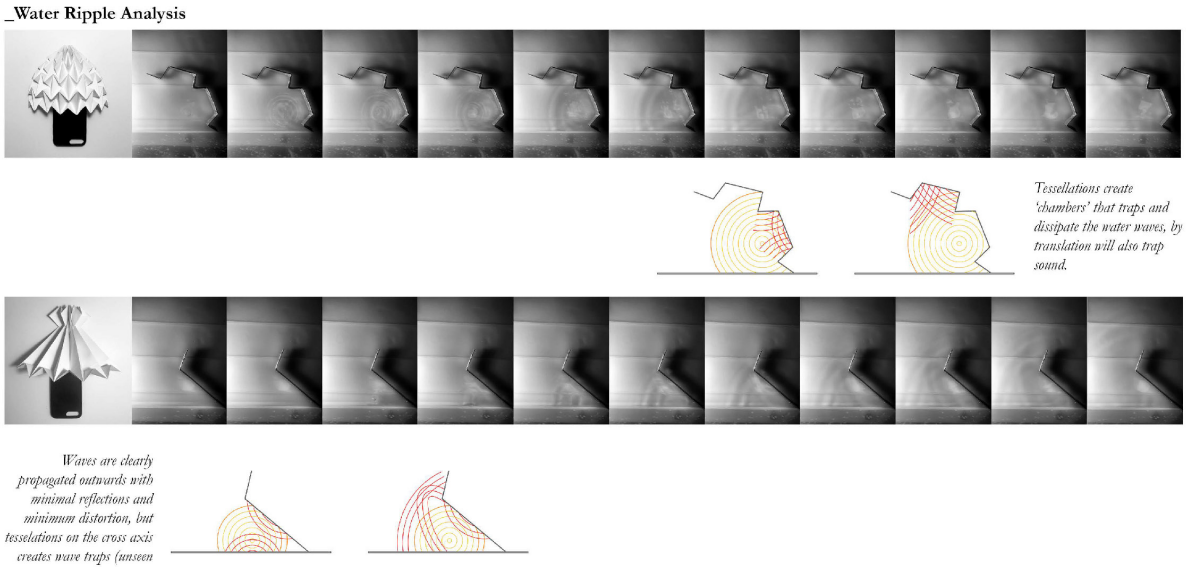

Figure 11. Water testing of diffusion and scattering-like effects by Vincent Heru (reproduced by permission).

For his architectural proposal, Vincent took the opportunity to explore scattering effects as a conceptual driver. Using a digital model for analysis and verification, Vincent developed a single reflector device suspended over the performance area, which distributed sound to the surrounding audience areas (Figure 12). Using precedents of vineyard-style concert halls, he recognised that acoustic performance could

also be compensated for by the lateral reflections of the side walls and back of the shells, resulting in the outdoor yet intimate performance setting.

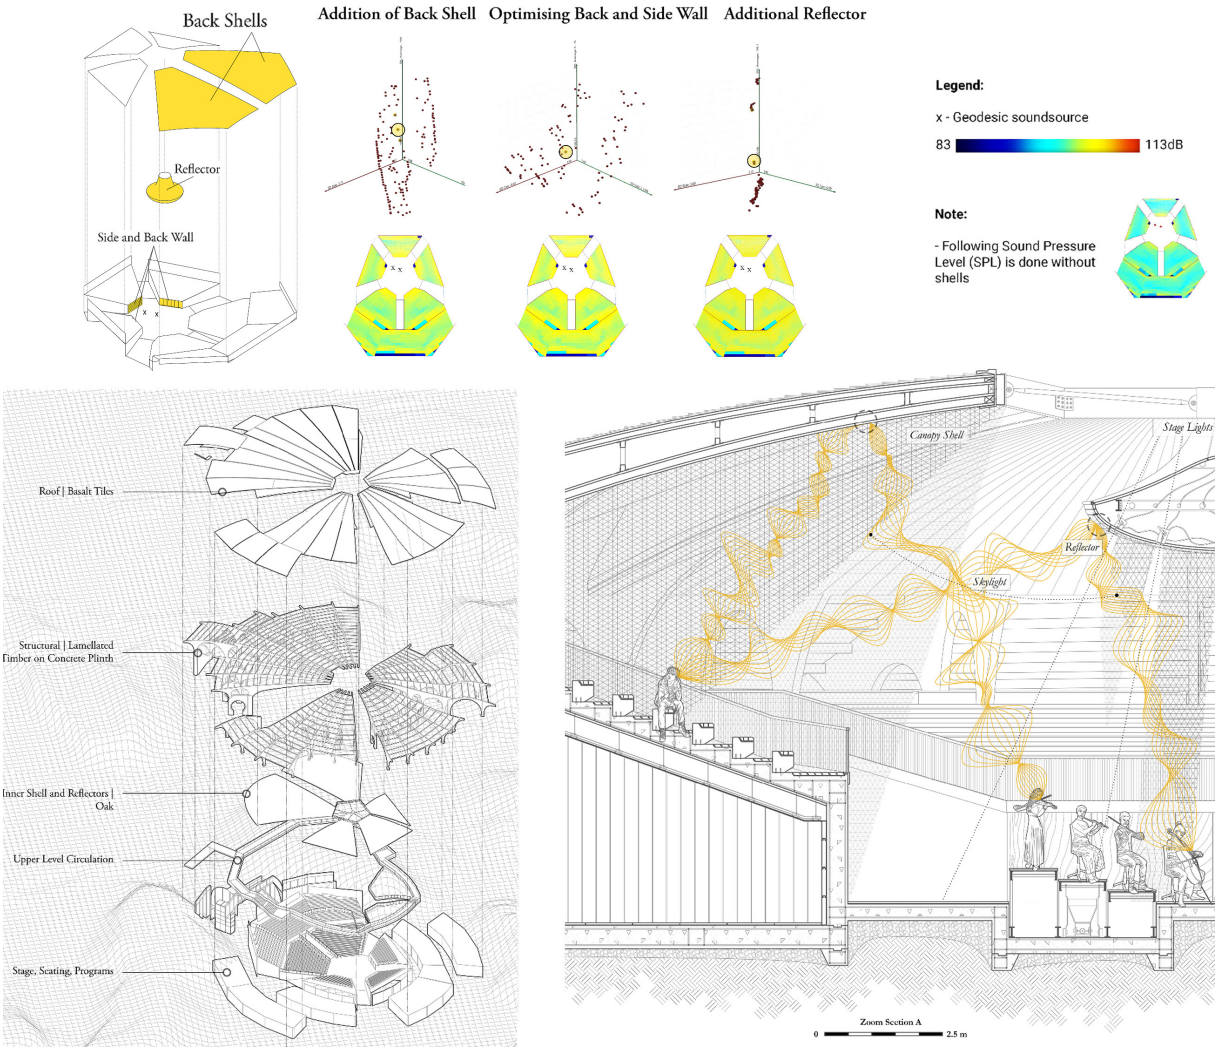

Figure 12. Architectural proposal of vineyard-style outdoor performance venue by Vincent Heru (reproduced by permission).

5. Conclusions

CDE Studio 45 presents a novel framework for teaching acoustic and structural design within Architectural discourse and embraces a radical removal of the boundaries between architecture and perforative, technical disciplines; it shows that a qualitative (and initially intuitive) approach to tectonics and acoustics can enable a creative approach to design and sustainable thinking. The examples in section 4 show how the pedagogical framework can successfully introduce students to acoustic design principles while remaining flexible enough to independently explore performance-based design solutions crafted around their individual interests and design propositions. As illustrated, students interested in structural techniques such as folding, or material exploration, can find accessible ways of developing acoustic design within their architectural education.

Though the early student explorations were largely within the scope of the AYP exercises, there is space for future research into how students utilise the ideas and develop them into the approach for their architectural proposals. Furthermore, the examples are taken from a Master of Architecture Course, with

students in their 4th and 5th year of architectural education. If applied earlier in the architectural curriculum, there may be an opportunity to understand how the framework may foster opportunities for acoustic design considerations and performance-oriented approaches, also at the undergraduate level.

Architectural education can easily provide opportunities for architecture students to learn about the relationship between performance-based design and aesthetics while providing a comprehensive education that includes both technical and creative aspects of building design, leading to a holistic understanding of the opportunities and limitations of their design decisions. Architecture students would then be able to graduate with the skills and knowledge needed to work collaboratively with engineers and develop more innovative and sustainable building designs.

Acknowledgements

We acknowledge the exceptional support of Professor Donald Bates, Chair in Architectural Design at the Faculty of Architecture, Building and Planning of The University of Melbourne, and master's studio coordinator at the same institution. We also acknowledge Peter Fearnside, former CEO and founder of Marshall Day Acoustics Australia, for the enthusiastic encouragement, patient guidance and useful critiques throughout the delivery of our teaching activities. His passion, knowledge and attention to detail inspired our students and us. We were lucky to have Gabriele Mirra as a technical tutor for our design studio because, on top of his technical knowledge, he allowed our students and us to use his work-in-progress version of *Aeolus*, a *Grasshopper* acoustic modelling plugin to analyse and optimise acoustic shells that was later made publicly available in March 2023.

Abstract

It is difficult for those new to structural mechanics to imagine a cross-sectional force diagram. For this reason, we have created structural educational tools aimed at deepening the understanding of structural mechanics for students studying structure. It is capable of vibrating a small model and visualizing the cross-sectional forces of the structure. To calculate the cross-sectional forces from the deformation of the structure, ArUco markers in OpenCV were pasted on the nodes to obtain the deformation. ArUco marker is a marker that can be detected and its coordinates obtained by taking a picture with a webcam. Calculate the cross-sectional force using the amount of rotation obtained from the coordinates of the four corners of the marker. The calculated cross-sectional forces can be viewed in real time by drawing them on the model in the shooting screen. The structures targeted in this study are arched and framed shapes.

Keywords: open CV, python, arch, ArUco marker, educational tools

1. Introduction

In understanding structure, it is very important to be able to visualize mechanical phenomena. Since forces are invisible, the only way is to imagine them. But it is difficult for beginners to imagine the cross-sectional forces that occur within the members when a structure is deformed. We believe that struggling with these basic areas and feel uncomfortable. For this reason, we have created a structural education tool that aims to deepen understanding of structural mechanics by enhancing the ability to visualize cross-sectional forces, and to stimulate their interest in structures. The system consists of two parts: a behavior display system created from Python and OpenCV that can display model behavior and cross-sectional forces in real time, and a model. We can observe changes in the sectional force of a model when it is vibrated. The model is captured by a webcam. And calculates cross-sectional force from the rotation angle of a node and draws a cross-sectional force diagram on the shooting screen. It is not important to see the exact cross-sectional force values, but to be able to see the distribution of cross-sectional forces and the relationship between ones. By using this educational tool to deform your own model and view cross-sectional force diagrams, you will acquire the ability to visualize cross-sectional forces, which we believe will help facilitate your subsequent study of structures. This part describes the creation of a behavior display system, a structural model, and a vibration table. The structures targeted in this study are arched and framed shapes.

2. Outline of behavior display system

2.1 Calculation of cross-sectional forces

Measuring deformations with strain gauges or displacement sensors can provide accurate values, but it is not practical to measure multiple points simultaneously. Therefore, in this study, we will capture deformations from a web cam. However, it is difficult to take a photograph and recognize the shape of

Copyright © 2023 by Ayaka KONDO and Shigehiro MOROOKA. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

the structure from the image data and draw a cross-sectional force diagram from the deformation of the structure, because depends largely on the accuracy of the webcam and takes a lot of time to recognize images of moving objects. It can also lead to misrecognition if the images are very confusing and difficult to judge. Since the deformation between nodes is small, it was decided to recognize the nodes of a structure with large deformations, and to calculate and visualize the sectional forces based on changes in node positions.

ArUco marker was used to recognize nodes (see in Figure 1). ArUco marker is an extension module of OpenCV. It can easily recognize a marker by simply capturing it with a webcam and the coordinate values of its four corners and the id number of the marker can be obtained. By attaching this to a node, it is possible to easily recognize the node and track its movement.

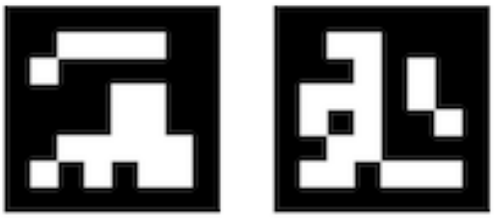

Figure 1. ArUco marker

First, I checked if it is possible to draw a sectional force diagram using Aruco markers. Two ArUco markers are recognized by taking a picture with a web cam.

Calculate the deformation v and the sectional force of a member based on the rotational angles θ_1 and θ_2 obtained from the coordinate values of the four corners of ArUco markers at both ends of the member (see in Figure 2).

$$M(x) = -EIv''(x) \tag{1}$$

$$v(x) = a_0 + a_1 x + a_2 x^2 + a_3 x^3 \tag{2}$$

$$a_0 = 0\ , a_1 = \theta_1 \tag{3}$$

$$a_2 = (-2\theta_1 - \theta_2)/L \tag{4}$$

$$a_3 = (\theta_1 + \theta_2)/L^2 \tag{5}$$

E is the Young's modulus, I is the moment of inertia, and L is the length of the member.

The bending moment M and the shear force Q can be calculated as follows by using the coefficients a_0, a_1, a_2, a_3 obtained from the above equations.

$$M = -(2a_2 + 6a_3 x) \times EI \tag{6}$$

$$Q = -6a_3 \times EI \tag{7}$$

In this case, the initial state is set as the shape recognized by the ArUco marker first, and the rotation amount from that state is used. By overlaying the calculated sectional forces onto the model in the captured image, a real-time sectional force diagram was displayed. (see in Figure 3)。 The performance of the webcam used in this study was 1920 x 1080p pixels at a frame rate of 30 fps.

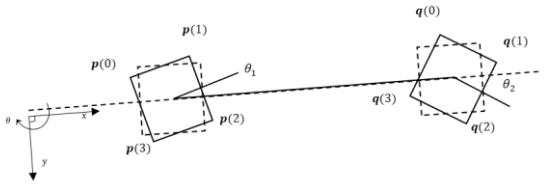

Figure 2. The rotation angle of the node

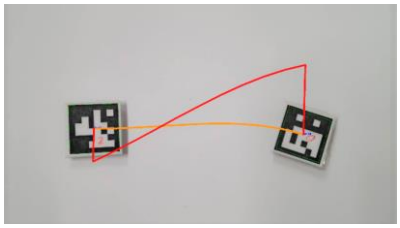

Figure 3. Bending moment calculated from the amount of rotation of the ArUco markers at both ends.

2.2 Arch shape

Create an arch model with ArUco markers and display a cross-sectional force diagram. The arch model was created using cardboard with a length of 450mm and a width of 20mm, a double clip with a width of 13mm, and magnets with a size of Φ5×3mm. A double clip was attached to a cardboard, and an ArUco marker was attached to the double clip with a magnet (see in Figure 4). An arch shape was created by bringing both ends of the cardboard close together and fixing them (see in Figure 5).

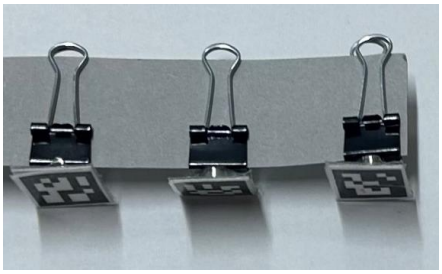

Figure 4. Details of combination

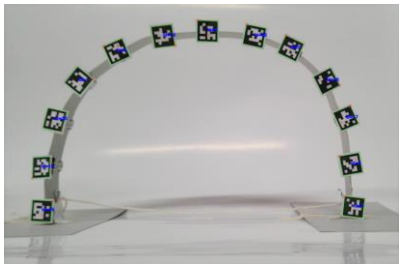

Figure 5. Overall view of arch model

The shape of the model before deformation is read and recognized as the initial state. By hanging a weight at the center of the model and deforming it, it is possible to see the bending moment diagram by calculating the sectional force from the change in the ArUco marker from the initial state.

Figure 6 displays a cross-sectional force diagram of a model divided into 12 parts using ArUco markers.

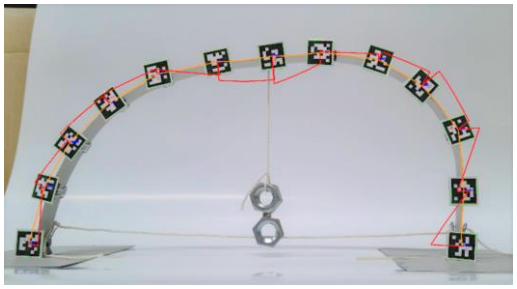

Figure 6. Bending moment of Arch model

2.3 Frame shape

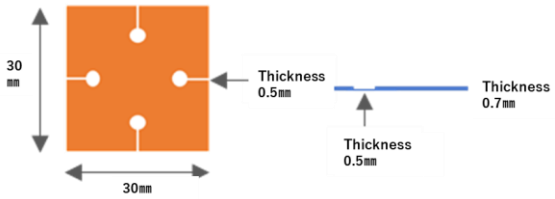
To enable learners to create various shapes freely, model kits with frame shapes are constructed separately with nodes and members, rather than one frame model (see in Figure 7). Nodes require a 30mm square wooden material to attach ArUco markers and to provide enough mass for visible changes

in tremors to be observed by the eye. For members, we searched for materials that are easy to bend and decided to use PVC sheets. The widths of the members are changed so that the changes in the cross-sectional force diagram can be seen due to differences in stiffness. The difference in stiffness is distinguished in the program by changing the color of the member parts. This time, we prepared three types of members: green, blue, and red. The nodes and members were joined by inserting a 0.5mm-thick member into the nodes with a slit of 5mm depth and 0.5mm thickness on the fourth surface. However, problems occurred, such as members not being inserted completely or at an angle. Therefore, we changed the method of joining the nodes and members by partially shaving 0.2mm of a 0.7mm-thick PVC sheet with a CNC machine and inserting it from the side of the node part to avoid discrepancies caused by incomplete or angled insertion (see in Figure 8).

.

(a) Frame model (b) Parts of frame structure

Figure 7. Frame Model Structure



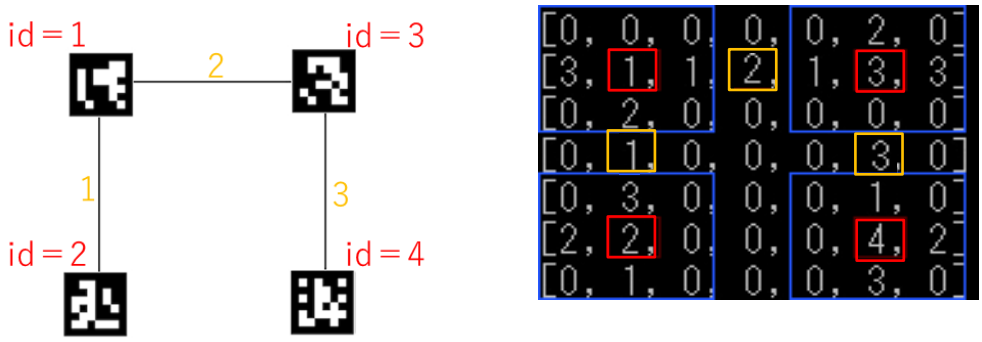


Figure 8. Details of node and member

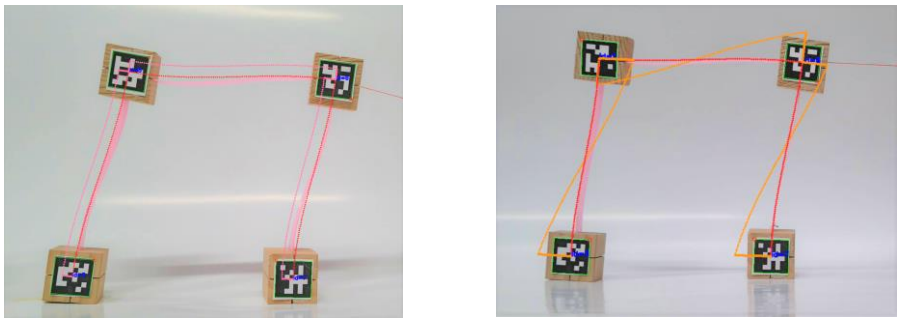
The method of calculating cross-sectional forces for frame structures and arch models is the same, but it is designed to be able to handle various shapes of structures, so it is necessary to recognize the assembled shape by checking whether there are members between the recognized nodes with ArUco markers. To recognize the members, we searched for the specified color within the middle one-third range between the nodes to determine whether or not there were members. However, there were cases where parts could not be recognized well due to changes in color caused by the lighting conditions and the thinness of the parts.

Therefore, a new method for recognizing parts was considered. First, the model is vibrated. In this case, since the model is read from the state where it is being vibrated, the initial state of the structure is assumed to be one in which the columns and beams pass through the center. Using the image differencing, assuming that there are members in the moving parts in the image, we determine whether there are members between nodes. Then, if a member is recognized, the color of the member within the middle one-third range between the nodes is read, and a histogram is created. Then, we adopted the method of determining the color of the member as the one with the highest number of data in the histogram.

To facilitate data processing, the position relationship between the recognized nodes and members is stored on a table (see in Figure 9). The blue square area within the 3x3 table is where the node information is recorded. Put the id number of the ArUco marker in the red square, and the face number to know which side of the marker is connected to the member on the top, bottom, left and right of the id number. When a member is found between adjacent nodes, the member number is entered in the orange square in order of discovery, starting from 1. By following this procedure, the program is able to understand the shape of the structure.



(a) Model to be read (b) location table of nodes and members

Figure 9. How to memorize structures on the program

After recognizing the shape, we calculated the sectional forces from the rotation angles of the nodes, and then plotted them on the captured image (see in Figure 10).

We also displayed the time history graph and the FFT results of the horizontal displacement of the specified nodes, and calculated the natural period (see in Figure 11).

By adopting a member recognition method using image differencing and identifying only the part of the member, we were able to recognize colors independently of the background of the model. On the other hand, while the column section can be recognized, there are times when the beam section cannot be recognized due to small differences in the differential. In addition, the nodes and members are created by hand, which slightly affects the cross-sectional forces depending on their accuracy. However, the distribution of the cross-sectional force diagram is displayed correctly, so there is no problem in terms of understanding the cross-sectional forces.

(a) shear force diagram (b) bending moment diagram

2.4 Recognition of bracing material and calculation of axial force

To create a structural educational tool that allows for viewing of sectional force diagrams for various combinations of structural elements, we added bracing materials. We used rubber bands as bracing materials. Because the addition of brace materials required the ratio of stiffness between the brace and column-beam, experiments were conducted to determine the stiffness. We added brace members as shown in Figure 12. The recognition range is set slightly inside from the node. Search for the color specified as representing braces within the recognition range and determine the presence or absence of brace material. The axial force of braces cannot be calculated using the rotation angle of the nodes. Therefore, the axial force of the brace was calculated using the deformation amount of the brace length.

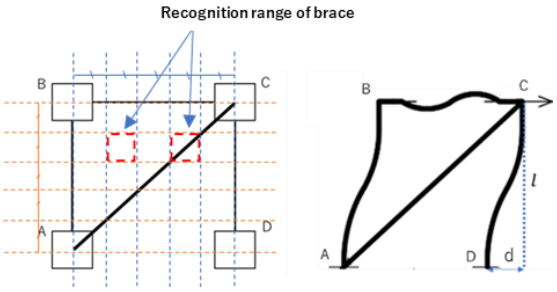

Figure 12. Deformation of structure with braces

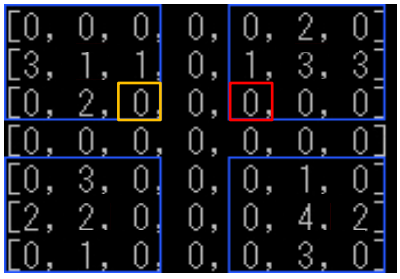
Similarly, for the brace material, the braces are numbered from 1 in the order they are found in the positional relationship table and stored in the program. If there is a brace with a right diagonal line, put the number in the red square, and if it has a left diagonal line, put the number in the orange square (see in Figure 13).



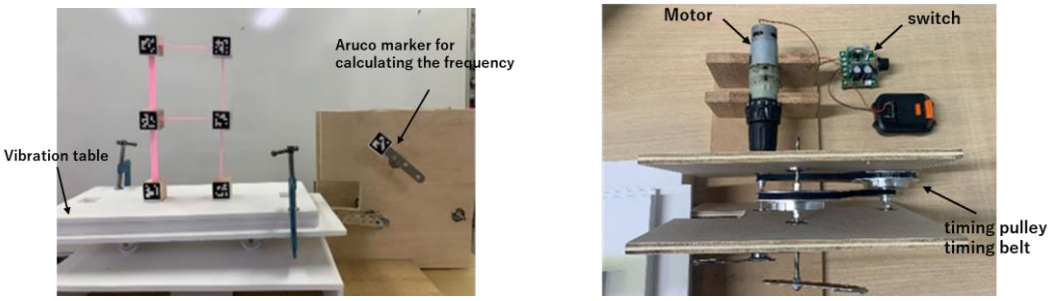


Figure 13. location table of brace

3. Vibrating table

A vibration table was created that can vibrate a model actually created (see in Figure 14). Styrofoam board is used for the foundation, and the power unit applies vibration using the motor of an electric drill.

To give a long-lasting vibration at a constant speed, the switch of the drill was replaced with a volume control type, allowing easy speed adjustment.

Furthermore, the vibration frequency of the vibration table was displayed on the shooting screen to match the behavior display system (see in Figure 15). Calculate the frequency from the coordinate values of an ArUco marker. However, it is difficult to obtain accurate values because the amplitude is small when tracking the behavior by attaching a marker to the vibration table. Therefore, we decided to install ArUco markers on the motor part to determine the vibration frequency. However, it is impossible to track the behavior of the ArUco marker because the rotation of the motor is too fast. By creating a mechanism to slow down the rotation using a timing pulley and timing belt, it became possible to track ArUco markers and determine the vibration frequency.

(a) Overall view of vibration table (b) Power unit and a mechanism

Figure 14. Vibrating table

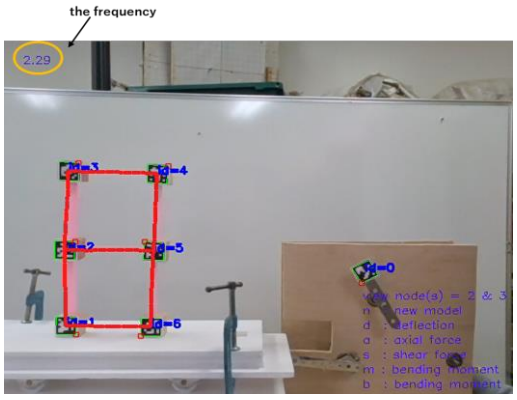

Figure 15. the frequency of the vibration table

4. Conclusion

As the model parts are made manually, there are variations in quality, which affect the cross-sectional force diagram. Furthermore, since the vibration table was made of styrofoam board to reduce weight, there is a possibility that there is a wobble due to the weight of the model. Therefore, it is necessary to improve the quality of the nodes and change the material of the vibration table. Another challenge for the future is to develop a method to easily recognize the model without using ArUco markers and to adapt to pin connections.

Abstract

This paper explores the state of flux within civil engineering education with universities facing demand from the ever-evolving industry to develop graduates with the desired skillsets and values. It discusses the transition in pedagogic approaches towards learner-centred models and evaluates the implementation of the Project-Based Learning (PBL) tool to shape the next generation of practicing civil engineers. A case study application of such a tool is explored in the form of the Design, Assemble and Dismantle (DAD) Project delivered during the first year of the civil engineering undergraduate programme at the University of Surrey. This Project is of an experiential nature where the student is placed at the centre of the pedagogic process. In order to fully understand the advantages of integrating this pedagogic tool in higher education in terms of enhancements it can make to the attributes developed and growth experienced by students, interviews with 20 participants of the DAD Project between 2015-2021 were conducted. The collated reflections depict the Project as an effective mechanism for developing an array of skills and values, including problem-solving, team working, leadership, communication, and cultivating a shift in mindset whereby students become more holistic, active, and conscious learners with a greater sense of accountability; all of which are paramount for the challenges of the 21st century.

Keywords: design, fabrication, spatial structures, civil engineering, tactile education, pedagogy, globalisation, collaboration

1. Introduction

'Tell me, and I will forget. Show me, and I may remember. Involve me, and I will understand.' The importance of a collaborative, interactive and engaging approach to pedagogy in which a hands-on student-centred model enhances the learning and retention process was recognised as early as 551 BCE by philosopher and politician Confucius.

There have been significant developments in civil engineering higher education over the last few decades with a shift in both the content delivered and pedagogic approaches adopted. The trend has transgressed from the traditional 'chalk-and-talk' format towards a more active learning, student-centered approach, focusing on the integration of engineering theory with hands-on practice in a multidisciplinary environment [1]. This transition is arguably steered by the increasing pressures placed on higher education institutions from of a multitude of external industrial, societal, and environmental challenges, to ensure that future generations of civil engineers are equipped with the skillsets required to overcome these. However, despite this increasing shift in teaching methods, civil engineering higher education is deemed to still consist predominantly of deductive one-way pedagogic frameworks [2].

This paper discusses the main skillset domains that higher education institutions aim to develop within their students and the changing requirements within these relative to the wider changes in the civil engineering industry. It outlines the two main methods through which institutions can meet these changing demands; the content of their courses and the pedagogic methods through which they are delivered. The paper then explores the implementation of the PBL tool through a discussion and evaluation of the hands-on collaborative initiative, the DAD Project.

The DAD Project is a two-phase hands-on initiative which was developed at the University of Surrey in 2014 for civil engineering (and architecture) students, integrating both design and fabrication. The first phase of the Project involves groups of students designing a full-scale steel spatial structure and preparing all the required documents for assembly, including technical drawings, a list of requirements, method statements and risk assessments. During the second phase, a design exchange occurs in which each group is given the set of documents prepared by another group during phase one to assemble and dismantle the designed structure within a two-hour time limit. This example of PBL embodies all of the fundamental aspects of inductive pedagogy through its student-centred hands-on approach, developing team working and leadership skills, communication skills encompassing both verbal and written forms, interdisciplinary collaboration, problem solving skills and providing the freedom to cultivate creativity and independent thinking. The paper evaluates the benefits of the above initiative in terms of the skills and attributes it instills within its participants. In order to attain mid-to-long term reflections, the research conducted is in the form of a qualitative evaluative one-to-one interviews with selected participants who had participated the Project two or more years ago. Thematic content analysis is then undertaken to determine common patterns and trends, thus composing a holistic view on the value of PBL pedagogy.

2. Literature Review

Higher education is a pivotal stage in the development of civil engineers entering the industry. The abilities and attributes that higher education institutions aim to cultivate in their students can be categorised into two main domains: defining skills and enabling skills [3]. Unique to engineering students, the former encompasses technical skills consisting of sound disciplinary knowledge of fundamentals built on a strong mathematical foundation and the ability to apply that theory in practice in a creative and innovative manner [4]. The latter category consists of a set of abilities that are deemed to enable students to integrate and work capably within the industry through effective communication, problem solving, decision making, team working and leadership skills [5]. It is the combination of these two domains, as illustrated in Figure 1, that forms the 'core competencies' of a well-rounded engineering graduate and underpins their role in the industry today as a technical specialist who can work across boundaries in a complex environment, providing creativity, innovation, and effective leadership in the face of new challenges [4].

Of the aforementioned skills, those deemed most important for engineering graduates entering the industry are theoretical understanding, practical application, creativity, and innovation. However, one of the biggest current concerns is the lack of practical application within the theoretical framework delivered by civil engineering higher education institutions [3]. This integration of theory and practice within the learning experience is deemed critical in developing innovative graduates who can work through open-ended challenges [4]. While the primacy of the defining skills is clear, several studies also stress the equal importance of the enabling skills and deem those as the attributes that ultimately make a successful engineer in the long term [3]. Perhaps the criticality of the latter arises from their increasing importance within the wider evolving industry. The disciplinary fundamentals required of an engineer are of a more fixed nature, however the array and degree of enabling skills required continues to vary over time.

However, the critical aspect is not the shifting paradigm of what the challenge is for engineers but their ability to respond to it, which ultimately depends on the development of the relevant skillset and nurturing of the required mindset [3]. The Royal Academy of Engineering report [4] places the

responsibility of ensuring that graduates possess these skills upon entering the industry on higher education institutions. Thus, it is essential that these institutions constantly keep abreast with the evolving demands facing graduates in a wide range of professional contexts to ensure that future engineering graduates are able to tackle the challenges facing them [5].

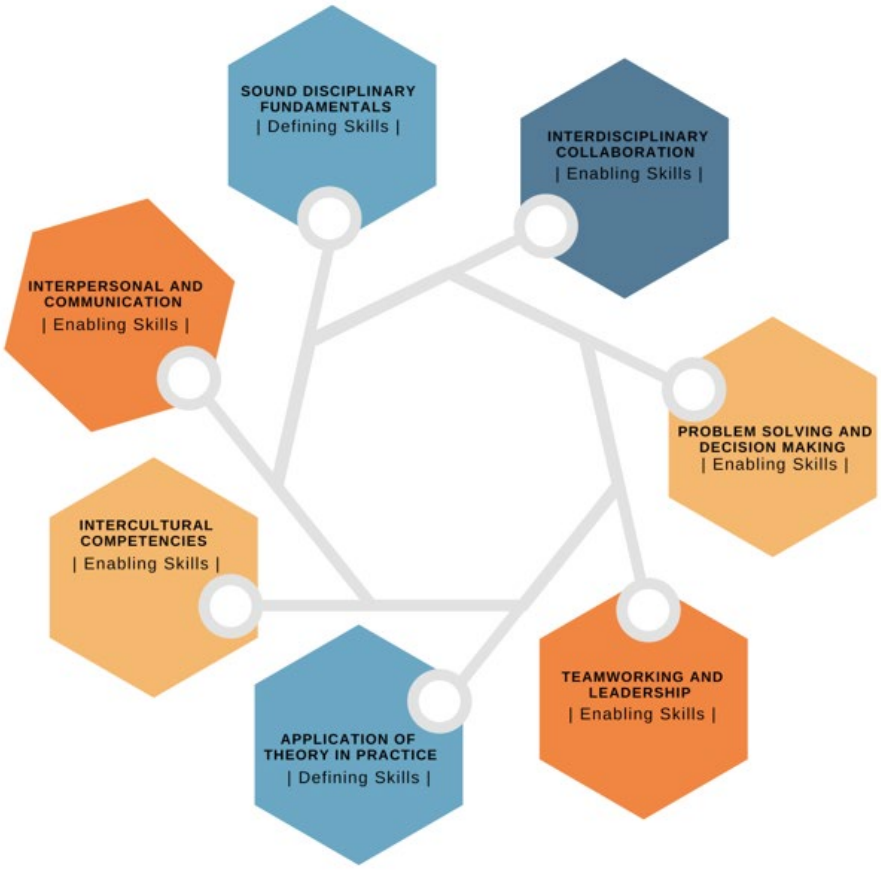

Figure 1. The Core Competencies of Engineers [4]

2.1. The Pedagogic Transition

In order to cultivate the desired skillset domains in future graduates, it is deemed that the pedagogic methods implemented by higher education institutions must be adapted. The pedagogic boundaries inherited from the 19th century have resulted in engineering courses being founded upon an instructor-centered model of teaching consisting of a deductive pedagogic manner, in which material is delivered through a highly structured framework. In this three-stage model, the lecturer would begin with an explanation of the general principles involved to a derive mathematical model. The next stage would be the application of the model to simple examples, reinforced by similar derivations and applications in tutorials. The third stage would then consist of more formal assessments. This model renders traditional pedagogic forms as predominantly auditory, deductive, passive, and sequential, promoting surface learning. However, engineering students are deemed to be visual, sensory, inductive, and active learners who reflect through action. These fundamental differences and imbalances are being recognised as preventing the full potential of effective pedagogy and as such, educational and cognitive research is increasingly encouraging the implementation of more inductive learning approaches [2].

Historic boundaries are now being transgressed with an increasing shift towards learner-centered models consisting of an inductive teaching manner based on the principle that knowledge can be developed and further enhanced through experience and interaction. This method of active and experiential teaching

consists of a fundamental shift in the pedagogical relationship between students and lecturers, to more symmetrical and interactive forms. It requires lecturers to assume the role of a facilitator encouraging students to navigate the 'indeterminate zones of practice', instinctively encouraging students to become active learners and impelling them to accept more responsibility for their own learning and development [6]. There is an array of inductive teaching methods that are gaining more recognition; inquiry learning, experiential learning, case-based teaching, discovery learning and PBL [2].

This paper will focus on the PBL approach which provides a framework of collaborative practical application to cultivate teamwork and leadership skills, independence, problem-solving skills, communication and interpersonal skills and creativity, within which the student is responsible for what needs to be learned and can influence the method by which it can be learned [3]. The model provides opportunities for deep learning and life-long learning [7]. It is argued that further benefits of this pedagogic approach are improved retention of knowledge, stronger reasoning and analytical skills, development of higher order skills, an enhanced ability to appreciate differing perspectives, greater motivation, and awareness of non-technical issues, all of which align to the demands of the evolving industry [2].

The following sections explore and evaluate the PBL approach through its application in the DAD Project, in order to ascertain the importance of integrating hands-on initiatives combining both design and fabrication in higher education to shape the future generations of civil engineers.

2.2 The Design, Assemble and Dismantle (DAD) Project

The DAD Project is fundamental in immersing first year students to the world of civil engineering and providing them with a unique experience of both the design and fabrication aspects of the industry across just one semester. The probability that knowledge and skills will effectively transfer to industrial settings has been argued to correlate to the similarity ratio of the two environments [2]. The DAD Project inherently mirrors the civil engineering industry, through the roles it assigns to students as consultants and contractors, as well as the project-long focus on health and safety, sustainability, and collaboration.

Over the course of its delivery, the DAD Project has undergone many developments in both its complexity and reach, in response to the evolving skillset demands from the civil engineering industry. The main developments are summarised in the timeline in Figure 2.

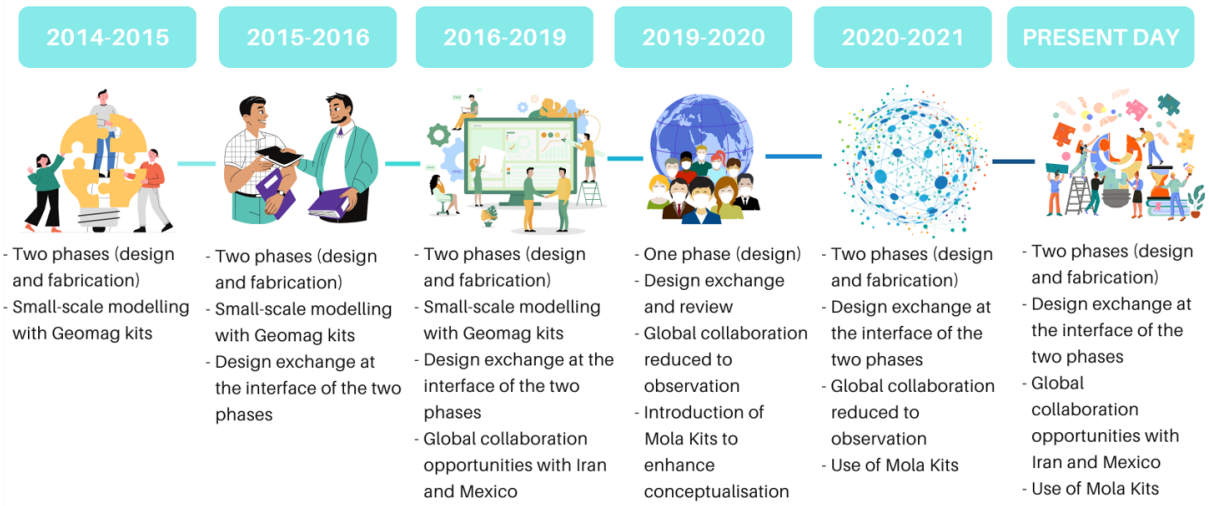

Figure 2. Development Timeline of the DAD Project

In the first year of its delivery each group of students designed a full-scale spatial structure, with the ability to develop a small-scale model, using Geomag kits and later Mola kits, as seen in Figure 3, and constructed the full-scale structure within a two-hour time limit, as can be seen in Figure 4. In its second

year across 2015-2016 a design exchange was introduced at the interface between phases one and two, whereby each group was given the set of documents prepared by another group in phase one to assemble and dismantle. This development aimed to increase the complexity of the Project and the communication and presentation skills required from the students through their design documents such that the required equipment, method of construction and relevant constraints and risks would be understood by another group.

In 2017 international collaborations were introduced into the design exchanges between students at the University of Surrey and civil engineering and architecture students in the 7th and 8th semester of their degrees at ITESO University in Mexico and with architecture students at the Ferdowsi University of Mashhad in Iran [8]. This development enabled students to cultivate a range of intercultural competencies, such as the ability to work across time, cultural and lingual differences, as well as an appreciation for different cultures, perspectives and of the wider globalising industry. As a result of the restrictions posed by the pandemic, in 2019-2020 and 2020-2021, no full-scale construction took place. However, the global design exchange and full-scale practice assembly were still achieved. To further facilitate conceptualisation of their designs in a virtual setting, students were provided with small-scale magnetic Mola kits. Furthermore, in 2020-2021, the design exchange was enhanced through competitive bidding whereby groups were able to choose which groups design they would construct, thereby reflecting some commercial elements of the industry. From 2021-2022, the DAD Project recommenced without the restrictions of the pandemic, with students being able to undertake the full-scale construction phase.

Since its conception, the DAD Project has extended even further throughout the world, through partnerships with the University of São Paulo in Brazil and Universiti Malaysia Pahang in Malaysia [8], offering even more opportunities for future global collaborations.

3. Methodology

Module evaluation is an essential element of reflective practice models in higher education consisting of the collection of evidence which can be reflected upon to formulate actions for improvement in pedagogy [9]. Continuous evaluation of modules and academic programmes is deemed crucial for maintaining standards and promoting student engagement [7].

Student evaluations proving short-term reflections are integrated within the framework of the DAD Project through the videos they produce summarising their experience while undergoing the Project and through a short qualitative questionnaire that students are required to submit upon immediate completion of the Project. To assess the mid-to-long term reflections in this paper, the research conducted was in

the form of virtual one-to-one interviews with some participants who had undertaken the Project at least two or more years ago. The sample group consisted of participants from a range of cohorts in order to explore any patterns or correlations in the skills or values cultivated alongside the developments in the modules design since it was first introduced. The sample group aimed to have a balance between male and female participants to mitigate any bias. To explore the transferability of the skills acquired across other modules and industry, all selected participants had at least two months of industrial experience, whether through summer placements, yearlong placements, or graduate positions. A summary of the participants composing the sample group is presented in Table 1 below.

Table 1. Breakdown of Sample Group

Cohort	Sample Group							
2014-2015	Participant 1	F	Participant 2	F				
2016-2017	Participant 3	F	Participant 4	F				
2017-2018	Participant 5	M	Participant 6	M	Participant 7	F	Participant 8	M
2018-2019	Participant 9	F	Participant 10	M	Participant 11	F	Participant 12	F
2019-2020	Participant 13	M	Participant 14	F	Participant 15	M	Participant 16	F
2020-2021	Participant 17	F	Participant 18	M	Participant 19	M	Participant 20	F

The interview questions were designed to elicit qualitative data from participants, engaging responses that would go further than the surface approach of satisfaction-oriented surveys, and reveal the true perceptions, thoughts, and feelings of participants regarding the PBL approach [9]. A four-part series of questions were produced to determine the following:

- Prior exposure to civil engineering before participation in the DAD Project to ascertain the extent to which any skills developed were directly attributable to the Project
- Academic and professional journeys since the DAD Project, to explore any opportunities and applications that arose from their experience in the Project
- Personal or professional skills or values developed as a result of the DAD Project
- The transferability of those attributes to other modules or industrial experiences

While the above provided a framework for the interviews, it was an inherently open format with the potential for individual discussions to allow the emergence of questions not formerly contemplated, encouraging conversational flow attached to the emotions and experiences of each participant [6].

It is important to note that for the process of data collection, ethical considerations were adopted. Primarily, through fundamental communication ethics recognising all participants as voluntary interlocutors having understood the intentions and implications of the research being conducted. This was ensured through informed consents from all participants. Furthermore, confidentiality, anonymity, and data protection of all recordings and transcripts were guaranteed [6].

3.1 Data Processing

Upon completion of the data collection stage in which interviews were conducted, recorded and transcripted with all participants through Microsoft Teams, the data processing stage was commenced. Thematic content analysis was chosen as the method of data processing - in which the data set was analysed to identify common themes and patterns. Upon completion of the first interview, one initial scheme of variables was established, and after each subsequent interview this was redefined in terms of the categories and codes identified [6]. The final scheme consisted of 20 attributes and skills which had been commonly identified by at least two individual participants, which will be discussed in Section 4.

In order to efficiently manage, process and present all of the collected data, MAXQDA was adopted in the data processing stage in the following way:

1. All recordings and corresponding transcripts were imported into MAXQDA
2. Transcripts were reviewed to unify the written form through the removal of any non-verbal utterances, such as laughter, or nodding
3. Transcripts were corrected by making references to the recordings to fix grammatical mistakes and incomplete sentences to obtain a readable, concise, and clear transcript
4. A coding system was generated in which codes corresponding to the identified skills and attributes were created and assigned to the relevant segments of each transcript

Following this, the data was analysed to explore and visualise the progression of themes across the interviews both qualitatively and quantitatively.

4. Data Analysis and Discussion

Upon undertaking the thematic content analysis of all interviews conducted, there were several recurring skills and values that were attributed to the DAD Project. The most common themes and experiences across the entire dataset were extracted in MAXQDA and are presented in a word cloud as shown in Figure 5. The size of the attribute or reflection corresponds directly to its commonality across the interviews. As can be seen from the word cloud, most participants referred to the experiential nature of the DAD Project, which they deemed different to others in the course. The experience of partaking in the Project was described as immeasurable, insightful, and invaluable and one which '*helps shape the rest of your degree'* as stated by Participant 15.

Figure 5. Word Cloud of Recurrent Themes, Attributes, and Experiences

A broad array of common attributes was brought to the forefront including communication, leadership, team working, time management and organisation. Shifts in fundamental mindsets were also expressed in which there was an increased appreciation of industry relations and global collaboration, respect and appreciation of different perspectives, a more active and conscious learning approach, and a greater sense of accountability for work produced. The percentage of participants that mentioned each identified common attribute is shown in Figure 6. The following section will explore the reflections of the participants with regards to some of these attributes in more detail.

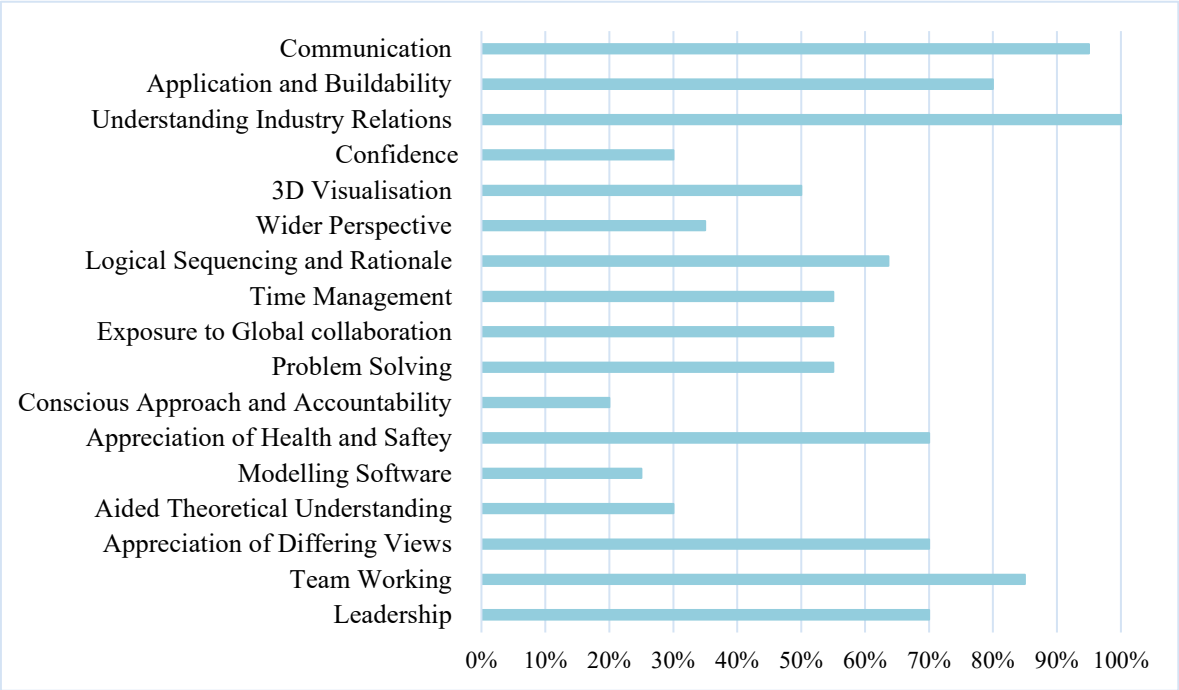

Figure 6. Percentage of Participants vs Attribute Developed

4.1 Industrial Awareness

The PBL tool allows students to understand the complex and multifactorial nature of professional practice, due to its inherent real life practical application [6]. This is in line with the findings in this study in which all participants agreed that they gained a deeper understanding of working in industry.

4.1.1 Consultant and Contractor Relations

Through the two phases of the DAD Project, in which students are able to first assume the role of a consultant and then of a contractor when working with the full-scale model, the interlinked and intricate relationship between the two are delineated and demonstrated to students. Participant 7 believed that *'the DAD Project mirrors what you get in the real world, because you have your consultant and contractor relationship, and I think it's really important to understand how that all works and how that will mesh together as early as possible'.* Being aware of the dynamic roles and relationships between the various stakeholders in the civil engineering industry is fundamental in providing wider context to the work undertaken and an insight into the systems of work in industry, which is reflected in Participant 13's view that the two phases enabled them *'to learn how projects are planned out and how they're efficiently done.'*

Furthermore, this arguably increases their insight into the considerations and challenges that each stakeholder faces, which they are then able to address more effectively through the design and construction processes. Participant 8 expressed that '*through the two phases, you got to see things from another perspective of not only designing something but being able to interpret someone else's designs and sketches'*, while Participant 5 believed that the Project '*definitely gave that awareness and thought process you need to have when designing something for construction'*. This implies a fundamental shift in the thought processes and approaches adopted by students from a purely theoretical mindset to one which can think ahead into the conceptualisation phases and the implications of decisions made. This was confirmed by Participant 11 who stated the following: '*I remember thinking to myself about whether the design would work in practice, which usually I wouldn't think about at all.'* The above reflections suggest that the Project was able to cultivate a development in mindset, whereby students were able to consider the challenge faced not only through one role, but through the multiple roles involved in the delivery of the solution, which according to Participant 3 was '*eye opening'*. Of the participants, 80%

expressed an increased awareness of buildability issues associated with the designs they produced or received. This was reflected in Participant 9's experience who stated that '*it made you realise the practicality of your designs; it's very easy to design things but not understand the implications of it'.* The 20% of participants who did not express a particular development in their awareness of buildability issues were those who were unable to participate in phase two of the Project due to the restrictions of the pandemic, highlighting the importance of the hands-on construction stage.

4.1.2 Globalisation

The era of globalisation in the civil engineering industry, which has gained significant momentum over the past couple of decades, has created demands and challenges for engineers to integrate efficiently into an increasingly complex and multicultural environment, with a particular focus on intercultural competencies consisting of the ability to collaborate in teams of individuals from various backgrounds, communicate effectively despite any lingual barriers and have cross-cultural knowledge. It is paramount for future generations of civil engineers to develop intercultural competencies across three tiers: a general understanding of cultural differences, awareness of cross-cultural differences within professional communication and the ability of effective cross-cultural communication in engineering practice [10].

Of the sample group, 100% of the participants involved in global design exchanges said that the DAD Project was fundamental in their exposure to global collaboration, the challenges it encompasses and the benefits it brings, predominantly through the international design exchanges. Participant 7 reflected that the Project '*really does mimic the industry, where we work with clients and colleagues abroad and that communication barrier can be quite a big challenge between different cultures, languages and regions.'* While global design exchanges were put on hold in 2019-2021, due to restrictions of the COVID-19 pandemic, participants were still able to experience some aspects of global collaboration as members of their teams were in other countries during lockdown. As such, they were still faced with some of the challenges associated with time differences and team working.

4.2 Practical Application

The unique hands-on approach adopted in the DAD Project through the use of both small-scale and full-scale models and the benefits that this brings was recognised by 80% of the participants. For most, this marked the first and only PBL project encountered in their higher education journeys and '*the first opportunity to put visions into realisation'* as noted by Participant 2. Prior to this, it was believed by Participant 6 that students '*don't think beyond the brief about how designs work and how it all comes together'*. This highlights how the interactive hands-on approach broadens the perspectives of students, enabling them to take on a more holistic view of the challenges posed and the steps needed to overcome them, ensuring that the work *'makes more sense and has more meaning'* as expressed by Participant 9, and reflected in Participant 8's views who stated that it gave them *'a better understanding of how a project works and how people work on a project'.*

Most students highlighted that there are few opportunities in higher education to address practical situations related to real-world practices, and that the realism reflected in the Project cultivated a more conscious approach. Participant 7 expressed that because of the Project, '*you're making more conscious decisions and having more conscious ideas and your perspective is slightly different throughout university,'* while Participant 14 stated that '*it was like the real world rather than coursework that you know is meaningless and you're just doing for a mark. It was nice to know that your design was going on to someone else and it made me want to perfect it, so they didn't come back with questions'.* It seemed the design exchange also instilled a sense of accountability for work produced as reflected by Participant 7's view: *'because the contracting team will come back to you with queries and clarifications, you have more accountability for your deliverables, they need to all join up to create the whole picture'*, while Participant 6 believed that '*being both consultant and contractor made me realise my design decisions really do matter'.*

In traditional pedagogy, the role of students is relegated to a receptive and passive one, where they encounter minimal challenges in which they can assume a pre-determined level autonomy to make decisions [6]. The student-centred approach places more responsibility on the student for their learning as they actively reconstruct their own reality, while the teacher merely acts as a facilitator [11]. This approach develops independent thinking, problem solving and logical reasoning, as confirmed by 64% of the participants. Participant 10 expressed that '*it gives you different skills that you need to be able to implement; the logistics of things and how you construct something in sequence'.* Furthermore, Participant 6 stated that the Project *'developed my logical reasoning skills and insight into systems of work, you see what needs to be done, you think about how to tackle the issue, then you move onto the next*.' It seems that it is in this process of PBL that real learning and problem solving resides [6].

It has been argued that PBL enables students to relate theory to practice and that the combination of the two produces enhanced results [9]. This is reflected in Participant 5's experience who noted that 'by *building the structure yourself you get an understanding of how the forces interact within the structure, you're not learning the calculations behind the structure, but in the long term when you're trying to learn the calculations you can apply it to a real life situation you've been in, it's easier to remember and understand it.'* Fundamental to the DAD Project is the use of physical models to understand structural behavior and construction requirements, which is first achieved through the use of the small-scale magnetic Geomag or Mola kits. For 50% of participants a key ability developed through the small-scale realisation of the designs was that of visualising a design in 3D space. Participant 6 mentioned that *'being able to visualise designs and see forms, doing it hands-on, really helps the initial understanding of scales; the tactile experience was invaluable.'* The above suggests that the assimilation of knowledge with application of theory in practice in different scales, during the formative undergraduate years of civil engineering offers greater benefits to overall educational development [11].

4.3 Communication

The DAD Project encourages effective communication not only verbally but through other means, such as written and visual forms, which is reflected in the experience of Participant 17 who mentioned: '*we had a few challenges trying to change the method statement and make it a bit easier to follow. Eventually, instead of just giving a written method statement, we had step-by-step photos and videos to explain how it works.'* Similarly Participant 4, who was involved in an international collaboration, stated the following: *'we had to ensure that the pictures and infographics made sense for them so that they could understand what we wanted them to do due to the language barrier'.* The ability to employ different means of communication has always been paramount for effective communication across a range of people, however even more so today due to the increasing virtual nature of collaboration in the industry which can limit some traditional forms of communication and understanding.

The design exchange shifts the focus of communication to whether the receiving group will be able to understand what is being expressed through the design documents. Participant 20 stated that this experience meant that when undertaking work, the predominant thought is '*if anyone ever looks at this from the outside, will they understand what I'm trying to say.'* The international collaboration aspect of the Project added a further level of communication required as Participant 15 believed that one of the most important takeaways was '*being able to communicate with different nationalities.'* Thus, interpersonal, and communicative skills constitute one of the main benefits of this form of pedagogy.

4.4 Collaboration

The DAD Project is based on a foundation of collaboration, whether that is within groups during phase one and two, across groups during the design exchange, or across the globe for those partnered with groups in Iran or Mexico. Collaboration is crucial within the civil engineering industry, and the DAD Project allows students to appreciate both the challenges and benefits it brings. Participant 8 expressed that '*the Project encouraged us to work with other people, which reflects the real-world experience really well – you don't work in silos, you have to work collaboratively to achieve the best results.'*

During the Project, students are required to collaborate effectively within their teams, managing group conflicts and varying levels of involvement from team members. Participant 14 stated that the experience '*gave me the idea that not everyone in your group is going to be as willing as you to play a part'.* This was embodied in the experience of Participant 17: '*it was easier to work with some people than others in the group. But then overtime you learn to put things in a way that everyone can understand.'* This confirms that the collaborative approach of PBL can cultivate the development of a range of managerial and team working skills, which is essential for engineers.

According to the perceptions of 85% of the participants, the teamworking aspect of the Project allowed them to consider points of view that, until then, had not been a part of their thinking schemes. This is reflected in the views of Participant 5: *'you develop new skills when trying to take into account new personalities and accommodate everyone's opinions.'* Participant 13 reflected that '*I learnt about becoming more open to listening to people's opinions',* and Participant 7 stated that *'it really opens up the spectrum to lots of different solutions and ideas.'* Thus, it seems that the PBL process is one of reconstructing participants knowledge schemes to integrate a more complex and polyhedral vision [6].

4.5 Health and Safety

This was the first encounter to health and safety within the civil engineering industry for most participants and learning about it in a practical framework through the full-scale construction meant that the responsibility to ensure it was on the students. Participant 19 expressed that '*coming to university, you don't care about health and safety, so being introduced to it at the start is really important',* thus indicating a fundamental shift in the attitudes and approaches of students which creates an important foundation for the rest of their careers. During the Project, every team assigns a health and safety manager responsible for ensuring that safety was inherent within the designs and method statements. Participant 6 confirmed that *'working on the design while being the health and safety officer allowed me to build safety into the design'.* Furthermore, the construction process requires students to think about how safety can be achieved on site, Participant 13 explained how '*because the structure designed was very tall, we had to figure out how to build it in a way which was within health and safety regulations.'*

4.6 Wider Benefits

The benefits for academic learning and professional development are tangible, with 100% and 75% of participants confirming that the skills developed through the DAD Project were transferrable to other modules and their industrial experiences respectively. Participant 3 stated the following: '*the Project gave us an appreciation for what needs to be done on both sides, which translates to the workplace because we always have to work with contractors, sub-contractors and clients'*. Many participants viewed the DAD Project as the sole experience in their higher education experience which allowed an insight into the world of contracting. Participant 7 believed that '*at university because we're not as practical, it's easy to fall into that design world rather than the contracting world'*, while Participant 18 stated that '*the Project helps you to decide which type of placements you want to do…and I think without it there is no way you could know'.* Participant 3 highlighted '*a lot of people are on the design side when leaving university, especially females, because contracting is more male dominated'.* As such it is believed that the Project gave a good insight into contracting even for whom it may seem less accessible in industry. Furthermore, several participants expressed that the Project sparked wider interests, as confirmed by Participant 14: '*without the DAD Project, I would not have gone to Mexico a few years later for a bamboo workshop and I wouldn't have been doing a dissertation on bamboo now'.*

Of the participants, 40% expressed that the Project enabled integration into their cohort at the start of their higher education journey, particularly crucial over the years affected by the pandemic. Another attribute highlighted by 30% of participants was that of confidence, predominantly in those who assumed the roles of project managers. Participant 17 reflected; *'I think that was probably the first group project that I was taking charge in, it gave me the confidence to do that more often'.* Furthermore, as

PBL reflects real world practice, students consider the work as relevant and thus are more motivated to [11]. This was a strong recurring theme in the data collected, with Participant 10 stating that *'it was amazing being able to see your design come to life and feeling that satisfaction',* highlighting a greater level of meaning and significance being associated to the work undertaken through the PBL approach.

5. Conclusion

The imbalance between theory and practical application is a systematic issue in civil engineering education; the challenge stands as the amalgamation of the two. However, the effectiveness of more hands-on approaches in engineering education is still open to question. This paper considers an application of such a method in the form of the DAD Project based on the PBL approach with small-scale and full-scale models. In order to fully understand its mid-to-long term implications and benefits, interviews with 20 participants of the Project are conducted and their reflections are subject to qualitative and quantitative analysis. Significant benefits are highlighted in the adoption of PBL as a pedagogical strategy, with improved attributes such as collaboration, communication, conceptualisation, and intercultural competencies. The observed benefits transgress beyond skills and attributes into shifted mindsets with greater appreciation of the wider context, health and safety considerations, different perspectives and students who assume the roles of active learners with an increased sense of accountability, motivation, and confidence.

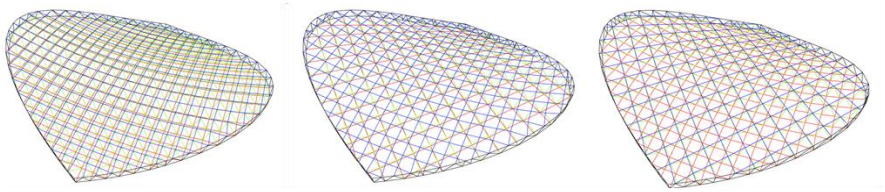
Abstract

Many gymnasiums have been built with cable suspensions, and such buildings have roofs made of precast concrete and cables. As an example, this paper focuses on the gymnasium in the Kyushu region built with such the manner. The roof span of this building is 57 meters in the longitudinal direction, 51 meters in the short direction and 12 meters in ascending order. Since the main building will be used as a multipurpose hall from the gymnasium facility, we are considering the application of a double-layer lattice pattern that is resistant to additional loads for seismic reinforcement. If you are applying a double-layer lattice pattern, examine the square-on-square (SS), square-on-diagonal (SD), and diagonal-on-square (DS) meshes. In comparing these three types of lattice patterns, it is made clear that the SS type of mesh has the greatest material efficiency but is easily affected by boundary conditions. Although the material efficiency of the SD type is smaller than that of the SS type of mesh, it is revealed that the SD type of mesh is the shape that is least affected by boundary conditions.

Keywords: seismic retrofitting, hyperbolic paraboloid, cable suspension dome, double-layer grids

1. Introduction

The target is a suspension structure using cables with an HP curved roof structure as shown in Figure 1, which is composed of PC slabs and cables. As seismic retrofit, we are considering the application of double-layer lattice grids that could resist additional loads. In applying the double-layer lattice pattern, three types are investigated: Square-on-Square (SS), Square-on-Diagonal (SD), and Diagonal-on-Square (DS) meshes as shown in Figure 2.



In previous studies, Yan [1] has clarified the influence of member placement on the elastic buckling behaviour of flat roofs, cylindrical roofs and domes, and Zhang [2] [3] has clarified the influence of member placement on the elastoplastic behaviour of flat roofs, cylindrical roofs, and domes.

To determine the extent to which the following lattice patterns can be applied to systems of suspended structures on HP curved surfaces, we specifically compare the load resistance system in the mesh and the flow of force to the boundary ring. Figure 2. (a), (b), and (c) show the mesh shape of the roof to be studied and they are composed of an upper chord member, a lower chord member, a web member, and an arch-shaped boundary ring beam.

Figure 1. Exterior of the gymnasium

(a)SS (b)SD (c)DS

Figure 2. Lattice pattern

2. Roof shape

The arch-shaped boundary rings that make up the roof are provided for each upper and lower chord surface, which are composed of upper and lower chord members, respectively. The curve indicating the arch is expressed by the following Eq (1). The all nodes are yielded by the equation and the constituent members are straight and connecting two nodes.

$$y = \pm 18.0 \times \sqrt{\frac{28.5 - |x|}{14.25}} \tag{1}$$

The nodes of the upper chord of the roof are coordinated based on the following Eq (2) used in the design of the existing building.

$$z = 5.12 + \frac{5.0}{28.5^2} \cdot x^2 - \frac{4.0}{22.5^2} \cdot y^2 \tag{2}$$

The three plans of lattice patterns shown in Figure 2 are created: SS type, SD type, and DS type. The plan views of the upper and lower chord surfaces of the SS, SD, and DS types are shown in Figure 3.

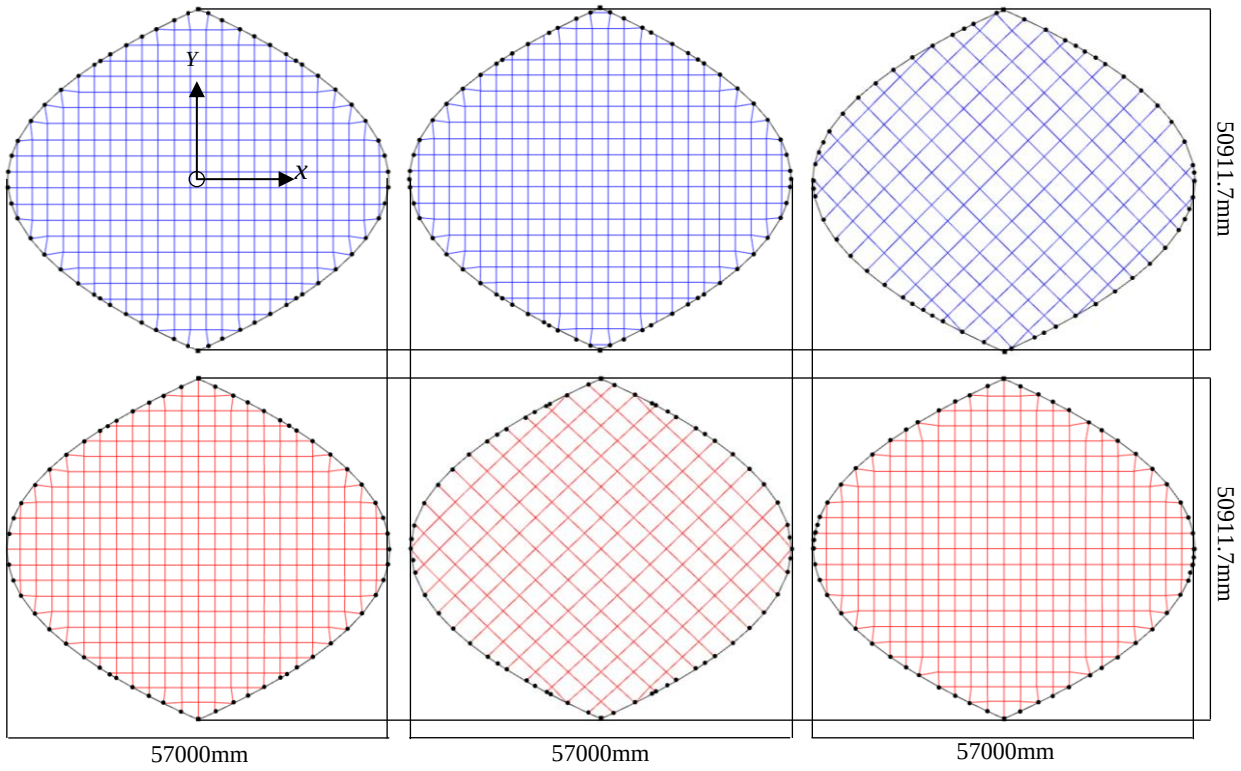

Figure 3. Plan

Table 1. Cross-sectional dimension

Member	Sectional Dimension (mm)	Cross Sectional Areas (cm^2)	Geometrical Moment of Inertia (cm^4)
Chord member	φ203.0×12.0	72.01	3300
Boundary ring member	φ298.5×16.0	142.0	14200
Young's Modulus	2.05×10^4kN/cm^2		

The cross-sectional dimensions of the HP shell roof are shown in Table 1. Except for the boundary ring, an upper chord node is provided so that the length of the SS type upper chord member is 240 cm. Starting at the intersection of the diagonals in the rhombic shape of the smallest unit composed of four upper chord nodes, the lower chord node is provided at a point 3394 mm (= 2400 mm $\times\sqrt{2}/2$: half the length of the diagonal) in the normal direction on the side toward the ground surface.

A square mesh is formed based on the upper and lower chord nodes for two layers of the SS type. Diagonal mesh is formed based on a above square mesh. To arrange web members, the tetrahedron consisting of four chord members and four web members is considered.

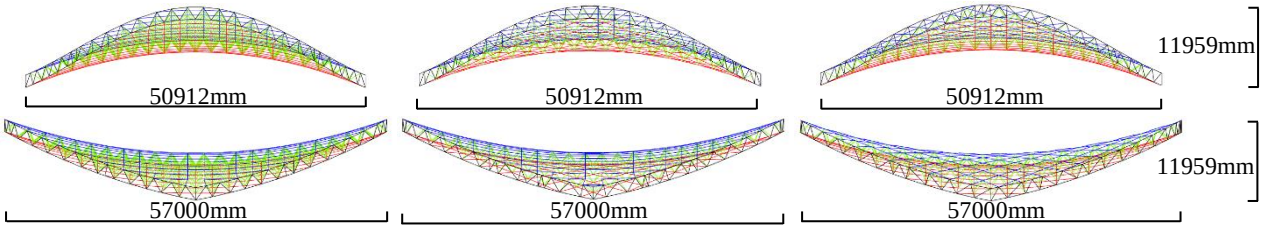

Figure 3. Elevation of upper and lower layers (a)SS type, (b)SD type and (c)DS type

It is necessary to design the tetrahedron to be formed so that the overall balance is not greatly disturbed even near the boundary ring. The boundary ring consists of two parallel chord members and web members. The constituent nodes are necessarily connected to chord members in each layer.

3. Loading and support conditions

There are two types of support conditions: pin support and roller support. The pin support is horizontal and vertical constraints at all the upper and lower nodes of the boundary ring beam. The roller support is only vertical constraints only except for the intersection of the two boundary ring beams. Therefore, the boundary ring intersection points are pin supported.

Table 2. Roof area and reference load

Roof area (m^2)	1935
Weight per area (kN/m^2)	2
Total reference load (kN)	3870

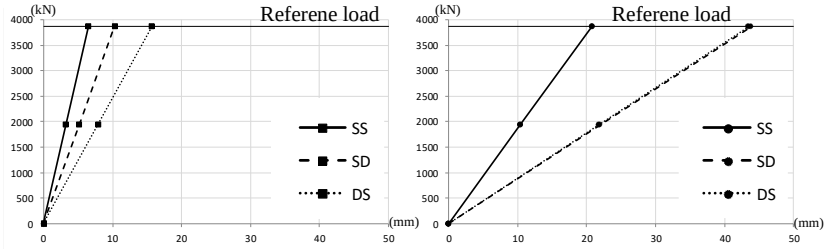
Table 3. Number of inside nodes on the top surface and load per node

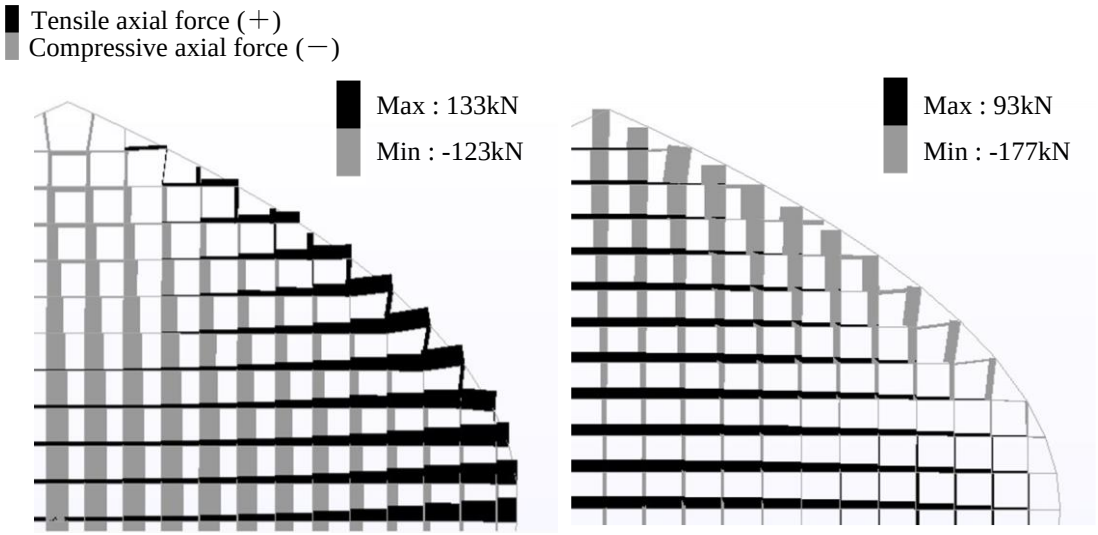
Lattice Pattern	SS	DS	SD
Number of nodes	324	162	324
Load per node (kN)	12.0	23.9	12.0

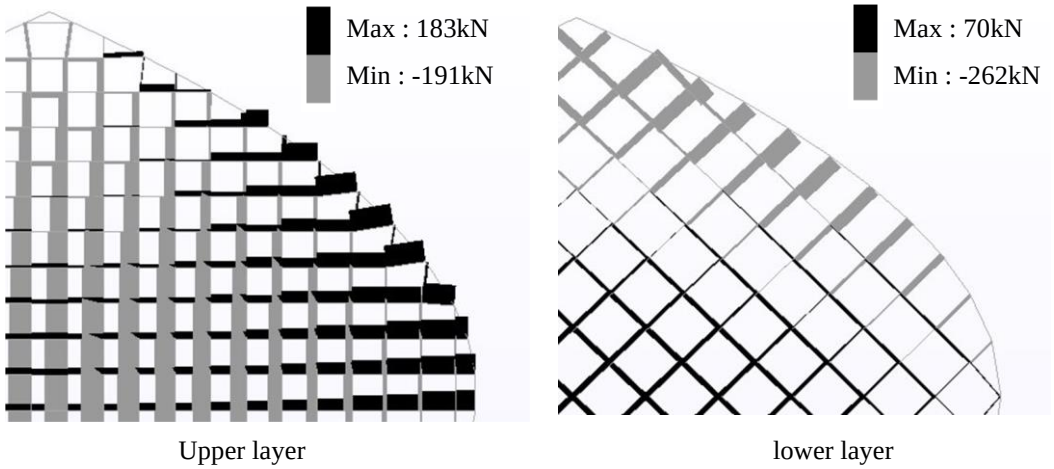
In addition to the load due to the roof structure, it is assumed that the load of $2kN/m^2$ is applied to the roof area. As shown in Table 2, the total load on the roof is the reference load. In Table 3, it is assumed that the reference load is divided by the number of upper chord nodes and the divided load is applied on each node.

4. Analysis Results

Figure 4 is a diagram comparing vertical displacements in the pin support and roller support of the SS type, SD type, and DS type up to the reference load. The vertical displacements are values of the central nodes in the lower layers, and the vertical axis means the total loads on the upper layers. On the case of pin supports, SS type is the smallest and DS type is the largest. On the case of roller supports, SS type is smaller than the other types and the other two types are almost equal.







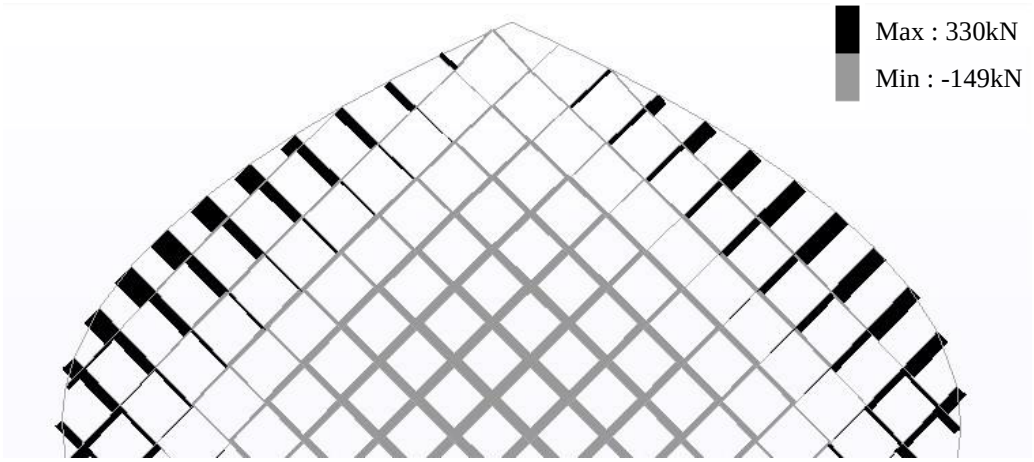


Figure 4. Vertical load displacement relationship

Figure 6. Axial force distribution diagram under reference load (Roller support)

Figures 5 and 6 show the axial force distribution under the reference load in which the tensile axial force is positive and compressive axial force is negative. In these figures, the maximum and minimum values shown in the chart are shown separately for the chord members and the ring beams, and the value of the chord member is shown in the upper right and the value of the boundary ring member is shown along the ring. The reaction forces of the buttress on the boundary ring intersection points are shown in Figure 7. In Figure 6(b), the value in parentheses expresses the maximum value except that of the neighbour member of the intersection (buttress) points. The member of 862kN is subjected to large tensile axial forces due to the roller support condition.

(a)Square-on-Square type (b)Square-on-Diagonal type (c)Diagonal-on-Square type

Figure 7. Reaction Forces (Roller support)

Figure 7 shows the magnitude of the reaction forces at the roller support. In any mesh model, the reaction forces at the boundary ring intersection (buttress) points are larger than the reaction forces at the other support points. The summation of the reaction forces in the upper and lower meshes in the DS type is about 1.5 times larger than the value of the other two meshes. The reaction force on the lower surface of DS type is greater than the reaction force on the upper surface of DS type. In comparing the reaction force in the two surfaces, the value of the lower surface is about 2.9 times of the upper surface for SS type (in Figure 7(a)), about 1.1 times for the SD type (in Figure 7(b)), and about 2.0 times that of the DS type (in Figure 7(c)).

5. Consideration

[Pin-support] At the case of pin support as shown in Figure 5, the x direction is tensile, and the y direction is compressive to resist the load for the SS type. For the SD type, the upper surface is similar as the SS type, but the lower surface is a diagonal mesh, and the axial force distribution is changed remarkably. The lower members near the boundary are in compression. The axial forces are smaller than the lower surface of SS type. For the DS type, the diagonal mesh of upper surface is tensile near the boundary ring and compressive in the central part, that is contrary to the SD type. The lower surface shows the tension in the central span of the x direction and the large compression near the ring beam of the y direction, such as SS type.

[Roller-support] At the case of roller support as shown in Figure 6, the upper surface of the SS type is compressive, and the lower surface is tensile, that is the resultant is a bending moment type. The upper chord members of the boundary ring are compressive, but a part of the lower chord members is tensile, except the members near the intersection (buttress) points. The same distribution is shown in the SD type, but most of the diagonal lower surface is tensile. For the DS type, most of the diagonal upper surface is compressive, and the lower surface is compressive near the intersection (buttress) points. The upper cord members of boundary rings are compressive for the 3 types, due to the horizontal freedom on the supports.

Tables 4 summarizes the maximum and minimum axial forces of Figures 5 and 6 under the reference load at both support conditions. The axial force of boundary ring at the pin support is omitted because it is approximately zero.

In comparing the axial forces of chord members at both support conditions, the ratios of Table 4 are shown in Table 5. The fluctuations of values are small in the SD type and large in the SS type. It can be said that SD type is relatively tough at the support conditions.

Table 4. Axial forces in Pin and Roller support (kN)

Lattice pattern	SS	DS	SD
Maximum value in chord member (Pin support)	133	330	183
Minimum value in chord member (Pin support)	-177	-334	-262
Maximum value in chord Member (Roller Support)	305	722	298
Minimum value in chord Member (Roller support)	-1038	-1510	-504
Maximum value in ring Member (Roller support)	181	189	199
Minimum value in ring Member (Roller support)	-604	-1104	-1089

Table 5. Axial force ratio of pin support and roller support

Lattice pattern	SS	DS	SD
Maximum value Roller/Pin	2.3	2.2	1.6
Minimum value Roller/Pin	5.9	4.5	4.2

6. Summary

The suspension system is replaced with double layer grid system for the purpose of seismic retrofit and multipurpose facility. Three typical lattice patterns, Square-on-Square (SS), Square-on-Diagonal (SD) and Diagonal-on-Square (DS) are compared from the viewpoint of the member axial force distributions.

At the same load level, Square-on-Square (SS) type shows the least deformation and high material efficiency at both the pin and roller support. However, it can be said that the Square-on-Diagonal (SD) type is stronger than the two others in the comparison with the axial force fluctuations by the differences of the two support conditions.

Abstract

The stadium is the main venue of the Asian Beach Games located in the tropical area where severe typhoon lands frequently. With a construction area of 86,000 m^2, the stadium can host up to 45,000 seats. The outline of stadium roof is 305m long and 270m wide. The long-span roof structure is composed of inner cable-membrane structure with a cantilever of 45m and outer steel structure. A spoke-type cable truss structure composed with Carbon Fiber Reinforced Polymer cables is designed. CFRP cable and high-strength cast steel G10MnMoV6-3 were used for the first time in large-scale spatial structures, realizing the lightweight of the structure and promoting the technological progress of the new material manufacturing industry. A horizontal truss structure supported by hinged columns is designed, and the section size of the ring beam is reduced by the overall action of the horizontal ring truss. Convex cable truss is used to deal with severe typhoon, which makes the structure safer, more comfortable and more economical. A kind of form analysis technology is used, which can significantly decrease the design duration of the entire project and increase the effectiveness of coordination between disciplines and avoid reworks. Connection detail of the arch supporting the PTFE membrane is designed, which has not only clear load path of transmitting vertical force and horizontal force, but also can provide out of plane support for the upper radial cable and improve the stability of the convex cable truss.

Keywords: spoke-type cable truss structure, CFRP cables, high-strength cast steel, convex cable truss, form analysis technology, connection detail design

1. Introduction

The stadium of Sanya International Sports Industry Park is the main venue of the Asian Beach Games located in the tropical area where severe typhoon lands frequently. With a construction area of 86,000 m^2, the stadium can host up to 45,000 seats. The outline of stadium roof is 305m long and 270m wide, shaped by an irregular pentagon with filleted corners. The shape of the inner oculus is composed of four arcs with different centers and radius, with a short axis of 134m, a long axis of 171.8m and a maximum elevation of about 46m.The long-span roof structure is composed of inner cable-membrane structure and outer steel structure. The inner cable-membrane structure has a cantilever of 45m, formed by spoke-type cable truss structure, which is consist of fully locked coil cable and CFRP cable; The outer steel structure is a ring-shaped plane truss structure composed of inner ring beam, outer ring beam and the cross-intersected beams between them, and sits on a supporting system formed by a series of hinged columns. The outer steel structure provides a reliable support for the inner structure. (Figure 1 to 3.)

2. Key technologies in the design and research on this project

2.1. Application of CFRP cables

This project is located in the coastal area where severe typhoon lands frequently. According to the wind tunnel test, the wind load extreme values on this project are 3.8kN/m^2 and -3.7kN/m^2, and the Cp values are 2.2 and -2.3. The deformation caused by wind load is the governing factor of the lightweight roof structure design of the project. Setting cross-bracing cables between the upper and lower tension ring can significantly improve the stiffness of the roof structure and reduce the wind-induced deformation. (Figure 4.)

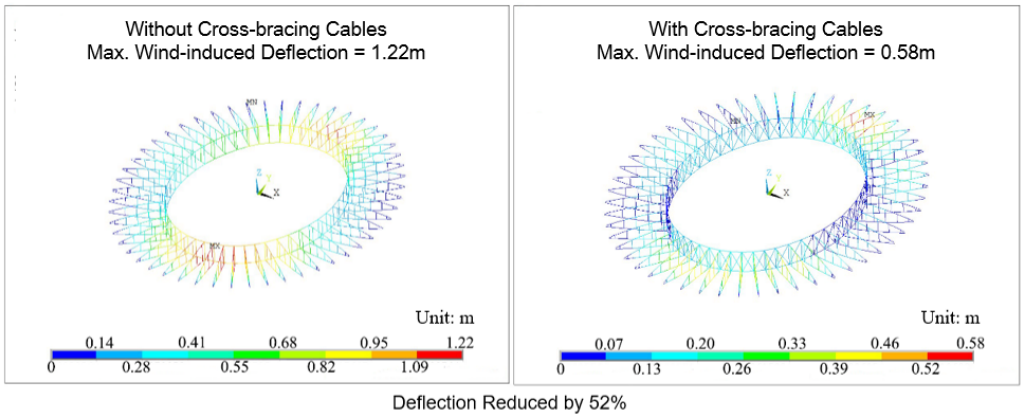

Figure 4. Benefit of setting cross-bracing cables between the upper and lower tension ring

The structural engineers noticed two important characteristics of the influence of cross-bracing cables on the structural performance (Figure 5):

a) a small axial stiffness (EA) of cross-bracing cables can significantly improve the structural stiffness, but further increasing of EA will have no obvious effect on further improving the structural stiffness.

b) The wind-induced unbalanced force at the cable clamp connection will increase along with the EA increases, which will consequently lead to increasing of the clamp size and weight on the roof.

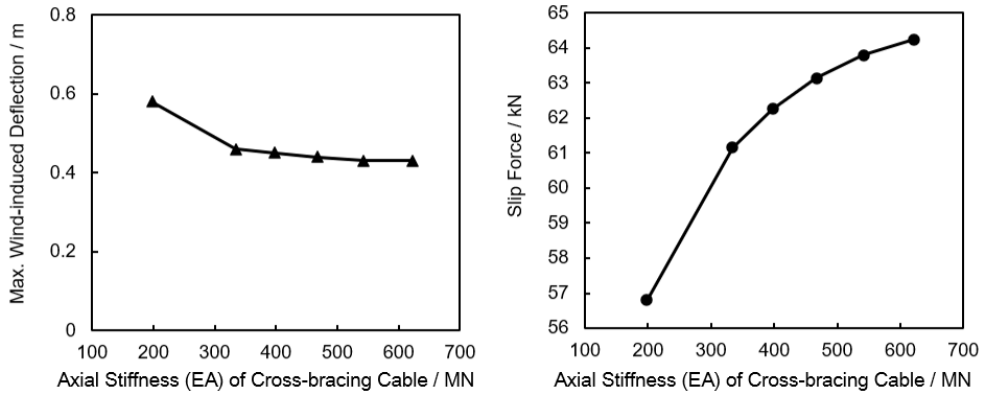

Figure 5. Influence of axial stiffness (EA) of cross-bracing cable

In this project, the designer selects CFRP cables as the cross-bracing cables. By making full use of its high strength and low elastic modulus characteristics [1], i.e., to keep smaller EA with small section area (A) and low elastic modulus (E), the contradiction between improving structural rigidity and reducing unbalanced force of cable clamp is creatively resolved. See the CFRP cable and its anchorage device of this project in figure 6.

This project is the first application of CFRP cable in large-scale spatial structure, which improves the

performance of the structure and is a beneficial attempt of new materials. After the completion of roof structural installation, the project team has invited 20 experts from universities, construction companies, steel and cable contractors to share all the acknowledge obtained from the project, including the design methods, technical standards, manufacture and installation specifications for CFRP cable in spatial structure. Together with a couple of patent and research papers which are all open to public, this project demonstrates and promotes the application of CFRP cable in the field of spatial structure. Yue Qingrui, academician of the Chinese Academy of Engineering, commented that "This project can be considered as an important milestone for a successful application of corrugated anchor CFRP parallel plate cable for the first time in the world, and is a breakthrough in the application of CFRP cable in long-span spatial structures."

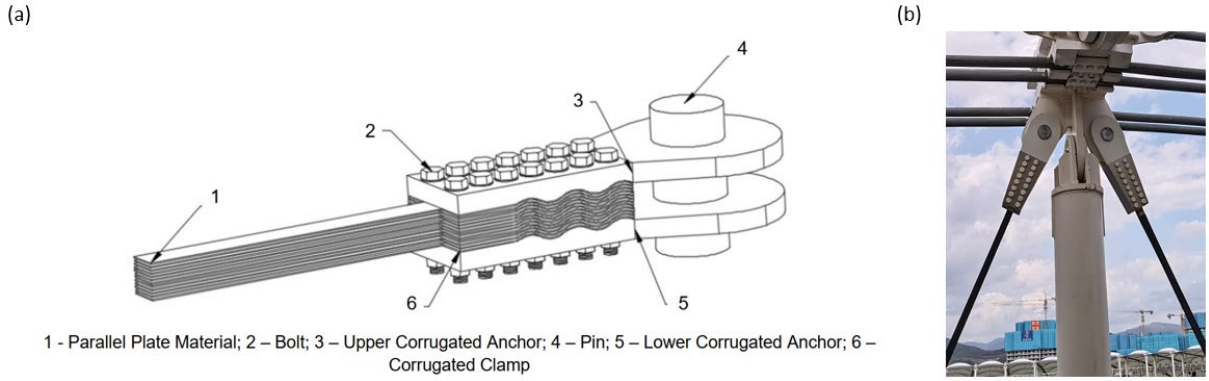

Figure 6. CFRP cable and its anchorage device: (a) schematic diagram, (b) live photo

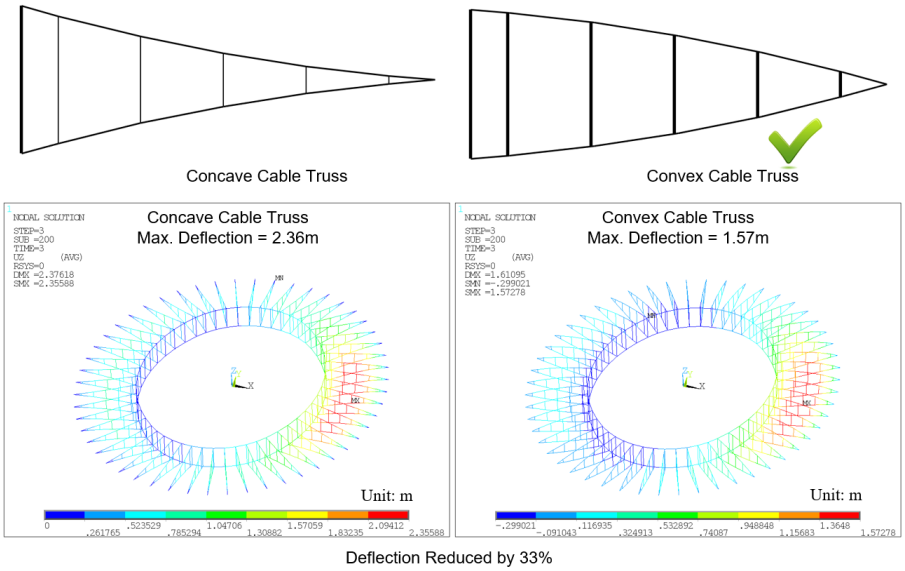
2.2. Form selection of cable truss

The architect initially proposed to use concave cable truss as the roof structure. Although it has been successfully applied in many projects, the concave cable truss was proved having insufficient stiffness to deal with severe typhoons in this project. Therefore, the structural engineers suggested to change the form of cable truss from concave to convex, which has 33% higher stiffness. (Figure 7.) The advantage of the change includes: More economical - less material when achieving the same performance target; More safe – protect secondary structures from huge wind-induced deformation; More comfortable - the spectators will not suffer from insecure caused by large movement of the roof.



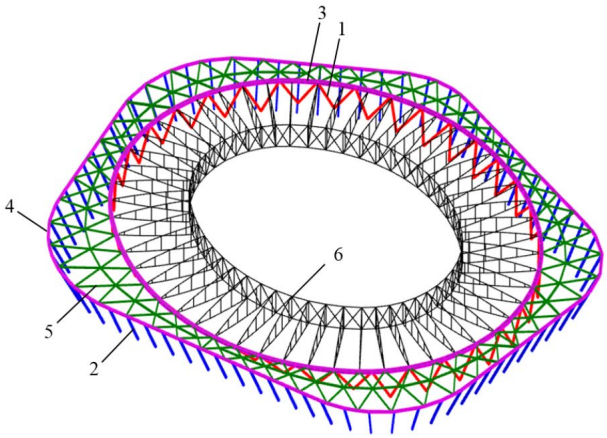


Figure 7. Comparison between concave and convex cable truss

2.3. Ring-shaped plane truss structure supported by hinged columns

The tension force of the cable truss of the inner roof is relatively large due to the location of the project which is coastal area with large wind load. According to the function of the building, the architect set up a ring of flat roof outside the inner ring roof. The structural engineer decided to use the bearing capacity of the entire outer roof to resist the horizontal force from the cables. As the support boundary of the cable truss, the ring-shaped plane truss structure was formed by arranging the inner and outer ring beams and the cross-intersected beams between them [2]. Meanwhile, all the supporting columns were designed as hinged at both ends, and the inner ring columns were arranged into continuous V-shape, which formed a reliable lateral force resistance system. (Figure 8 to 9.)

1- Inner hinged V-shape columns; 2 - Outer hinged columns; 3 - Inner ring beam; 4 - Outer ring beam; 5 – Cross-intersected beams; 6 - Cable truss

Figure 8. Layout of the ring-shaped plane truss structure supported by hinged columns

Figure 9. Live photo of the ring-shaped plane truss structure supported by hinged columns

By forming an integrated bearing system for the cable forces, the section size of the ring beam is reduced by 40%. By taking the axial force only and using the material strength in the most efficient way, the hinged steel columns reduce the amount of steel consumption and simplify the connection details between steel and concrete structure.

2.4. Advanced form analysis technology

In order to meet the requirements of architectural roof cladding geometry, the form of the cable structure roof in this project is determined by the balance between applied tension force and weight of the structure [3]. Once the weight of the roof structure is changed, the applied tension force should be adjusted to keep the position of the upper tiers consistent with their original position.

In the early stage of design, structural engineers can only make preliminary form finding based on an assumed weight of components on the roof. With the development of design and detailing, the weight value of each part of the roof become gradually determined. After all the weight of roof is finally determined, a final form finding is required to obtain the accurate theoretical shape of the roof after the construction. With advanced form analysis technology, when the weight of the roof changes, only the shape of the lower cable is required to be adjusted, while the position of the upper cable can maintain the shape and consistent with the form required by the architects. (Figure 10.) Therefore, the design of the roof cladding system, drainage and other related disciplines which depend on the cable position of the upper layer can be commenced from the early stage without being affected by the structural form found in the later stage. This technology can significantly decrease the design duration of the entire project and increase the effectiveness of coordination between disciplines and avoid reworks.

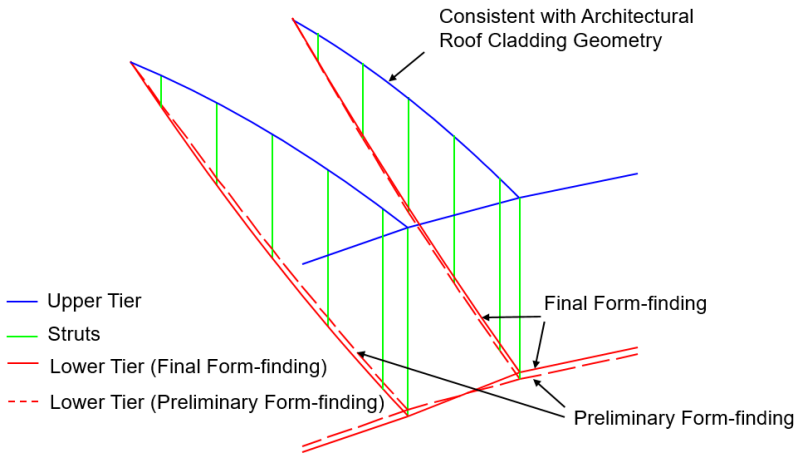

Figure 10. Schematic of the form analysis technology

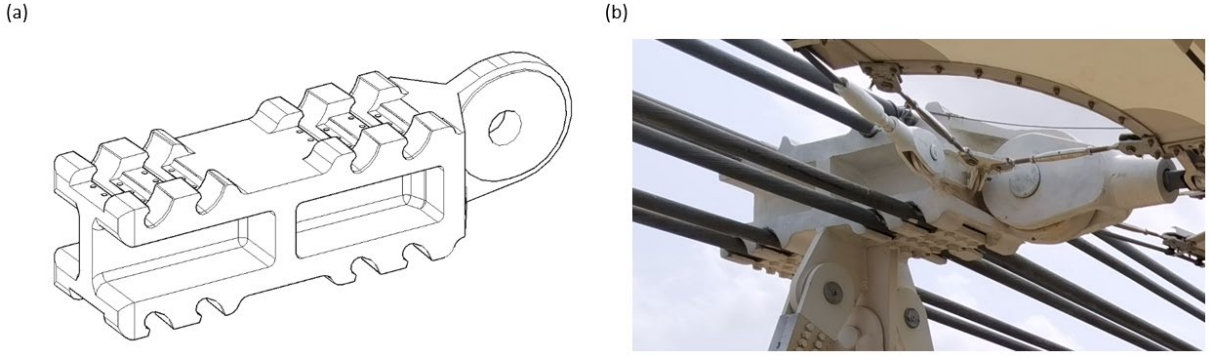
2.5. Design of cable clamp with high-strength cast steel G10MnMoV6-3

The weight of cable clamp connection accounts for a large proportion of the self-weight of the whole cable-membrane structure, which has a great impact on the economic efficiency of the entire structure. The design needs high-strength cast steel to reduce the weight. The common structural cast steel materials G17Mn5 and G20Mn5 have a maximum yield strength of only 300MPa. Therefore, the structural engineers selected cast steel G10MnMoV6-3 with yield strength 33% higher than common material [4], which significantly reduced the weight of cable clamp by 30% while the same bearing capacity was maintained. By the use of G10MnMoV6-3, the weight of roof structure was reduced and the tension force of the cable truss was decreased. (Figure 11.)



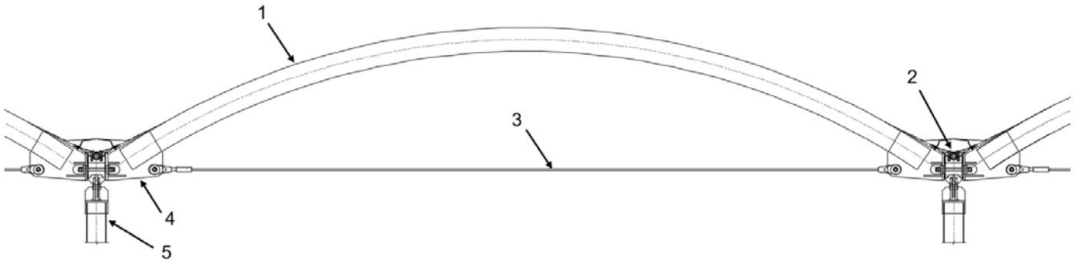


Figure 11. Cable clamp with G10MnMoV6-3: (a) schematic diagram, (b) live photo

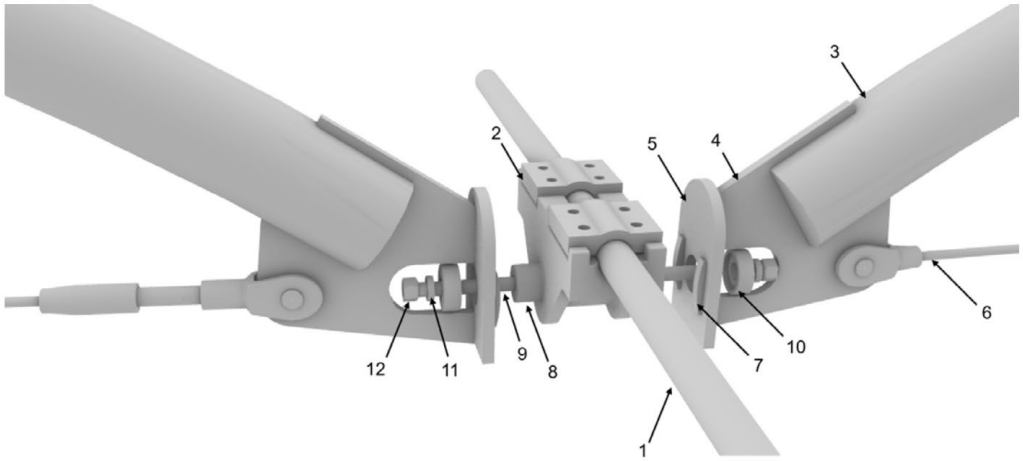
G10MnMoV6-3 material is applied for the first time in China, which makes the casting connection to

be stronger and more lightweight. Driven by the design requirements of this project, Chinese cast steel foundries have conducted a lot of tests in the chemical constituent ratio and heat treatment process, formed a stable manufacturing process and met the performance requirements in European standard.



2.6. Creative type of connection detail at the support of the PTFE membrane

The PTFE membrane is supported by the arch with a balance cable set between the arch supports. (Figure 12.) In most of other projects with similar arch supporting membrane, the arch is designed to be relatively independent to the radial cable. However, for this project, a creative type of connection detail between the arch supports and radial cable clamps is designed in order to improve the stability of convex-shape cable truss. The radial cable clamp is designed to have a cylindrical cantilever bracket with bolt hole in the centre. The vertical reaction from the arch is transmitted to the bracket through the perforated end plate at arch support, where the cylindrical cantilever bracket can insert into. A high-strength bolt passes through the central hole of the bracket and is fixed through the convex nut and concave washer. By working together with a pair of chambered bosses designed on the end plate, both tension and compression can be transmitted reliably between the arch balance cable, arch and the upper radial cable while rotation ability between them is maintained to avoid the bending of the bolt due to structural deformation. (Figure 13 to 14.) This kind of connection detail has not only clear load path of transmitting vertical force and horizontal force, but also can provide out of plane support for the upper radial cable and improve the stability of the convex cable truss.

3. Conclusion

a) The stadium of Sanya International Sports Industry Park is the main venue of the Asian Beach Games located in the tropical area where severe typhoon lands frequently.

b) A spoke-type cable truss structure composed with CFRP cables is designed. CFRP cable and high-strength cast steel G10MnMoV6-3 were used for the first time in large-scale spatial structures, realizing the lightweight of the structure and promoting the technological progress of the new material manufacturing industry.

c) A horizontal truss structure supported by hinged columns is designed, and the section size of the ring beam is reduced by the overall action of the horizontal ring truss. The use of hinged columns save the steel consumption and simplify the connection details between steel and concrete structure.

d) Convex cable truss is used to deal with severe typhoons, which makes the structure safer, more comfortable and more economical.

e) A kind of advanced form analysis technology is used, which can significantly decrease the design duration of the entire project and increase the effectiveness of coordination between disciplines and avoid reworks.

f) A creative type of connection detail of the arch supporting the PTFE membrane is designed, which has not only clear load path of transmitting vertical force and horizontal force, but also can provide out of plane support for the upper radial cable and improve the stability of the convex cable truss.

Abstract

The annular crossed cable net structure has strong collapse resistance and can continue to bear the load after local cable breaking. To quantitatively evaluate the bearing capacity of the structure after cable failure, a multiple-step loading and unloading method was proposed. The failure grades of cables were classified in the gradual cable breaking process. In addition, the bearing capacity reduction coefficient was put forward to quantitatively evaluate the reduction degree of bearing capacity. According to the curve of bearing capacity reduction coefficient, the residual ultimate load corresponding to different cable failure numbers can be quantitatively evaluated. The results show that delaying the failure of the grade I cables of the cable-net structure is the key to improving the ultimate bearing capacity. An effective way to change the bearing capacity of the structure is by adjusting the breaking order of the cables. Therefore, three effective design measures (using CFRP cables, increasing the cross-sectional area of load-bearing cables, and increasing the number and grade of cables) were put forward to improve the bearing capacity of the structure.

Keywords: annular crossed cable net structure, bearing capacity reduction coefficient, failure grades of cables, evaluate of bearing capacity, new design measures

1. Introduction

Cables, as members with stiffness and bearing capacity provided by pre-tension, have an important influence on the anti-collapse performance of these structural systems. Asghari R et al. [1] put forward a hybrid cable-strut system which is composed of tensegrity rings and a Levy cable dome and studied the initial collapse behavior of the structure by numerical simulation with ABAQUS software. Zheng J et al. [2] studied the failure mode of the cable dome structure and its mechanical performance after a cable rupture. Lu J et al. [3] investigated the failure effect of a planar truss string structure with a 6 m span through both experiments and numerical simulations. Zhou H et al. [4] analyzed the uncertainties of bearing capacity by combining the finite element method with the Monte Carlo simulation, proposed a simplified approach to establish a more realistic limit state equation of the beam string structure under both full-span load and half-span load, and carried out the bearing capacity reliability calibration considering the random properties of load ratio. However, little research has focused on the residual bearing capacity and anti-collapse mechanisms of the single-layer cable-net roof structure, such as cable force redistribution and configuration change after cable failure. Furthermore, the corresponding analysis methods and evaluation indexes for cable-net structures are rarely put forward.

The single-layer cable-net roof is a flexible full-tension structure system with all structural members consisting of prestressed cables. A the cable failure will lead to significant changes in cable force redistribution and configuration. Meanwhile, the cable force and configuration change characteristics,

force transmission mechanism, and collapse resistance are quite different from those of other spatial structure systems. Therefore, this paper took the Annular Crossed Cable-net Structure (ACCN) as the research object and first puts forward the method of determining the load-bearing level of cable elements and the scheme of cable grade classification. To study the anti-collapse mechanism of the cable-net structure and to evaluate the bearing capacity of the structure after the cable failure, a collapse process analysis method of the cable-net structure is proposed. Finally, two effective design measures to improve the load-bearing capacity of the cable-net roof are presented.

2. Analysis model of ACCN

ACCN (Figure 1) [5] is a flexible full-tension saddle-shaped single-layer cable net system, in which both ends of the cables are directly connected to saddle-shaped outer ring beams. By arranging the cables in a circular cross, a large opening is formed in the center. This architectural shape is similar to a single-layer wheel-spoke cable-net, but there is no inner ring cable, so it is also called the single-layer cable-net structure without inner ring [6].

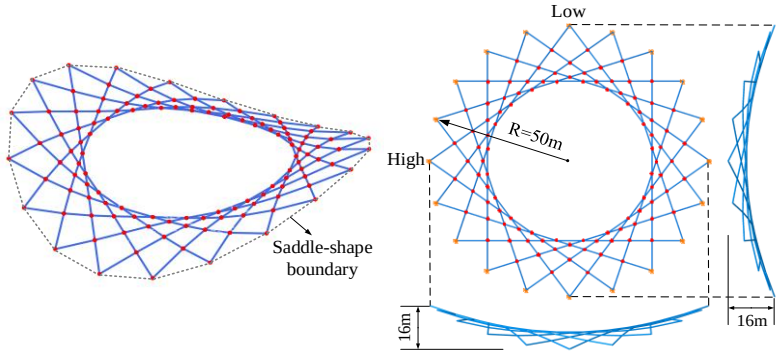

Figure 1 The model diagram of ACCN

The analysis model of ACCN was established with a structural span of 100m, the height difference of the hyperbolic outer ring boundary is 16m, and 20 cables are arranged in an annular direction. The structural layout is shown in Figure 1. The density, elastic modulus, and ultimate strength of the cable are 7850 kg/m^3, 160 GPa, and 1680 MPa, respectively. Considering the gravity of the membrane roof and equipment, the dead load is 0.15kN/m^2 and is equivalent to node concentrated load. The density of the cable is enlarged 1.2 time considering the gravity of the cable clamps at the node. The live load is considered to be 0.3 kN/m^2. The diameter of the cables that meet the structural design requirements [7,8] is 64mm, and all of the cables share the same size. Only the cable net is analyzed, and the boundary constraints are hinge constraints. The load combination (1.2 dead loads + 0.5 live loads) is used according to the code [9]. The cable element between nodes was divided, so that each cable has 11 elements, thus the total element number of 20 cables is 220.

3. Classification of load-bearing grades of cables

The strain energy is selected as the parameter by considering the cable force and deformation from the energy point of view. The greater the proportion of the strain energy increment of a cable element in the cable net to the total strain energy increment when the load is increased under normal conditions, indicating that the bearing grade of this cable element is higher. The corresponding Eq. (1) is as follows:

$$\gamma_i = \frac{U_{1i} - U_{0i}}{\sum_{i=1}^{n}(U_{1i} - U_{0i})} \tag{1}$$

where, γ_i is load-bearing coefficient of cable element i, U_{0i} is the strain energy of the cable element i at the normal state, U_{1i} is the strain energy of the cable element i after increasing the load ΔF. The cable element is in an elastic state and only bears the axial tension, and the strain energy can be expressed as follows:

$$U_i = \frac{0.5{F_i}^2 L_i}{E_i A_i} = \frac{0.5{\sigma_i}^2 V_i}{E_i} \tag{2}$$

where, F_i is the cable force of the element i, L_i is the cable length of the element i at the zero-stress state, σ_i is the stress of the element i, V_i is the volume of the element i at the zero-stress state, and E_i and A_i are the elastic modulus and cross-sectional area of the element i, respectively. Substituting Eq. (2) into Eq. (1), the load-bearing coefficient γ_i can be obtained as follows:

$$\gamma_i = \frac{({\sigma_{1i}}^2 - {\sigma_{0i}}^2)V_i}{\sum_{i=1}^{n}({\sigma_{1i}}^2 - {\sigma_{0i}}^2)V_i} \tag{3}$$

Eq. (3) indicates that the change degree of stress square difference of the cable element before and after increasing the load ΔF. The larger γ_i is, the higher of load-bearing the corresponding cable element is. According to the model shown in Figure 1, the load increment is 1 time of the live load. The load-bearing coefficients of the cable elements are calculated according to Eq.(3) by the incremental load method.

It is illustrated in Figure 2 that the load-bearing coefficients are obviously divided into two parts. The ones greater than 0 are the load-bearing cable elements, and the other ones less than 0 are the stable cable elements. The maximum load-bearing coefficient of all elements in each cable is selected and ranked for all cables in descending order, as shown in Figure 3. The maximum load-bearing coefficient of the elements in each grade of cables is listed in Table 1. The load-bearing value of cables from grade I to grade VI decreases step by step. Grade I to grade III are load-bearing cables and grade IV to grade VI are stable cables. The elements (122, 132, 166, 167) with the greatest load-bearing coefficient appear at the two ends of the grade I cable (C12, C16) (Figure 3). They are the most load-bearing elements of the whole cable-net structure.

4. Evaluation of load-bearing capacity for ACCN

4.1. Multi-Step loading-unloading method

The key to the load-bearing capacity analysis is to determine the ultimate load and residual ultimate load of the structure, which can effectively analyze the structural performance in each stage of cable failure. Due to the changing trend of F_n (n = 0,1,2,···), a multi-step loading-unloading method is proposed to calculate the residual ultimate load at each stage of cable failure. The algorithm steps are as follows:

1) The dead and weight load of the cable-net structure in the normal state are included, and the incremental load is equivalent to the node concentrated load according to the full live load. The incremental load is calculated by the Bisection method. First, the cable force is calculated by taking a larger load F_p which ensures that F_0 is between 0 and F_p. The load range is reduced so that F_0 is between $F_p/2$ and F_p, and then this range is continuously reduced until F_0 is obtained.

2) The first group of failed elements reaching their ultimate strength (1680MPa) is deleted. The residual structure is loaded step by step from 0 to F_0 in small increments, i.e., the increment force $\Delta F = F_0/m$ (m=1000). When certain elements reach their ultimate strength in step n, these elements are the second group of failed elements, and the load at this step is calibrated as F_1, i.e., $F_1 = n_1 \Delta F = \beta_1 F_0$,

   where n_1 is the step number of the load increment, β_1 is the reduction coefficient of bearing capacity at the failure of the first group of cables.

3) The second group of failed elements is deleted. According to the same method used in step 2, the load F_2 and the corresponding failed elements are obtained. This process is repeated, until the structure loses bearing capacity and collapses. The corresponding loads $F_0[1, \beta_1, \beta_2, \cdots, \beta_n]$ and failed elements at each stage are obtained.

The failure mechanism of the cable-net structure is analyzed according to the cable force redistribution and configuration changes in each stage of the cable failure. Two indexes both average and maximum displacement are used to reveal the changing trend of configuration of the structure. The curve of the reduction coefficient of bearing capacity is used to evaluate the anti-collapse performance of the cable-net structure.

4.2. Collapse process analysis for ACCN

The ultimate load F_0 obtained by the above method is 6.3 kN/m^2. The curves of displacement change, and the reduction coefficient for bearing capacity are shown in Figure 4, and Figure 5, respectively.

It can be seen from Figure 4 that the order of cable failure follows the grade standard defined by the load-bearing coefficient in Figure 3. Grade I cables, as the most important load-bearing cables, fail first, and then it is grade II to grade V in turn. After the fifth group of cables fails, the cable net deformation increased sharply (from 5.3m to 9.5m in Figure 4), and only two cables (grade VI) were left to connect, and the structure lost bearing capacity. The trend of average displacement (Figure 5) shows a parabolic decline. With the increase in failure times, the displacement increment gradually increases. The maximum displacement (3.3m) before the cable failure is smaller than that (2.5m) when Grade I cables fail. This is mainly because F_1 is less than F_0, which makes the middle area of grade VI cables suffer from large node forces.

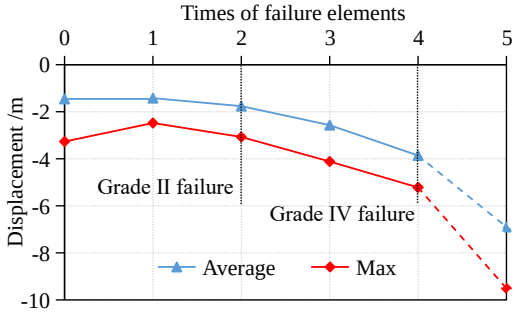

Figure 4 Curve of displacement change.

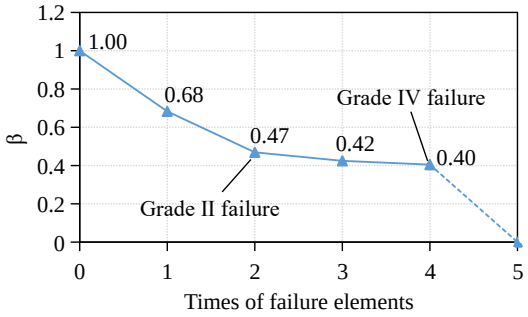

Figure 5 Curve of the reduction coefficient of load-bearing capacity.

It is possible to evaluate the structural bearing capacity in any cable failure through the curve of reduction coefficient for bearing capacity (Figure 5). Table 2 shows the residual ultimate loads corresponding to the number of failed cables.

Table 2 Residual ultimate loads corresponding to numbers of failed cables

Number of failed cables	0~2	3~6	7~10	11~14	15~18
Residual ultimate loads /F_0	1~0.68	0.68~0.47	0.47~0.42	0.42~0.40	0.40~0

5. Load-bearing performance improvement

It can be found from the above analysis that delaying the failure of the grade I cables of the cable-net structure is the key to improving the ultimate bearing capacity. An effective way to change the collapse failure mode of the cable-net structure is by adjusting the breaking order of the cables. Therefore, three effective ways to improve load-bearing performance are presented.

5.1. Improve the strength of cables and use CFRP cables with high tensile strength

The density, elastic modulus, and ultimate strength of CFRP cables are 1500kg/m^3, 160GPa and 2.4GPa, respectively. The density of CFRP cables is 0.19 times that of steel cables, and their ultimate strength is 1.43 times that of steel cables. Under the same conditions except for the replacement of cable materials, the importance grade of cables is not changed. The failure sequence of the cables is the same as that in Figure 3. Thus, only the ultimate bearing capacity is analyzed here.

The ultimate load F_0 calculated by the steel cable structure is taken as the unit comparative value. The curve of reduction coefficient of bearing capacity for the structure with CFRP cables is shown in Figure 6. The ultimate load of the CFRP cable structure is about 1.74 times higher than that of the steel cable structure. After the first group of cables fail, the residual ultimate load F_1 of the CFRP cable structure is still greater than the ultimate load F_0 of the steel cable structure. The changing trend of both curves is similar. The residual ultimate load of the CFRP cable structure in each stage is obviously improved. This indicates that replacing steel cables with CFRP cables can effectively improve the bearing capacity and collapse resistance of the structure.

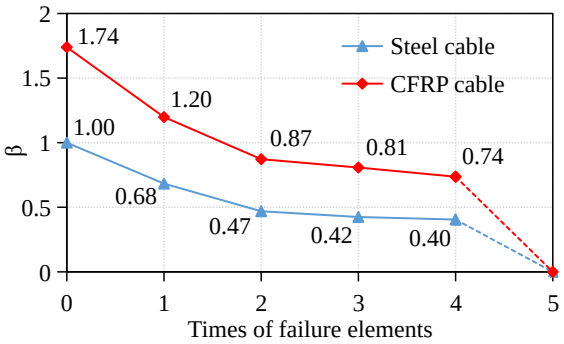

Figure 6 Comparison of bearing capacity curves between CFRP cables and steel cables

5.2. Increase the cross-sectional area of the load-bearing cable

Based on the model in Figure 2, the cross-sectional area A of the cable is doubled according to the three situations of the grade I cables (A1), the grade I cables to grade II cables (A12), and the grade I to grade III cables (A123) in Figure 3. It can be seen from Eq. (3) that the importance grade of the cable is unchanged. The ultimate cable forces of some cables are doubled, however, which will change the order of cable failure. At the same time, the ultimate load and the residual ultimate load in each stage also change accordingly, as seen in Figure 7. The reduction coefficient of bearing capacity and failure order of the cables have been listed in Table 3.

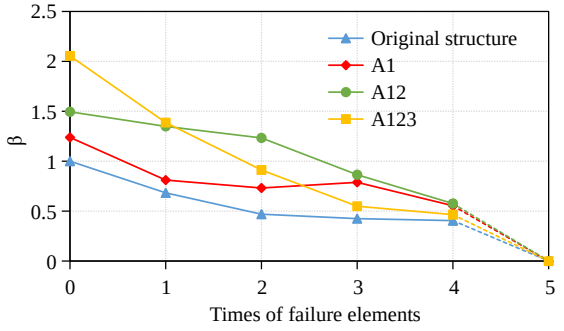

Figure 7 Influence of increasing cross-sectional area of load-bearing cables on bearing capacity

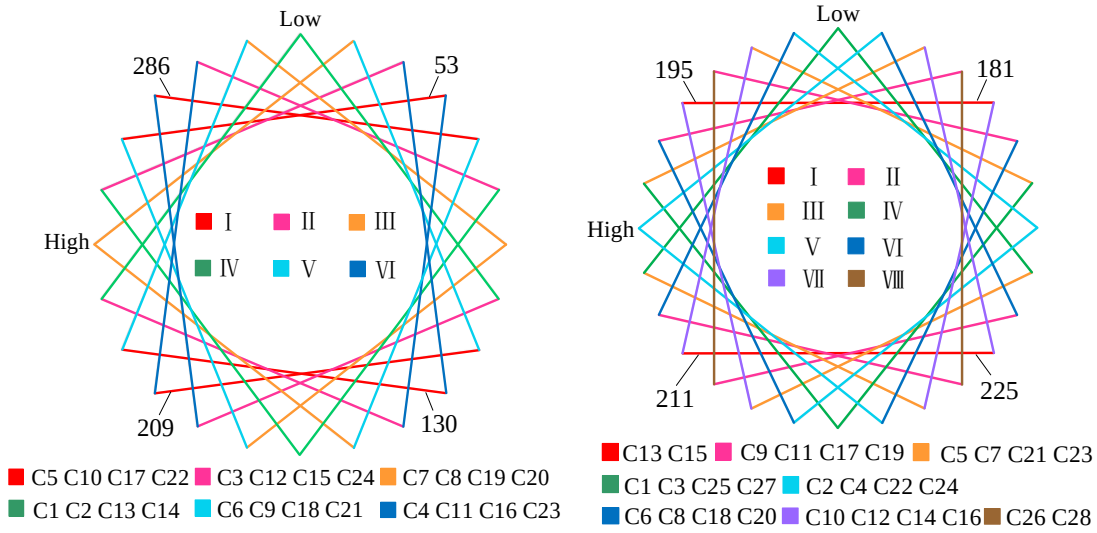
It can be seen from Figure 7 and Table 3 that the ultimate load F_0 gradually increases with the increase of the cross-sectional area from the grade I cables to the grade III cables. Meanwhile, the residual



ultimate loads of each stage in the three schemes are higher than the corresponding value of the original structure. This indicates that increasing the cross-sectional area of the load-bearing cable according to the rank order can effectively improve the collapse resistance of the structure. For scheme A1, the residual ultimate loads from the first failure to the third failure are all close (0.81,0.73,0.79). The residual ultimate load for A1 decreased significantly after the fourth failure, i.e., after the grade I cable was broken. This illustrates that the increase of the ultimate cable force of the grade I cable can improve the residual bearing capacity of the structure. For scheme A123, the ultimate load has increased to twice that of the original structure and the failure sequence of the cables is the same as that of the original structure. When the second group of cables fail, the residual ultimate load for A123 is already smaller than that of the corresponding A12. The residual ultimate load for A123 is close to that of the original structure when the third cable fails.

Table 3 Changes of bearing capacity of the structure by increasing the cross-sectional area of the load-bearing cable

Failure times		0	1	2	3	4	5
Reduction coefficient of bearing capacity	Original structure	1.00	0.68	0.47	0.42	0.40	0.00
	A1	1.24	0.81	0.73	0.79	0.55	0.00
	A12	1.50	1.35	1.23	0.86	0.58	0.00
	A123	2.06	1.39	0.91	0.55	0.46	0.00
Failure cable	Original structure	None	grade I	grade II	grade III	grade IV	grade V
	A1	None	grade II	grade III	grade IV	grade I	grade V
	A12	None	grade III	grade IV	grade II	grade I	grade V
	A123	None	grade I	grade II	grade III	grade IV	grade V
Number of failed elements	Original structure	0	4	4	4	16	32
	A1	0	4	4	16	4	32
	A12	0	4	16	4	4	32
	A123	0	4	4	4	16	32

5.3. Increase the number and grade of cables

The number of cables in the original structure (Figure 1) is 20. Two new models were designed, named M1 and M2 respectively. The number of cables in M1 is 24. Each cable is divided into 13 elements (Figure 8a). The number of cables in M2 is 28. Each cable is divided into 15 elements (Figure 8b). The rest of the conditions are the same as the original structure. For the two new schemes, the cable grades obtained by the importance coefficient of the cable elements according to Eq. (3) are shown in Figure 8. Their maximum importance coefficients are 0.028 and 0.023 respectively, and the corresponding cable elements are also shown in Fig. 8. Compared with the original structure, the maximum importance coefficient decreases with the increase of the number of cables, which shows that the influence of a single cable failure on the structure is gradually decreasing.

(a) (b)

Figure 8 Schematic diagram of cable importance grade for two new schemes:(a) M1 (24 cables), (b) M2 (28 cables).

For scheme M1 (24 cables), the cable importance grade is divided into 6 levels, which are the same as the original structure, but the quantities of grade I and grade VI cables have increased from two to four. For scheme M2 (28 cables), the cable importance grade is divided into 8 levels. The number of grade I and grade VIII cables is two, which is the same as the number of grade I and grade VI cables in the original structure. Due to the increase in the number of cables and nodes, the cable net becomes denser, the load shared by each cable decreases, and the bearing capacity will be improved, as shown in Figure 9.

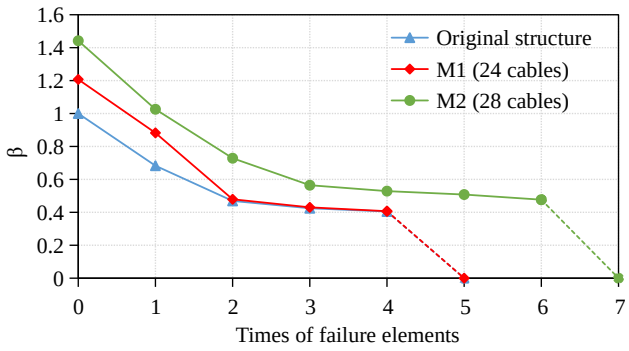


Figure 9 Influence of increasing number of cables on bearing capacity of structures

The failure sequence of the cables of the two new structures also follows the ranking of cables. The grade I cables are the first to break, their failure positions are the same as those of the original structure, and they all appear at the ends of the cables (Figure 3). With the increase in the number of cables (20,24,28), the ultimate load increases proportionally (1:1.21:1.44), as seen in Table 4. The residual ultimate load for M1 after the failure of the grade II cables is close to that for the original structure. Adding grade VI cables has no effect on the bearing capacity of the structure, and structural collapse still occurs after the failure of the grade V cables. For M2, as the cable grade increased by two levels, the structure collapsed only after the failure of the grade VII cables. The whole collapse stage of M2 is prolonged with the increase of cable grades, and the residual ultimate load of each stage is higher than that of the original structure.

Table 4 Comparison of reduction coefficients of bearing capacity for different cable numbers

Cable failure grade	None	I	II	III	VI	V	VI	VII
Original structure	1.00	0.68	0.47	0.42	0.40	0.00	—	—
M1 (24 cables)	1.21	0.88	0.48	0.43	0.41	0.00	—	—
M2 (28 cables)	1.44	1.03	0.73	0.56	0.53	0.51	0.48	0.00

6. Conclusion

This paper took the annular crossed cable-net roof structure (ACCN) as the research object and put forward the load-bearing grading method of cables and the evaluation of load-bearing capacity according to the characteristics of the cable-net structure. The bearing capacity and failure mode of ACCN were detailed. Three effective measures to improve the load-bearing performance of the structure were put forward. Some important conclusions are as follows:

(1) The load increment method is used to calculate the strain energy increment of the cables for the cable-net structure. This method can effectively judge the load-bearing level of the cable elements, divide the load-bearing cables and stabilizing cables, and determine the load-bearing grade of the cables. The load-bearing grade of the cables for ACCN is mainly related to the number of cables and the saddle-shaped boundary conditions.

(2) The ultimate load and the residual ultimate load in the collapse process analysis of the cable-net structure can be calculated by using the multi-step loading-unloading method. Through drawing the curve of reduction coefficient of bearing capacity, the failure sequence of the cables can be sorted out and the bearing capacity of each stage can be evaluated. The load-bearing grade of the cables is the key index to determine the failure sequence of the cables.

(3) Using CFRP cables, increasing the cross-sectional area of the load-bearing cables and increasing the number and grade of cables can effectively improve the load-bearing capacity of the cable-net structure. For ACCN, increasing the section area of all load-bearing cables is the most effective way to improve the ultimate load, followed by using CFRP cables; increasing the number of important grades of cables is the most effective way to increase the residual ultimate load and delay the collapse of structures, followed by using CFRP cables.

Abstract

The main stage of Chengdu Open-Air Music Park is one of the iconic projects in Chengdu's effort to build a music city. It is the world's largest semi-open-air and semi-indoor double-sided theater with panoramic sound and will also serve as the main venue for the closing ceremony of the 31st World University Games. The main stage roof is composed of two parts: an independent canopy and a grandstand canopy. This article focuses on the independent canopy. The independent canopy adopts a system of inclined plane arches, single-layer cable nets, and double-sided covering membranes. The arch span is 180 meters, and a pentagon-shaped solid rib arch with a jewel cross-section was used through boundary stiffness calculation and morphological comparison analysis. Hyperbolic paraboloid cable nets were used between the inclined arches, with a load-bearing span of 90 meters and a stable span of 136 meters. By optimizing the parameters of the cable net, such as sag, arch height, initial tension ratio between the load-bearing cable and the stable cable, and cable net spacing, the structural force, material consumption, and construction difficulty were all optimized to achieve the best comprehensive state. A reinforcing ring was installed between the arches at a height of 15 meters above the ground, which effectively reduced the outward bending moment of the arch surface by 50%. This not only saved materials and reduced the weight but also enriched the building facade effect. The cable net is covered with an inner and outer double-layer membrane, with an inner membrane of about 5,000 square meters of smooth surface, forming a projection canopy for music performances. The outer membrane, combined with the parameterized simulation of drainage, uses a bamboo-shaped arch membrane. The roof form of cable and membrane significantly reduces the weight of the structure and is advantageous to the foundation design. The support adopts a gravity-type anti-push foundation scheme, embedded in medium-weathered sandy mudstone.

1. Introduction

Chengdu Open-Air Music Park is located in the northern third ring road of Chengdu City, Sichuan Province, and is one of China's top cultural and artistic theme park. The main stage has a projected area of approximately 14,400 square meters, making it the world's largest semi-open-air and semi-indoor double-sided theater with panoramic sound. The roof is mainly composed of two independent structural units: a grandstand canopy supported on the concrete grandstand and an independent canopy, as shown in Figure 1. The following highlights the independent canopy.

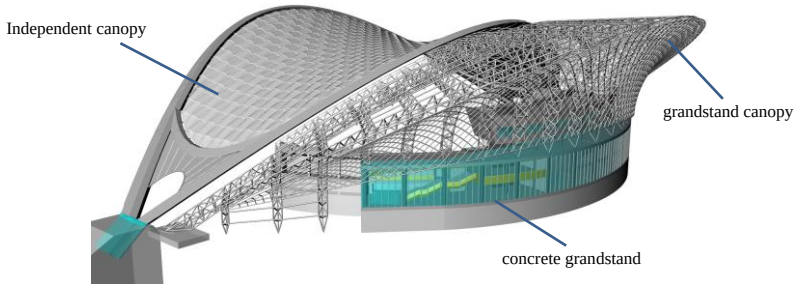

Figure 1: Schematic Diagram of Main Stage Composition

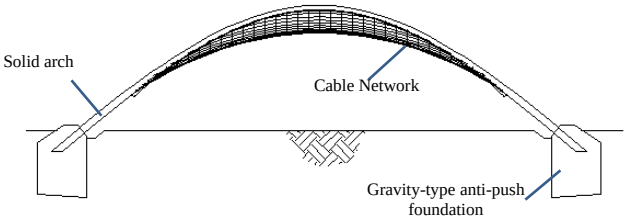

2. Structural system

The stage design for outdoor performances with varying formats has no precedent to draw on. The strategy for architectural design is to provide a sufficiently large space and well-reserved conditions to meet the demands of different forms of performances. The coverage area of the main stage canopy is over 10,000 square meters, which can be used for semi-outdoor performances of up to tens of thousands of people in the space under the roof, or outdoor performances using the terrain. The stage position can be adjusted according to different performance needs, creating the concept of a double-sided viewing experience.

The design philosophy of the building requires a large, transparent roof that can provide shade and shelter. The weight of the roof and the components that transmit wind and seismic forces to the foundation should be as small as possible, to achieve an outdoor-like viewing experience under the roof.

To realize the above design philosophy of the architect, the independent canopy adopts a large-span space structure with only two ground supports and a span of 180 meters between supports. This structure is composed of multi-sided steel arches with full-section support, intersecting at two oblique planes, and supporting a single-layer hyperbolic paraboloid cable net. The two main arches on the left and right are oblique arches, and their axes are obtained by the intersection of oblique planes and hyperbolic paraboloids. The angle between the oblique plane and the horizontal plane is 46.548°. The two oblique arches are connected by two strengthening rings to enhance the overall performance of the structure. The longitudinal span of the main arch is 180 meters, the horizontal distance between the top axes of the two main arches is 90 meters, and the height of the arch is 47.5 meters (±0.000, above 44.5 meters). The overall structural diagram is shown in Figure 2.

The hyperbolic paraboloid cable net is supported on the oblique arches and strengthening rings, with 33 horizontal load-bearing cables and 21 vertical stabilizing cables. The maximum span of the central load-bearing cable is 90 meters, the sag is 9 meters, and the sag-to-span ratio is 1/10. The maximum span of the central stabilizing cable is 136 meters, the arch degree is 22 meters, and the arch span ratio is 1/6.2. The horizontal projection distance between the load-bearing cable and the stabilizing cable is 4 meters, and both use Φ48 high-vanadium cables.

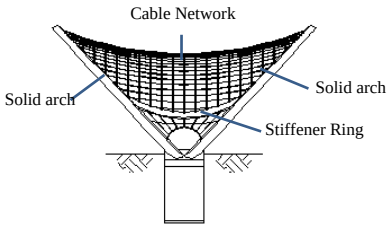

Figure 2: Schematic diagram of double oblique arches supporting a single-layer hyperbolic paraboloid cable net structure

The arch is located in the inclined plane, and the gravity points away from the arch plane. In addition to the force component within the arch plane, gravity also has a component pointing outside the arch plane, causing bending stress on the arch. For a sloping arch with a top height of about 45 meters and a vector height of about 65 meters within the arch plane, this bending moment is significant. The tensile force of the cable located on the other side of the arch plane is such that its external force component largely cancels out the gravity's external component. As shown in Figure 2, by adding a stiffening ring to the appropriate position of the arch, the calculation span of the bending moment outside the arch can be significantly reduced. At the same time, the maximum bending moment inside the arch and the maximum bending moment outside the arch occur at different positions, greatly reducing the demand for the arch section and making the material more effectively utilized. Adding stiffening rings also enriches the building's elevation.

The single-layer cable net provides balance for the gravity load's external component for the sloping arch, and the solid steel arch of the sloping plane, with a large external stiffness, in turn serves as the rigid boundary of the single-layer cable net. The single-layer cable net and the solid steel arch of the sloping plane work together to form a stable spatial structural system.

The upper and lower surfaces of the canopy's single-layer cable net are covered with a PVDF film. The outer film uses a bamboo joint-type arch film combined with drainage in a parametric simulation, serving as a sunshade and rain shelter. The inner film forms a smooth inner surface of about 5,000 square meters, which, when used for performances, projects changing and stunning light and shadow effects in conjunction with the sound effects.

Figure 3: Actual performance scene

3. Analysis and design

The project is located in an area prone to earthquakes, and the effects of seismic motion on the structure cannot be ignored. The project is adjacent to the city viaduct and hills, with a complex wind environment, and the response of the structure under wind loads needs to be carefully studied. The exposed polygonal solid ribbed steel arch is subjected to significant temperature differences between the sunny and shady sides due to solar radiation, which may significantly affect the structure. Individual cables should not break and cause continuous collapse of the structure due to accidental factors. The effect of construction procedures on the distribution of internal forces in the structure needs to be understood clearly before determining the final construction method. The structural engineer needs to have a precise and clear understanding of the mechanical behavior of the structure under all possible loads and actions during

construction and use throughout the entire life cycle before adopting targeted design strategies and using them to guide structure construction.

The designer conducted various static analysis or quasi-static analysis, dynamic analysis, stability analysis, and other calculation analyses for the structure under various working conditions. The following mainly introduces the calculation and analysis of the static and seismic performance of the structure and the analysis and design of the steel arch.

3.1 Static analysis

Static analysis or quasi-static analysis is the basis for other analyses. The analysis considers dead, live, and wind loads, and unfavorable situations such as non-uniformly distributed live loads.

Under typical working conditions of the double inclined arch carrying a hyperbolic paraboloid cable net structure, the maximum stress ratio of the main arch is 0.753, the maximum stress ratio of the stiffening ring is 0.668, the bearing cable is 0.289 times the breaking force, and the stability cable is 0.498 times the breaking force. Under each typical working condition, the maximum deflection in the arch plane is 123mm, and the deflection-to-span ratio is 1/1453; the maximum deflection outside the arch plane is 356mm, and the deflection-to-span ratio is 1/505; the maximum vertical displacement of the cable net is 576, and the deflection-to-span ratio is 1/236. The stress ratio of each component (breaking force of the cable) and the vertical displacement of the structure are all smaller than the limit values in the Chinese specifications.

Supplementary analysis was performed using plate shell elements for the solid ribbed steel arch. Near the nodes of the solid arch and the stiffening ring, and near the nodes of the arch feet, the stress level of the plate shell element model is significantly smaller than that of the beam element model. The reason is that when modeling with plate shell elements, the size effect of the nodes can be reflected, and the solid arch and the stiffening ring near the nodes have been merged into a common cross-section under the same force, which cannot be reflected by the beam calculation.

3.2 Seismic performance

The project is located in an area prone to earthquakes, and to ensure the safety of the project under seismic action, the structure was analyzed under earthquake action.

The first 300 modes of vibration of the structure were calculated. The first 6 modes of vibration are mainly in-plane or out-of-plane vibration of the arch. The first mode has a period of 2.40s and is an out-of-plane vibration of the two arches in phase. The second mode has a period of 1.54s and is an in-plane anti-phase vibration of the two arches. The third mode has a period of 1.51s and is an in-plane in-phase vibration of the two arches.

The combination of the effects of three-directional seismic actions, with horizontal earthquakes as the main component, and the combination of effects of three-directional seismic actions, with vertical earthquakes as the main component, were considered separately and analyzed using the response spectrum method. Under rare earthquake actions, all components remained elastic, and the maximum stress ratio of the arch foot was approximately 0.727.

Two sets of ground motion records and one set of artificial waves were selected for rare earthquake time history analysis. Under rare earthquake actions, the stress ratios of all critical components were within 0.66, meeting the performance objectives of elastic behavior during large earthquakes.

3.3 Analysis and design of boundary arches

The hyperbolic paraboloid cable net has no stability issues. The stability of the boundary arches of the cable net and stiffening rings in the structural system should be investigated.

Taking into account the buckling characteristics of the arch and applying initial defects, when applying "half-span longitudinal (along the direction of the arch span)" live loads, the first-order eigenvalue

buckling mode (internal buckling of the arch surface) is used as the initial defect for calculation. When applying "half-span transverse" live loads, the third-order eigenvalue buckling mode (external buckling of the arch surface) is used as the initial defect for calculation.

Considering the arch as nonlinear and applying half-span live loads along the arch span, the minimum safety factor obtained through elastic-plastic full process analysis using the first-order eigenvalue buckling mode as the initial defect was 4.24.

The 180m-span steel arch requires a large section to bear the load. After visual analysis, both the main arch and stiffening rings use diamond-shaped pentagonal cross-sections, with the acute angles of the pentagonal cross-sections pointing towards the audience's line of sight, making the structure visible but not bulky. The cross-section gradually decreases from the arch foot to the arch top according to the internal force of the arch. The maximum contour size of the arch foot section is approximately 5m, and the contour size is reduced to approximately 3.2m at the arch top. The entire structure appears lightweight and dynamic.

The rigid-jointed hingeless arch scheme with arch feet connected was adopted. After the two arch feet were combined into one, they were directly inserted into the slot of the gravity anti-sliding foundation cast in place. The anti-sliding foundation was embedded in the rock to reliably transmit the vertical force, thrust, bending moment, and shear force from the arch to the foundation.

4. Conclusion

Through analyzing the structural system, force characteristics, static and dynamic properties, and seismic performance of the independent canopy of Chengdu Open-Air Music Park, the following main conclusions can be drawn:

(1) The addition of stiffening rings between the two arches can significantly reduce the out-of-plane bending moment of the arch, and the maximum bending moment inside the arch and the maximum bending moment outside the arch occur at different locations. As a result, the stress on the arch section is greatly reduced, balancing architectural aesthetics and structural economy.

(2) The structure has good seismic performance. Even under rare earthquake conditions, the arch remains elastic.

(3) Although the arch and cable network structure have only two ground supports, they still have high safety.

The main stage of Chengdu Open-Air Music Park was put into use in May 2019 and has successfully held many performances and public welfare activities. The canopy has become a place for daily family activities, rest, and entertainment for many people. The closing ceremony of the 31st World University Summer Games will also be held on the main stage, and it is believed that this uniquely designed building will leave a deep impression on young athletes and audiences from all over the world.

Abstract

Vibration excitation can take full advantage of the characteristics of high strength-to-weight ratio, low modal frequency and natural impact resistance of tensegrity structure. Resonance-based amplification of dynamic response of structure is a simple and low-cost method to achieve efficient structure driving. This paper proposes a six-bar tensegrity structure based on vibration driving and applies it to the rescue and search scene after a disaster. Through high-altitude delivery, the vibration-driven tensegrity structure can be dropped on the ruins on a large scale and explore the unknown environment. Using numerical simulation method to explore the parameters that affect the kinematic performance of this tensegrity structure, it is found that the low-order vibration modes of the structure exhibit significant vertical and horizontal motion, which can excite the potential jumping, creeping and rotating gaits of the structure by vibration. Besides, it can be observed that the location of motors at the lower edge of the lower group of struts is the best initial position to promote structural locomotion. In addition, directional movement can be achieved by controlling the switching state of motors at different positions. A small low-cost prototype of wireless vibration-driven tensegrity structure is established, which can move freely in the designed two-dimensional and three-dimensional spatial paths to find an exit. It is verified that the success rate for finding the exit is increased by changing the vibration strategy.

Keywords: six-bar tensegrity structure, vibration-driven, finite element numerical simulation, kinematic performance, prototype, multiple gaits

1. Introduction

Tensegrities are pre-stress stable structures, consisting of a set of discrete struts suspended in a network of continuous cables, which fits the natural law of continuous tensioning and intermittent compression [1]. This high-efficiency principle can be found at all scales of nature organisms from cellular cytoskeleton, the structure of proteins up to the tendinous network of the human hand [2], [3]. Because of tensegrity system's inherent ability to distribute external forces through a synergistic interplay of inner axial force, it possesses many appealing traits, which are impressive strength-to-wight ratio, high redundancy, natural resistance to impact and controllable morphology. Meanwhile, multiple degrees of freedom means that the structure is dynamic and displays a diversity of locomotive gaits. Thus, there are promising applications for tensegrities in the emerging fields of robotics engineering [4] for aerospace exploration technology [5], [6] and disaster rescue scenes [7]. Since 2011, UC Berkeley and the NASA Ames Research Center had been conducting research on next-generation space exploration robots — the tensegrity-based "SuperBall", which can fulfill folding, buffering and scrolling functions [8]. In 2019, a tensegrity robot prototype from Agogino's research team performed a disaster rescue test where it was dropped from a height of 180m into a rock pile by a drone and then searched the site and sent feedback immediately from the rugged terrain.

Due to the flexible characteristics of tensegrities, small changes in shape or internal forces can cause complex nonlinear dynamic responses in structures, such as vibration resonances and tight dynamic coupling between components. In conventional research, tensegrity-based structures or robots are considered quasi-static, implying high precision requirements of structural morphology controlling. Therefore, traditional engineering approaches take initiative control measures to avoid or suppress vibration to stabilize the structures in their equilibrium states and reduce harmful large deformations caused by resonance [9]. However, tensegrities with low and dense model frequencies are, by their very nature, highly sensitive to kinetic effect, which easily leads to high levels of vibration inspired by disturbance of external excitation [10]. Subsequently, a novel concept was proposed that exploiting complex dynamics of tensegrities as an advantage to facilitate their locomotion, rather than suppressing them at abundant cost [11].

Khazanov *et al*. [12], [13] designed a small (with 9.4cm struts) physical robot based upon a canonical six-bar tensegrity shape with open-loop actuation using three low-voltage vibration motors. The maximum linear locomotion speed of the robot was 4cm/s, and diverse gait behaviors were uncovered by changing the frequencies of motors. Liang from Zhejiang University revealed that the locomotive capabilities of vibration-driven tensegrity structure which include mode, linear speed and angular velocity have a discrete mapping relationship with the frequency parameters of vibration. Research at Union College lead by Professor John Rieffel [14] firstly fabricated a low-cost (approximately $100 for each strut with length of 15.5cm) wireless modular tensegrity robot with every self-contained module consisting of a vibration motor, a microprocessor capable of wireless communication, a three-axis motion sensor and two batteries. John Rieffel's research team [15] employed a Quality Diversity Algorithm to autonomously generate a behavioral repertoire of this robot, displaying110 distinct gaits, which is useful for adapting to changeable and complex conditions.

In addition to physical model tests, numerical simulation methods are also used for the study of the vibration characteristics of tensegrity structure. The results of research show that self-vibration properties of a tensegrity including natural frequency and its corresponding vibration modes depend on the equilibrium configuration of structure, the modulus of elasticity of material, and the magnitude of initial stress [16]. Besides, the parameters of excitation, including amplitude and frequency of vibration and the arrangement of actuators (position and number) will significantly affect vibration-driven dynamic response of structure, such as the direction and regularity of motion [17], [18].

Because of the complex dynamics of the tensegrity, vibration-driven motion exhibits a certain randomness, which is suitable for scenarios with low requirement for motion control accuracy, such as disaster rescue search. In the earthquake rescue, in order to prevent unknown danger, the tensegrity structures carrying infrared sensors, wireless communications and other devices can be dropped from high altitude into the large area of ruins and be used as the advance force performing a search mission to improve the efficiency and safety of the rescue. Besides, the scale of tensegrity structure can be miniaturized to enable them to enter inaccessible small space to humans, expanding the scope of rescue in depth and breadth. Benefitting by high impact-resistance of tensegrity, the structure and the devices carried can be well protected for repeated uses. Vibration driving is a simple method and only needs low-cost actuators, greatly reducing the expenses of rescue. Thus, research on kinematic performance of a vibration-driven tensegrity structure is promising both in its social and economic value.

Current studies on vibration-driven tensegrity are limited to a known and barrier-free level plane without considering the interaction between unknown and rugged terrain and the structure, which may influence the dynamic response of the structure. Furthermore, the control strategy of the tensegrity structure to explore within complex environments has not been systematically studied.

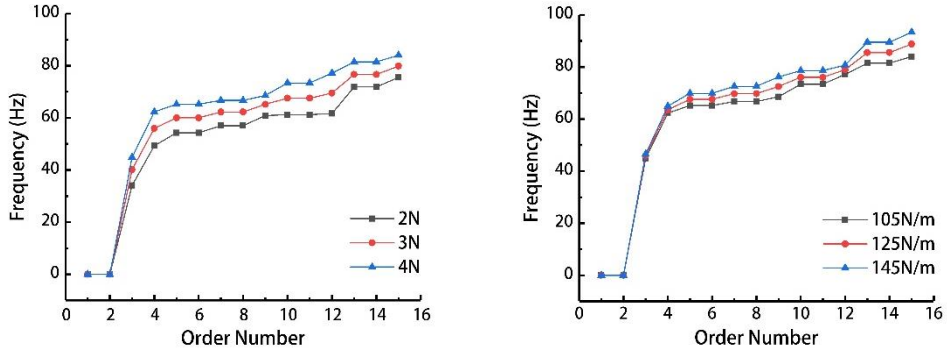
In this paper, in order to optimize the design of the physically vibration-driven tensegrity structure prototype and provide guidance for its motion control, we first investigate the effects of self-vibration characteristics, excitation parameters and the arrangement of motors on dynamic responses of a canonical six-bar tensegrity structure by using finite element numerical simulation methods. Next, we

develop a small low-cost and fully untethered tensegrity structure prototype excited by vibration, of which the total price will not exceed $20. Then, we construct two-dimensional and three-dimensional spatial paths with horizontal and vertical channels to simulate the complex terrain of disaster rescue search and conduct kinematic performance tests on prototype in the above environment. Finally, we summarize the control strategy for the vibration-driven tensegrity structure through experimental results to further promote the search capabilities of it in disaster rescue scenario.

2. Numerical simulation and analysis of vibration-driven tensegrity structure

A key point of using vibration excitation to drive the tensegrity structure and to fully exploit potential and beneficial dynamic response is to produce a resonance phenomenon. The tensegrity structure is a structural system with multi degrees of freedom, which has multiple inherent frequencies corresponding to multiple vibration modes. Some vibration patterns can help the structure jump higher and some can control the movement direction. Only if the pre-stress modal analysis of the tensegrity structure is carried out can we determine the appropriate vibration frequency range to accurately and safely guide the tensegrity structure to realize various functions. Through transient dynamic analysis, the effect of vibration frequency and vibration amplitude on the dynamic response of the tensegrity structure should be further investigated after considering the influence of the collision between the structure and the ground. Moreover, the location and quantity of motors have profound effect on efficiency and directionality of structural motion, so it is necessary to determine the optimal initial arrangement of motors and guide the motor switching strategies for changing the structural moving behaviors by numerical simulation.

A canonical six-bar tensegrity structure we based upon consists of six 10cm length carbon-fibre material struts that is connected to 24 identical springs and each strut end emanates four springs. Struts have tubular cross-sectional size of 6mm*8mm. Carbon-fibre material used for struts has awesome property with modulus of elasticity of 230GPa density of 1.67g/cm^3, significantly reducing the weight of structure. The spring selected with elasticity factor of 1.05N/cm will provide 3.28N pre-tension to the tensegrity structure.



2.1. Modal analysis based on Ansys Workbench

Modal analysis of above tensegrity structure is performed using the Pre-Stress Modal procedures in ANSYS Workbench. The plane where a closed triangle on the surface of the structure is located is positioned as the X-Y plane of local coordinate system. The mesh of each strut is divided into individual beam elements and springs connect strut ends according to the topology of structure. Subsequently, gravity fields are applied and the freedom of touchdown nodes at the vertical direction are constrained. Static solution is performed first, and then modal analysis is carried out considering the effect of structural deformation and its pre-stress stiffness on the natural frequency and vibration modes.

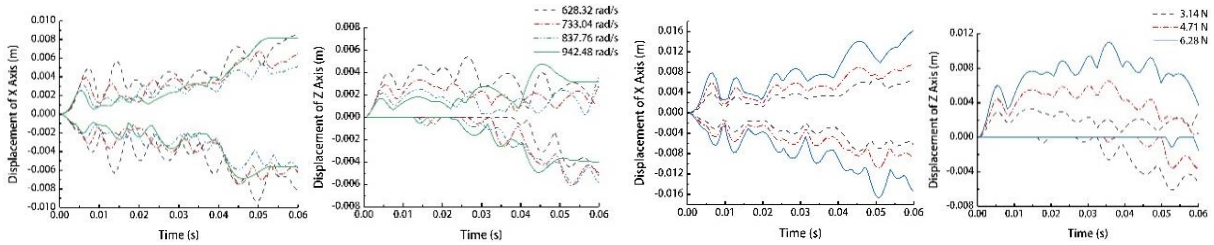
The results of the static analysis show that the ratio of tension to pressure accords with the theoretical value of 0.4082 and the inner forces are redistributed under gravity, which proves the validity of the numerical simulation model. Then, from the outcomes of structural pre-stress modal analysis, it can be concluded as follow:

(1) The first two orders of vibration modes are rigid body displacement, and the third shows bouncing up and down, the resonance of which may improve the jump height of structure;
(2) In the fourth to sixteenth vibration modes, the stretch and swing in X and Y directions appear in pairs corresponding to the same vibration frequency, which may explain the linear creeping gait, and the torsional pattern will appear randomly between above vibration patterns, which may be the essential reason for rotating gaits;
(3) The frequencies for different vibration modes have obvious gaps, which is conducive to controlling the structural locomotion characteristics by distinct frequency sets and carrying out regular motion of tensegrity structure;

(4) Starting from the sixteenth order, a completely new vibration mode that rigid struts swing in place appears, leading to an abrupt enlargement in the frequency values.

(a) different pre-stress under 105N/m (b) different spring elasticity factor under 4N

Figure 1. Comparison of natural frequencies of the first fifteen orders of tensegrity structures



The overall stiffness of the tensegrity structure is composed of the initial stress stiffness and the elastic stiffness. Through further investigation, we find that in the first fifteen orders of vibration modes, increasing the pre-stress can significantly enhance the low-order natural frequency, which suggests that the initial stress stiffness contributes drastically to the overall stiffness of the lower-order vibration modes. Besides, improving the spring elasticity factor causes growth in the natural frequency with the increase of the order by raising the elastic stiffness of the structure. Above the sixteenth order, the overall stiffness of structure is controlled by elastic stiffness of strut which is much larger than pre-stress stiffness and spring elasticity stiffness. The conclusions indicate that the spring modulus and pre-stress of the tensegrity structure should be selected properly so that the natural frequency range of the low-order useful vibration modes falls within the vibration frequency range of motors.

2.2. Transient dynamic analysis based on Ansys Workbench

In this model, a rectangular rigid body with fixed bottom surface is used to simulate the ground and the struts with hemispherical ends are created as solid elements. Then, the contact with frictional factor of 0.02 is set between the touchdown faces of structure and the ground. In a local coordinate system with the ground as the X-Y plane, a gravity load and cyclic vibration loads perpendicular to the axis of struts are applied to the structural model. The cyclic vibration load is decomposed by the inertial force of an eccentric mass block performing circular motion, which can be express as $F_I = m_1 e\omega^2$ from D'Alembert's principle (the mass of the block is m_1, the eccentric distance is e, and the angular velocity is ω). Its components in the X-axis and Y-axis can be represented by $F_{Ix} = F_I\cos(\omega t)$, $F_{Iy} = F_I\sin(\omega t)$ respectively. Since the tensegrity structure will emerge large nonlinear deformation when simple harmonic loads are applied at struts, the direct-integration method (Newmark method) is chosen to calculate. The total analysis time is set to 0.06s with automatic time step activated.

2.2.1. Analysis of the effect of vibration frequency and vibration amplitude on structural dynamic response

For physically wireless vibration-driven tensegrity structure, the vibration frequency selection is limited by the mechanical properties of the vibration motors, and the vibration amplitude is also influenced by vibrator mass and eccentric distance. The rotating speed of the vibration motor is between 6000RMP and 9000RMP after measured, so we take the circular frequencies ω of simple harmonic loads as 628.32rad/s, 733.04rad/s, 837.76rad/s, 942.48rad/s. The vibration amplitude is taken as 3.14 N for m_1=2g, e=1.768mm, ω=942.48rad/s, and at the same frequency, the amplitude of the vibration will vary in multiples to carry out the research.

(a) different vibration frequency (b) different vibration amplitude

Figure 2. Displacement-Time diagram in the X-axis and Z-axis for models

Figure 2(a) shows displacement-time diagrams in the X-axis and Z-axis for models with different vibration frequency applied under the same amplitude. The lower the vibration frequency, the larger the displacement of the structure, the reason of which maybe that the lower vibration frequency is closer to the low-order natural frequency of the structure. The spatial symmetry of the structural geometric configuration and applied loads leads to roughly symmetrical displacement in the x-direction. The reason for the negative value of the minimum displacement on the Z-axis is that part of the structure continues to move downward after collision of the structure with the ground, the figure also shows that the larger the vibration frequency, the earlier the structure falls and collides with the ground.

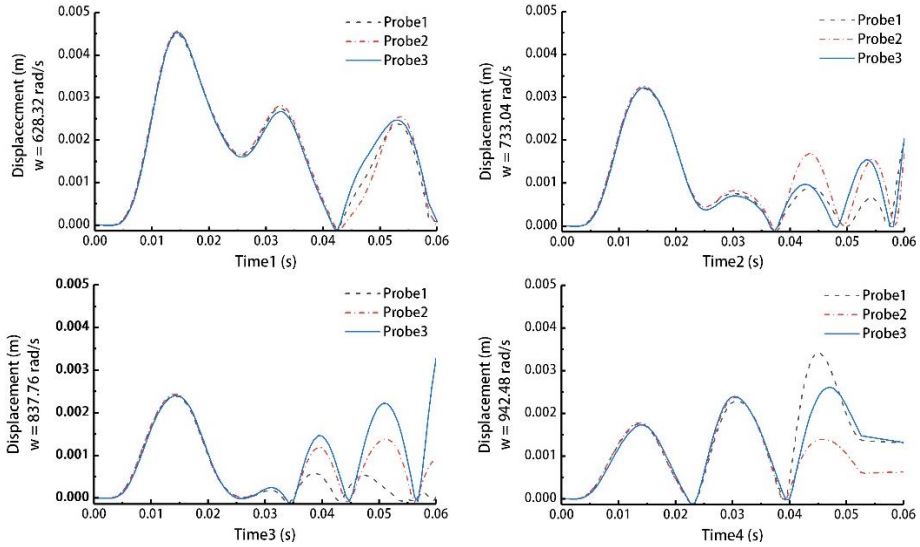


Figure 3. Displacement-Time diagram of the touchdown nodes in the Z-axis under different vibration frequency

According to displacement-time diagram of the touchdown nodes in the Z-axis, we can find that the displacements of different touchdown nodes deviate after the initial collision with the ground, and the difference gradually grows with the increase of vibration frequency. It indicates that the structure tends to be unstable and asymmetric under the excitation of high vibration frequency. Under different vibration frequency, the peak displacement of different touchdown nodes is ordered randomly. The displacement of the structure with high frequency vibration becomes larger after the collision with the ground. It implies that the reaction force of the ground can further promote the movement of the structure.

Figure 2(b) shows that the displacement of the structure multiples according to the variation of vibration amplitude. The smaller the vibration amplitude, the sooner the structure falls and collides with the ground.

2.2.2. Analysis of the effect of the location and quantity of motors on structural dynamic response

When a closed triangle surface of the structure contacts with the ground, the six struts can be divided into upper and lower groups. The loads are set at the middle (Site 1,2) and the lower edge (Site 3,4) of these two groups of struts respectively. When the research object is the quantity of motors, "one motor" load is applied at the middle of the upper strut connected to the node where Probe 3 is located, "two motors" loads are applied at the middle of the upper struts connected to the Probe 3 and Probe 2 respectively, and "three vibrations" all act in Site 1.

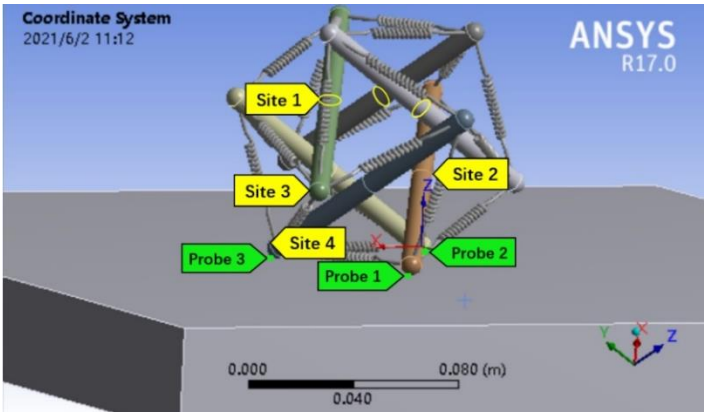

Figure 4. Vibration load position diagram

It can be concluded from the simulation results that the motor loads act at the lower edge of the struts cause much larger displacements than that acting in the middle, and its growth rate is significantly higher. The displacements also increase when loads act in lower group of struts. Minimum displacements on Z-axis caused by loads acting in Site 3 and Site 4 fluctuate immediately, the reason is that the vibration at the lower edge of the struts incurs rotation on the upper edge in the opposite direction. This leads to the lateral expansion and contraction of the structure. Therefore, it can be inferred that the location of motors at the lower edge of the lower group of struts is the best initial position to promote the dynamic response of structure. Meanwhile, the research presents that the larger the quantity of motors, the larger the displacement of the structure.

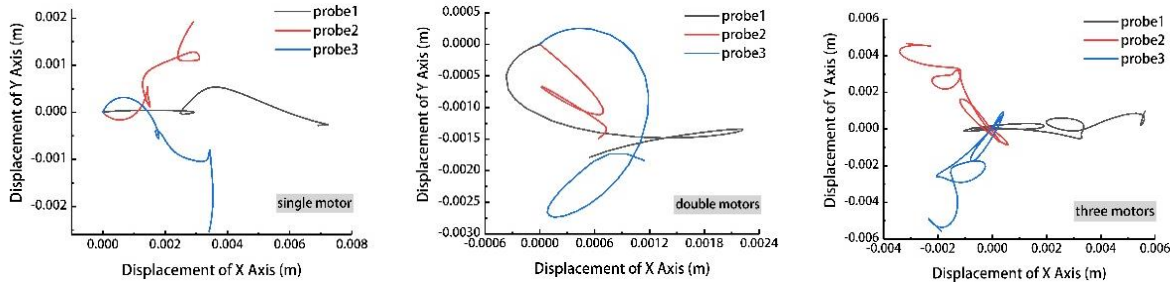

Figure 5. Trajectories of three touchdown nodes in the X-Y plane

Figure 5 shows that when exciting a single motor or double motors, the locomotion of three touchdown nodes is clearly directional while the trajectory under three vibration motors exhibits spatial symmetry. The results indicate that structural locomotion can be controlled by the switching state of the vibration motors.

3. The design of physically wireless vibration-driven tensegrity structure prototype

Our design criteria for this wireless vibration-driven tensegrity structure are as follows:

• **High Strength-Weight Ratio** - According to theoretical calculations, load provided by the vibration motor does not exceed 5N, so the lighter the weight of the structure, the smaller the energy loss of the

vibration drive. Considering that the tensegrity structure is used in disaster rescue scenarios where there exists a lot of hard debris which will cause severe wear on material, a tubular carbon-fibre strut with a cross-sectional size of 5mm*7mm is chosen.

• **Appropriate Natural Frequency -** In order to realize resonance-based motion control, a spring with an elasticity factor of 97 N/m and original length of 30 mm is selected as the tensile element of the structure, combining the experience of numerical simulation and the actual model parameters.

• **Modular –** The tensegrity structure possesses simple and equal-length elements, the assembly process can be expedited through modular joint design. The integrated joints are produced by 3D printing using nylon material. They are convenient for positioning, installing, and disassembling the components, increase the stability of the structure touching the ground and significantly reduce the mass of the joints. The prototype is built in the order from line to surface then from surface to body, which only takes 10 minutes for a single person.

• **Wireless-Driven –** It is important for the tensegrity structure to explore untethered in unknown and complex environments. So, a distributed self-powered vibration motor is used for wireless driving. The vibration motor is circuit welded to the button battery box with switch, and they are fixed to the strut with epoxy ab glue, so that the force of the vibration motor is steadily transferred to the structure.

• **Small Scale -** the length of each strut is 10cm, which allows this tensegrity structure to enter the narrow passages inside the ruins of the building.

• **Low Cost –** the actuate method of vibration-driven tensegrity structure is simple and the price of dynamical system is extraordinarily cheap compared to conventional actuator. The overall prototype only cost about $20, which is affordable for disaster rescue scenarios.

4. Kinematic performance tests against the tensegrity structure

The main purpose of the model tests is to verify the multi-directional motion performance, multi-gait kinematic performance and impact resistance of the vibration-driven tensegrity structure. After ensuring that the prototype is in normal working condition, the vibration motor is positioned at the lower edge of the lower group of struts as the optimal initial position, the motors are switched on and the prototype is placed at the beginning of the spatial path. The locomotion of the prototype is observed and intactly recorded by a stable fixed camera device. Each test will be stopped if the prototype stays at a position for more than one minute. It is seen that whether the tensegrity structure could change locomotion direction when encountering obstacles, whether it could find the exit smoothly, and what the influence is on structural dynamic response after the tensegrity structure falls and collisions with rigid slab.

4.1. Two-dimensional spatial path test

The wireless vibration system can control the switching state of vibration motors at different positions to achieve changes in vibration strategies of the tensegrity structure. We use the initial number of vibration motors as a variable in the two-dimensional spatial path test, and add a “combination” working conditions, that is, if the structure is trapped in the process of movement for more than 30s, the switching state of the motors are changed randomly to alter the dynamic behavior of the structure.

The two-dimensional spatial path test device is built with large particle blocks which can be freely assembled and a transparent acrylic panel encapsulating one side of the device which makes it easy to observe the locomotion of the prototype. The device possesses two horizontal motive directions and vertical falling spaces with maximum height difference of 25.6cm. The detailed dimensions are shown in Figure 6.

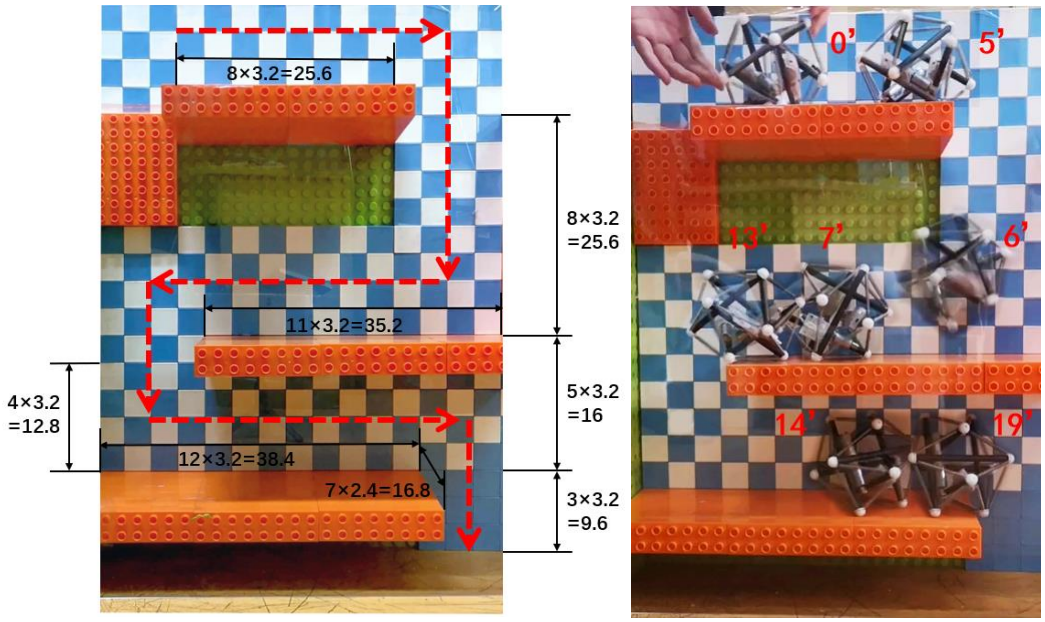

Figure 6. Dimensional diagram of the two-dimensional test device (left) and the record of the locomotion of the vibration-driven tensegrity structure (right)

We can conclude the kinematic performance of the vibration-driven tensegrity structure moving in the two-dimensional spatial path by repetitive experiments as follow:

(1) The speed test results shows that $V_{\text{triple-motor}} > V_{\text{dual-motor}} > V_{\text{single-motor}}$, the fastest unidirectional motion driven by three motors can reach 12.55 cm/s.
(2) The tensegrity structure will rotate anticlockwise or clockwise. The initial rotation direction is influenced by the vibration strategy. Then the structure will adjust the moving direction on its own based on the surrounding obstruction, moving forward or backward along the wall panel.
(3) The tensegrity structure performs stable vibration creeping gait before drops. Bouncing gait occurs after structure falls and collides with the rigid slab, and position of each strut changes correspondingly. When the structure continues moving and collides with the surrounding wall panels, the counterforce and gravity cause a rolling gait of the structure to adjust its gestures. Although there is no advanced control system, the vibration-driven tensegrity structure is sensitive to the surrounding environment and can find the exit successfully for its multiple degrees of freedom, multi-gait nature and easy perturbation of structural characteristics.
(4) The deformation of the tensegrity structure can buffer the collision impact, which ensures that it can move normally after falling. This exhibits high impact resistance of the tensegrity structure.
(5) If no manual control is applied to the vibration of the prototype during its locomotion, the success rate of the vibration-driven tensegrity structure in finding the exit is 65%. In the "combination" working condition, the prototype can stop ineffective movement in a dilemma and excite the complex dynamic response by changing the vibration strategy, after which it will alter the kinematic performance and find a way to move on. In this way, the success rate increases to 100 %.

4.2. Three-dimensional spatial path test

The three-dimensional spatial path test device is built by three uncovered boxes with a square bottom and a notch in one corner as the falling position. Different numbers of clapboards are arranged in the box under the principle of maximizing the travel routes of the prototype from the starting point to the notch, forming planar motion paths of different complexity. By adjusting the stacking order of the three boxes and changing the relative positions of the notches by rotation, we can achieve three-dimensional spatial paths of different complexity. The falling heights of this device are both 20cm and other detailed

dimensions are shown in Figure 7. The material used in this device is transparent acrylic for the convenience of observation.

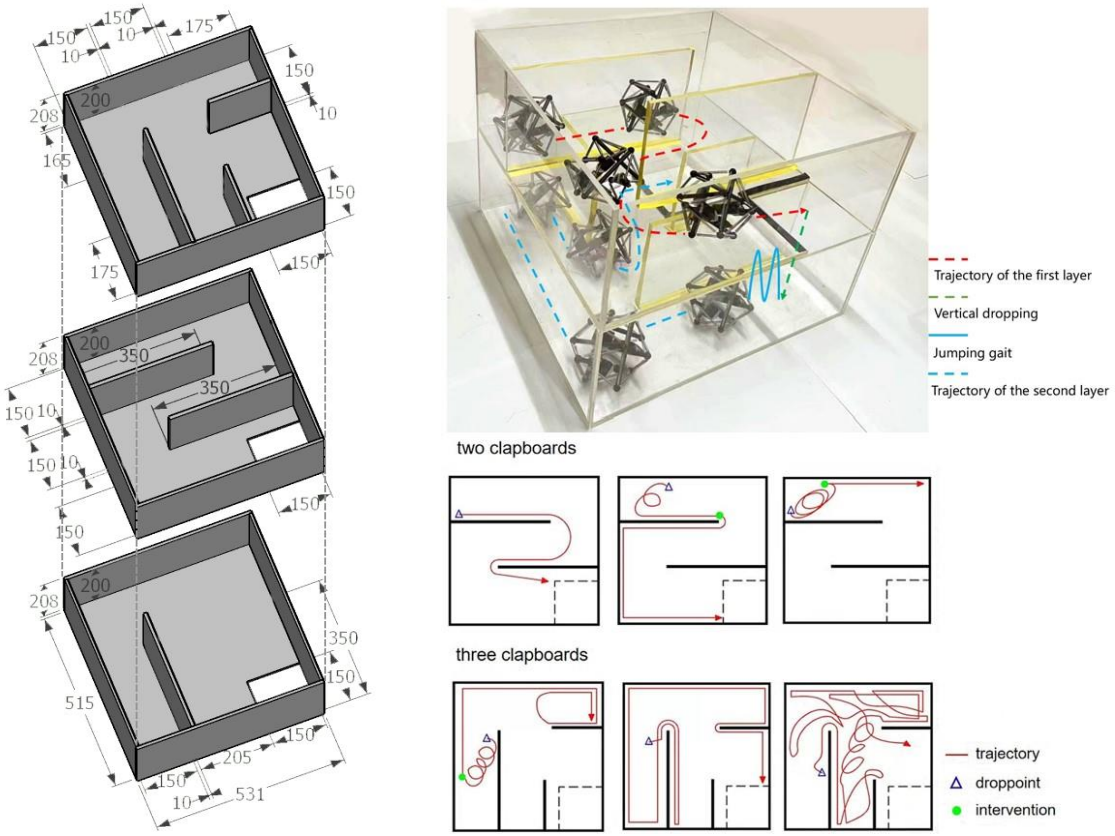

Figure 7. Dimensional diagram of the three-dimensional test device (left) and the record of the trajectory of the vibration-driven tensegrity structure (right)

We first place the prototype in single-layer box with different complexity for plane motion tests with obstacles. Based on the test results, we can conclude that the complex dynamic response of the tensegrity structure allows it to spontaneously adjust its motion angle by rotating gait to explore the passable path under the action of vibration motors and the interaction with the surrounding obstacles. At the same time, this dynamic complexity also adds randomness to the structural locomotion. After repetitive tests are carried out in the same environment, large discreteness of the time it takes to find the exit is observed for each experiment. Overlapping trajectories for each experiment can basically cover the whole plane space, which means full coverage of the exploration environment can be achieved by launching this tensegrity structure on a large scale. As the complexity of the planer paths increases, there is no significant difference in the success rate of the prototype in finding the exit, indicating that the vibration-driven tensegrity structure is highly adaptable to complex environments.

Three boxes are stacked together for three-dimensional spatial path tests, we are currently focusing on a fixed three-dimensional complex environment to discuss the strategy for controlling the vibration-driven tensegrity structure. The intervention scheme is used to adjust the switching state of the motors at different positions when the structure enters a dead end for a long period of time and cannot get out of the trap. Since the driving force of a single motor is too small, it is necessary to ensure that at least two motors are in working condition when adjusting. The results show that the success rate of the vibration-driven tensegrity structure in finding an exit in a 3D complex space without active intervention is only 30%; however, the success rate increases to 60% after intervention, indicating the necessity of

adding a controlled intervention module to the prototype. We also explore a more appropriate adjustment time, and finally decide to take 10s as the time criterion for performing active intervention.

5. Conclusion and future work

In this paper, the vibration modes obtained from numerical simulation reasonably explain the locomotion gaits exhibited by the vibration-driven tensegrity structure in the tests. Moreover, the transient analysis also verifies the complex dynamic responses of structure after collision, indicating the randomness of the structural motion. Further, the optimal initial arrangement of the vibration motor is determined, which can promote steady and efficient structural locomotion. Finally, the vibration-driven tensegrity structure shows awesome adaptation to complex environments, and its success rate in finding exits is significantly improved by the active intervention scheme.

We look forward to applying a closed-loop control strategy to the vibration-driven tensegrity structure, which can give feedback from on-board sensors such as accelerometers and carry out active intervention without manual operation. In addition, we are interested in using machine learning to further explore better control strategy and improve the ability of the structure to explore complex environments. It is also one of our ambitions to further enhance functions of the structure in real disaster rescue scenarios.

Abstract

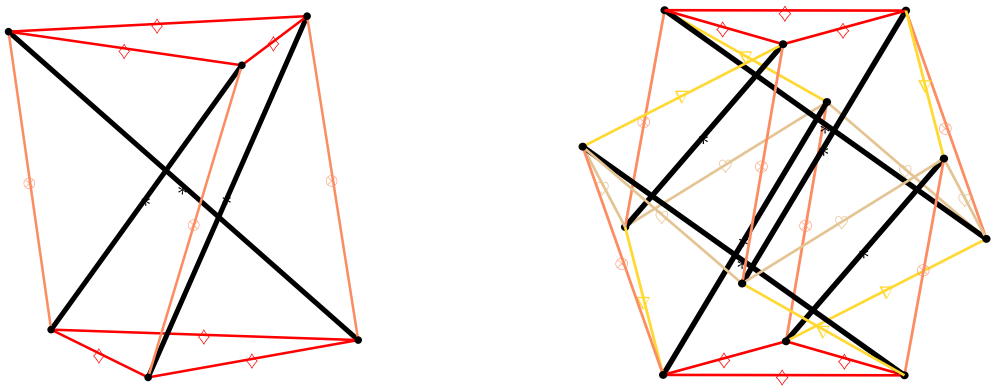
A tensegrity robot is a type of locomotive robot that is based on the principle of tensegrity, which can change their shape by adjusting their internal tension. Tensegrity robots can be classified into different categories according to their shape, such as spherical, quadruped, or spine-like, of which the spherical tensegrity robot has received the most attention. However, current designs tend to be relatively simple and lack standardized criteria for evaluating their locomotion capabilities. To address this issue, we propose an optimization approach using the force density method to generate new spherical regular tensegrity configurations. This is achieved by parameterizing the topology and configuration of the structure, while taking into account structural symmetry and evenness of internal forces. Our proposed approach not only generates classical tensegrities but also novel configurations suitable for locomotive robots. To evaluate the locomotion adaptability of these tensegrity configurations, we propose an evaluation method based on several geometric indicators such as inner space, foldability, prestress evenness, path rectilinearity, and geometrical instability. These indicators reflect the ability of tensegrity robots to move efficiently in different environments as well as manufacturing difficulty, storage ratio, and other characteristics, of different tensegrity configuration as potential robot candidates. A comparison study between existing tensegrity configurations and those obtained from optimization design is conducted.

Keywords: optimization design, spherical tensegrity, form finding, locomotive evaluation, geometric indicators

1. Introduction

The tensegrity is a kind of self-stressed pin-jointed system consisting of compression struts and tensile cables [1]. “Self-stress” means pre-stress equilibrated by itself. A distinguishing feature is that they change shape by adjusting their prestress, and they have advantages such as high resilience, adaptability, and energy efficiency, which makes it have potential applications as shape controllable and motion systems, such as smart structures, deployable structures, and locomotive robots.

Tensegrity robots can be divided into different categories such as spherical, prismatic, or spine-like according to their shapes. There have been many studies on these different types of tensegrity in recent years, among which the study on motion control of spherical tensegrity robots has received the most attention. This is due to the fact that spherical structures have a smoother outer shape, which makes it easier to rolling by changing their rest length. Shibata et al. experimentally validated the rolling behaviors of six-strut spherical tensegrity robots [2]. Wang et al. proposed a light-powered six-strut spherical tensegrity robot using liquid crystal elastomer-carbon nanotube composites as the light-powered actuator [3]. A novel spherical tensegrity robot based on a rhombicuboctahedron-like 12-strut tensegrity, i.e., T12-R, was able to move in a straight line and prevent the loss of momentum associated with the zig-zag path [4]. Baines et al. discussed the effect of the outer shape of different spherical tensegrity robots on motion ability [5].



Copyright © 2023 by Meijia WANG, Xian XU and Yaozhi LUO. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

Tensegrity robots are often limited to 6-strut and 12-strut structures due to control difficulties caused by increasing strut numbers and limitations of spherical tensegrity types, as the common spherical structures are generally derived from Archimedean polyhedra and Platonic polyhedra. In fact, there are many methods to find new tensegrities. Wang et al. proposes a method for determining the optimal topology and positions of struts and cables in a tensegrity structure [6]. Liu et al. proposes a method that seeks a topology of the tensegrity that is within a given geometry [7]. The design of tensegrities with better motion performance and the evaluation of different tensegrity configurations as spherical possible tensegrity robot candidates are likely to further extend the application prospects of such structures. In this paper, the optimization design problem is simplified as a form-finding problem with given member topology using the force density method. An evaluation method based on several geometric indicators, i.e., foldability, inner space, prestress evenness, path rectilinearity, and geometrical instability that reflect the locomotive ability and other characteristics is put forward to evaluate not only the existing tensegrities but also the designed tensegrities as locomotive robots.

2. Topology and configuration design of a new spherical tensegrity

2.1. Topology of a new spherical tensegrity

Snelson's patent "Continuous Tension, Discontinuous Compression Structures" describes the construction of highly complex tensegrities from simple modules, a typical example of which is a two-layer, 6-strut tensegrity (Figure 1(b)). These two unit tensegrities can be deemed as a combination of two reciprocal counterpart single 3-strut prismatic tensegrity, i.e., a right-handed prismatic tensegrity (Figure 1(a)) and a left-handed prismatic tensegrity, with the combined overlap replacing the triangular cables with saddle-like cables, and the addition of diagonal cables. All nodes of the structure are constrained on a sphere.

(a) (b)

Figure 1. (a) 3-strut prismatic tensegrity, and (b) 2 3-strut prismatic tensegrities combine a modular 6-strut tensegrity. The nodes, cables and struts are represented by black dots, thin colored lines, and thick black lines respectively.

This approach can be extended to the topology of any higher dimensional tensegrity. For a combined tensegrity with m unit tensegrities of which each has n struts, there are $2mn$ nodes, arranged on $2m$ layers. Each basic unit tensegrity with $2n$ nodes in upper and lower bottom surfaces, respectively, is constrained to the interior of a sphere (Figure 1(a)). All struts in the same unit tensegrity have equal deflection angles. The unit is a prismatic tensegrity if the radii of the node distribution circles on the upper and lower surfaces are equal, and a conical tensegrity if they are different. A new modular tensegrity can be obtained by sequentially combining the right-handed and left-handed prismatic/ conical tensegrity units. The concept of this design is as follows (Figure 2): all the horizontal cables in the middle layer are replaced with saddle cables in wavy arrangement, and diagonal cables connecting two adjacent units are added to ensure the stability of the structure; in addition, the vertical cables on the initial units are arranged accordingly. The nomenclature of the nodes as well as the relationship in which nodes are

subordinate to layers is shown in the Figure 2, and finally a *n*-stage *m*-torus modular tensegrity containing 4*mn* cables, *mn* struts, and 2*mn* nodes can be obtained. Each node connects to 1 strut and 4 cables.

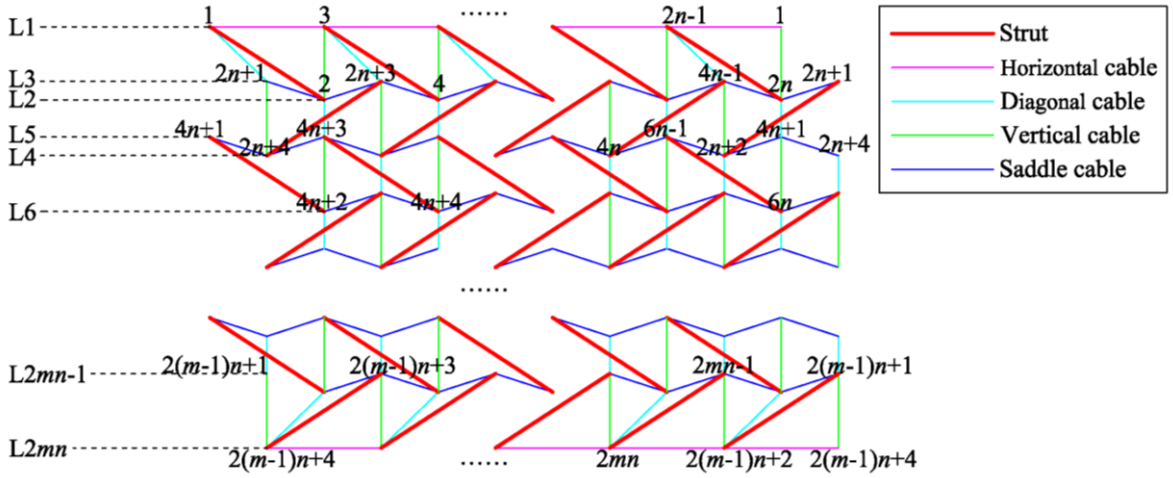


Figure 2. Topological connection of spherical tensegrity

2.2. Node coordinates

In this paper, the node coordinates are first represented by a spherical coordinate. The parameters required to determine the node coordinates of the spherical tensegrity are as follows: the number of modules *m*, the number of compression struts per module *n*, the nodal radial distance ***r***, and the polar angle $2m\times1$ matrix $\boldsymbol{\theta}$ and azimuthal angle $2m\times1$ matrix $\boldsymbol{\varphi}$ of the first nodes of each layer in the spherical coordinate system, which together determine the torsional angle of each unit and the offset angle between adjacent layers. The node numbering and coordinate definition of a 6-strut tensegrity is shown as an example in Figure 3. As for the remaining nodes in each layer, their polar angle remains the same as the first node, while azimuthal angle is added $2\pi/n$ by in clockwise order according to the azimuthal angle of the first node

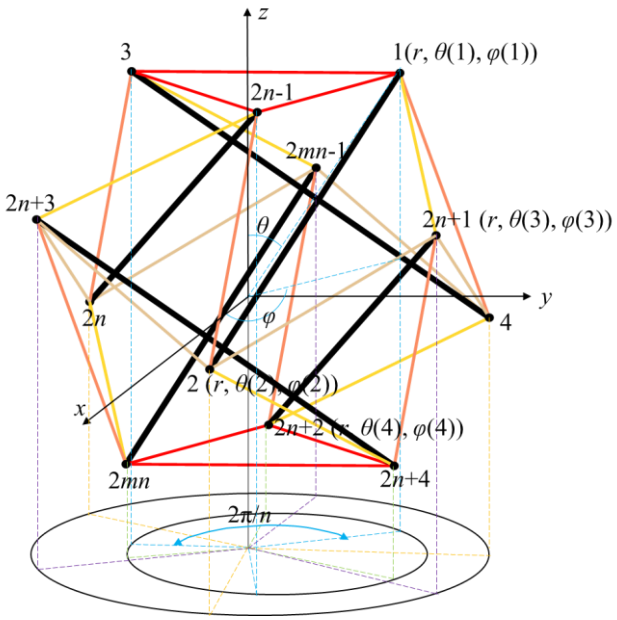

Figure 3. Coordinate representation of a 2-layer 6-strut spherical tensegrity

To ensure the symmetry of the tensegrity, constraints are also placed on the two units that are symmetric to each other in the upper and lower. For example, the first unit of the top layer is symmetric with the *m*th unit of the bottom layer. Therefore, the polar angles of the first and last layers should correspond to each other, i.e., $\theta(1)+\theta(2mn)=\pi$; similarly, $\theta(2)+\theta(2mn-1)=\pi$, etc. In addition, the strut torsional angles of the two corresponding units should also remain equal, and when *m* is an even, $\varphi(1)-\varphi(2)=\varphi(2mn)-\varphi(2mn-1)$, or $\varphi(1)-\varphi(2)=\varphi(2mn-1)-\varphi(2mn)$ when *m* is odd. The relationship between intermediate units are also in the same rule. And all the nodes are also constrained on a sphere. These constraints guarantee in advance that the tensegrity obtained to be spherical, regular and symmetric as well as have more uniform internal force.

2.3. Constraints and objective function

In this paper, the following properties are assumed for the tensegrity structures: (a) Members are in elastic range, and buckling or yielding is not considered; (b) No external load is applied and the self-weight is neglected; and (c) Members are connected by pin joints. In addition to the constraint on node coordinates as well as topology, the following conditions are also constrained.

2.3.1. Equilibrium constraint

For a 3-dimensional structure with n_e members, n_c nodes, its member connectivities can be expressed by a connectivity matrix $\mathbf{C}\in\mathbb{R}^{m\times n}$ defined in the field of graph theory [9]. By converting the spherical coordinates $\boldsymbol{r}$, θ , and $\boldsymbol{\varphi}$ to Cartesian coordinates, **X**, **Y**, and **Z** which represent the coordinate components in *X*-, *Y*-, and *Z*- directions respectively. And $\mathbf{Q}(\in\mathbb{R}^{m\times m})$ is a diagonal square matrix which is given by $\mathbf{Q}=diag(\mathbf{q})$, where $\mathbf{q}=(q_1,q_2,\cdots,\ q_m)\in\mathbb{R}^m$ is the force density vector determined as internal force per unit length. For simplicity, matrix **D** is defined $\mathbf{D}=\mathbf{C}^{\mathrm{T}}\mathbf{Q}\mathbf{C}$. Without external load, the equilibrium equation can be written as

$$\begin{aligned}\mathbf{D}\mathbf{X}&=0\\ \mathbf{D}\mathbf{Y}&=0\\ \mathbf{D}\mathbf{Z}&=0\end{aligned}\tag{1}$$

2.3.2. Member length evenness constraints

To control the evenness of member lengths, a set of constraints as follows are appointed

$$\begin{aligned}&l^s s_i+\varepsilon_l(1-s_i)\le l_k^2\le(l^s+e_l^s)s_i,\forall k\in E\\ &\underline{l}_s^2\le l^s\le\bar{l}_s^2,\underline{l}_s^2\le l^s+e_l^s\le\bar{l}_s^2,\\ &e_l^s\ge 0\\ &l^c c_i+\varepsilon_l(1-c_i)\le l_k^2\le(l^s+e_l^c)c_i,\forall k\in E\\ &\underline{l}_c^2\le l^c\le\bar{l}_c^2,\underline{l}_c^2\le l^c+e_l^c\le\bar{l}_c^2,\\ &e_l^c\ge 0\end{aligned}\tag{2}$$

where $\underline{l}_s$ and $\bar{l}_s$ are the lower bound and upper bound of strut lengths respectively; $\underline{l}_c$ and $\bar{l}_c$ are the lower bound and upper bound of cable lengths respectively. e_l^s and e_l^c are auxiliary continuous variables. In this way, smaller e_l^s or e_l^c means more even strut lengths or cable lengths respectively.

2.3.3. Force density evenness constraints

To control the evenness of force densities of struts or cables, a set of constraints is defined as

$$\begin{aligned}
&(q^s - e_q^s)s_k + \underline{q}_c c_k \le q_k \le q^s s_k + \bar{q}_c c_k, \forall k \in E \\
&\underline{q}_s \le q^s \le \bar{q}_s, \underline{q}_s \le q^s + e_q^s \le \bar{q}_s, \\
&e_q^s \ge 0 \\
&\underline{q}_s s_k + q^c c_k \le q_k \le \bar{q}_s s_k + (q^c + e_q^c)c_k, \forall k \in E \\
&\underline{q}_c \le q^c \le \bar{q}_c, \underline{q}_c \le q^c + e_q^c \le \bar{q}_c, \\
&e_q^c \ge 0
\end{aligned} \tag{3}$$

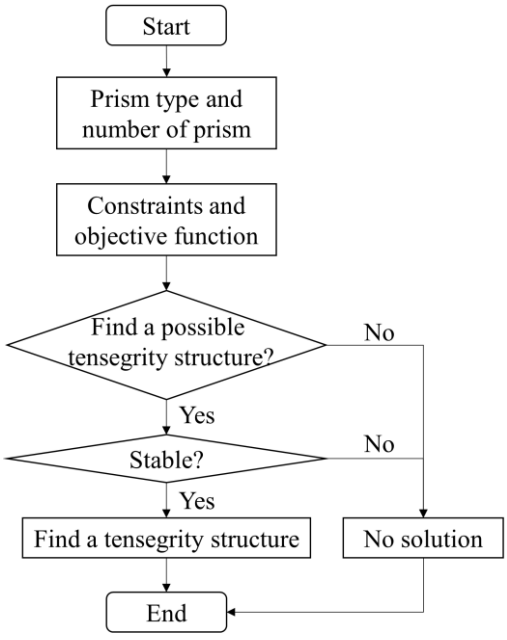
where $(s_k, c_k) = (1,0)$ indicates that member *k* is a strut, while $(s_k, c_k) = (0,1)$ indicates that member *k* is a cable. $\underline{q}_s$, $\underline{q}_c$ are lower bounds of force densities of struts and cables respectively, while $\bar{q}_s$ and $\bar{q}_c$ are upper bounds of force densities of struts and cables respectively. e_q^s and e_q^c are auxiliary continuous variables. In this way, smaller e_q^s or e_q^c means more even strut force densities or cable force densities.

2.3.4. Objective function

In order to minimize the number of cables and get more even member lengths and force densities, the objective function can be written as

$$f = \alpha_1 e_l^s + \alpha_2 e_l^c + \alpha_3 e_q^s + \alpha_4 e_q^c \tag{4}$$

Member topology (s, c), nodal positions (**X**, **Y**, and **Z**), and force density (**q**) are given as conditions for optimization in this model, which makes it effective for optimization of tensegrity structures. In addition, the stability of the tensegrity structures will be checked after they are identified by the optimization process. A flowchart for the proposed approach is shown in Figure 4.



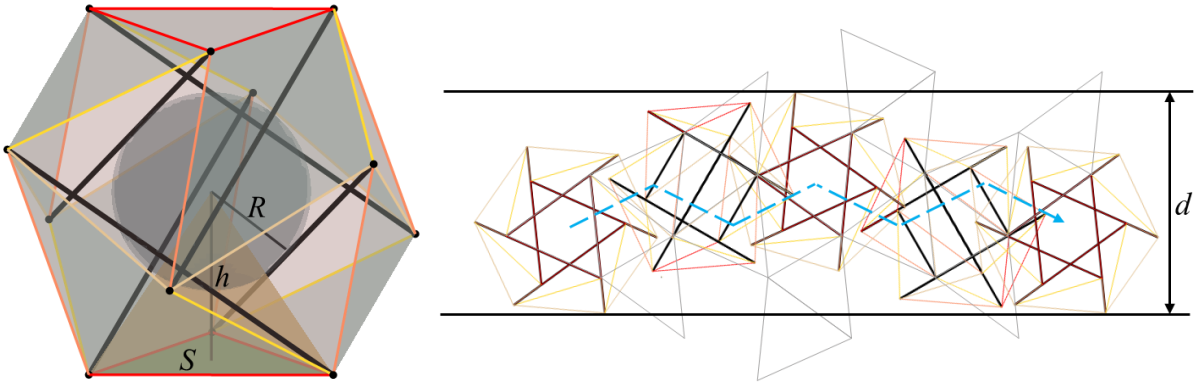


Figure 4. Flowchart of optimization process

3. Design of geometric evaluation indicators

This paper aims to generate more tensegrity configurations suitable for locomotive robots and provide a practical way to evaluate them. To be exact, the design a locomotive robot candidate that can not only meet the basic locomotive needs, but also conform to the current trend of robot development, with advantages such as lightweight, efficient, highly redundant, motion controllable, and so on, is our concern. In such needs, we propose several evaluation indicators that combines both theoretical locomotive capabilities and other geometric indicators that reflect the structural characteristics.

(a) (b)

Figure 5. (a) Inner space of 6-strut tensegrity, and (b) the 6-strut tensegrity traveling along the theoretical zigzag path generated by the surface expansion from a top view.

3.1. Inner space

The inner space is quantified as the ratio of the volume of the free inner ball with radius R that does not come into contact and collision with any component to the volume of the robot in its initial state. This can be useful for tensegrity robots or protectors design in which a central space may need to contain some functional devices. The geometry of the inner space of 6-strut tensegrity is illustrated in Figure 5.

3.2. Foldability

The foldability assesses the ability of the robot to survive in extreme terrain such as narrow spaces and is defined as the ratio of the volume of the robot when all struts are reduced to the minimum driven lengths to the volume of the robot in its initial state.

3.3. Prestress evenness

This prestress evenness is defined as the variance of the absolute value of the normalized prestress forces of all components. It measures the degree of uniformity of internal forces in each member and reflects the symmetry and regularity of the structure. In addition, more uniform internal prestress in the robot indicates it's easier to manufacture, and more controllable.

3.4. Path rectilinearity

The path rectilinearity embodies the degree of straightness of the theoretical motion path obtained from the surface expansion, which is defined as the ratio of the width d in the X-Y plane along the theoretical path to the length of the robot.

3.5. Geometrical instability

The geometric meaning of instability is the ratio of the height h of the robot's mass center to the area of touching-ground surface S [8]. It can assess the stability of the structure under a certain touching-ground state and the degree of susceptibility to rolling.

These five evaluation indexes identified above are all related to the geometric shape and the initial prestress state of the tensegrity only.

4. Evaluation of different tensegrity configurations as robot candidates

In Chapter 2, a method to develop modular spherical tensegrity configurations as optional locomotive robots is presented, which can be obtained for any tensegrity with *m* unit prismatic tensegrities of which each has *n* struts. However, as the unit number *m* or the number of compression struts per unit *n* increases, the difficulty of fabrication increases as well. According to the previous research, the control as well as construction difficulty of tensegrities with the number of compression struts more than 15 will be greatly increased. Therefore, we carried out the optimization design mainly for the cases of two and three units, i.e. *m*=2 or 3. In this paper, the 2-layer 8-strut tensegrity (Figure 6(b)), 3-layer 12-strut tensegrity (Figure 6(c)), and 3-layer 15-strut tensegrity (Figure 6(e)) are chosen as the robot candidates.

On the other hand, the 6-strut tensegrity is often studied because it is simple to construct and its external appearance resembles the Icosahedron, which is a classic polyhedron. Other tensegrity configurations based on the known Platonic and Archimedean polyhedron have been developed as well, such as the 12-strut tensegrity based on the Rhombicuboctahedron (Figure 6(d)), and the 30-strut tensegrity based on Snub Dodecohedron (Figure 6(f)), both of which have been discussed for their locomotion capacity. In fact, the aforementioned 3-layer 12-strut tensegrity (Figure 6(c)) can also be obtained based on the Snub Cube through form-finding.

Based on this, the above 6 tensegrity configurations are taken as the evaluation objects. The evaluation is carried out for the indicators in Chapter 3, and the characteristics of the different configurations are compared as shown in Figure 6. It can be seen that the characteristics of different configurations are also various. If the indicator of path rectilinearity is considered as the priority indicator, the motion paths of configurations (c), (d), (e), (f) both conform to a better straightness. Both configurations (a) and (b) do appear to have a less smooth motion path due to the small number of components. However, these two configurations are more controllable, and the foldability is also one of their advantages. In addition, the 30-strut tensegrity has a more balanced and outstanding performance, but too many actuating members can complicate the actuation and limit its development. Although the motion path of configuration (d) as a robot candidate could be a normal straight line, the inner space is small and the folding ability is not that good, and the existence of contact and collision between the struts is also a problem that needs to be solved. Among the several configurations put forward, it is considered that the 3-layer structures (e.g., (c) and (e)) have potential as robot candidate, since they can basically travel along a straight line, and all indicators are relatively balanced. The number and distribution of actuating members are reasonable, so that their motion capability can be further analysed and discussed.

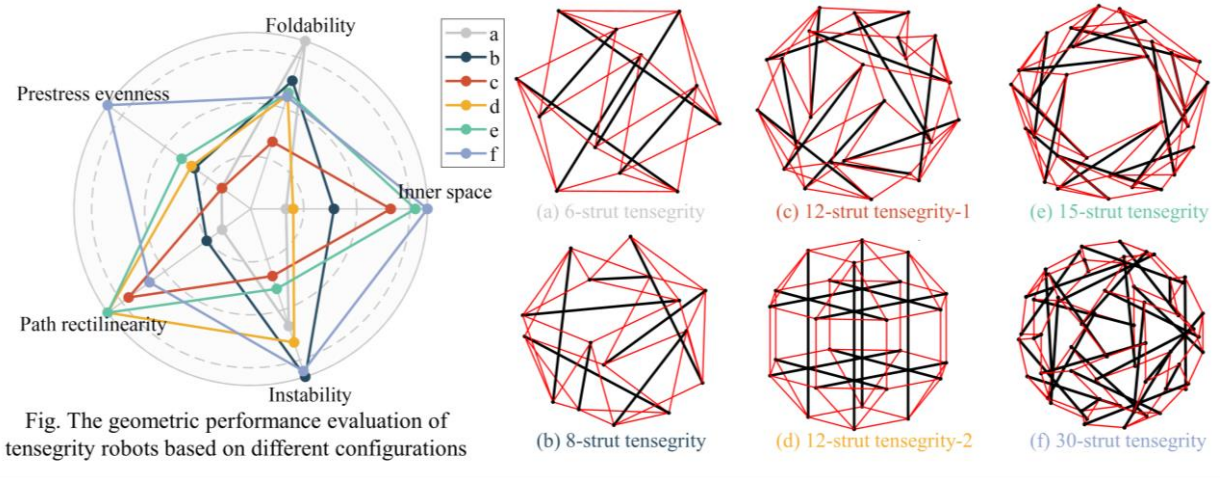

Fig. The geometric performance evaluation of tensegrity robots based on different configurations

Figure 6. The geometric performance evaluation of tensegrity robots based on different configurations

5. Conclusion

In this paper, an optimization approach aimed to generate spherical regular tensegrity structures is proposed. It provides a practical way to design the initial configuration of a regular spherical tensegrity that not only classical tensegrities but also novel spherical regular tensegrities are obtained by the proposed method. In order to generate more tensegrity configurations suitable for locomotive robots and evaluate the adaptability of different tensegrity configurations as robot candidates, an evaluation method based on several geometric indicators, i.e., foldability, inner space, prestress evenness, surface smoothness and geometrical instability is put forward. It assesses not only the locomotive capacity but also manufacturing difficulty, storage ratio, and so on, of different tensegrity configuration. Based on this evaluation, the 12-strut tensegrity and 15-strut tensegrity are identified as the most promising designs for future study.

Static performance of an open Levy cable dome with partial CFRP cables

Weijing ZHANG[a,*], Yizhou HU[a]

[a,*] Beijing University of Technology, Beijing 100124, China
zhangweijing@bjut.edu.cn

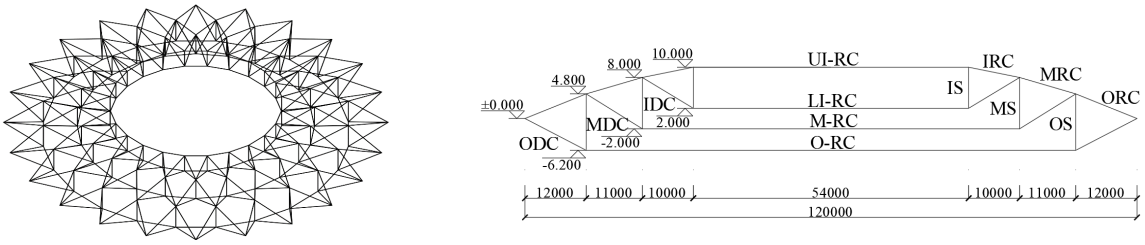
Abstract

Carbon fiber reinforced polymer (CFRP) has the advantages of high tensile strength, low weight, corrosion resistance and fatigue resistance, which is suitable for cable domes. In order to study the static performance of the cable dome after the application of CFRP cables, part of the steel cables in a Levy type open cable dome with span of 120m was replaced with CFRP cables. The cables in the cable dome can be divided into three kinds of ridge cables, diagonal cables and ring cables according to their functions, and ten groups of cables according to their positions, such as outer ridge cables, middle ridge cables, inner ridge cables, outer ring cables, middle ring cables, etc. The simulation results show that: In all cases, the static performance of Levy open cable dome with part CFRP cables is little different from that of steel cable dome structure. The stress of each group of cables decreases within 8%, and the maximum vertical displacement of nodes changes within 10%. The replacement of ridge cables and upper inner ring cable with CFRP cables can increase the structure stiffness and reduce the vertical displacement of Levy type open cable dome. The research in this paper can provide reference for the application of CFRP cables in cable domes.

Keywords: cable dome, CFRP cables, static performance

1. Introduction

As a kind of long-span spacial structure, cable dome structure is widely used in exhibition facilities, transportation hubs, sports venues and other important projects because of its light weight, large span, beautiful structure and other advantages [1]. At present, most types of cable dome structures are full coverage systems without openings, which are rarely used in long-span stadiums requiring openings. Chengdu Fenghuangshan Stadium is the first football stadium building in China to adopt a large opening Levy type cable dome structure [2]. Combining the opening demand of the stadium roof with the cable dome structure is an innovation in the form of cable dome structure.



The materials of cable in cable dome structure have also been studied extensively.Compared with steel, CFRP has advantages such as light weight, high strength and good corrosion resistance, and is an ideal material for constructing long-span structures. At present, the application and research of CFRP in long-span structures are mainly focused on bridges [3]. The research of CFRP in spatial structure has just started [4], and there are few studies on CFRP cable dome structure. Due to the great difference between CFRP and steel in material properties, it is necessary to study the static performance of CFRP cable dome structure. Considering the current application degree of CFRP cable, it is difficult to realize the cable dome structure with all CFRP cables. A Levy open cable dome with 120m span is taken as the object, the mechanical properties of the cable dome structure with part of CFRP cables are studied and compared with steel cable dome.

2. Finite element analytical model of open Levy cable dome

2.1. Introduction of structural model

As shown in Figure 1, the open Levy cable dome structure [5] has a span of 120m, a rise height of 10m, a rise-span ratio of 1/12, and an opening diameter of 54m. The cable dome is composed of 10 groups of cable members and 3 groups of strut members. There are inner ridge cable (IRC), middle ridge cable (MRC) and outer ridge cable (ORC). Diagonal cable has inner diagonal cable (IDC), middle diagonal cable (MDC) and outer diagonal cable (ODC). The ring cable includes upper inner ring cable (UI-RC), lower inner ring cable (LI-RC), middle ring cable (M-RC) and outer ring cable (O-RC).The strut has inner strut (IS), middle strut (MS) and outer strut (OS). The cables are made of 1670 grade 7mm steel wire bundle, and the steel pipes are made of Q345 grade steel.The bar CFRP cable of equal diameter was obtained. The carbon fiber prefilament was made of standard high-performance carbon fiber, and the ultimate tensile strength was 2500MPa and the elastic modulus was 172GPa. The specific specifications and parameters of the component are shown in Table 1.The material parameters of components are shown in Table 2.

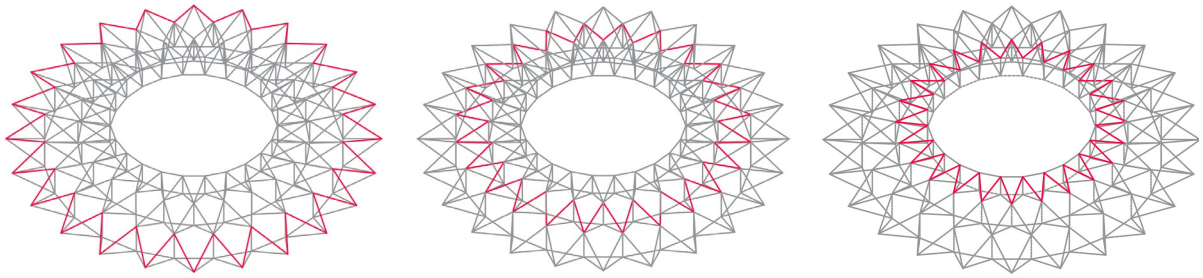
Table 2. Material properties used for structural analysis

Member Type	Materials	Density (kg/m^3)	Modulus of Elasticity (MPa)	Ultimate Tensile Strength(MPa)
cables	CFRP	1600	1.72×10^5	2500
	Steel	7850	1.95×10^5	1670
struts	Steel	7850	2.06×10^5	345

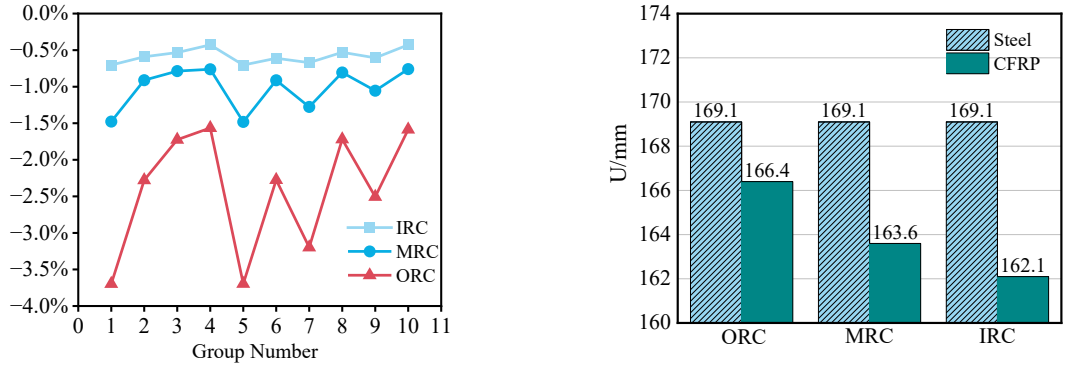
According to the relevant specifications, considering the design requirements of rigid roof, the dead load is 0.6kN/m^2, live load is 0.5kN/m^2, the roof load is equivalent to the concentrated load on the strut node.



The static analysis of the Levy type cable dome structure with large opening was carried out by ANSYS. The cables were simulated by LINK10 element, and the struts were simulated by LINK8 element. The support was simplified to be fixed hinged support, and the initial prestress was applied by adding initial strain. Geometric nonlinearity of the system was considered in the analysis process.

3. The static behaviour of structure before and after the replacement

CFRP has the advantages of light weight, high strength and good corrosion resistance, but its elastic modulus is smaller than that of steel cables. When applied to structures, it may lead to structural stiffness reduction and displacement increase. In order to study the static properties of the structure after the application of CFRP cables, cable replacement was carried out for the Levy open cable dome structure, and the influence of cable replacement at different positions on the static properties of the structure was studied.



3.1. Replacement of ridge cables

According to different positions of ridge cables, three replacement cases were considered: 1) replacement of ORC 2) replacement of MRC 3). replacement of IRC, as shown in Fig.2. The cable stress changes of each group in the open Levy cable dome structure (group number is shown in Table 1) and the maximum vertical displacement of the inner ring nodes is shown in Fig.3.

(a) ORC (b) MRC (c) IRC

Figure 2. Replace the ridge cables in different positions: (a) outer ridge cables, (b) middle ridge cables, (c) inner ridge cables.

(a)The percentage change in cables stress (b)The change in nodes displacement(in mm)

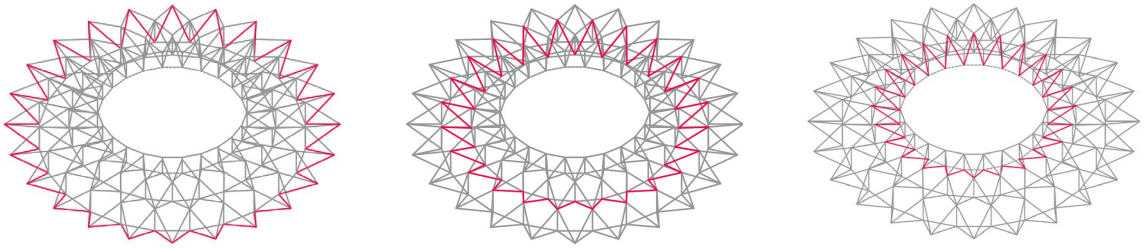


Figure 3. Member stresses and displacements before and after the replacement of ridge cables

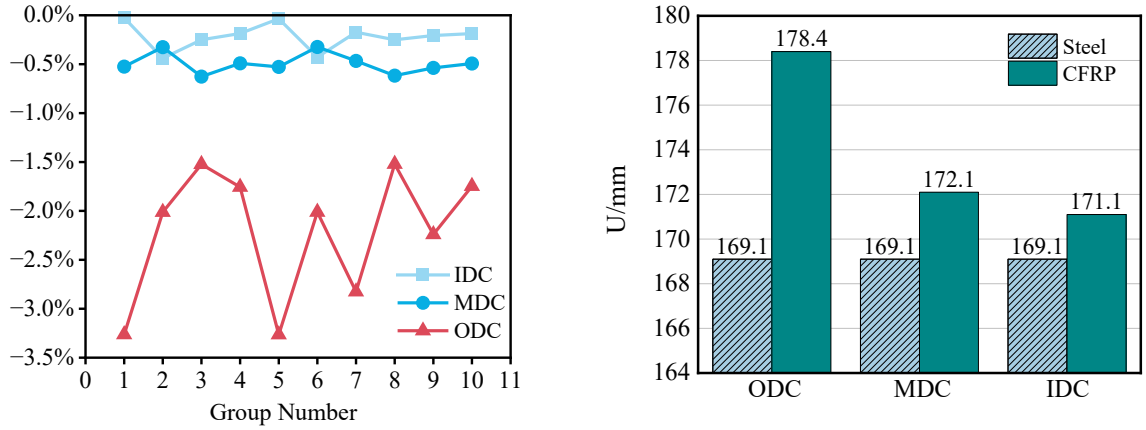
As can be seen from Fig. 3 (a), when the ridge cables at different positions were replaced, the cable stress in each group decreased somewhat, and the range of stress reduction gradually increased from inside to outside with the replacement of ridge cables. The variation of cable stress in each group was roughly the same:(1) The stress reduction reached the maximum at the upper inner ring cable (Group number 1) and the inner ridge cable (Group number 5), which was 3.7% when the outer ridge cable was replaced, and 1.5% when the middle ridge cable (Group number 7) was replaced. (2) On the whole, the stress reduction rate of ring cable was upper inner ring cable (Group number 1) > lower inner ring cable (Group number 2) > middle ring cable (Group number 3) > outer ring cable (Group number 4), and the stress reduction trend of diagonal cables and ridge cables was similar to that of ring cable. (3) Except for the upper inner ring cable, the stress reduction of ridge cables is greater than the other two kinds of cables.

Vertical displacement of nodes on the innermost ring of cable dome structure was selected for comparison, and its changes before and after replacement were shown in Fig.3 (b).As can be seen from the figure, when the ridge cables at different positions are replaced, the node displacement of the cable dome with part of CFRP cables is smaller than that of the original cable dome structure. In conclusion, although the elastic modulus of CFRP cable is lower than that of steel cable, the structural stiffness increases and the displacement of the node decreases when the ridge cables at different positions are replaced with CFRP cables.



3.2. Replacement of diagonal cables

When replacing steel diagonal cable with CFRP cable, three cases are considered: 1) Replace the outer diagonal cables 2).Replace the middle diagonal cables 3). Replace the inner diagonal cables, as shown in Fig. 4. Fig. 5 shows the cable stress changes of each group (group numbers are shown in Table 1) and the maximum vertical displacement of inner ring nodes.

(a)ODC (b)MDC (c)IDC

Figure 4. Replace the diagonal cables in different positions: (a) outer diagonal cables, (b) middle diagonal cables, (c) inner diagonal cables.

(a)The percentage change in cables stress (b)The change in nodes displacement (in mm)

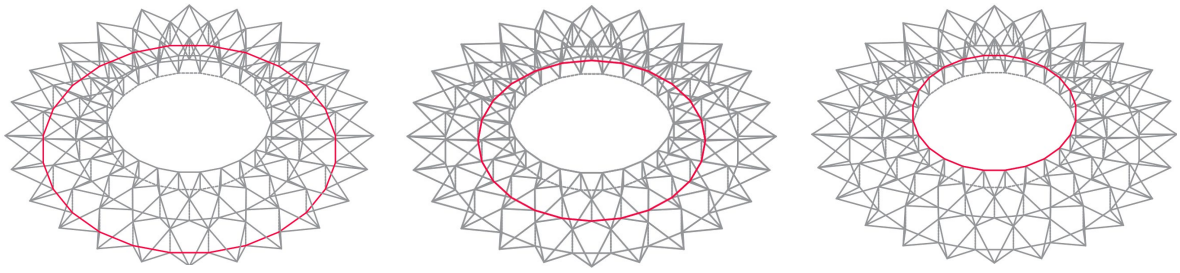


Figure 5. Member stresses and displacements for open Levy cable dome before and after the replacement of diagonal cables with CFRP cables

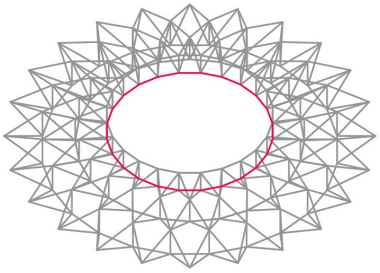
As can be seen from Fig.5 (a), the cable stress of each group in the structure decreases after the diagonal cables are replaced by CFRP cables. When the outer diagonal cables are replaced, the cable stress drop in the cable dome structure is significantly greater than that when the other two kinds of diagonal cables are replaced. When the CFRP cable replaces the outer diagonal cable, the maximum cable force reduction of the cable dome structure appears in the upper inner ring cable (Group number 1) and the inner ridge cable (Group number 5), reaching 3.3%. When middle diagonal cables or inner diagonal cables are replaced by the CFRP cables, the overall cable force of cable dome structure does not decrease by more than 1%.

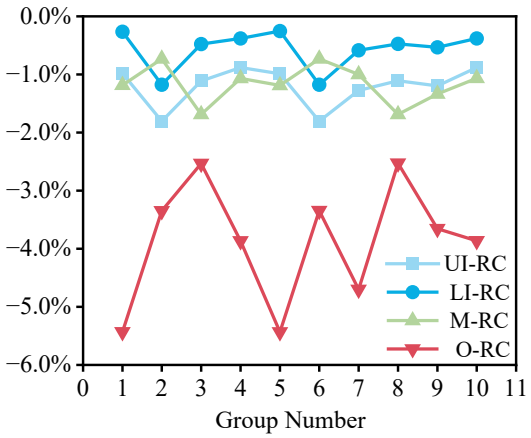


Before and after replacing the CFRP cable, the vertical displacement changes of the nodes on the innermost ring of the cable dome structure are shown in Fig.5(b).As can be seen from the figure, when different diagonal cables are replaced by CFRP cables, the node displacements are all larger than those of the original structure, and the joint displacements increase by 9.3mm when the outer diagonal cables are replaced by the CFRP cables, showing the largest increase. Contrary to the stress variation trend, the node displacement increases from inner to outer with the replacement cable position.When CFRP cablea are used to replace steel diagonal cables, the structural stiffness decreases and the joint displacement increases.

3.3. Replacement of ring cables

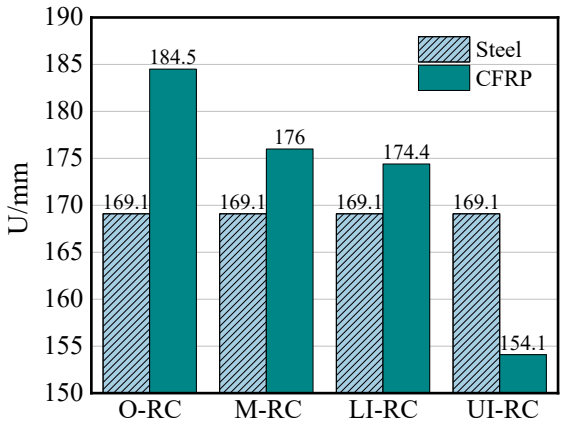
When replacing ring cable with CFRP cable, four conditions are considered: 1). Replace outer ring cable 2).Replace central ring cable 3). Replace upper inner ring cable 4). Replace lower inner ring cable, as shown in Fig6. Fig. 7 shows the cable stress change diagram of each group of Levy cable dome structure with opening (group number is shown in Table 1) and the maximum vertical displacement diagram of the inner ring node when the four types of ring cables are replaced.

(a)O-RC (b)M-RC (c)UI-RC



(d)LI-RC

Figure 6. Replace the ring cables in different positions: (a) outer ring cables, (b) middle ring cables, (c) upper inner ring cables, (d) lower inner ring cables.

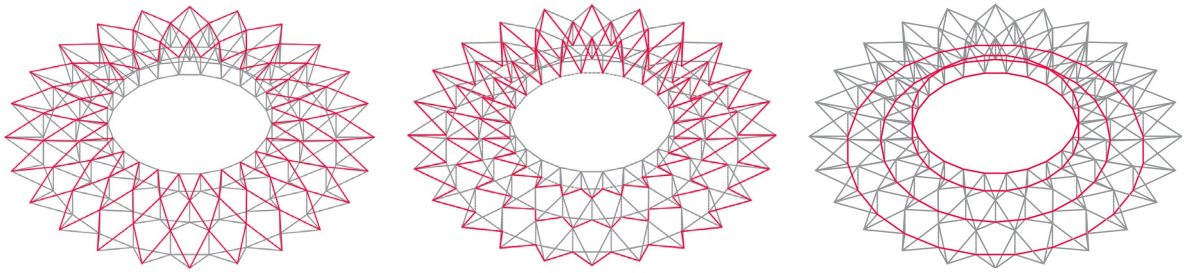


As can be seen from Fig.7 (a), the cable stress in the cable dome structure decreases after the replacement of the ring cable with CFRP cable. When the outer ring cable is replaced, the cable stress drop in the cable dome structure is significantly greater than that in the replacement of the other three kinds of ring cable. The cable force drop is close to that in the replacement of the middle ring cable and the upper inner ring cable, and the cable stress drop is the lowest when the lower inner ring cable is replaced.

When CFRP cable is used to replace the outer ring cable, the maximum stress drop occurs at the upper inner ring cable and the inner ridge cable, reaching 5.4%, which is the maximum stress drop when single group of cable is replaced. When the ring cable is replaced, the outer ring cable has a great influence on the internal force distribution of each group cables, while the other ring cables have little change on the stress of each group cables.

The vertical displacement of nodes on the innermost ring of cable dome structure was selected as the research object, and its changes before and after replacement were shown in Fig.7 (b). As can be seen from the figure, when the upper inner ring cables are replaced by CFRP cables, the vertical displacement of nodes decreases by 15mm compared with the vertical displacement of the original structure, and when other ring cables are replaced, the vertical displacement of nodes increases. When the outer ring cable is replaced, the node displacement increases 15.4mm, with the largest increase of 9.1%.When the ring cable is replaced, the displacement increase of the structure vertical decreases from inner to outer.The effect of upper inner ring cable on the vertical displacement of structure is different from that of lower inner ring cable.

(a)The percentage change in cables stress

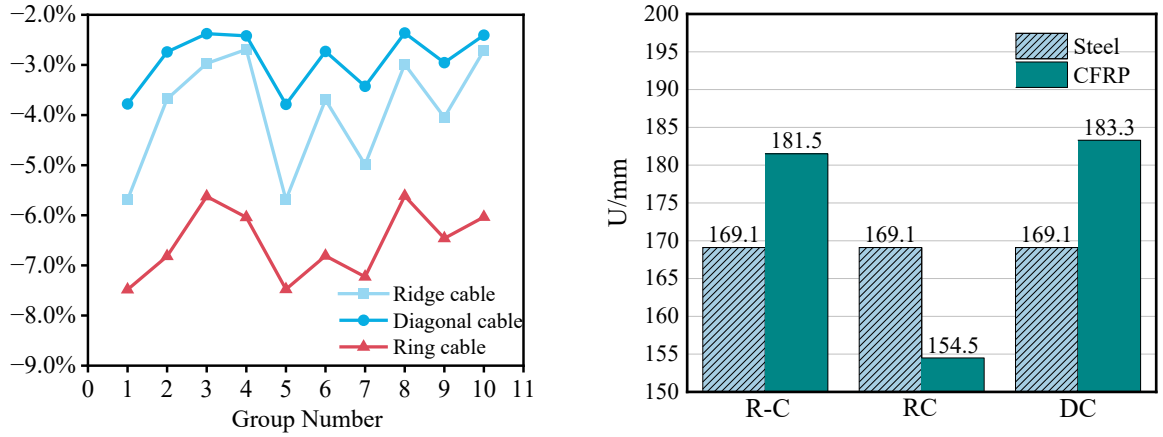


(b)The change in nodes displacement (in mm)

Figure 7. Member stresses and displacements for open Levy cable dome before and after the replacement of ring cables with CFRP cables

3.4. Replacement of different types of cable

Three cases were considered when all the same type cables were replaced with CFRP cables: 1).Replace the ridge cables 2).Replace the diagonal cables 3). Replace the ring cables, as shown in Fig. 8. Fig. 9 shows the maximum vertical displacement of the open Levy cable dome structure and the change of cable stress in each group when three kinds of cables are replaced.



(a)RC (b)DC (c)R-C

Figure 8. Replace different types of cables: (a) ridge cables, (b) diagonal cables, (c) ring cables

It can be seen from Fig. 9 (a) that when single type of cables are replaced, the stress of each group decreases, and the change trend is roughly the same. The change range of the stress of each group is the largest when the ring cable is replaced, while the change range is the smallest when the diagonal cable is replaced. When the three kinds of cables were replaced, the maximum amplitude of stress change appeared in the upper inner ring cable (Group number 1) and the inner ridge cable(Group number 5), which decreased by 7.5%.

The vertical displacement changes of nodes on the innermost ring before and after replacement are shown in Fig.9 (b).As can be seen from the figure, when all ring cables and diagonal cables are replaced, the node displacement increases by 12.5mm and 14.2mm respectively.When the ridge cables are replaced, the structural stiffness increases and the maximum displacement of the node decreases by 14.5mm.

(a)The percentage change in cables stress (b)The change in nodes displacement (in mm)

Figure 9. Member stresses and displacements for open Levy cable dome before and after the replacement of different types of cables with CFRP cables

4. Conclusion

(1) Compared with the steel cable dome, the stress level of the cable dome structure with partial CFRP cables is reduced, but the reduction range of the cable stress is less than 8% for each group cables.

(2) The maximum vertical displacement of nodes changes within 10%. The replacement of ridge cables and upper inner ring cable with CFRP cables can increase the structure stiffness and reduce the vertical displacement of Levy type open cable dome

(3) The open Levy cable dome structure with partal CFRP cables has little difference in static performance with the traditional steel cable dome structure. Meanwhile, CFRP has the advantages of corrosion resistance and fatigue resistance, so CFRP cable has a promising application prospect in cable dome structure.

Abstract

String Crescent Structure (abbreviated as SCS) is the unique masonry structure with consisting of the blocks, lower strings, and connecting members or Cables, and this was proposed by the presenter. In previous studies, the experiments and analysis had shown that SCS with pin-roller support is stable structures. Build upon these results, in the paper, the arch shape with pin-pin support was adopted to ensure higher stability of SCS. Experimental and analytical results for this structure showed that no tension is generated in the lower strings under all load, but this tension is generated near the load point under partial distributed load. Although unstable deformation was expected to occur in SCS under partial distributed load, this did not happen. This stable state is due to the tension of the lower strings preventing the progression of slipping between the blocks. Next, the prestress effect of SCS with pin-pin support was studied. The prestressing members are made of strand rope, and the prestressing introduction component are the eyebolts that are set near the support points. The prestress effect of SCS with pin-pin support has never been studied before. Detailed experiments and analyses were done to confirm these.

Keywords: string crescent structure, reuse, kinetic system, unique masonry structure, arch with “pin-pin” support, all load, half load, prestress, analysis, load experiment

1. Introduction

1.1. Lightweight structure derived from traditional masonry arch

Elements of structural safety are strength, stiffness, and stability [1]. The structure must be strong enough to resist the loads and must not cause excessive deflection or unstable displacement. If these three elements can be full, the structure can be used as a building structure. However, in the design of masonry arches in the Middle Ages, only stability was considered among these elements. Before to the publication of "Dialogues Concerning Two New Sciences" by Galileo, the existence of stresses was not recognized [2]. Specifically, the stresses generated in the stone blocks of the masonry arches are small, and buckling measures are not considered. On the other hand, destruction due to slipping between blocks and unbalance forces is easy to occur, and it was necessary to ensure "stability" against this risk.

One of the most important factor for structural design in the 20th century was the balance between safety and economy. As a result, lightweight structures such as shell structures flourished, but masonry arches did not. This reason for this is that traditional masonry arches were not only vulnerable to earthquakes, and it was also difficult to manage a balance between economy and safety.

The structure that solve this weakness and improved the economics of the masonry arch exists [3]. This is the vault roof with hollow cells and extant on Djerba island, Tunisia (Figure 1). The basic shape of this hollow cell is a trapezoidal tube and its material is clay. After these blocks are assembled into the vaulted roof, the top of this roof is coated with mortar. This vault has many advantages such as light

weight, economy, and heat insulation. Blocks such as Tube type need to be checked for strength and stiffness, and application to vast roofs is difficult.

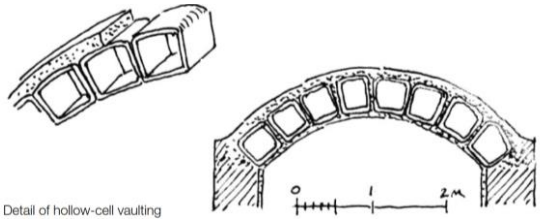

Figure 1. The vault roof with hollow cells

1.2. Development from the traditional masonry arch to the unique masonry arch

In the 21st century, the issue of the global environment has come under close scrutiny. The requirements for a technology to address this issue include not only stability and economy, but also environment-conscious performance (Figure 2). Environment-conscious performance is an important keyword for a sustainable society. CO2 emissions from large-lot production and consumption lead to climate variation, threaten global biodiversity, deplete natural resources, and cause environmental pollution. To prevent this, environment-conscious technologies and product approaches are needed. One of these environment-conscious features is 3R such as recycle, reuse, and reduce. Do these increasingly complex conditions make the design of masonry arches difficult?

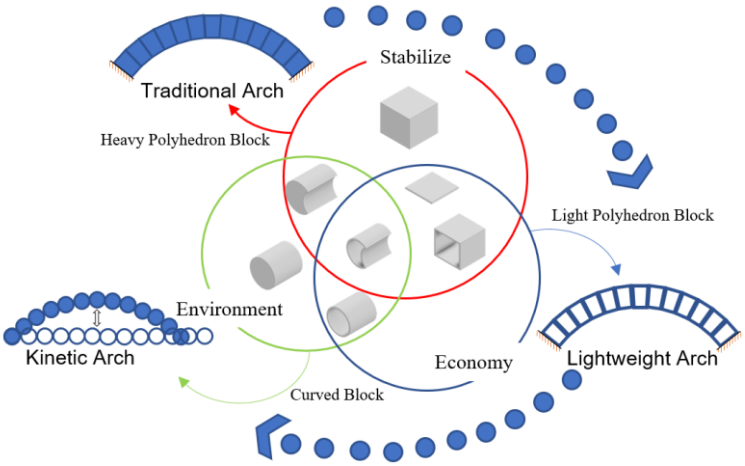

Figure 2. Development of block and masonry arches

Architectural shapes and scales are extremely diverse. In order to easy block diversion between different shape structures, the remanufacturing process such as combination process or a cutting process is need. The combination process is a remanufacturing process that combines parts of different geometries. However, this leads to an increase in the number of different types of parts, make complex joints and unnecessary materials. The cutting process is a remanufacturing process in which the blocks are cut after disassembly. However, the large volume of a single block increases the amount of waste during the cutting process and fuel for transportation. The requirement for environment-conscious blocks is that they can be reused into different shape structures while reducing the aforementioned processes (Figure3). To achieve this object, it is advisable to introduce blocks with curved surfaces such as bone joints, and to construct a kinetic system that allows rotational sliding between blocks. An example of a block with a curved surface is a cylindrical block. The structure with this block is free to move structural shape. An example of this is the arch proposed by Hiroishi et al [3]. The disadvantage of this structure is that the contact area between the blocks is very small, which tends to occur stress concentration.

To ensure both environmentally friendly performance and stability, the block must have contact curved surface and a sufficient contact area. The block shape that can satisfy this condition is the crescent column shape. In order to achieve both lightness and rigidity of this block, it was further developed into

a wheel-shaped block. The structure with crescent block becomes unstable structure. To stabilize this, the lower strings and PS Cables are needed. The name of this unique masonry structure with the crescent block and tension members is SCS.

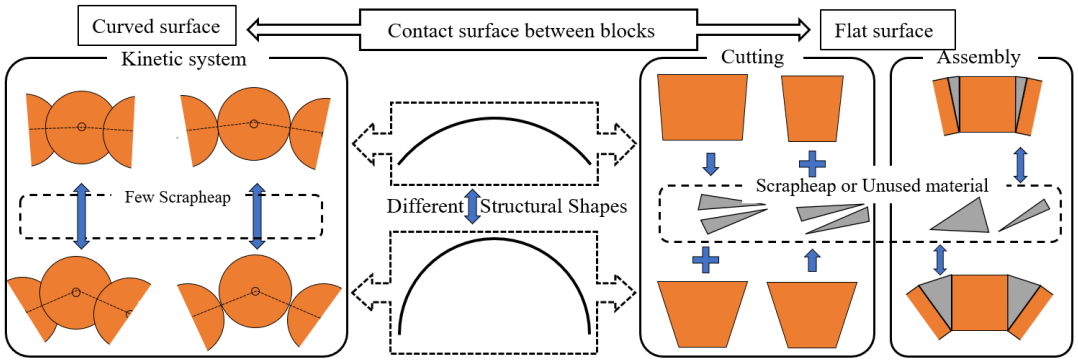

Figure 3. Block remanufacturing process

1.3. Assumptions of SCS structural properties and research objectives

Before a description of the structural characteristics of SCS, the block contact problem is considered. Regardless of the shape of the block, the supporting pressure of the block during compression may easily maintain the stability of the arch during All loading. However, the joints between the blocks under moment or shear may be unstable.

First, the contact states between the blocks under the moment are described. In trapezoidal blocks, bearing pressure occurs on the compression side and separation occurs on the tension side, and in crescent-shaped blocks, rotational slipping occurs between the blocks (Figure 4a). The case of shear forces is described next. Shear slip occurs when trapezoidal blocks are subjected to shear, while bearing pressure and separation occur for crescent-shaped blocks. Different shapes of blocks may lead to different destruction mechanism of the structure.

These contact state between crescent block become the unstable structure. To solve this problems, tension member is needed. The role of this member is to prevent separation for trapezoidal blocks and prevent rotational slipping for crescent-shaped blocks.

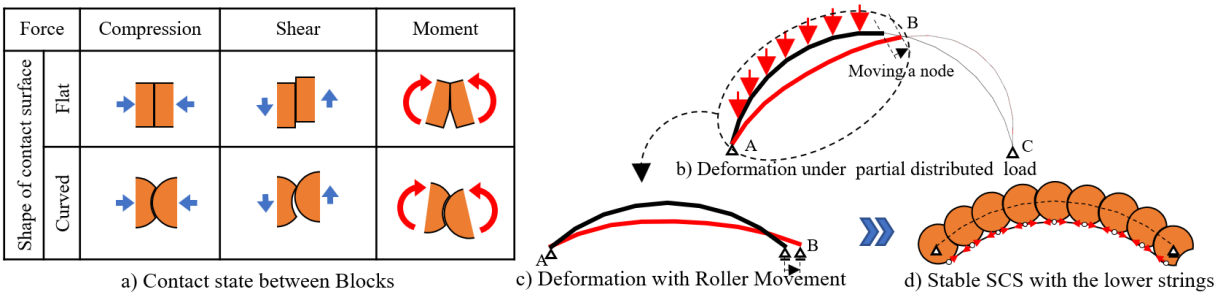

Figure 4. Stabilization of SCS considering contact condition between blocks

Figure 4b shows the deformation of ArchABC with pin-pin support under partial distributed load. Arch AB in the area of load application is detached from this arch, and this is replaced by the arch with pin-roller support (Figure4b-c). Then the deformation of arch AB is caused by the thrust of B (Figure4c). If Arch AB were replaced by a masonry arch with crescent-shaped blocks, this arch become an unstable structure with rotational slipping between blocks. To stabilize this structure, the lower chords are required. The effectiveness of Addition of the low string has already been demonstrated by load experiments of SCS with pin-roller support[5]. The description returns to the deformation of the entire arch (Figure4b). Upward deformation occurs at the area of non-load B-C. Will this deformation adversely affect the stability of the entire arch? Based on this assumption, the stability of SCS with pin-pin support under partial distributed load must be tested. This is one of the study objectives.

The results of studies already showed that the structural behavior of SCS with pin-pin support is more stable under cyclic load than that of SCS with pin-roller support [7]. But that of SCS with pin-pin support has not yet been studied.

The subject of this study is SCS with pin-pin support, and the objective of the study is to verify the differences in structural behavior and PS effects that occur between all and partial distributed loads. For this purpose, the load experiments and structural analysis were done.

2. Experimental and analytical models

2.1. Experimental models

The components of the experimental model are (1) Blocks and (5) Lower Strings, (3) PS Cables, and (6) Lower Joint (Figure5). The rise-span ratio of the arch based on the shape of "(3)PS Cable" is 0.2. "(3)PS Cable" passes directly through the eye bolt placed in the center of "(1)Block" and is fixed by "(4)PS Eye Bolt" provided at both ends of SCS. To reduce friction between "(1)Block" and "(7)Support Plate", the rolling bearings are installed between the through-bolt of the block and the bolt hole.

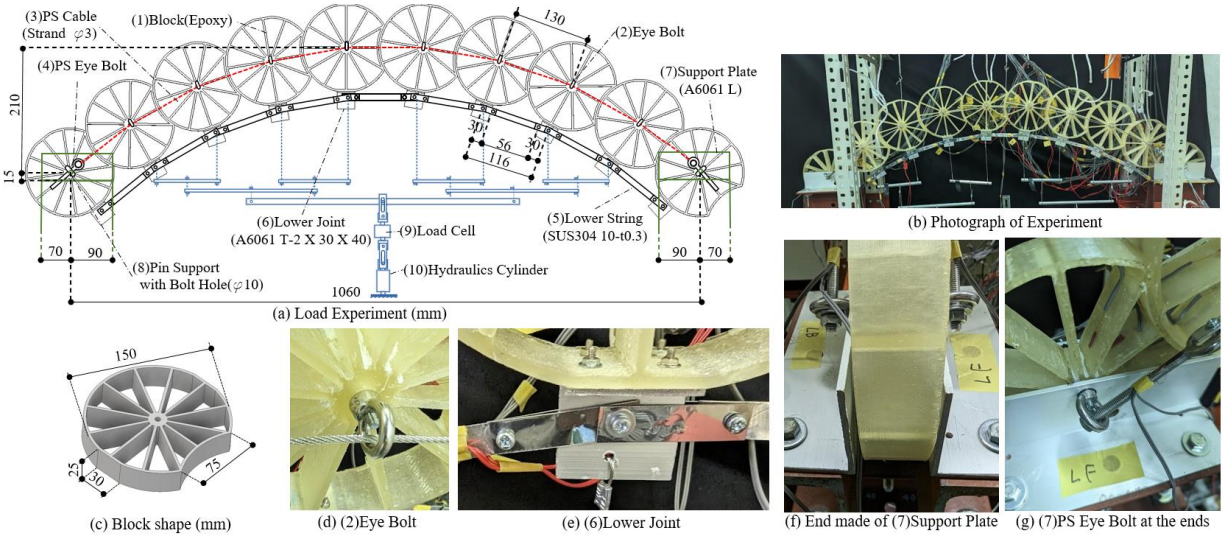

Figure 5. Experimental model

2.2. Analytical models

The geometry of the analytical model are determined based on the experimental model, and the structural specifications are given in Table 1. The block material is epoxy resin and was fabricated by the presenter. The difference in environmental conditions during this manual work affects Young's modulus. For this reason, the following work was performed to determine the Young's modulus of the epoxy resin. First, poor quality blocks are selected from among many "(1) Blocks". The indication of poor quality is the presence of cracks or large bubbles inside the block. A reinforcing member is cut from the selected block and used as a beam specimen (span: 50 mm, thickness: 3.0 mm, width: 21 mm). Twelve experiments were conducted in which the beams under concentrated loads. Based on this results, Young's modulus was calculated. Based on these results, the average value of Young's modulus was decided 1500 N/mm2, and this value was entered into the analysis software. However, this material property does not take into account the plastic range. Truss elements such as "(5) Lower Strings" and "(3) PS Cables" resist only tension. "(11) rods" is introduced in the center of "(1) Block" and "(12) Contact Element" are installed between "(3) PSCable" and "(11) rods" (Figure6). The pin joint between "(3) PS Cable" and "(12) Contact Element". The sliding joint was installed between "(11) rods" and "(12) Contact Element". Based on the results of the IASS 2021 friction tests, the friction coefficient of the sliding joint was set to 0.2 [6] and the stiffness factor was set to 1. This stiffness factor is not a

contact stiffness but a parameter for convergence of the analysis with Inventor Nastran [8]. This analytical model was made and used for nonlinear analysis including contact analysis with NASTRAN.

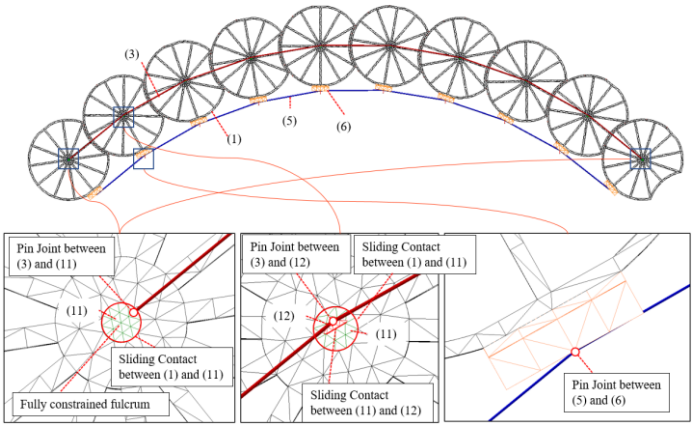

Figure. 6 Analytical model

Table.1

Name	Colour	Material	E (N/mm^2)	Shape, Cross-sectional Area
(1)Block		Epoxy	1500	
(3)PS Cable		Strand Cable	$6.7X10^4$	$4.8mm^2$
(5)Lower String		Stainless	$2.0X10^5$	$3.0mm^2$
(6)Lower Joint		AL6061	$6.9X10^4$	T-2X30X9
(11)Rod		Steel	$2.1X10^5$	φ6.0mm
(12)Contact Element			$1.0X10^6$	

2.3. Load Condition

A.L., H.L.L., or H.R.L. is selected as the load condition, and P.S. is used in addition (Figure7). These applies to experiments and analysis. The load method is pressurization by "(10) Hydraulics Cylinder", and "(9) Load Cell" and a tournament are set between the SSS and the "(10) Hydraulics Cylinder". Two partial distributed load conditions are prepared. This reason is that the choice of H.L.L. and H.R.L. may make different structural behavior of SSS. The reason for this assumption is that the shape of the SSS with asymmetric blocks is asymmetric.

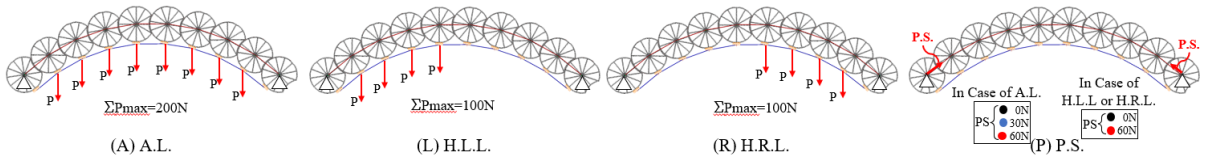

Figure. 7 Load Contidion

3. Result

3.1. Tension in the lower strings

Regarding the generation of tension in the lower strings under A.L.. It is already understood that these tension are generated when the boundary condition is pin-roller [6]. On the other hand, in this experiment, no tension was generated regardless of the presence or absence of P.S. because the support condition was pin-pin (Figure 7A). This result was consistent with the analysis and the experiment, showing that the lower string under A.L. had no mechanical role. Regardless of H.L.L. or H.R.L., the tension in the lower string occurred in the area load application, whereas that did not occur in the area of non-load (Figure. 7LR). This result tended to be consistent with the analysis and the experiment.

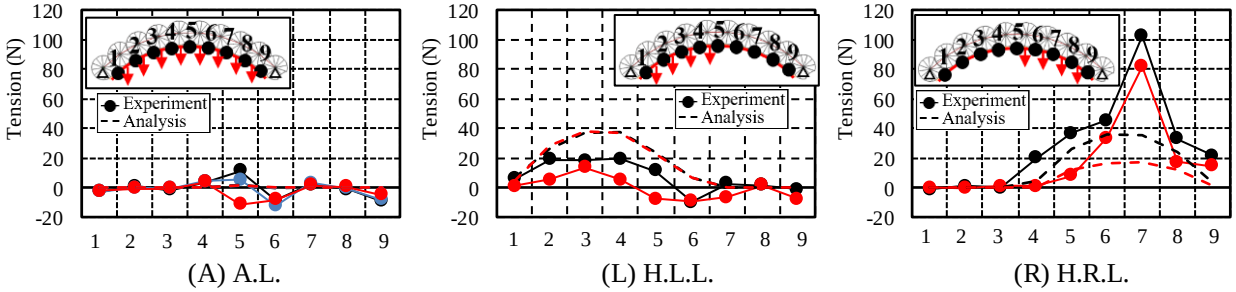

Figure. 7 Tension distribution of the lower strings

Experimental results show that P.S. reduce the generated tension. This cause was that P.S. leads to a state of close contact between the blocks, reducing slipping.

3.2. Tension in PSCable

The shape of PS Cable overlaps the axis of the entire arch. As a result, the tension of PS Cable under A.L. did not increase. An increasing P.S. led to the increasing load level that the slackness in PS Cable occurs. This result was consistent with the analysis and the experiment (Figure. 8A).

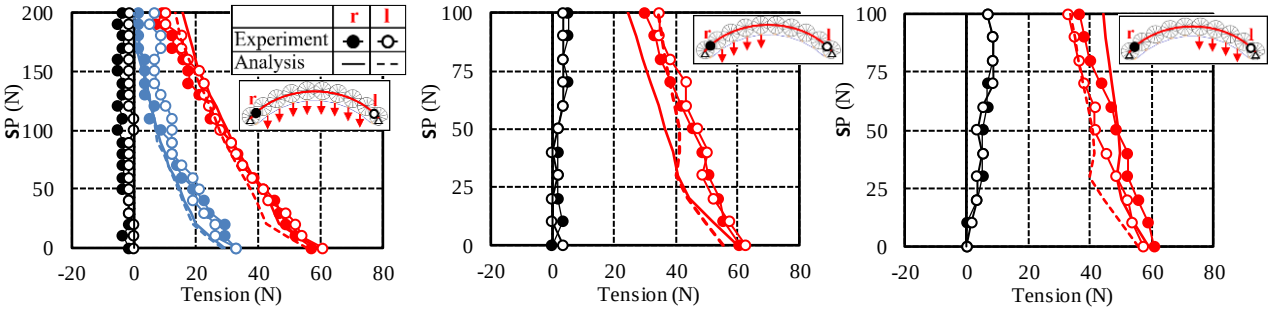

Figure. 8 Tension in PS Cable

Regardless of H.L.L. and H.R.L., P.S. led to a loosening of PS Cable tension under load. In contrast, no-P.S. led to the generation of this tension (Figure 8LR). This cause can be explained as follows: this generation is caused by the reduction of both the progressive separation between the blocks (Figure 10) and the upward deformation in the area of non-loaded (Figure 9).

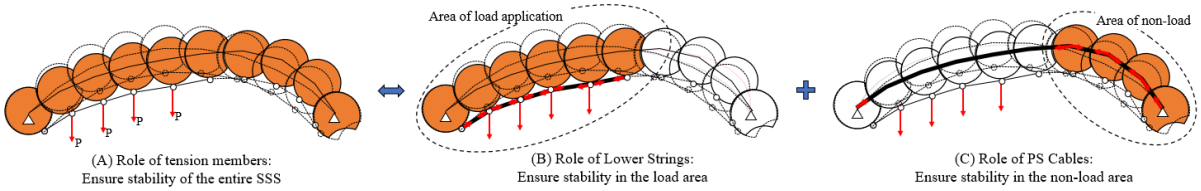

Figure. 9 Mechanical role of tension members in SCS

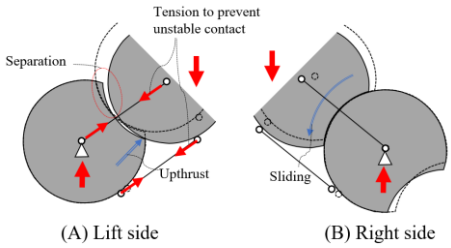

Figure. 10 Detail view of contact state between blocks

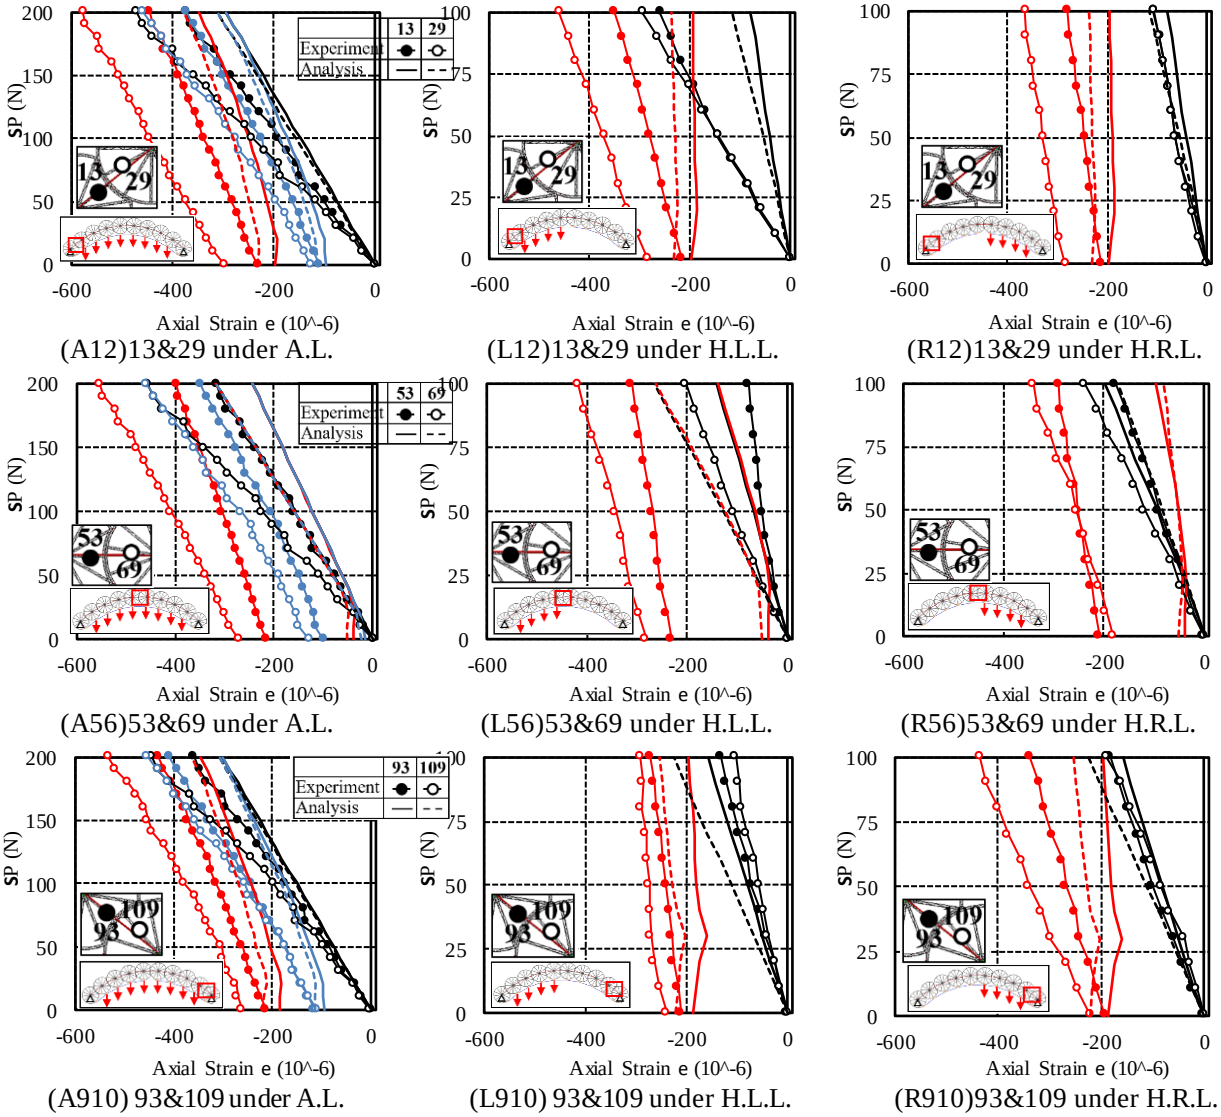

However, the analytical model without P.S. did not generate tension unlike the experimental model. The cause of this difference can be attributed to the incompleteness of the analytical model.

3.3. Axial strain of the block near axis of the entire arch

In both the experimental and analytical results, compressive strains occurred at all measured points regardless of the load conditions, and P.S. led to increasing compressive strain before load (Figure 11). This result indicates that the blocks must be designed under conditions that reducing stress due to P.S. is not expected.

The total amount of load ΣP as load condition is narrowed down to 100N, and the strain between each load is compared. There was no significant difference between the strains on the area subjected to loading under H.L.L or H.R.L. and strains under A.L.. In contrast, the strain at the non-load-bearing area under H.L.L or H.R.L. tended to be slightly smaller than the strains under A.L..

In the case of models without P.S., the results of the analysis and the experiments were in close agreement, but in the case of models with P.S., this tended to be not the case. The cause of this may be the initial imperfection of the experimental model and the incomplete analytical model pointed out in Section 3.2.

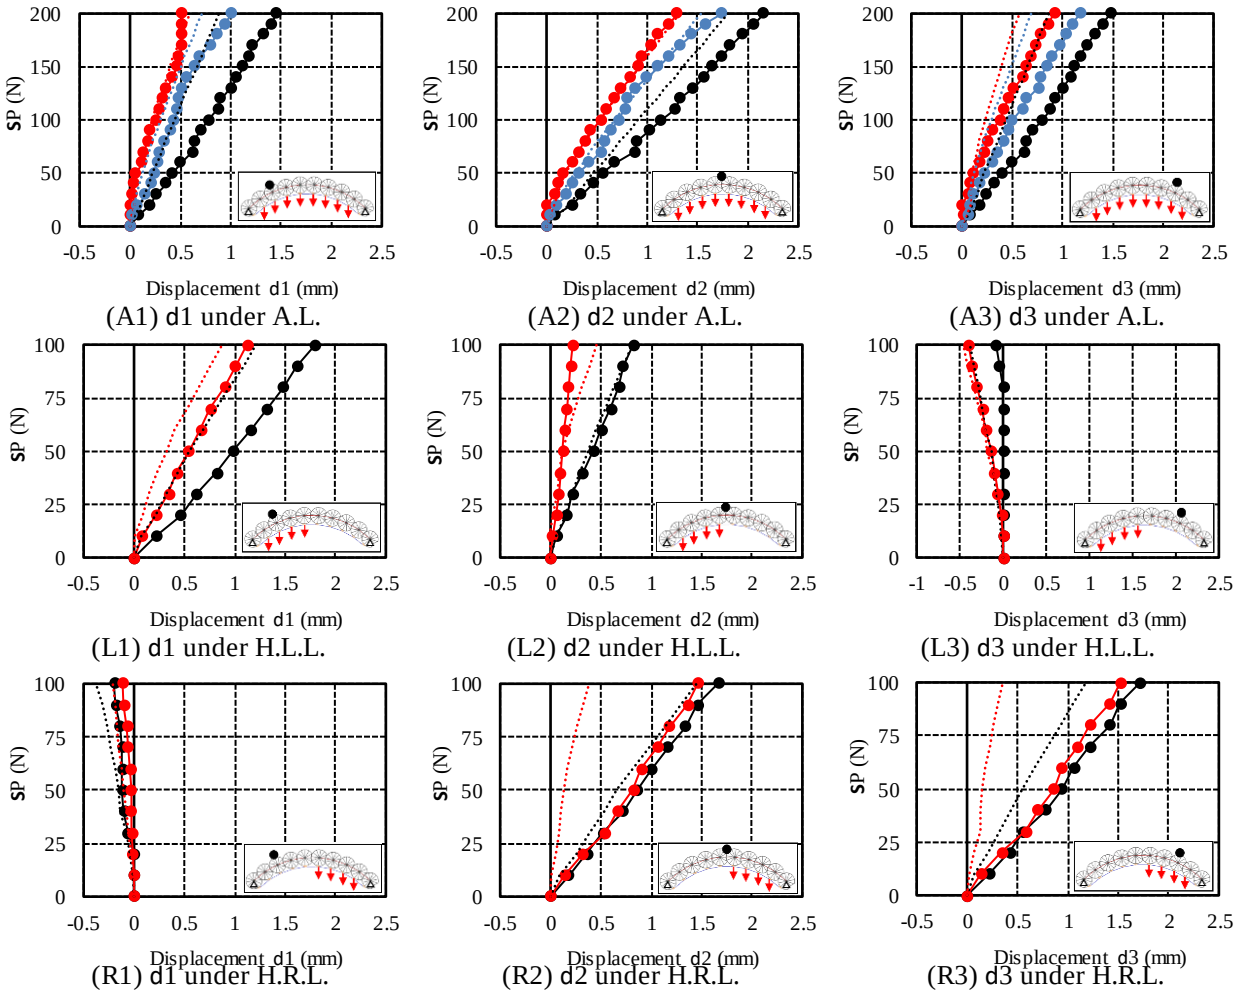
Figure. 11 Axial Strain in Block



3.4. Displacement

P.S. led to the reducing displacement of SSS under A.L. (Fig. 12A1A2A3). However, the model without P.S. showed symmetrical deformation, while increasing P.S. leds to asymmetrical deformation, such that the displacements on the left side are reduced more than those on the right side. This cause is the different contact conditions between the blocks, shown in Figure 10. For example, the convexity of the block at left end pushes up the neighboring block on the right. In contrast, the non-convexity in the block at the right end does not pushing up the neighboring block on the left. The increasing P.S. makes these differences in contact conditions clear.

In the case of H.L.L., P.S. reduced the maximum displacement (Figure 12L1L2), but not in the case of H.R.L. (Figure 12R1R2). In addition, a comparison between H.L.L. and H.R.L. showed a difference in

the state of upward deformation in the area of non-load. For example, P.S. reduced the upward displacement under H.L.L. (Figure 12L3), but not so under H.R.L. (Figure 12R3).

The cause of the different H.L.L. and H.R.L. displacements is the contact state in Figure 10, which were discussed in detail in the discussion of displacement under ALL.

Figure. 12 Displacement

5. Conclusion

The structural behavior of SCS with pin-pin support is different from that of SCS with pin-rollers. These are explained as follows based on analytical and experimental results.

*Since SSS under A.L. is the axial resisting system, the lower string has no mechanical role. However, the lower string under half load has the role of stabilizing the contact state between the blocks.

* The role of PS Cable is to reduce the separation between the blocks and the upward deformation of the entire SCS and to stabilize SSS under partial distributed load.

* The PS effects such as increasing stiffness of SCS can be expected in the case of A.L.L., but this may not be expected in the case of H.R.L.

* The PS effects under partial distributed load is to reduce the tension of the lower string under load.

* The introducing PS leads to an increasing compressive strain of the block. This shows that the adequate PS must be need so that the amount of PS is not excessive.

Future tasks are as follows: experimentally verify the fracture of the SSS and design the geometry of the block based on these results. Specifically, the thickness of each part and the arrangement of each parts in the block must be considered. Differences between experimental and analytical values are observed in the case of partial distributed loads, and a complete analytical model must be developed.

Abstract

The paper presents a suspended tensegrity "cloud" structure as an interactive art installation with computer vision. Actuated by 12 pneumatic rubber muscles, the research discusses the design, engineering and fabrication challenges of a dynamic tensegrity "cloud". Through material testing and physical prototyping processes, the design workflow enables a cross-disciplinary approach to the problems with feedback and an iterative static analysis approach. The project demonstrates a cross-disciplinary design collaboration between artists, architects, engineers, and the fabricator towards refinement in the engineering of dynamic structures. Using a pneumatic actuation system combined with tensegrity structures, the project demonstrated a method to develop active, controlled, deployable and form-changing envelopes and structures on a larger scale.

Keywords: tensegrity, fabrication, prototyping, automation, dynamic structure, interactive structure

1. Introduction

A tensegrity structure is typically used for large, spanning self-equilibrium systems composed of continuous prestressed tension cables and individual compression struts, such as the Georgia Dome by Levy [1]. Its use as a dynamic structure to shape space is rare. While there is much speculation about its interactive potential in architecture, typically through a single cell or a spine-like array, to explore transformational (as movements) or collapsible structures as soft robotics [2]. They are usually built as small-scale prototypes as proof of concept [3]. Actuations generally are limited to replacing the tension members to produce movement and are constrained by strut congestion, poor load response, and fabrication complexity.

This paper presents a suspended tensegrity structure actuated by a set of pneumatic muscles driven by a computer vision feedback system. The paper examined the engineering and fabrication of the design with a focus on the tensegrity "cloud". The project, titled the Anthropomorphic Machine, is an interactive art installation, in collaboration with the artist STELARC, that responds to the crowd's behaviour in a gallery setting, see figure 1. The paper outlines the design process balancing structural stability, integrity, and dynamic performance through prototyping. The physical prototyping process incorporates feedback from the system's virtual stress analysis and reaction forces, as well as tensile stress testing of the typical connection joints. The paper concludes with the assembly procedure of the tensegrity structure. It points towards the new potential of using tensegrity structure to modulate spatial experience through automation and machine visions. The project's significance is in demonstrating how to achieve a large-scale dynamic tensegrity structure that is atypical of its use in architecture and engineering.

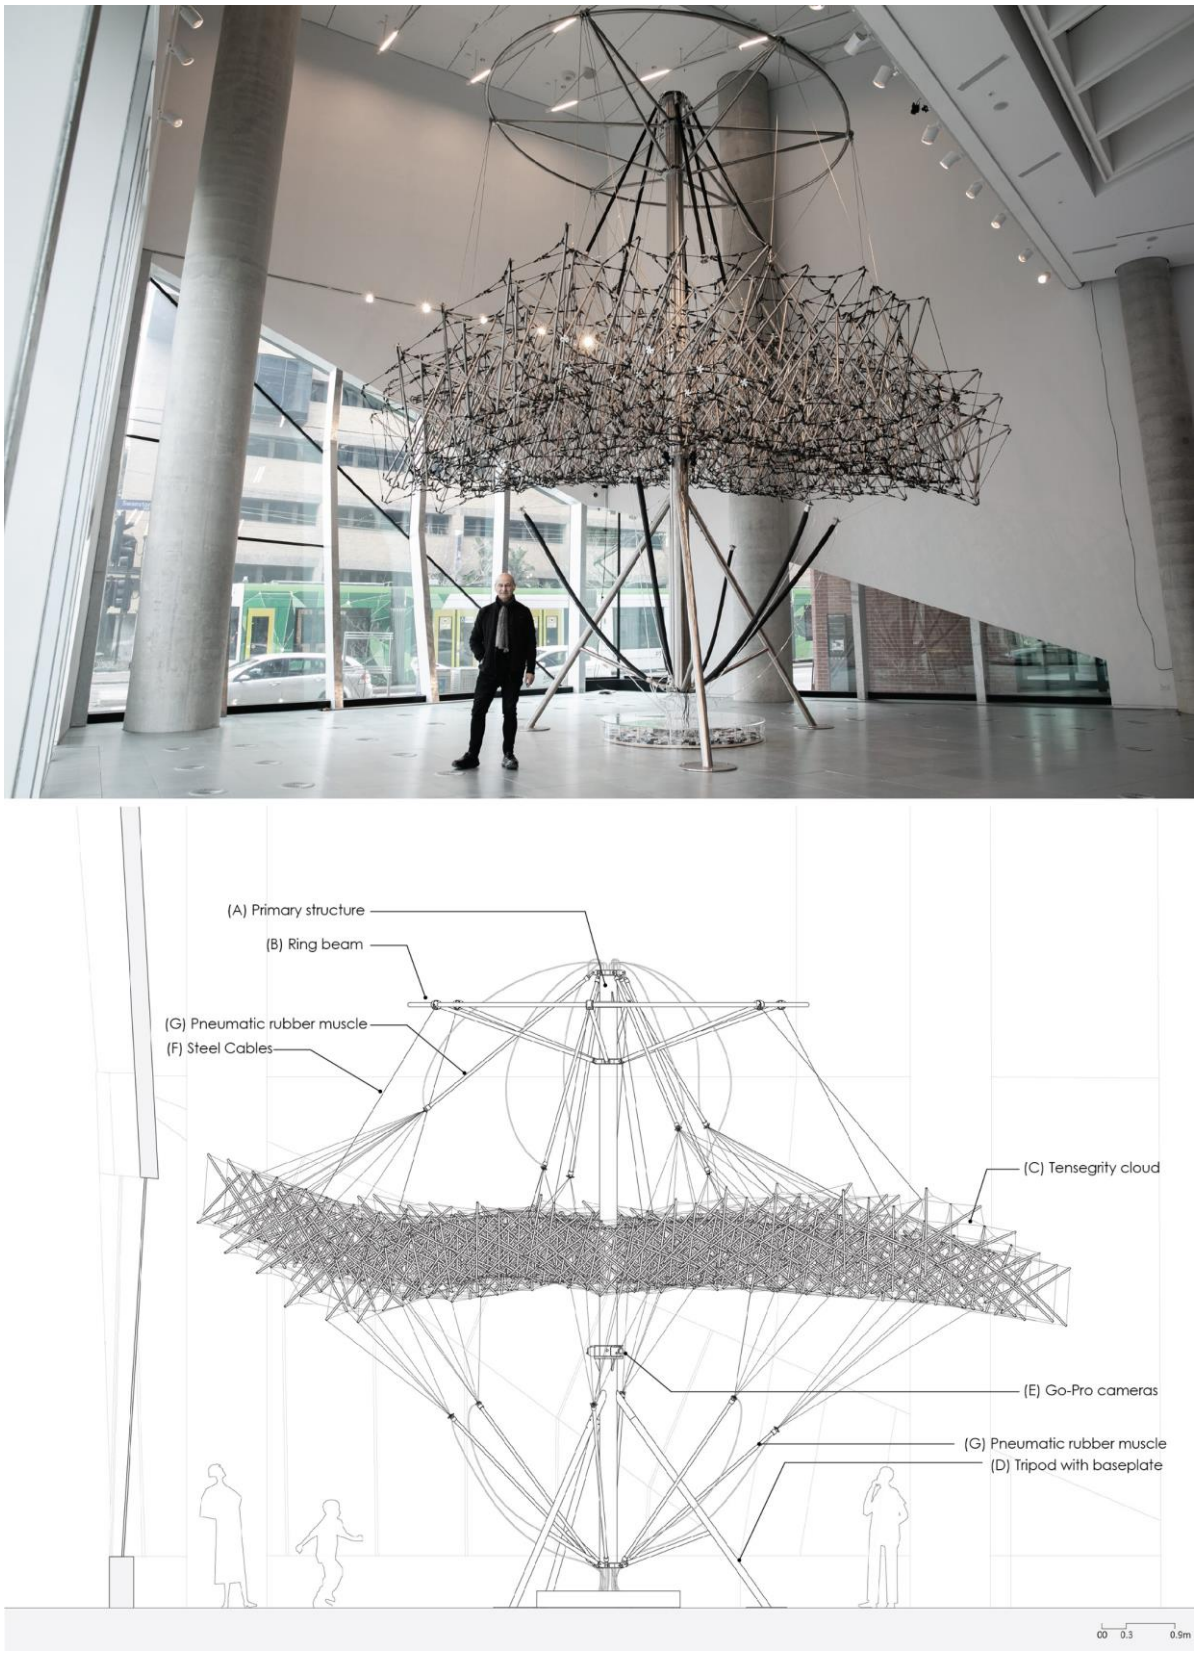

Figure 1. The 8-meter tall Anthropomorphic Machine installation in an art gallery with an actuated suspended tensegrity "cloud".

2. Background

The Anthropomorphic Machine is an interactive art installation presented as part of the Swarm exhibition at the Science Gallery Melbourne. The research was a two-year collaborative project with multiple contributors, as acknowledged at the end of the paper. Led by LLDS architects in collaboration with the artist STELARC, the structure analysis was performed by Bollinger+Grohmann engineers with the cooperation of the fabricator, Pelican Studio. The fabrication team was given a 5-month period to fabricate the structure. The installation needed to be operational 24 hours, seven days a week, as the installation was also linked to a proposed web interface that allows remote interaction. The project was intended to be in the Gallery for three months, and this was extended to 12 months post-installation.

2.1. Design of the anthropomorphic machine

The project consists of an 8-meter-tall stainless-steel primary structure with a circular ring boom and supporting struts at the top from which the tensegrity "cloud" is suspended, figure 1A, B and C. The structure sits on the raised floor of the Gallery on a tripod support structure with baseplates, figure 1D. The tensegrity "cloud" is 8 meters in diameter and consists of 204 tensegrity cells. It is suspended 4 meters off the ground using 5mm diameter stainless-steel cables, see figure 1F. Twelve pneumatic rubber muscles actuate the "cloud", each 2.5m long, that take advantage of the dynamic quality of the tensegrity to create a set of choreographed movements, see figure 1G.

2.2. Problems with tensegrity structures

A tensegrity system consists of a set of discontinuous compression components (struts) interacting with continuous tensile members (cable or cords) to define a stable 3-dimensional form. Buckminster Fuller first used the term in his 1959 patent on "Tensile-Integrity Structures" [4]. Its geometries (in various configurations) and mathematics have since been widely studied. However, the design and fabrication of tensegrity structure remain challenging. Burkhardt [5] highlighted the four obstacles in the design and fabrication of a tensegrity structure, namely: (1) strut congestion, (2) poor load response (with high deflection), (3) fabrication complexity and (4) inadequate design tools. This research utilised the high deflection of the system to produce an interactive artwork. The strut congestion becomes part of the design intent – designing opportunities for the stainless-steel struts to generate sound as they strike each other when actuated. The later section will discuss the fabrication complexity, primarily around the dynamic behaviour and connection details. As the system are difficult to predict [1], the research team develops prototypes throughout the build process to test and counteract issues around fabrication, assembly, and installation. Typically, tensegrity is designed as either a single cell (with unique arrangement) or part of dome geometry (either as a higher frequency sphere or double-layer system); a planar array is limited in its configuration [5].

3. Suspending tensegrity for interaction

The early concept of the Anthropomorphic Machine took inspiration from Loren Carpenter's Audience Participation project based on his Cinematrix Interactive Entertainment System presented at the 18th Annual Conference on Computer Graphics and Interactive Techniques [6]. Carpenter pioneered the deployment of computer vision, moving from bi-directional one-on-one interaction between a human and a computer towards multiple audience participation using images captured with a conventional camera and a computer to process the image as data [7]. In SIGGRAPH 1991, the system was tested on an audience of participants, each provided with a green and red paddle to collectively play the classic computer game, Pong [8].

3.1. Computer vision for interaction

In this project, we used an open-source software called OpenPose connected to three go-pro cameras to provide a 360 degrees vision of the Gallery, see figure 1E. OpenPose is a real-time multi-person human pose detection library [9]. The interactivity in the Gallery was based on the overall dynamic of the

human crowd movement; their speed and density (number of people) were mapped to four pre-defined sets of choreographed performances. Each set of performances creates a seamless behaviour that changes the cloud shapes and form, with a typical play length varying from 10s to 15s. The performance was caused by actuating the pneumatic rubber muscles at different speeds and frequencies. Six pneumatic muscles hung from the top to actuate the top surface of the cloud, and a further six pneumatic muscles were located below the "cloud". Aside from its self-weight, the tensegrity "cloud" must withstand the dynamic forces resulting from the performances. The design of the performance and actuation sequences are outside the scope of this paper.

3.2. Actuation system

Early experiments with students at the Melbourne School of Design explored using OpenPose to trigger a pneumatic rubber muscle - a single-action actuator which contracts up to 25% of its nominal length, actuated using compressed air (typically at 6 bar pressure) regulated by valves with no mechanical system. Figure 2 illustrates early prototypes that explored the actuation of a one-cell and 12-cell tensegrity prototype. The positioning of the pneumatic muscles is critical in maximising the dynamic effect of the cloud. When the actuator replaces one of the tension cords, the movement is precise, but its impact is minimal as a network. When the pneumatic muscle is located outside the system, its action is amplified across the network. The latter is used in the gallery installation; each muscle has a set of 2mm diameter steel cables (called tendons with 6 to 12 arrays) that connect the "cloud" as a network. The initial test also identified that all the tension members should be elastic as this help to amplify the movement; we used an industrial multi-strands shock (or bungee) cord for the installation.

Figure 2. Left, pneumatic muscle interaction with OpenPose. Right, the 12-cell tensegrity prototype actuated through OpenPose.

The final installation used twelve 2.5 meters long, 40mm diameter pneumatic muscles, with a 250 kg freely suspended additional load capacity. Each weighs 2kg with wrought aluminium alloy press-fitted connections.

3.3. Detailing of the T-prism cell

As discussed in 2.2, the tensegrity structure has several fabrication limitations and constraints. With five months to engineer and fabricate the steel structure and the 204 tensegrity cells, the design and detailing of the cell were critical to the success of the project. The design team developed a system where the individual cell was prefabricated and joined together to form a planar assembly on site.

The design team proposed using a tensegrity prism (also known as the T-Prism) as the primary cell for the planar assembly. The planar arrangement repeats rows of T-Prism with a half-cell offset; see figure 3-left. Each cell comprises of three 22.2mm diameter stainless-steel tubes acting as the compression struts (figure 3A). Two end connectors are fitted to both ends of the struts (figure 3B). The tension cables are 8mm diameter multi-strand industrial shock cords (figure 3C) with hooked connector fixtures to both ends (figure 3D). The hook is connected to the end connectors enabling the fabricator to pre-assemble the unit. A triangular arrangement of cords is on the top and bottom planes of the cell (figure 3E). These triangular cords are connected with temporary connectors (figure 3F), allowing neighbouring cells to attach and expand as an array. Once the neighbouring cells are added, the triangular cord forms part of the tensegrity network. Figure 3-right illustrates the prefabrication of a three cells cluster. With dynamic forces acting on the connectors and the cords (figure 3B, C and D), these components were tested to satisfy the dynamic load of the system, see 4.2.

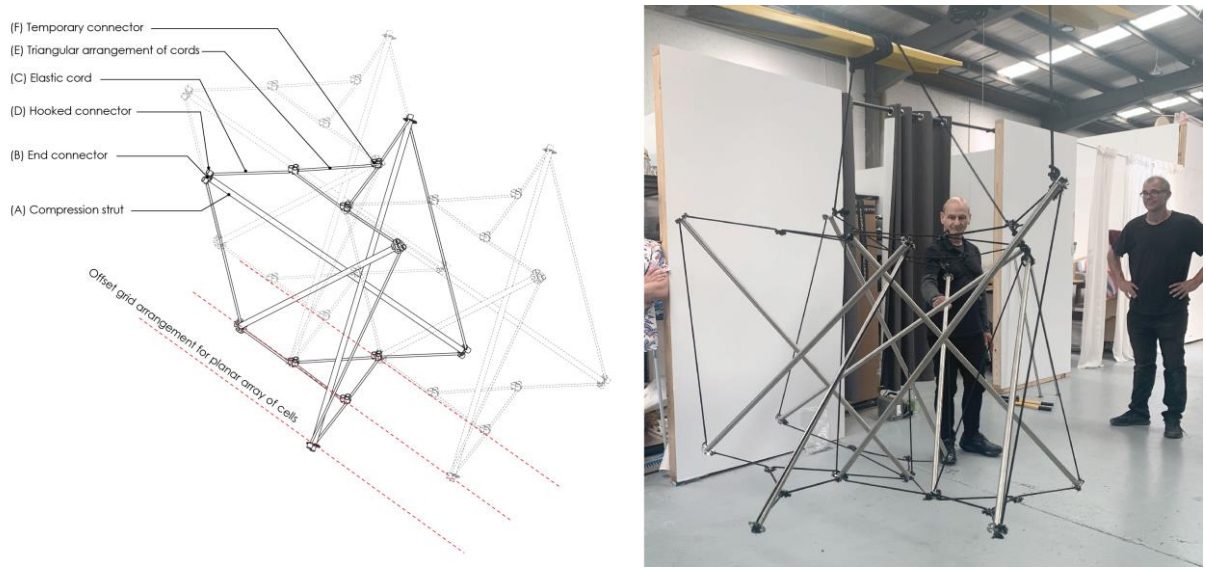

Figure 3. Left, Single T-Prism and planar arrangement of the "cloud". Right, the 3-cell cluster prototype at Pelican Studio.

4. Engineering dynamic system

This section focuses on designing and engineering the tensegrity "cloud". It comprised 204 prefabricated T-Prism cells with 612 struts, each 1340mm long. There were 1400 meters of 8mm diameter multi-stands industrial elastic (shock) cord cables that acted as tension members. In addition, 50 meters of 5mm diameter stainless-steel wire cables supported the "cloud" structure. A further 50 meters of 2mm diameter steel (tendon) wires spread the linear actuation force from the pneumatic muscle to the tensegrity network. The tensegrity "cloud" weighs 780kg. The dynamic performance of the tensegrity "cloud" posed challenges in structural evaluation. Critically, much of the materials used to fabricate the T-Prism were non-standard or unknown, particularly the elastic cord and connectors.

4.1. Testing material and connection details

The first author conducted three sets of tensile strength tests at the mechanical lab at the University of Melbourne using an Instron 5569A electromechanical Universal Testing Machine – (1) industrial elastic cord, see figure 4A, (2) strut's end connectors, see figure 4B, and (3) hooked connector fixtures to the elastic cord, see figure 4C & 4D. The data collected in the tests inform the design of the connection details and engineering analysis.

Figure 4. Ultimate Tensile Strength testing of connectors and elastic cords.

4.1.1 Tensile tests of elastic cord

The shock cord manufacturer cannot provide the material's tensile strength. The research team conducted two-sample tests; both samples were 8mm diameter industrial elastic cords with a rest length of 95mm. Sample 1 yields an Ultimate Tensile Strength (UTS) of 3.6MPA and elongation of 200.5%.

Sample 2 produces a UTS of 3.3MPA, and elongation of 183%, see figure 4A. Both samples have similar break patterns—for example, in Sample 1, the outer shell fabric tears at 190.46mm displacement at the clamps. Between 350-375mm, the individual strain of rubber breaks one at a time. In the final displacement calculation of the structure, a typical elongation of 140% was permitted, with the maximum permissible elongation of 200%.

4.1.2 Tensile tests of connecting fixtures.

The initial design for both ends of the compression struts consisted of a bespoke end connector using a 3mm laser-cut steel profile, see figure 4B. The open hook end was to connect the tensile cords. The steel distorted at 0.65kN and released the elastic cord at 0.89kN when displacement reached 455mm.

The weakness came when we tested the fixture to the tensile cord's ends. Figure 4C illustrates the initial design with a 6mm diameter stainless steel tube and a crimp joint to the end of the cord. It yielded a UTS of 1.7MPA and elongation of 152%. The worst-case scenario illustrated that the crimp connection is half as effective as the elastic cord itself. The fabricator and the architects need to reconsider the detail.

The fabricator required a quick-to-assemble solution and proposed a proprietary PET plastic hooded fixture with a compression-fit as a solution, see figure 4D. It yielded a UTS of 6.1MPA and elongation of 280%. In Sample 1, we observed the outer fabric of the elastic cord failed at the claws of the clamp. In Sample 4, the fabric failed at the compression-fit joint; we suspect this explains the higher UTS and elongation.

4.2. Structure evaluation

Typically tensegrity structures are categorised as non-linear structures. For a large arrangement of cables and struts, it is computationally complex to find its equilibrium state, especially if it is a kinematic-driven and controlled shape in continuous flux. Therefore we decided to apply a static analysis approach at various critical positions of the different shapes. The evaluation was concerned with finding the maximum internal stresses of the tension cables, compression forces in the struts to its dimension and suitable material thickness for the cables.

The overall behaviour of the different states also governed the dimensions and design of the supporting stainless steel column with its tripod legs and circular boom structure for the suspended cables. The five different states were as follows:

- Static (figure 5A). None of the muscles is activated. All the tendons (cables) are loose and should not receive any force. The main structural cables (figure 1F) support the tensegrity structure.
- Dynamic All (figure 5B): all the muscles are activated, and the tendons receive various forces.
- Dynamic V1 (figure 5C): some muscles are activated, and some tendons receive various forces.
- Dynamic V2 (figure 5D): some muscles are activated, and some tendons receive various forces.
- Dynamic V3 (figure 5E): some muscles are activated, and some tendons receive various forces.

The simulation considered a maximum of 200% elongation for the multi-strand elastic cord. The results showed the highest reaction forces nearest the "cloud" centre at 9kN. The highest displacement of the structure came from the splicing of the support legs, resulting in a maximum deformation of 40mm. The stainless steel support structure reached a maximum of 60% utilisation, and the support cables had a maximum normal force of 1.6 kN. The analysis showed that some suspension cables would fail under tension forces during dynamic behaviour. However, due to the redundancy in the system, the structure was always predicted to be stable.

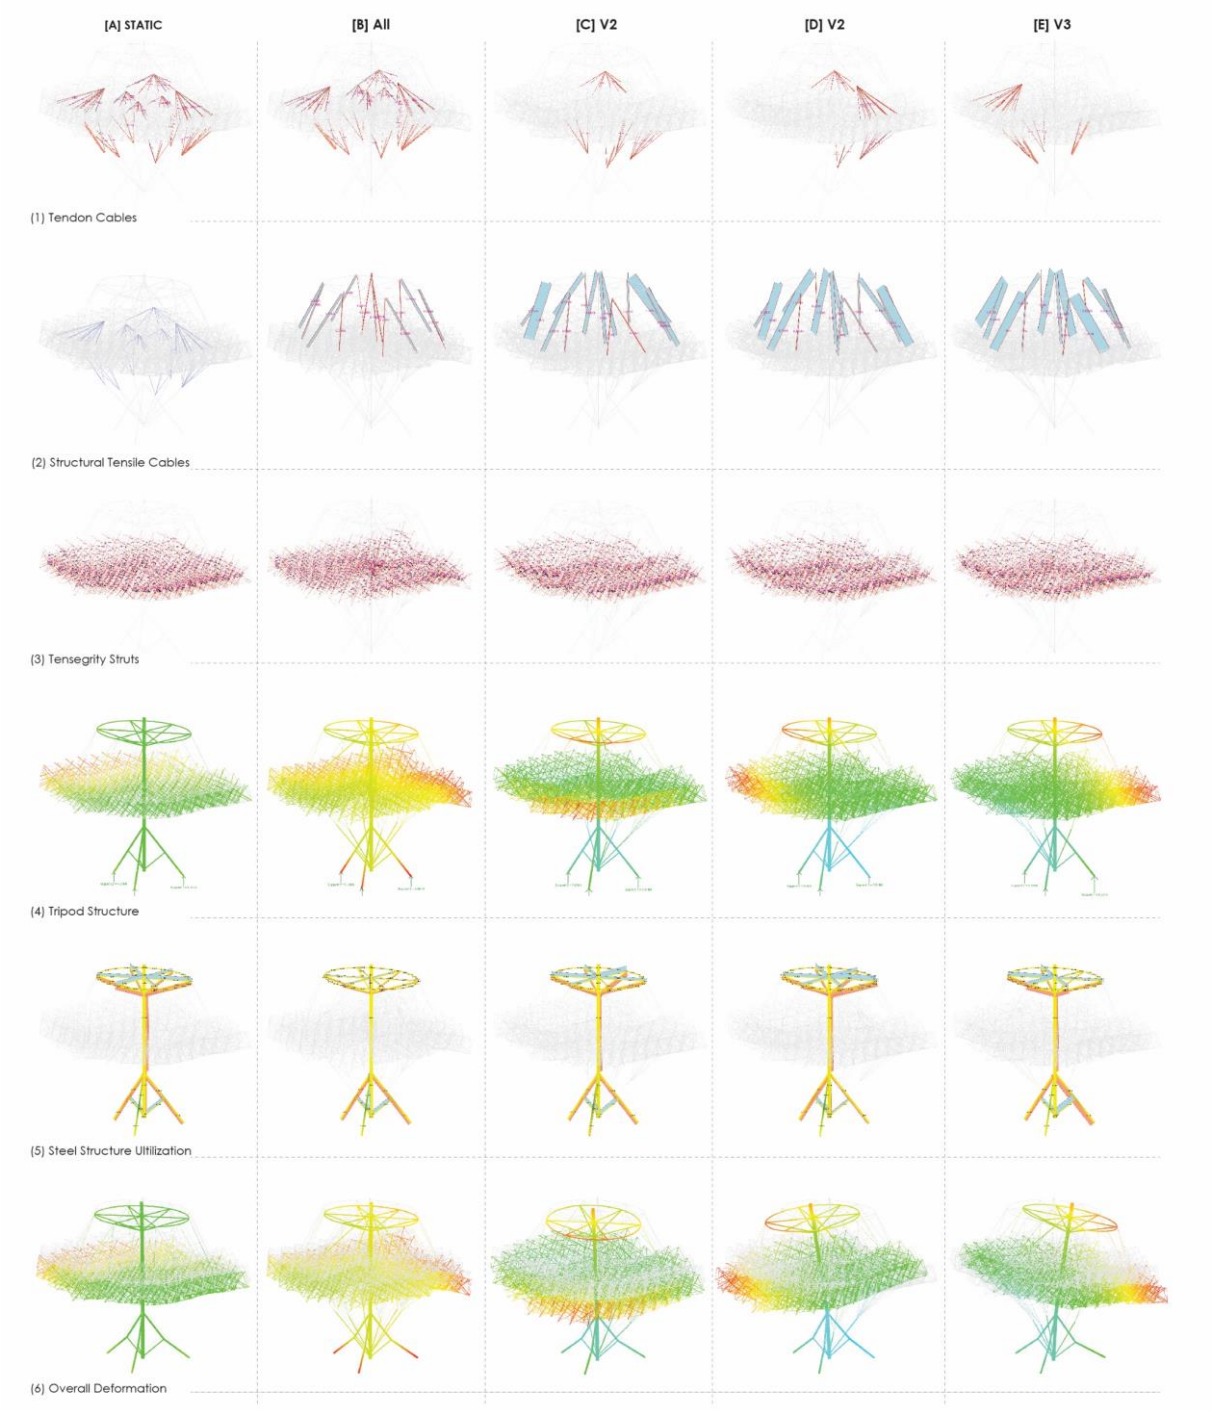

Figure 5. Matrix of static analysis across the five different states. (1) Forces on tendon cables caused by pneumatic muscle actuation. (2) Maximum internal stresses of the tension cables at the various states. (3) Compression forces in the tensegrity struts. (4) Forces on the tripod support structure and its impact on the raised gallery floor. (5) Steel utilisation of the primary structure. (6) Overall deformation at the various states.

5. Assembly of the tensegrity cloud

The primary frame was erected in the Gallery in two parts. Figure 6 illustrates the assembly of the tensegrity "cloud". The design of an individual cell allowed all the parts to be prefabricated off-site and assembled in the Gallery. As the cells were assembled, parallel lines denoting the row alignments were set out on site. Rows of tensegrity were built and then connected together. Once the cloud was completed on the ground, it was lifted 300mm higher than its final position and suspended with 12 steel cables connected to the circular ring boom. This allowed the installer to slowly adjust the "cloud" into position after installing the pneumatic muscles. The pneumatic muscles must remain in a "relaxed" position and not take the tensegrity load until it is inflated with air. The bunching of the tensegrity cell was challenging for the installation when it was suspended. The configuration is unpredictable, despite the best effect to simulate it in Grasshopper 3D. It resulted in an uneven load distribution across the 12 supporting steel cables, causing them to twist and tangle. The suspension cables and the positioning of the wires were manually adjusted; this amplified the human error affecting the "relaxed" state of the "cloud". These effects are hard to predict and simulate, and as Knippers stated, physical prototypes are necessary when engaging with new materials and material systems [10]. Therefore, during the installation phase, the engineer checked and worked with the installer to adjust the cable positions to ensure an evenly distributed load. The installation took over five days, followed by one week of testing with the dynamic performance.

During the testing phase, three shock cords broke, resulting from the actuated movement. The congested struts, predominantly around the central column of the primary structure, caused some of the elastic cords to rub against the steel connectors and tear its outer fabric. Additional stay cables were introduced to pull the tensegrity away from the column. Three inner cells were also removed during the testing process.

5.1. Discussions

When actuated, the Anthropomorphic Machine produces a variety of dynamic performances. The most compelling is the slow inhalation and exhaustion of air mimicking 'breathing'. This results in the 'cloud' animating slowly above the visitors, changing the experience of the space. Since installation, prominent Australian dancers, artists and musicians have created performances interacting with the structure.

There are several key lessons learnt in this project. First, the project could only be possible through interdisciplinary knowledge and collaboration. The architects have also taken on a significant role in prototyping the design and developing the actuation system – this interdisciplinary bridge is critical. Second, the project results from design and engineering research through testing and prototyping. The knowledge gained through the fabrication process informed the final design. Last, the project demonstrates a refinement in engineering towards dynamic structural design. The use of pneumatic elements in combination with tensegrity structures illustrates a method to develop active, controlled, deployable and form-changing envelopes and structures on a larger scale. However, the system still requires a level of maintenance (visual inspection and replacing shock cords). The shock cords seem to rapture in an irregular pattern while the Machine is operational. The team believes this might be because the dynamic load on the cord and the increased state of change in elongation (cycling through the different performance modes) are causing the cords to break faster than expected. Further on-site testing and investigation, especially into the shock cord layout and material composition, should be conducted to identify the issues and to be able to suggest improvements to extend the life expectations of the structure.

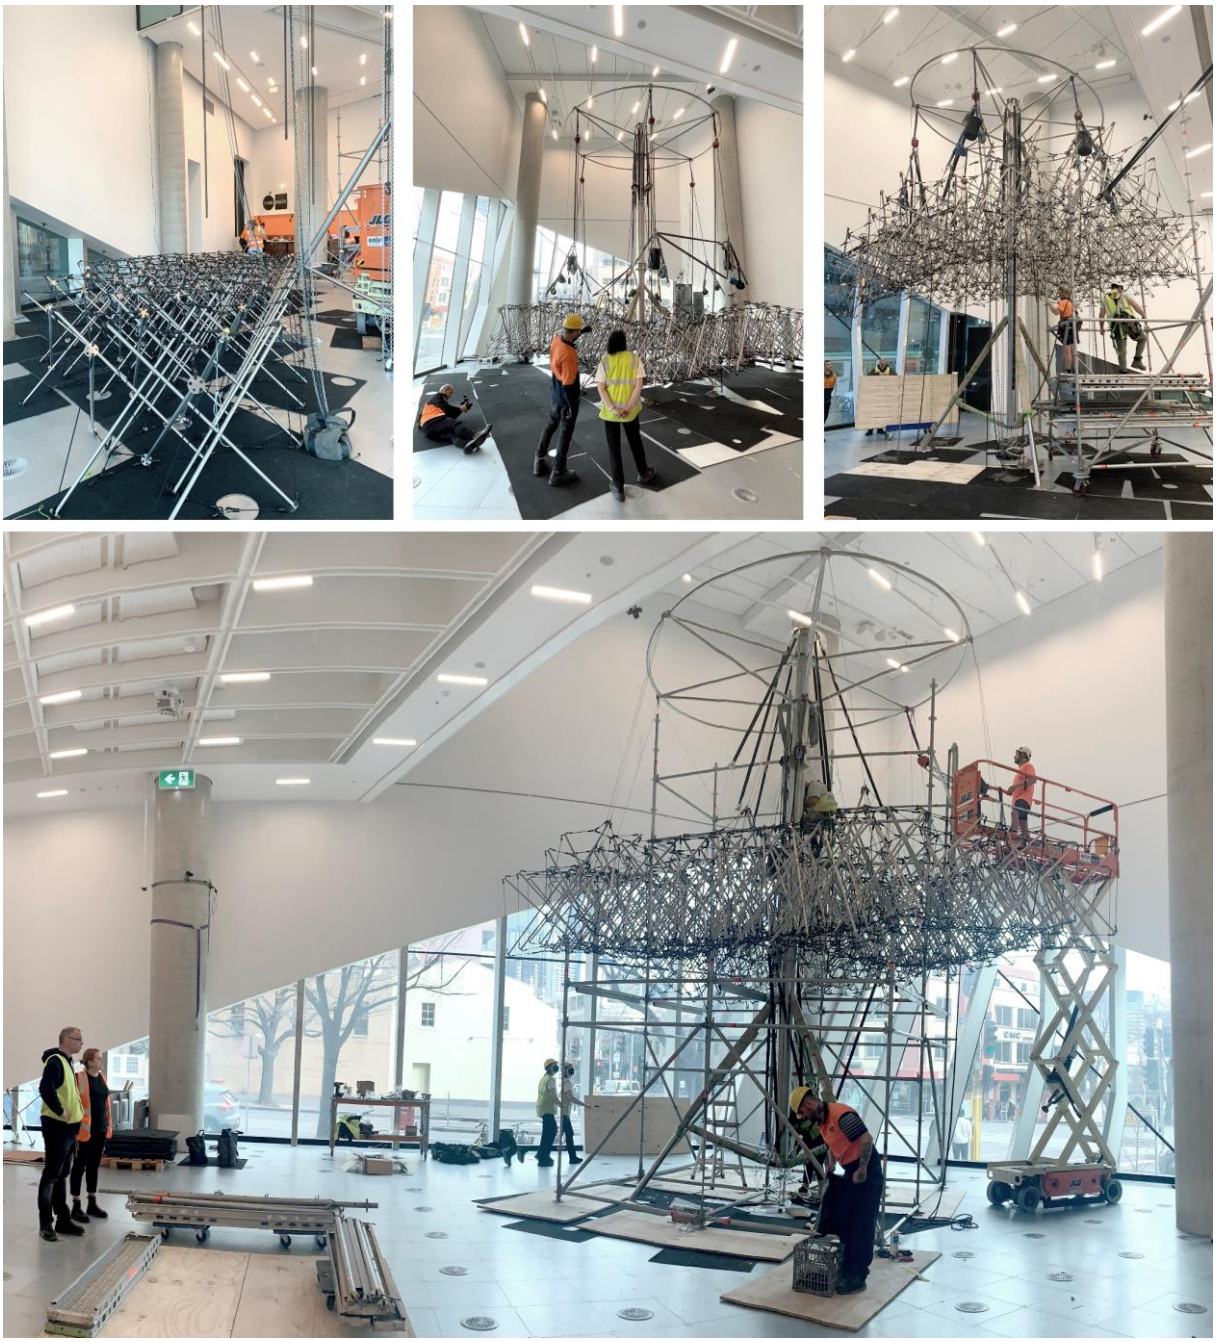

Figure 6. Top left, setting up of T-Prism planar array for the tensegrity cloud. Top centre, Suspension of tensegrity cloud. Top right, lifting of tensegrity cloud into position. Bottom, adjustment to tension cable to distribute the load evenly. Pneumatic muscles are in relaxed mode without air inflation.

6. Conclusion

The paper presents an unconventional use of tensegrity structure as a suspended and dynamic interactive installation. The high deflection of the tensegrity is maximised as part of the performance design, which creates challenges in the system's design, prototyping, fabrication and installation. The design and fabrication of the tensegrity were refined through material testing, and data was used to evaluate its dynamic behaviour through an iterative static analysis approach. The project illustrated a method of assembling T-Prism tensegrity cells into a planar arrangement and discussed the challenges of the

assembly process. It demonstrates a successful cross-disciplinary design collaboration between artists, architects, engineers, installers and fabricators.

Abstract
Active control has been increasingly used in civil engineering to improve the performance of structures in service and to avoid serious damage to structures. Hybrid string structure is an efficient hybrid system composed of upper chord rigid components, lower chord flexible components, and struts. Based on an optimization-based model, this paper proposes a set of active control approach for hybrid string structures including the beam string structure (BBS) and suspen-dome structure (SDS) by applying the genetic gradient algorithm (GGA) and multi-population genetic algorithm (MPGA). To verify the validity of GGA and MPGA in terms of search control strategies, an experimental case and two numerical cases are investigated. The test and simulation results show that the active control based on the GGA and MPGA can effectively optimize the mechanical properties of BBS and SDS (e.g., the stress, displacement, and strain energy), which validates the validity of GGA and MPGA. The research methods and conclusions of this paper can provide valuable references for the active control of hybrid string structures or similar structures.

Keywords: active control, hybrid string structure, member stress, nodal displacement, strain energy, genetic gradient algorithm, multi-population genetic algorithm

1. Introduction

According to the tension elements, the tension structures is divided into two types: (1) membrane structures and (2) string structures [1]. Tension members such as cables, rods, and chains belong to strings. The string structures includes pure tension structures and hybrid tension structures, where pure tension structures are those made up of strings only, and hybrid tension structures is the structures created by mixing tension and rigid members (e.g., arches, beams, and struts), which mainly includes the beam string structures (BBS) and suspen-dome structures (SDS). Because of good mechanical properties and high utilization rate of material strength, the BBS and SDS have been extensively applied in various civil infrastructures and large construction structures [2,3], for example, the Shanghai Pudong International Airport Terminal, National Indoor Stadium, Tianjin Sports Center Bicycle Gymnasium, and Xuancheng Stadium, as shown in Fig.1.

The civil structures are traditionally designed to remain static and passively endure external loading, resulting in heavy structures, high material consumption, and significant CO2 emissions. The statistical research indicates that this sector is responsible for a significant amount of global non-renewable material consumption and energy-related CO2 emissions [4]. However, incorporating active adaptation to civil structures could lead to lightweight structures that autonomously adjust to changing environmental conditions. While this poses challenges, it also presents an opportunity to address industry issues [5]. Active structures have sensors and actuators that detect and respond to external loading, improving the structure's performance [6]. Yao originally introduced active control to civil engineering [7], and Soong and Manolis put forward a modern concept of active civil structures for the first time [8]. Through decades of sustained development, a large number of active control devices and technologies (e.g., the hybrid active mass damper, shape memory alloy actuator, and magnetorheological damper) have been developed for vibration control [9-12]. Furthermore, active control has also been applied to various applications such as retractable roofs [13], antenna structures [14], and daylight regulation in buildings [15].

Previous researches have focused on active spatial structures. Senatore et al. proposed a set of design and control methods for active truss structures based on whole-life energy minimization systematically, and tests of two active trusses and various numerical cases provided strong evidence of the validity of the method [16-19]. Wang et al. presented an integrated formulation for achieving the total energy optimization of active tensegrity structures [20]. Besides, a general approach for designing the active tensegrity structure with minimal mass is also provided by Wang et al., and active designs can reduce material usage compared to passive designs, resulting in lighter tensegrity structures [21]. Korkmaz extended the study on active control of tensegrity structures to self-repair of structural damage, utilizing active components to implement an intelligent control method based on the stochastic search, the repair function meets the requirements for safety and availability in the event of cable damage [22,23]. Fest et al. created an active structure consisted of five tensegrity units, in which some compression bars were constructed as linear actuators and proactive modifications based on preset procedures well fulfill the structure's usage needs in various operating modes [24]. Lu et al. developed an internal force control method using ant colony algorithm for cable dome structures and discussed the effect of optimizing the internal force under different actuator arrangement strategies [25]. With sensors for force detection and active components for modifying the stiffness configuration and stress properties of the structure, Kmet et al. applied a Levy cable dome to investigate how sensing and actuation systems can adapt a structure to changes in external loads [26]. As far as BBS and SDS are concerned, a great deal of researches has been carried out for their static and dynamic analysis, thermal analysis, wind effects, seismic behavior and parameter optimization [27-32], but little research has been done for their active control.

In this paper, a set of active control approach for hybrid string structures including the BBS and SDS by using the genetic gradient algorithm (GGA) and multi-population genetic algorithm (MPGA) based on an optimization-based model. To verify the validity of GGA and MPGA for searching control strategies, an experimental case and two numerical cases are investigated, and the validity of GGA and MPGA are validated through analysis of numerical and experimental results.

2. Active control model

The BBS and SDS are both made up of upper chord rigid components (i.e., the beams of BBS and latticed shell of SDS), lower chord flexible components (i.e., the cables), and struts connecting the upper and lower chords. The rigid components withstand external loading directly, and the prestressing is introduced into the cables to improve the mechanical properties of upper chords. Struts play an important role in the structural systems of BBS and SDS, and changes in their length can lead to the significant redistribution of internal forces. Therefore, the active control of BBS and SDS is able to be achieved through the length changes of struts. In this paper, the struts are embedded in the actuators so that they can change lengths linearly.

The equilibrium of BSS and SDS under external loading is expressed as

$$KU = P \tag{1}$$

Where K is the stiffness matrix, U is the nodal displacement matrix, and P is the external loading matrix.
The active control process of BBS and SDS is limited by the material characteristics of components, specification of actuators, and overall synergy of the structure, and the following constraints should be satisfied:

$$d^l \le d \le d^u \tag{2}$$
$$\sigma_u^c \le \sigma_u \le \sigma_u^t \tag{3}$$
$$\sigma_s^c \le \sigma_s \le \sigma_s^t \tag{4}$$
$$\sigma_l^m \le \sigma_l \le \sigma_l^t \tag{5}$$
$$-F_s^b \le F_s \tag{6}$$
$$\Delta L^l \le \Delta L \le \Delta L^u \tag{7}$$

Where d is the nodal displacement, σ_u, σ_l, and σ_s are the stresses of rigid components, cables, and struts, d^u and d^l are the upper and lower limits of allowable node displacement, σ_u^c and σ_u^t are the allowable compressive and tensile stresses of the rigid component, σ_s^c and σ_s^t are the allowable compressive and tensile stresses of the strut, σ_l^m is the minimal stress at which the cable do not quit working, σ_l^t is the allowable tensile stress of the cable, F_s is the internal force of strut, F_s^b is the buckling load of strut, ΔL is the linear change of the strut, and ΔL^u and ΔL^l are the upper and lower limits of the actuator.
Without loss of generality, the active control objective of BSS and SDS is defined as $f(x)$, which can be the stress, displacement, or strain energy, etc. The active control model for BBS and SDS with the objective minimized is shown below:

$$\min f(x) \qquad \text{s.t. Eqs. } (1)\sim(7) \tag{8}$$

3. Search algorithm

3.1. Standard genetic algorithm

Standard genetic algorithm (SGA) originates from the computer simulation of biological system and is a random global search approach that simulates the selection, crossover, and mutation in natural selection and genetic evolution. Starting from any initial population, the population evolves to an increasingly better region of the search space through random selection, crossover and mutation operations to produce a group of individuals that are better suited to the environment, so that the population continues to reproduce and evolve from generation to generation, eventually converging on a group of individuals that are best suited to the environment and thus finding a quality solution to the problem. The main features of SGA are as follows:
(1) SGA is able to operate directly on the structure objects without derivation and function continuity restrictions;
(2) SGA has intrinsic implicit parallelism and good global search capability;
(3) In the absence of definite rules, SGAs use probabilistic optimization methods to automatically acquire and guide an optimized search space and adaptively adjust the search method.
The flow chart of SGA is shown in Fig. 2.

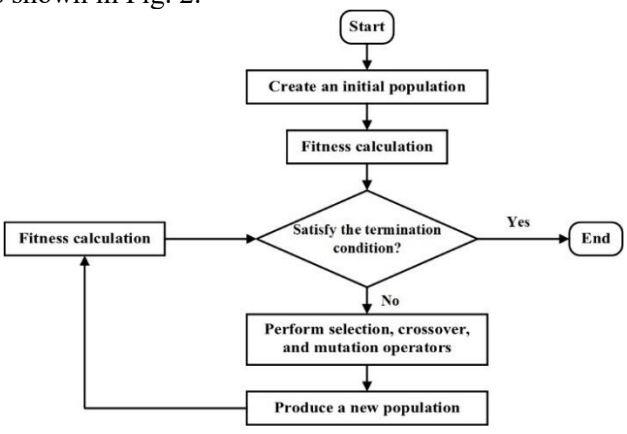

Fig. 2. Flow chart of SGA

3.2. Genetic gradient algorithm

Gradient descent (GD) is a type of iterative method that can be used to solve least squares problems. It iteratively searches for the minimum value along the gradient descent direction and can converge quickly to the optimal result. The general steps of GD are as follows:

Step 1: Specify the initial point $x^0 \in R^n$, set the termination error ε and maximum iterations N;

Step 2: For x^k, solve the gradient of the objective function $\nabla f(x^k)$, calculate the step size λ^k and move in the direction of the negative gradient for $\lambda^k \nabla f(x^k)$, thus $x^{k+1} = x^k - \lambda^k \nabla f(x^k)$.

Step 3: Cycle Step 2 until $f\left(x^{k+1}\right) - f(x^k) \leq \varepsilon$;

Step 4: Output x^k and x^{k+1}.

GD is shown schematically in Fig. 3. GD is fast and can easily obtain local optimal solutions near the iteration point, but for optimization problems with multiple local optimal solutions, this method is difficult to find other local optimal solutions far away from the current location point, making it difficult to search for the global optimal solution. It is noteworthy that SGA is good at global search, but have limited local convergence. Genetic-gradient algorithm (GGA) is a global search algorithm established by combining SGA and GD, and it has good local convergence as well as ensuring global search capability. The flow chart of GGA is shown in Fig. 4.

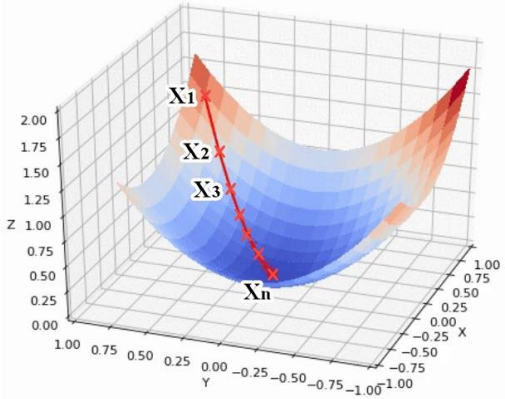

Fig. 3. Schematic diagram of GD

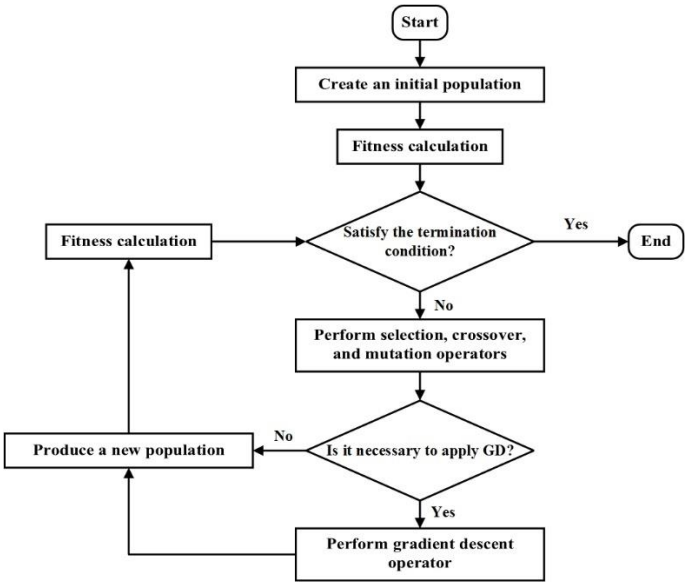

Fig. 4. Flow chart of GGA

3.3. Multi-population genetic algorithm

Multi-population genetic algorithm (MPGA) is based on SGA and introduces the concept of multi-population, which can solve the premature convergence problem of SGA. The main improvements of MPGA are as follows:

(1) MPGA breaks away from the framework of SGA, which only relies on a single population for the genetic evolution, and introduces multiple populations for the simultaneous optimization search, and different populations are assigned different control parameters to achieve different search purposes;

(2) The populations are connected by the transport operator, enabling the co-evolution of multiple populations, and the optimal solution is obtained as a combined result of co-evolution;

(3) The optimal individuals in each evolutionary generation of the various populations are preserved by the artificial selection operator and are used as a basis for judging the convergence of the algorithm.

Fig. 5 presents the flow chart of MPGA. In MPGA, the populations are relatively independent and are linked to each other by the transport operator, and the transport operator regularly introduces the best individuals from each population into other populations during the evolutionary process, enabling the exchange of information between populations; the elite population are not like other populations, and at each generation of evolution the best individuals from other populations are selected by the artificial selection operators and placed in the elite population for conservation; and the elite population is also the basis for judging the termination of the algorithm.

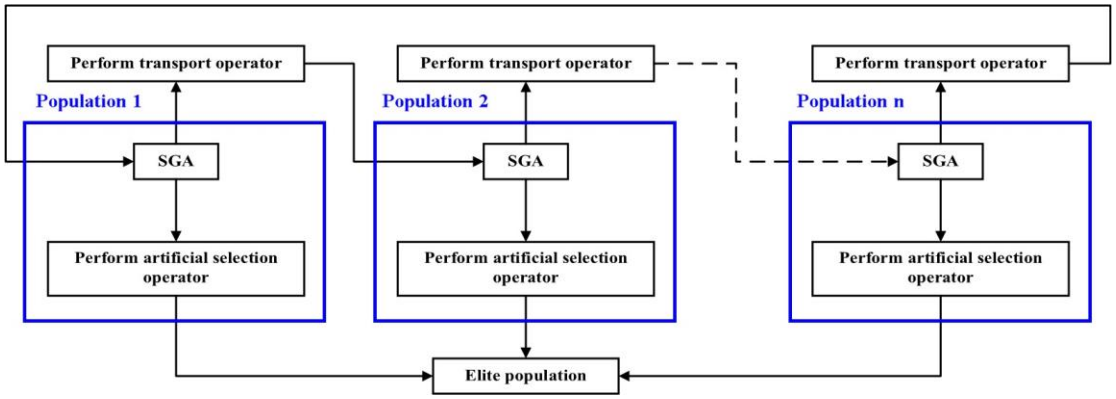

Fig. 5. Flow chart of MPGA

In this paper, GGA and MPGA are used to search for active control strategies of BBS and SDS, respectively.

4. Experimental case: single-span BBS model

A single-span BBS model with a span and sag of 4 m and 0.68m is developed for active control research. The model consists of a beam made of aluminum alloy, a cable made of carbon steel, and three struts made of cast iron. To measure the stresses and vertical displacements of the rigid beam directly subjected to load, four strain gauges are installed on the upper surfaces of spans 1/8, 3/8, 5/8, and 7/8 of the beam, while other four strain gauges are installed on the lower surfaces in the same position; and three displacement gauges are installed uniformly on the lower surfaces of the beam. As active elements, the three struts with the incipient lengths of 0.54 m, 0.68 m, and 0.54 m are specially customized, their total strokes are 100 mm, 150 mm, and 100 mm separately, and the extension and contraction strokes are the same for each strut. The installed BBS model is displayed in Fig. 6, and the layout of measurement points are shown in Fig. 7, where Si and Di denote the i^{th} stress measurement point and i^{th} displacement measurement point.

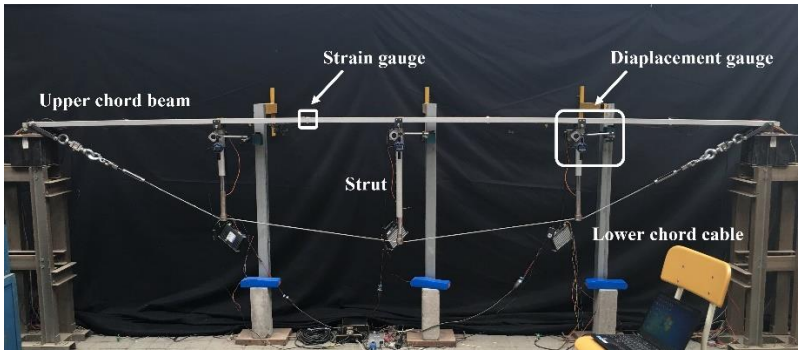

Fig. 6. Single-span BBS model at the experimental site

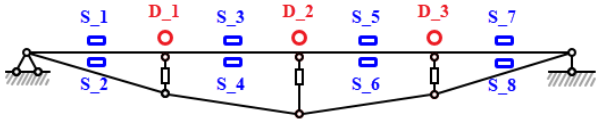

Fig. 7. Layout of measurement points

In this case, GGA is adopted for searching control strategy, and the active control objective is set to minimize the vertical displacement of the beam, which is expressed as

$$f(x) = \max d_i^v \tag{9}$$

Where d_i^v is the vertical displacement of the i^{th} observation point.

To simulate the external load acting on the test model, two loading scenarios are defined, as shown in Fig. 8. The tests are carried out using a nodal load loading method with the loading points evenly spaced on the beam, and nodal loads are simulated by means of weight blocks. Fig. 9 shows the loading schematics of two loads.

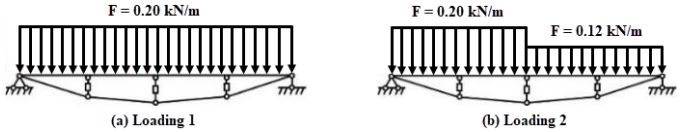

Fig. 8. Definition of loading scenarios

Fig. 9. Loading schematics of two loads

Fig. 10 illustrates the change in vertical displacement of the measurement points before and after the control, where the upward and downward vertical displacements are positive and negative, respectively. From the figure, for loading 1, the vertical displacements of the measurement points before control are -4.2 mm, -6.0 mm and -4.2 mm, which change to -0.2 mm, 0.5 mm and -0.1 mm after control; and for loading 2, the vertical displacements of the measurement points before control are -6.3 mm, -4.3 mm, and -0.2 mm, which change to 0.7 mm, 0.7 mm, and -0.1 mm after control. The average reduction in vertical displacement of the measurement points is 84.5%, with a maximum reduction of 97.6%. It shows that the implementation of active control strategy can significantly reduce the vertical displacement of the beam. Fig. 11 shows the variation in stress of the measurement points before and after the control, where the tensile and compressive stresses are positive and negative, respectively. From the figure, for loading 1, the maximum and mean stress of the measurement points are up to 5.8 MPa and 4.5 MPa, and they fall to 4.9 MPa and 2.9 MPa; and for loading 2, the maximum and mean stress of the measurement points are up to 9.2 MPa and 5.2 MPa, and they fall to 4.9 MPa and 2.6 MPa. The

results indicate that the process of controlling the vertical displacement also optimizes the stresses in the beam to some extent.

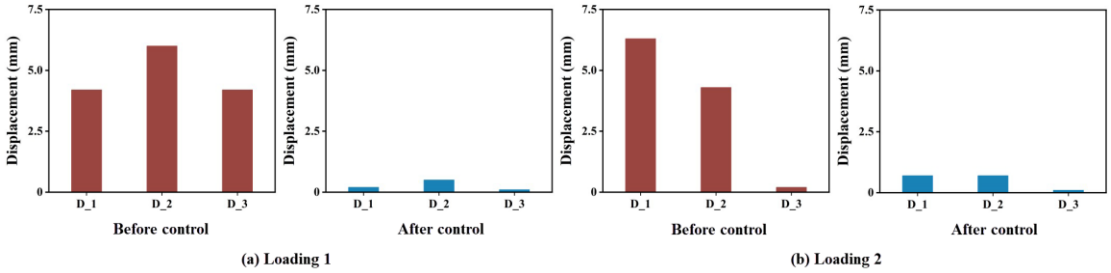

Fig. 10. Vertical displacements of measurement points before and after control

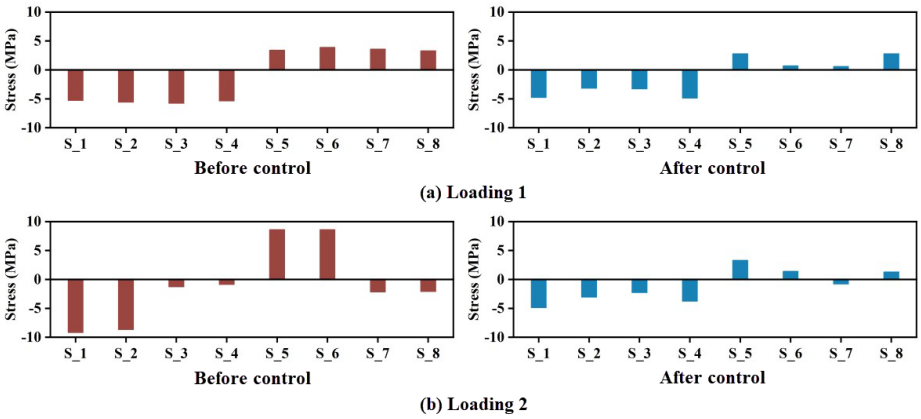

Fig. 11. Stresses of measurement points before and after control

5. Numerical case 1: Bi-directional BSS

In the structural analysis module of the software ANSYS, a 3D dimensional parametric finite element model of a bi-directional BBS is established. The bi-directional BBS has the size of 24 m×24 m×2.4 m. The simulation of the beams adopts the 3D linear finite strain beam element Beam188, the linear actuator element Link11 is applied to model the struts, and the 3D finite strain bar element Link180 is used for simulating the cables. The supports on each side of each span of the BBS are set as fixed and sliding supports separately. Fig. 12 presents the schematic diagram of bi-directional BBS. To simulate the external load acting on the bi-directional BBS, two loading scenarios are defined, as shown in Fig. 13.

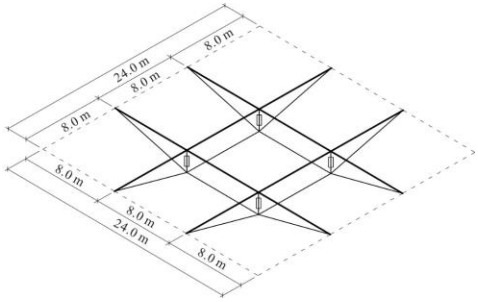

Fig. 12. Schematic diagram of bi-directional BBS

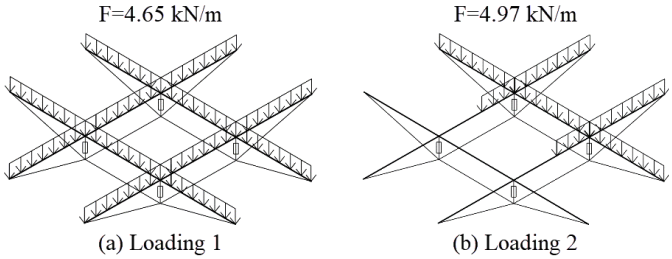

Fig. 13. Definition of loading scenarios

In this case, GGA is adopted for searching control strategy, and the active control objective is set to minimize the vertical displacement of the beam, which is expressed as

$$f(x) = \max \sigma_i \tag{10}$$

Where σ_i is the stress of the i^{th} observation point.

Table 1 lists the change in the maximum stress and displacement of the beams before and after the control. From the table, for loading 1, the maximum stress and displacement of the beams are 89.4 MPa and 95.9 mm, with the implementation of active control strategies they are decreased by 21.0% and 82.6% to 70.6 MPa and 16.7 mm; for loading 2, the maximum stress and displacement of the beams are 113.8 MPa and 76.4 mm, with the implementation of active control strategies they are decreased by 15.7% and 73.4% to 95.9 MPa and 20.3 mm. In general, after active control, the peak internal forces of the beams are effectively controlled and the beam deformation is also substantially improved.

Table 1. Simulation results before and after control

	Loading 1		Loading 2	
	Before control	After control	Before control	After control
Maximum stress (MPa)	89.4	95.9	113.8	76.4
Maximum displacement (mm)	70.6	16.7	95.9	20.3

6. Numerical case 2: Kiewitt SDS

In the structural analysis module of the software ANSYS, a 3D dimensional parametric finite element model of a Kiewitt SDS. The Kiewitt SDS has the size of 12 m×12 m×1.2 m. The latticed shell is simulated through the Beam188 elements, the cables are modelled by the Link180 elements, and the struts are simulated though the Link11 elements. The supports at the bottom of the structure are set as fixed supports. The schematic diagram of Kiewitt SDS is shown in Fig. 14, where the blue, red, and green elements denote the latticed shell, cables, and struts separately. To simulate the external load acting on the Kiewitt SDS, one loading scenario is defined, as shown in Fig. 15.

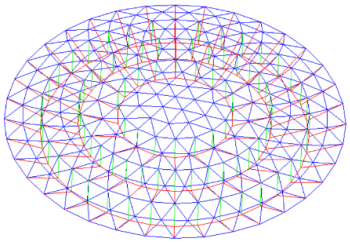

Fig. 14. Schematic diagram of Kiewitt SDS

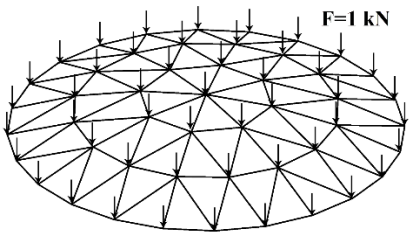

Fig. 15. Definition of loading scenario

In this case, MPGA is adopted for searching control strategy, and the active control objective is set to minimize the strain energy of the beam, which is expressed as

$$f(x) = \text{sum}\, U_i \tag{11}$$

Where U_i is the strain energy of the i^{th} element.

Based on the virtual work principle, the strain energy of SDS is equal to the work of the external forces. The density ratio of strain energy and strain energy of volume can be expressed by Eqs. (12) and (13) separately.

$$A = \frac{1}{2}\left(\sigma_x\varepsilon_x + \sigma_y\varepsilon_y + \sigma_z\varepsilon_z + \tau_{xy}\gamma_{xy} + \tau_{xz}\gamma_{xz} + \tau_{yz}\gamma_{yz}\right) \tag{12}$$

$$U = \iiint_V A\mathrm{d}V = \frac{1}{2}\iiint_V \left(\sigma_x\varepsilon_x + \sigma_y\varepsilon_y + \sigma_z\varepsilon_z + \tau_{xy}\gamma_{xy} + \tau_{xz}\gamma_{xz} + \tau_{yz}\gamma_{yz}\right)\mathrm{d}x\mathrm{d}y\mathrm{d}x \tag{13}$$

In term of the beam elements, strains and displacements can be expressed by the shape function and nodal displacement, as given in Eqs. (14) ~ (16).

$$\{f\} = [N]\{\delta\}^e \tag{14}$$

$$\{\varepsilon\}=\begin{Bmatrix}\varepsilon_x\\ \varepsilon_y\\ \varepsilon_z\\ \gamma_{xy}\\ \gamma_{xz}\\ \gamma_{yz}\end{Bmatrix}=\begin{Bmatrix}\frac{\partial u}{\partial x}\\ \frac{\partial v}{\partial y}\\ \frac{\partial w}{\partial z}\\ \frac{\partial x}{\partial y}+\frac{\partial y}{\partial x}\\ \frac{\partial z}{\partial y}+\frac{\partial y}{\partial z}\\ \frac{\partial z}{\partial x}+\frac{\partial x}{\partial z}\end{Bmatrix}=\begin{bmatrix}\frac{\partial}{\partial x} & 0 & 0\\ 0 & \frac{\partial}{\partial y} & 0\\ 0 & 0 & \frac{\partial}{\partial z}\\ \frac{\partial}{\partial y} & \frac{\partial}{\partial x} & 0\\ 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial y}\\ \frac{\partial}{\partial x} & 0 & \frac{\partial}{\partial z}\end{bmatrix}\begin{Bmatrix}u\\ v\\ w\end{Bmatrix}=\begin{bmatrix}\frac{\partial}{\partial x} & 0 & 0\\ 0 & \frac{\partial}{\partial y} & 0\\ 0 & 0 & \frac{\partial}{\partial z}\\ \frac{\partial}{\partial y} & \frac{\partial}{\partial x} & 0\\ 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial y}\\ \frac{\partial}{\partial x} & 0 & \frac{\partial}{\partial z}\end{bmatrix}[N]\{\delta\}^e \tag{15}$$

$$[B]=\begin{bmatrix}\frac{\partial}{\partial x} & 0 & 0\\ 0 & \frac{\partial}{\partial y} & 0\\ 0 & 0 & \frac{\partial}{\partial z}\\ \frac{\partial}{\partial y} & \frac{\partial}{\partial x} & 0\\ 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial y}\\ \frac{\partial}{\partial x} & 0 & \frac{\partial}{\partial z}\end{bmatrix}[N] \tag{16}$$

Where $[N]$ is the shape function, and $\{\delta\}^e$ is the nodal displacement vector.
Therefore, the strain energy is described by

$$\begin{aligned}U^e &= \iiint_V \{\varepsilon\}^T\{\sigma\}\mathrm{d}V = \iiint_V (\{\delta\}^e)^T[B]^T[D][B]\{\delta\}^e\mathrm{d}V\\ &= (\{\delta\}^e)^T\iiint_V [B]^T[D][B]\mathrm{d}V\{\delta\}^e\end{aligned} \tag{17}$$

$$U=\sum_{i=1}^{n}U_i^e \tag{18}$$

Where n is the element number.
As the strain energy contains both stress and displacement, it is reasonable to set the strain energy as an objective function. Table 2 lists the change in the maximum strain energy of SDS before and after the control. From the Table, the strain energies of SDS are 481.7 J and 289.7 J before and after executing the active control strategies, and a significant reduction of 39.9% in strain energy is achieved. The good control efficiency shows that the active control optimizes the structural strain energy, which also demonstrates that both member stresses and nodal displacements are improved.

Table 2. Simulation results before and after control

	Before control	After control
Stain energy of SDS (J)	481.7	289.7

7. Conclusions

In this paper, an active control method for hybrid string structures including the beam string structure (BBS) and suspen-dome structure (SDS) is proposed based on the genetic gradient algorithm (GGA) and multi-population genetic algorithm (MPGA), and the validity of the method is verified by tests and simulations. Some conclusions and salient observations are as follows:
(1) The concept of active control of hybrid string structures is presented by introducing active struts that can change length linearly. An optimization-based control model is established to minimize the active

control objective (e.g., the stress, displacement, and strain energy) to improve the mechanical properties of BBS and SDS.
(2) Standard genetic algorithm (SGA), genetic gradient algorithm (GGA), and multi-population (MPGA) are introduced, and their advantages and disadvantages are also analyzed. Among them, the GGA and MPGA are applied to search the active control strategies of BBS and SDS under loading.
(3) A single-span BBS model with a span and sag of 4 m and 0.68m is developed and constructed for active control research. With the minimization of vertical displacement as the control objective, the active control of the test model is achieved through the use of GGA. Test results indicate that the implementation of active control strategy can significantly reduce the vertical displacement of the beam, and the control process also optimizes the stresses in the beam to some extent.
(4) A bi-directional BBS with the size of 24 m×24 m×2.4 m is used for numerical analysis. With the minimization of stress as the control objective, the active control of the bi-directional BBS is achieved by applying the GGA. Simulation results show that after active control the peak internal forces of the beams are effectively controlled and the beam deformation is also substantially improved.
(5) A Kiewitt SDS with the size of 12 m×12 m×1.2 m is used for numerical analysis. With the minimization of strain energy as the control objective, the active control of the Kiewitt SDS is achieved by applying the MPGA. Simulation results show that the active control optimizes the structural strain energy, which also demonstrates that both member stresses and nodal displacements are improved.

Abstract

The use of partial safety factor method has become a prevalent practice in designing membrane structures. However, the application of standard partial safety factors for actions presents a challenge as membrane structure calculations are inherently nonlinear. If the relative increase in the effect of action exceeds the relative increase in the action itself, the solution is straightforward: apply the partial safety factors to the actions before calculating their effects. However, membrane and cable structures often include elements or areas where the relative increase in effect is less than the relative increase in action, raising concerns about safety deficits. In 1960, Basler's conclusion [2] was somewhat empirical, as the highly nonlinear nature of the problem made it impossible to simply calculate the safety index for the ultimate limit state function. The presumed safety deficit was incorporated into the Basis of Structural Design according to EN 1990:2012 [1], with further explanation provided by *Calgaro, Gulvanessian, and Holický* in the background document [3]. This standard suggests that, when relative increase in the effect is less than the relative increase in action, effect should be calculated first and then multiplied by their corresponding partial safety factor before conducting the verification. During the recent revision and expansion of EN 1990, some engineers working on membrane structure design raised objections [4]. The authors were able to resolve this issue prior to the introduction of prEN 1990:2022 [5] in practice, thus simplifying the process and promoting practical acceptance.

Keywords: architectural membranes, verification, partial safety factors, hybrid structures, non-linear behaviour, semi-probabilistic approach, reliability, Eurocodes, basis of design.

1. Introduction

EN 1990:2012 [1] provides guidelines, under provision 6.3.2.(4), on how to handle partial factors when dealing with non-linear problems and in special cases such as cable and membrane structures:

> (4) For non-linear analysis (i.e. when the relationship between actions and their effects is not linear), the following simplified rules may be considered in the case of a single predominant action:
>
> a) when the action effect increases more than the action, the partial factor g_F should be applied to the representative value of the action. (over-linear behaviour)
>
> b) When the action effect increases less than the action, the partial factor g_F should be applied to the action effect of the representative value of the action. (under-linear behaviour)

NOTE Except for rope, cable and membrane structures, most structures or structural elements are in category a).

Figure 1 illustrates how to interpret these provisions. According to the Note, cable and membrane structures are generally classified as exhibiting under-linear behavior, and most other structures or structural elements are classified as exhibiting over-linear behavior. However, this categorization may not always be applicable, particularly in the case of membrane structures, where both under-linear and over-linear behaviors may be observed depending on the specific design conditions. Additionally, non-linear structures may exhibit both under-linear and over-linear behavior at different design points, making it difficult to classify them under a single unique category.

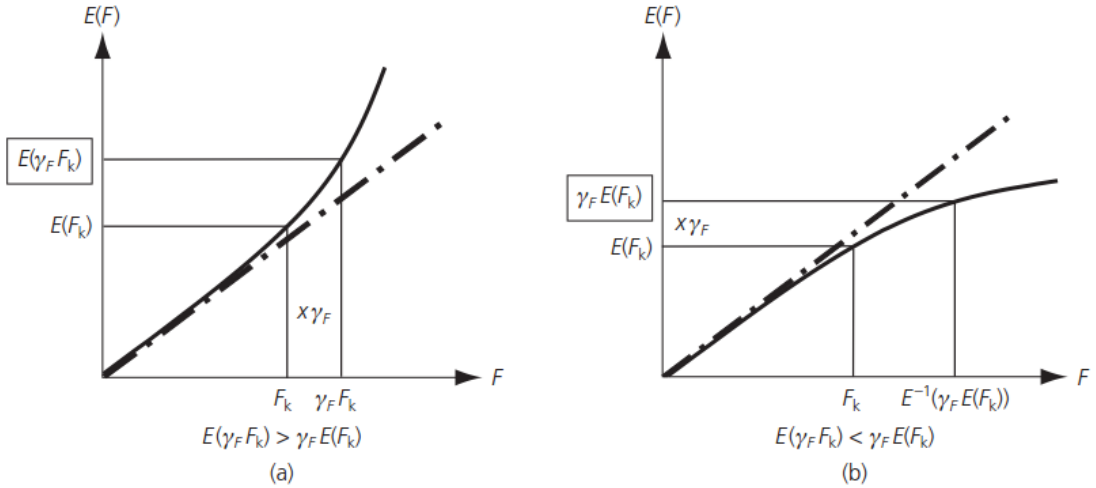

Figure 1. Application of the partial factor γ_F in the case of non-linear analysis (single action). (a) The non-linear action effect $E(\gamma_F F_k)$ increases more than the linear action effect $\gamma F_E(F_k)$ proportional to the action. (b) The non-linear action effect $E(\gamma_F F_k)$ increases less than the linear action effect $\gamma F_E(F_k)$ proportional to the action [3].

During the revision and extension of the standard, the corresponding passages in EN 1990 were subjected to a more detailed examination by the authors [6–8]. They started from the following hypothesis:

Hypothesis:

The safety is influenced by both:
1) The nonlinearity which is a characteristic of the system at the design point and it is preserved with the system;
2) The statistical properties of the basic parameters (normally characterized by the coefficient of variation and the distribution).

2. Nonlinearity and safety

The initial question to be addressed how the level of non-linearity in a structural system influences its reliability index. To address this, we employed the Monte Carlo method to ascertain the reliability index for varying degrees of non-linearity *n*

$$n = \frac{E(\gamma_F \cdot F_k)}{\gamma_F \cdot F_k} \quad (1)$$

taking into account the effect of different materials and actions (Figure 2).

The partial safety factors of actions γ_F were applied on the action side, regardless of the system's over-linear or under-linear behavior. The blue lines or points represent the Monte Carlo simulation (MCS) results for each combination of material and action. The red lines correspond to the maximum and minimum possible values of the reliability index β. The vertical dashed line separates the under-linear behavior from the over-linear behavior. The horizontal dashed black line corresponds to the value $\beta = 3.8$, which is the target reliability index.

The range between the two vertical lines, from $n = 0.8$ to 1.5, represents the safe range as it results in $\beta > 3.8$ for all possible combinations of materials and actions. For non-linear problems with $n < 0.8$, applying the partial safety factors on the action side results in unsafe outcomes. The behavior over the dashed red line on the right side is asymptotic, which means it tends not to deviate far from $\beta = 3.8$. This confirms the correctness of applying on the action side, without incurring any safety risk as previously assumed in [2].

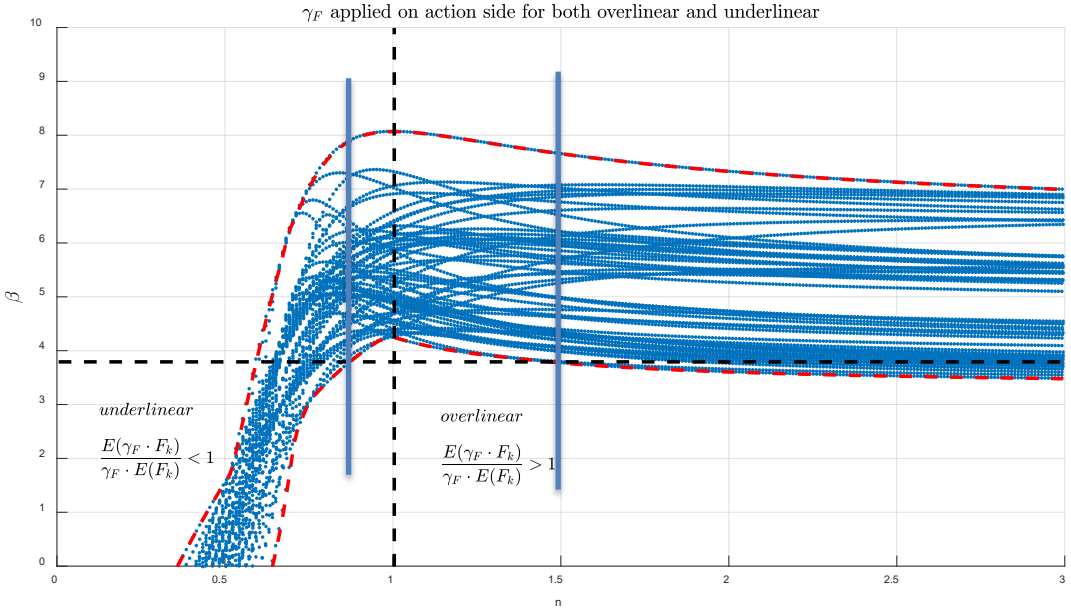

Figure 2. The variation of the reliability index ß with respect to the degree of nonlinearity n for different material-action combinations.

The subsequent phase involved identifying the areas in construction practice where non-linearities may emerge, particularly in cable and membrane structures. To accomplish this, we employed a simple cable system, as illustrated in Figure 3, to conduct our investigation.

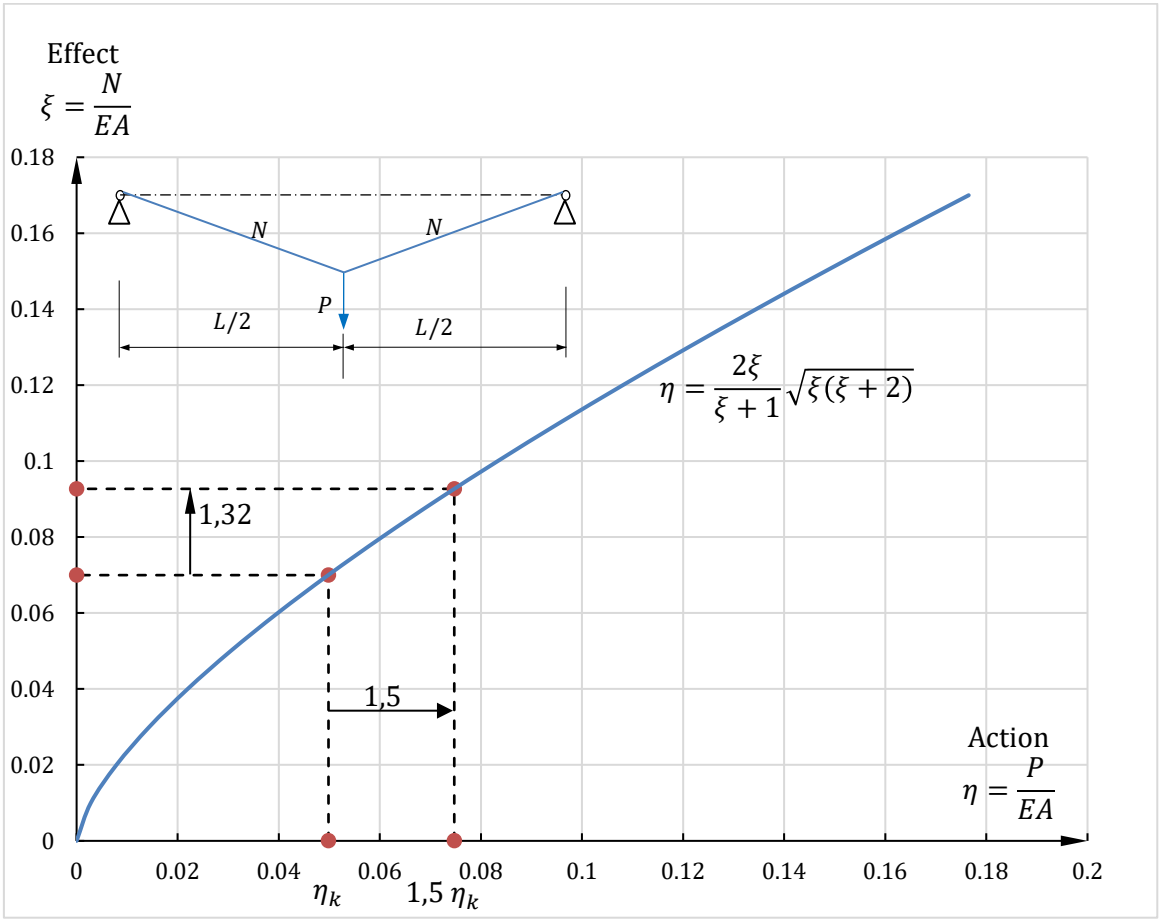

Figure 3. Horizontal cable with one vertical force. Representation of the effect and action relationship.

The system is deemed under-linear at every possible action point, as per the definition provided in 6.3.2 (4) of EN 1990:2012 [1]. This characteristic is evident in Figure 4, where the degree of nonlinearity is plotted against several characteristic actions.

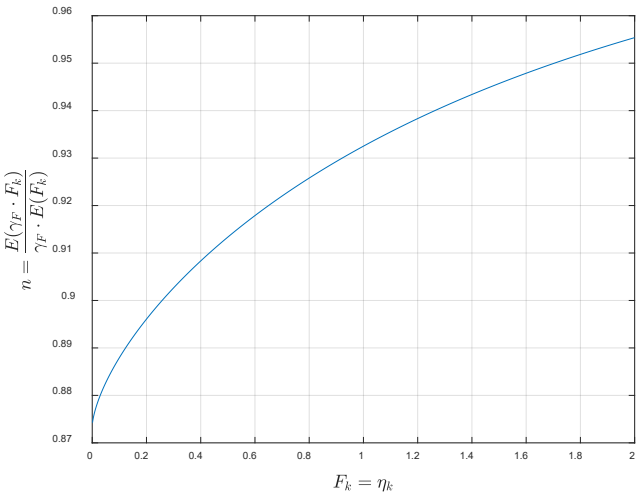

Figure 4. Calculation of degree of nonlinearity *n* at several characteristic loads.

The information conveyed by Figure 4 is crucial for interpreting the results of the reliability analysis presented in Figure 2 for cable and membrane structures in general. Specifically, Figure 4 shows that the degree of nonlinearity (n) for the cable system does not fall below 0.87.

Figure 5 illustrates another example of a simple double cable system created by simplifying a hyperbolic membrane, which has been previously discussed in the literature [6].

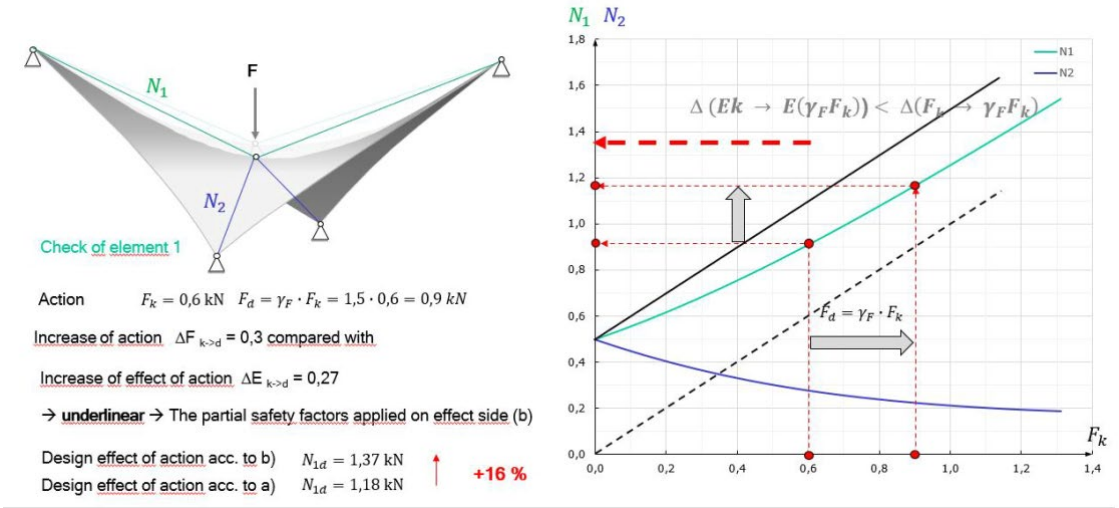

Figure 5. Simplified membrane structure and check of element 1 with concrete figures.

In case of element 1 the provisions of EN 1990:2010, 6.3.2 (4) lead to an over-design, which cannot be justified by the point of view of safety (see Figure 5; red dashed line).

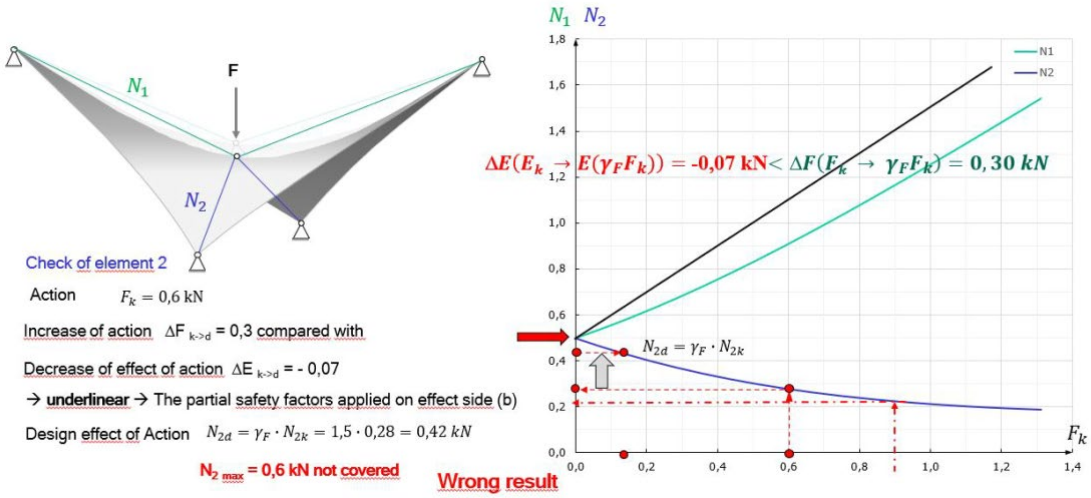

Figure 6. Simplified membrane structure and check of element 2 with concrete figures.

Conversely, applying the same provisions to Element 2 misleads the applicant (see Figure 6).

A closer examination of the non-linear effect course of Element 2 in Figure 5 suggests the need to determine whether the decisive design point is still being met or if another load combination should be

verified instead. The example of pre-tensioning in membrane structures serves as a relevant illustration. While Element 2 must be verified in the ultimate limit-state for the highest internal force that arises, it is essential to ensure that the structure does not experience folds or withdraw from the force distribution during relaxation. This state is more likely to be associated with the verification of serviceability.

Bakeer in his general theory [7–8] provides a compelling mathematical and theoretical proof that validates the hypothesis advanced by the authors. This important result serves to further confirm the accuracy of the hypothesis and solidifies its significance in the field of cable and membrane structures.

3. Example

A simple hyperbolic paraboloid example demonstrates that the regulations regarding the factoring of effects instead of actions, which were previously included in EN 1990:2010, are impractical and cannot be executed strictly. Instead, it is correct to always allocate partial safety factors to actions before calculating their effects. This necessitates the distinction between favorable and unfavorable actions, including those related to prestressing.

3.1. Input data

3.1.1. Geometry and Materials

Figure 7 presents an example of a membrane structure, where the membrane is stretched between boundary cables running between the top and bottom points. The top points are supported by steel columns, which are in turn stabilized by three cables each.

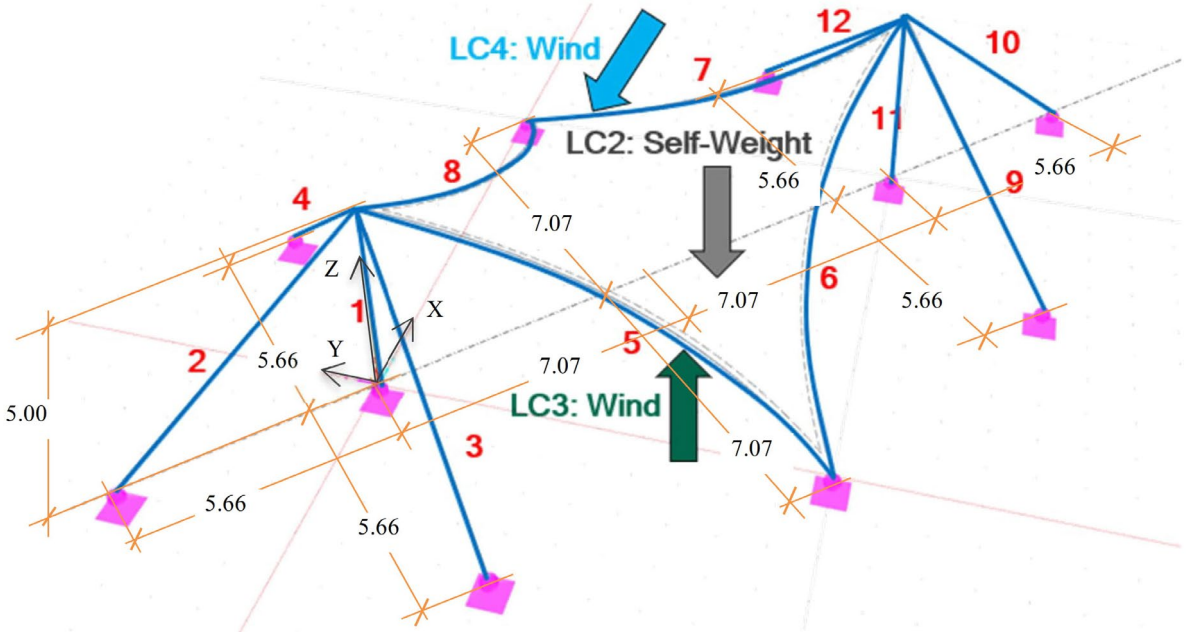

Figure 7. Geometry and load cases used as input for the Dlubal RFEM 6.0.

The material data are given in Table 1.

Table 1. Material data.

No.	Structural member		Type	Dimension / Area / Inertia	E-Mod	G-Mod.	ν	Specific weight
					[N/mm²]	[N/mm²]	[--]	[kN/m³]

2	cable	2, 3, 4, 5, 6, 7, 8, 9, 10, 12	Cable PE Pfeiffer	A=1,54 cm² It=0,38 cm4 Iy=Iz=0,19 cm4	130000	50000	0,3	80,00
3	membrane	membrane between 6, 7, 8, 9	PES-PVC (theoretical assumed, orthotropic)	d= 2 mm	448	153	0,464	10,70

3.1.2. Load cases & load combinations

The principal load cases considered, namely LC1: pre-stressing, LC2: self-weight, LC3: suction wind, and LC4: side wind, are depicted in Figure 7 and given in Table 2.

Favorable and unfavorable values are presented for both LC1 and LC2. However, only unfavorable values are provided for the actions in LC3 and LC4. Although the wind load case's actions were manually introduced for this example, there are more efficient ways to determine them, such as utilizing specialized software like the "wind tunnel" software [9].

Table 2. Magnitudes of actions considered.

Actions	Direction (local, global)	Magnitude
LC 1: Prestressing	local	$L_{c,rel}$=102% (6, 7) $L_{c,rel}$=102,65% (4, 5, 10, 11, 12, 13), membrane 1,0 kN/m
LC 2: Self weight	Z global	automatically considered
LC 3: Wind	Z global	0,2 kN/m²
LC 4: Wind	X global	-0,2 kN/m²

3.2. Results

In accordance with the provisions of EN 1990:2010, 6.3.2 (4), the analysis was conducted in two ways:

- Determining the effects of unfactored actions and then factoring those determined effects.
- Factoring the actions and then determining the effects of the factored actions.

An overview of some of the results obtained from these two methods is shown in Figure 8.

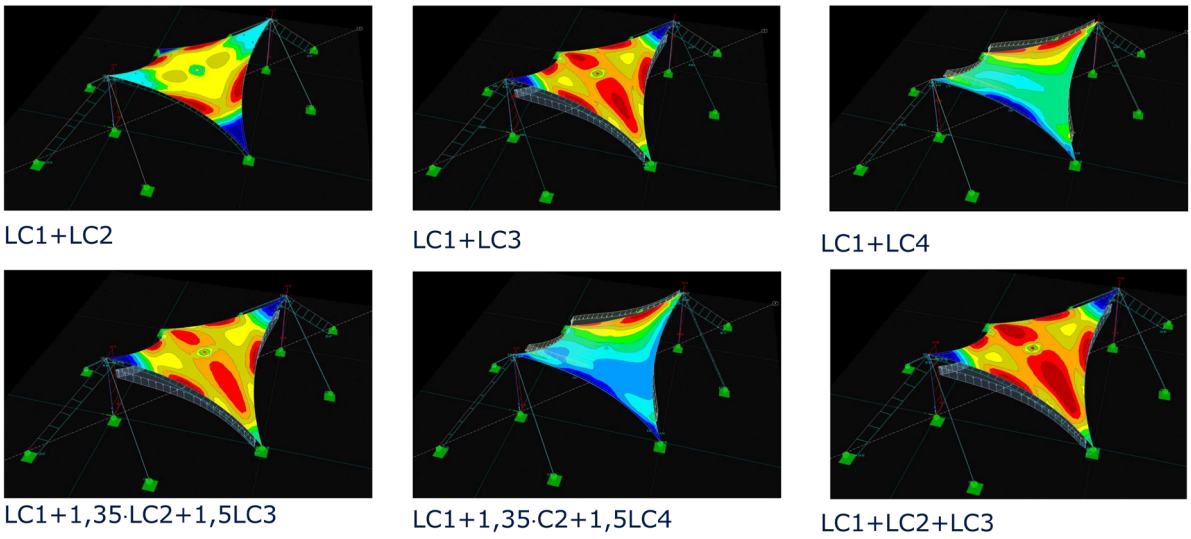

Figure 8. Results of the load combinations in Dlubal RFEM 6.0 [10]:
The top row shows the effects without factoring in the actions, whereas the bottom row presents the effects with the action factors accounted for.

It's crucial to note that load case 1 and load case 2 cannot be regarded as separate load cases due to stability considerations. Instead, they are jointly computed as part of the form-finding process when designing membrane structures. Without prestressing, it's impossible to independently analyze LC2, LC3, and LC4 load cases as the structure's stability relies on the prestressing load.

Table 3 and Table 4 demonstrate that LC 1 + LC 2 indicate that prestressing is taken into account as the initial form. Conducting separate calculations of load cases without prestressing is unfeasible due to the structure's instability.

Table 3. Results of the effects without factoring of the actions.

Effect	N1	N2	N3	N4	N5	N6	N7	N8	N9	N10	N11	N12
LC1	27.77	26.57	0.04	0.04	11.09	11.09	11.09	11.09	0.04	26.57	27.77	0.04

LC1+LC4	33.01	29.39	1.54	1.54	12.34	12.34	12.34	12.34	1.54	29.39	34.45	1.54

Due to instability, it is impossible to determine the effect

Table 4. Results of the effects with factoring of the actions.

Effect	N1	N2	N3	N4	N5	N6	N7	N8	N9	N10	N11	N12
LC1	27.77	26.57	0.04	0.04	11.09	11.09	11.09	11.09	0.04	26.57	27.77	0.04
LC2	x	x	x	x	x	x	x	x	x	x	x	x
LC3	x	x	x	x	x	x	x	x	x	x	x	x
LC4	x	x	x	x	x	x	x	x	x	x	x	x
LC1+1.35LC2+1.5LC3	30.69	25.47	1.84	1.84	18.79	18.79	18.79	18.79	1.84	25.47	30.69	1.84
LC1+1.35LC2+1.5LC4	25.56	17.29	6.16	1.03	1.67	11.74	29.83	13.8	8.68	48.72	58.45	0.86

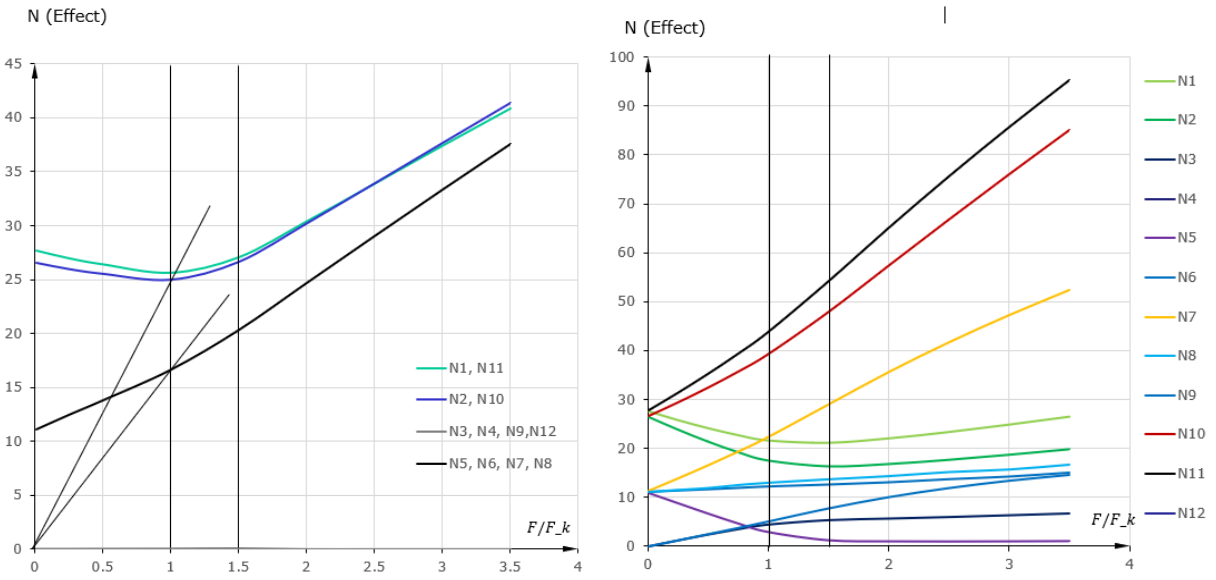
Due to instability, it is impossible to determine the effect

In order to be able to apply the specifications of EN 1990:2010 6.3.2 (4), we assume that the initial state is defined with the form finding and that the individual loads are then applied separately to this (see Table 3). The results – the effects - are then multiplied by the partial load factors and combined into the respective load combination. These numbers are now compared with the result of the calculation of the membrane with factored and combined actions (see Table 4).

In case of member 1 and the combination of the effects of prestressing, self-weight and horizontal wind leads to the following effects:

Application of the combination on the effect

28.05	*1,35+	33,01	*1,5 =	87,38	≫	25,56



The combination of the effects for member 1 therefore results in significantly larger values than the combination of the factored actions. In case of member 9 this leads to inverse effects:

Application of the combination on the effect

0.03	*1,35+	1.54	*1,5 =	2,35	<	8,68

The combination of effects for member 9 results in significantly lower values than the combination of factored actions.

The recommended way of applying the partial factors of EN 1990:2010 can be misleading as shown by the fact that if one factors the initial state of self-weight with prestressing by 1.35, it leads to a simultaneous increase in the prestressing and does not account for any loss or uncertainty of the prestress. Moreover, the ratio of prestress to dead weight is not proportional.

(a) (b)

Figure 9. Effect-Action curves as the action increases (a) increasing the wind action LC3, (b) increasing the wind action LC4.

Figure 9 presents the effect-action curves for all the key elements in the considered membrane structure. The following observations can be made:

1- The safety contribution of the action is dependent on the design point. For instance, in Figure 9 (a) under LC3, the effect in element 1 and 11 initially decreases as the wind load LC3 increases, then it increases. This indicates that the LC3 increase was favorable in the initial loading stage and later became unfavorable. This reaffirms that the safety assessment should be based on the system's non-linearity and design points.
2- The behavior of the membrane structure cannot be classified as under-linear. Many of the plotted effect-action curves in Figure 9 (a) and (b) indicate that both behaviors are possible, and this must be verified at the design point.
3- Over-linearity and under-linearity are typically used to describe the impact of unfavorable loads. However, the behavior under favorable loads can also exhibit both over- and under-linearity.

4. Conclusions

The paper highlights a misleading provision in the EN 1990:2010 guidelines regarding the application of partial safety factors to membrane structures. The definitions provided for over-linearity and under-linearity are based solely on the comparison of the increase of the effect with the increase of action, which differs from the mathematical definition in the background document [3].

Typically, membrane structures involve multiple actions with different partial safety factors. If the system is found to be underlinear according to EN 1990:2010, and the partial safety factor should be applied to the effect side, determining the appropriate partial safety factor becomes challenging. Even if the partial safety factor of the leading action is applied to the effect side, it could produce unsafe results, especially if the actions involved in the system have different statuses (favorable and unfavorable), which is quite common in membrane structures.

Furthermore, the over-linearity and under-linearity alone do not sufficiently characterize a nonlinear system without considering the design point. However, under the practically existing range of nonlinearity, applying partial safety factors on the action side is sufficient to achieve the target reliability index. This applies to both over-linear and under-linear cases.

Moreover, the study suggests that the exception for membrane and cable structures in clause 8.3.2.4(a) of FprEN 1990 is unnecessary, and the provisions for these structures in EN 1990:2010 are outdated and not expedient. The recommended approach of applying partial factors can be misleading as it fails to account for the loss or uncertainty of the prestress, leading to a disproportionate increase in the prestressing compared with the dead load. The aim of the contribution was to confirm the validity of the first part of the starting hypothesis.

These findings emphasize the importance of revising current guidelines to ensure accurate and reliable design values for membrane structures. Therefore, it is recommended that future research addresses the issues highlighted in this study to improve the safety and reliability of structural designs.

Acknowledgements

The study's findings were the result of a combination of our own research at the office and investigations conducted by Tammam Bakeer, utilizing Dlubal RFEM 6.0 [10] software to analyze the membrane example. We express our sincere appreciation to Dlubal Software GmbH Tiefenbach for their valuable support and collaboration throughout this work.

Abstract

The construction of complex buildings, such as tensegrity structures and freeform shapes, can be costly, labor-intensive, and time-consuming due to the challenge of reproducing the geometry of the shape and assembling the structure. This paper proposes an automation method for designing arbitrary freeform tensegrity structures by solving the inverse problem using freeform origami tessellations. This approach allows for easy construction of freeform tensegrity structures by even unskilled workers, using a single planar membrane as a guide. Developable membrane tensegrity structures are structures formed from single planar membranes used as tensile and struts used as compression members. They have advantages in manufacturing in that freeform surfaces can be erected by simply attaching struts to a single planar membrane while applying initial tension. We propose a design method of membrane tensegrity structures by solving the inverse problem using freeform origami tessellations by generalizing Resch's patterns proposed by Tachi [1]. In this paper, we demonstrate the feasibility of our method by constructing a full-scale mock-up. Specifically, we place the mountain creases of the tessellation with struts and the other parts with a membrane under initial tension, and show the tessellation can be formed as a tensegrity structure. In constructing the structure, we sewed pockets, shorter in length than compression members, into the mountain creases and applied tensile force across the membrane by inserting carbon fiber reinforced plastic (CFRP) rods as the compression members while pulling the membrane material. Since the joints between the CFRP rods and the basement are at an arbitrary angle, we created rotatable joints by three-dimensional (3D) printing. After inserting the CFRP rods, we clamped them to create a single, freely rotatable joint. Finally, we measured the coordinates of each joint of the structure with a three-dimensional laser distance meter. We compared them with the design model to assess the reproducibility of its geometry.

Keywords: membrane structure, freeform shape, origami tessellation, Resch's pattern, structural optimization

1. Introduction

Developable membrane tensegrity structures are tensegrity structures formed from single planar membranes used as the tensile member and struts used as the compression members. They have advantages in the manufacturing process as they can be constructed in planar states by laying out struts on a single pre-tensioned membrane and erected by releasing the pretensions. Several methods for "forward problems" to find the output, i.e., the three-dimensional resulting shape from the input, i.e., a two-dimensional layout pattern have been proposed.

However, the inverse problem, i.e., designing the planar pattern when the target shape is given, has not been solved. In this paper, we propose a design method of membrane tensegrity structures by solving the inverse problem using freeform origami tessellations by generalizing Resch's patterns proposed by Tachi (2013).

2. Related works

Several methods for “forward problems” to find the three-dimensional resulting shape from a two-dimensional layout pattern have been proposed.

One example is the MOOM Pavilion [2], created by students of the Tokyo University of Science under the supervision of Kazuhiro Kojima and Jun Sato(Ratschke et al. [3]). They developed a staggered arrangement of parallel struts and a tunnel-like structure with arches in the direction parallel to the struts and cables pulling in the transverse direction. The pavilion consists of 131 aluminum tubes and an elastic polyester mesh, and was successfully constructed as an 8 x 26 m.

Shigematsu et al. [4] presented the the basic configurations of Diamond and Zigzag models and confirmed that this structure could be established by static non-linear finite element analysis.Gupta et al. [5] extended the designable structure by placing compression struts in a reciprocal pattern on the membrane. They also demonstrated a workflow for accurately producing knits using CNC-produced knittings as the main tensile element. The process of creating these structures is form-finding through mechanical simulation and model making, solving forward problems to determine what 3D shape can be obtained from a given 2D strut pattern.

However, the inverse problem, i.e., designing the planar pattern when the target shape is given, has not been solved. In this paper, we propose a design method of membrane tensegrity structures by solving the inverse problem using freeform origami tessellations by generalizing Resch's patterns proposed by Tachi [1].

3. Geometry

In this study, we aim to make use of the universality of computational origami design, i.e., origami-based patterns can be computed for given polyhedral meshes for the design of membrane tensegrity structures that can be deployed from flat states. Specifically, we show that if we generate an origami tessellation by generalizing Resch's patterns proposed by Tachi, and replace the mountain crease of the tessellation with struts and the other parts with a membrane under initial tension, the tessellation can be formed as a tensegrity structure (Figure1).

The flow of membrane tensegrity structure generation is as follows,

1. Provide a target shape as a polyhedral mesh.
2. Origamise, i.e., apply the algorithm of Tachi [1]to create a generalized Ron-Resch pattern. We choose star-shaped wrinkle patterns inserted on the edges of the given mesh and let the corrugated surface be developable using an optimization scheme. Here, either Freeform Origami (Tach[1]) or Crane (Suto et al.[6])can be used for optimization calculations.
3. Replace the mountain crease lines of the obtained mesh with compression members and the other creases with tension members under initial tension by setting the target length to its scaled version by some scale factor $s<1$ (empirically chosen $s \fallingdotseq 0.90$). Support points are provided around the boundary of the mesh. To obtain the equilibrium position, we use dynamic relaxation. Kangaroo2 (Piker[7]) was used in our analysis.

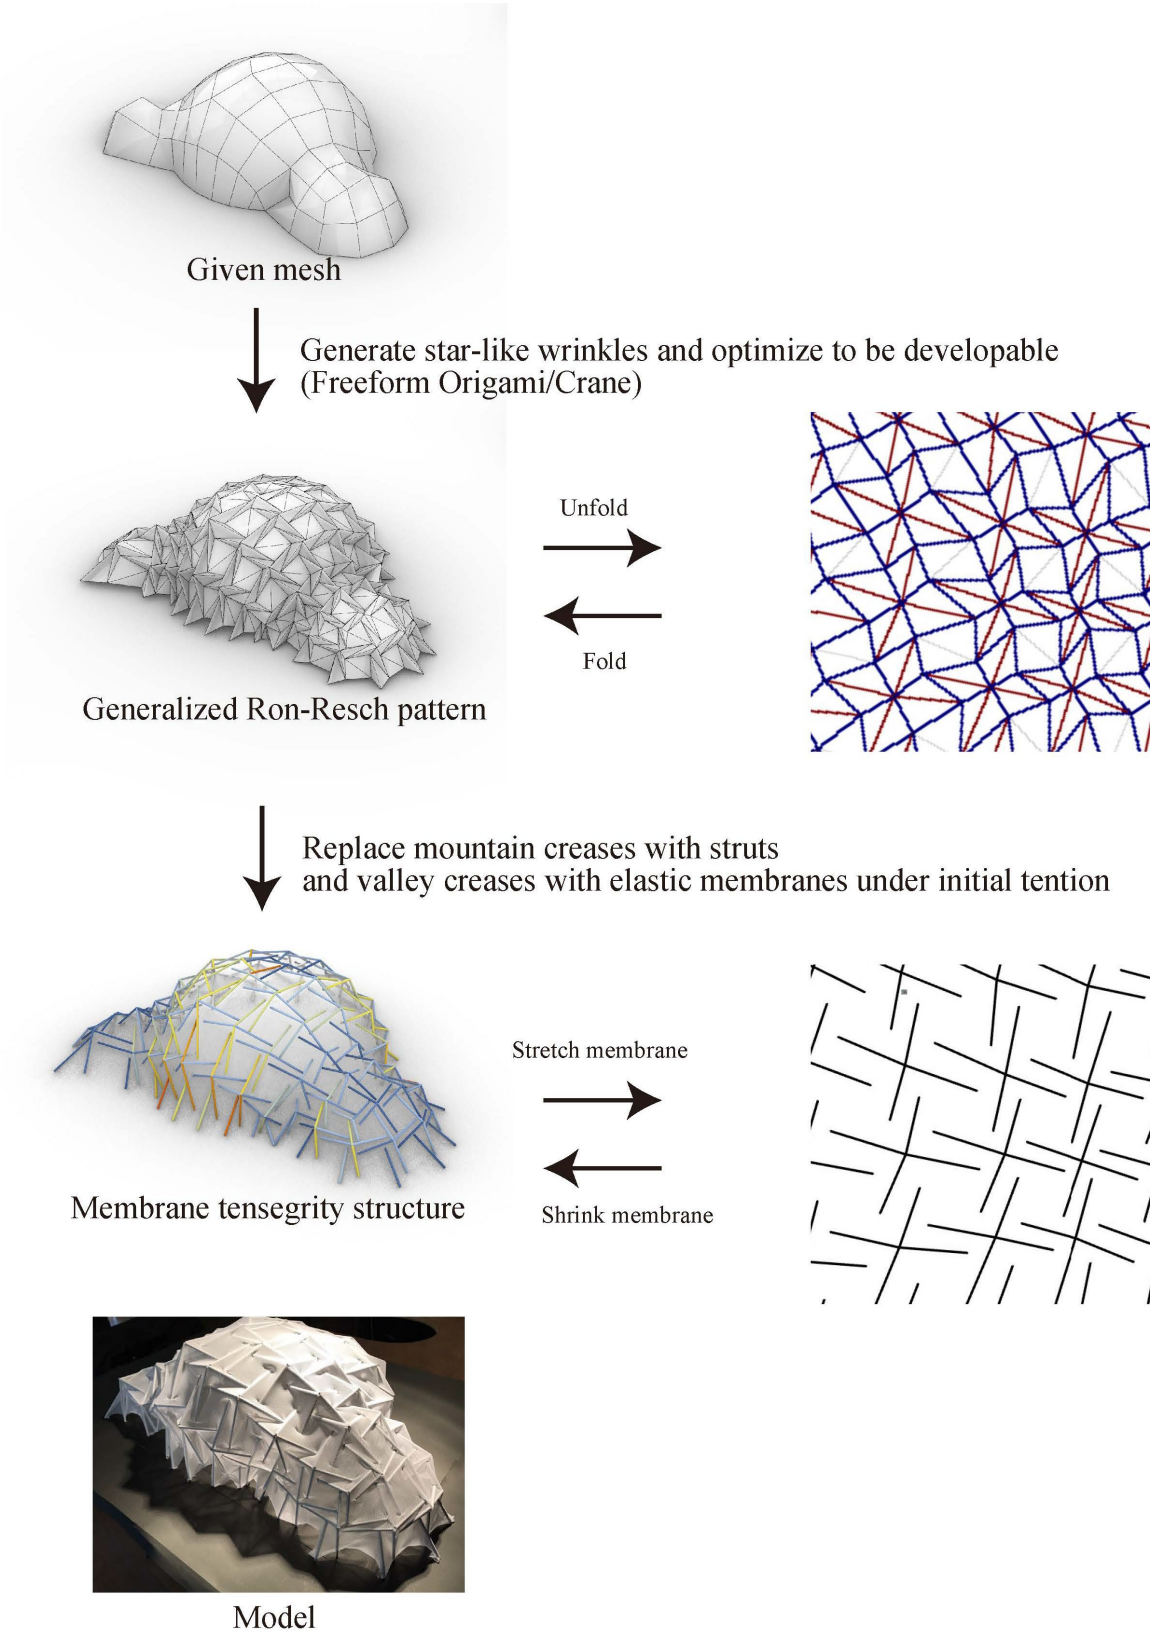

Figure 1. The process of solving inverse program of a membrane tensegrity structure.

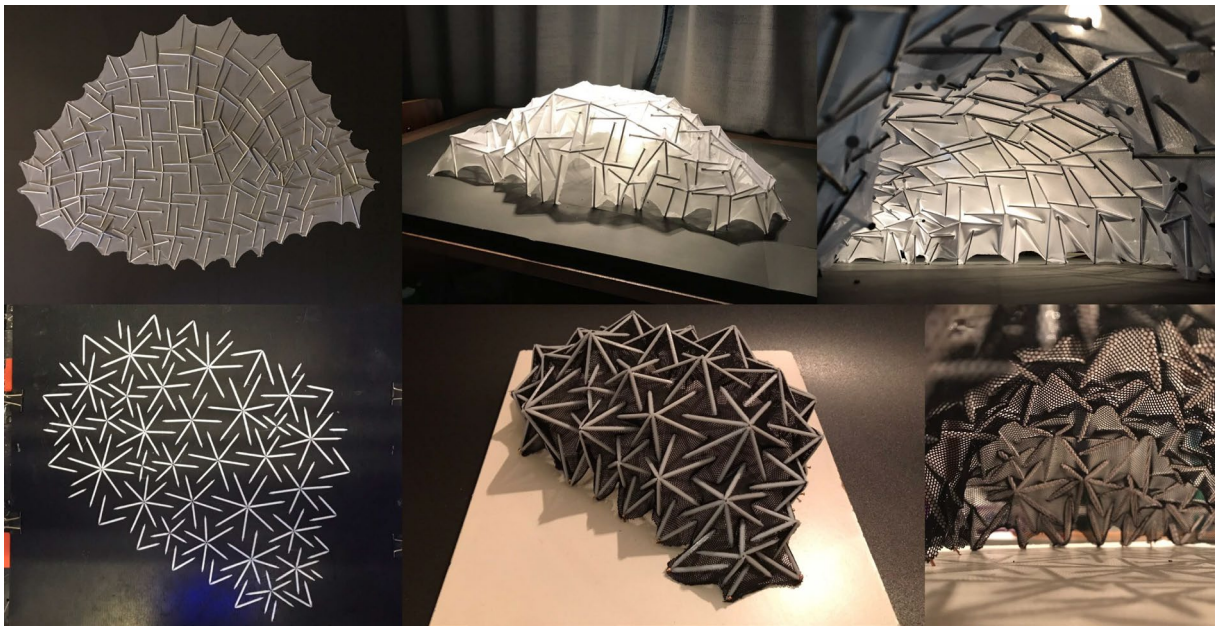

Figure 2. Process of model making. (Top left) Fixing aluminum pipes to stretched stretchable nylon cloth. (Top right) When the boundary is cut out and the foot is fixed, the structure stands up in the same shape as the given curved surface. (Bottom left) 3D printing PLA directly onto stretched stretchable nylon fabric.(Bottom right) When the boundary is cut out and the foot is fixed, a structure with the same shape as the given curved surface rises up.

After verifying the form under equilibrium, we stretch the membrane in a planar state by some scale factor 1/s and attach rigid material along the mountain creases of the crease pattern. Here, for a small-scale model, the attachment of rigid bars can be replaced by 3D printing directly to the membrane as in Tibbits [8]; Jourdan et al. [9](Figure2). We release the prestress by cutting out the boundary of the crease pattern; then the membrane's tension produces the curvature and after a small adjustment and the pinning at the support point. We obtain the desired membrane tensegrity structure.

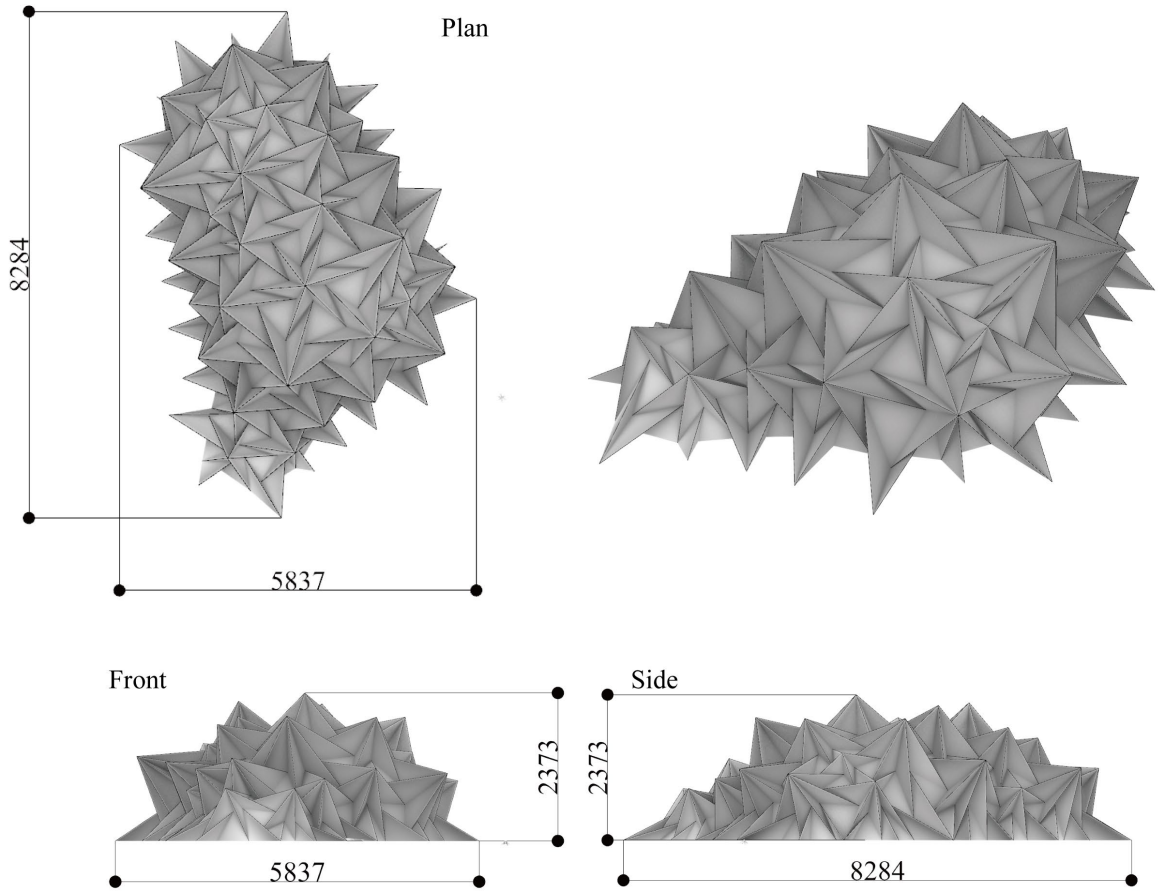
A feature of this structure is that the star shaped “spikes” can snap-through. It is important to avoid snap-through because it can lead to the collapse of the entire structure. One parameter that affects the ease of snap-through is the number of rods that gather around a single spike.

Considering the increase or decrease in energy in snap-through in a simplified model, the energy is proportional to $n*\sin(\pi/n)$, which increases as the number of struts increases. For example, a quad mesh consists of degree-4 vertices and thus gathers 4 struts, while a triangle mesh consists of degree-6 vertices and thus gathers 6 struts. Considering the ease of snap-through, we will proceed with the design based on a triangular mesh (Figure 3).

4. Verification of construction methods and details

4.1. Selection of membrane material

Considering its future deployment in outdoor structures, the need for durability to withstand localized forces at the ends of the compression members, and to allow tensile forces to be preloaded by human-powered pulling on site, “Shade Azul” manufactured by Taiyo Kogyo Corporation, an material with high elasticity can be used outdoor, was selected for the membrane material. Shade Azul is strong enough not to tear even when the fabric is pulled strongly in both the longitudinal and transverse directions, with a longitudinal tensile strength of 791 N/cm and a transverse tensile strength of 604 N/cm.



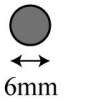


Figure 3. Dimensions of the pavilion designed and constructed for this project.

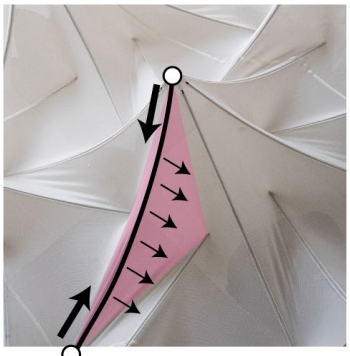
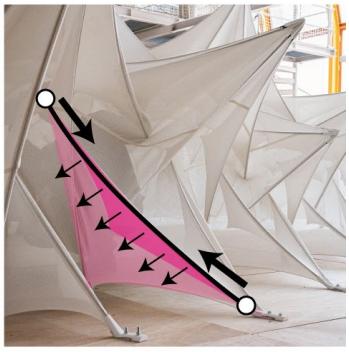


The longitudinal tensile stiffness is 62 kN/m and Poisson's ratio is 0.675. The performance of elongation against tension is homogeneous in both directions.

4.2. Selection of material for compressed members



Carbon fiber reinforced plastic(CFRP) rods was used as the compression member because it is lightweight and a hard material with a high Young's modulus. 218 rods ranging from 581mm to 1627mm was used. The geometry around the rods is the same in the floating part and the ground part of the structure, and the stresses do not change significantly, so the same cross section is used for all of them (Figure 4).

Length	Young' s modulus	Moment of inertia
L mm	E kN/mm²	I mm⁴
581~1627	390.4	63.6

Geometry and stresses of floating rod

Geometry and stresses of ground rod

Figure 4. Material and section of compressed members

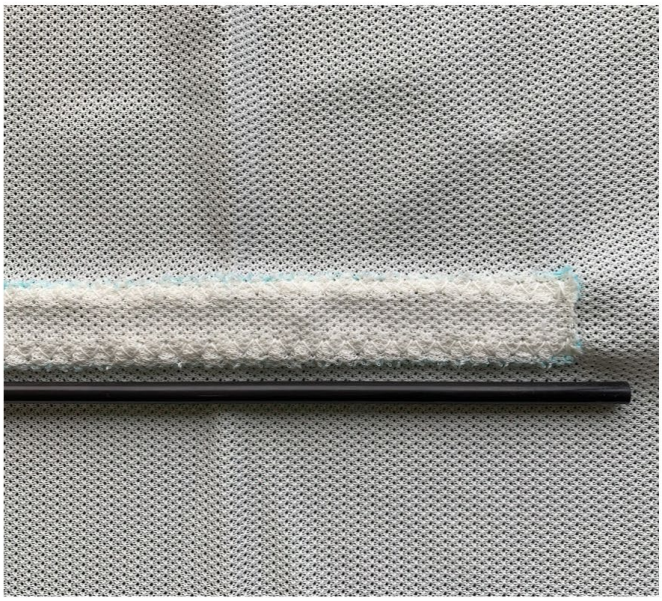


Figure 5. (Left) CFRP rod and pocket for rod attachment. (Right) Mock-up for rod attachment verification

4.3. Fixing method of compression members

In order to apply tension evenly to the membrane between the compressions and to prevent them from coming off, long pockets of the same material as the membrane is sewn in and the CFRP rods are inserted into the pocket, thereby securing the compressions to the membrane (Figure 5). A fold is provided at the edge of the pocket, and the inserted CFRP rod is hooked and attached to the pocket. The pocket is 19% shorter than the membrane when no load is applied, and the tension is applied into the membrane by inserting and securing the CFRP rods while pulling on this textile. For this method, we refer to a previous case study, the MOOM project's method[2] of fastening aluminum compression material.

4.4. Design and verification of compression member joints

Although the vertices where the compression members meet were structurally pin-jointed, there was concern that the contact points at the ends of the CFRP rods would shift due to expansion and contraction of the membrane when the it is attached to the compression members. In this experiment, the ends of the compression members were joined to each other with a Thermoplastic polyurethane (TPU) joint produced by 3D printing, and the joint was bolted to the membrane material to fix this contact point so that it would not shift from the membrane. TPU was used because it is a flexible material and shows flexible behavior in response to the movement and load of the membrane. If a load is applied to the apex in the out-of-plane direction of the membrane, snap deformation may happen. Therefore, we took one sample of the vertex, produced it, and applied a load to the vertex from above to see how much load the deformation could be caused by. When the elongation of the membrane was 19%, the load in the out-of-plane direction that could cause snap deformation was 4kgW, confirming that the membrane was sufficiently resistant to deformation even in full-scale tests (Figure 5).

4.5. Design and verification of 3D printed legs

The legs, which are the joints of the ground, were also made of TPU material by 3D printing. They were fixed to the floor surface with bolts in two places so that they would not rotate on the plane. Membrane material was wrapped around the inner bolt, and the bolt was hooked to the pigeonholes on the membrane, so that the leg could be held under tension.

5. Construction

5.1. Preparation for construction

In preparation for installation, the joints and legs were 3D printed with generic small size 3D print machine. Two joints were printed in pairs, and 24 hours were required for each pair. The legs took 6 hours. The joint number and branch number were engraved on the 3D printed outputs to prevent misplacement and misorientation during construction. A development drawing of the membrane was made, was sewn, the pockets were attached, and the pigeonholes were attached in the cooperative factory of Taiyo Kogyo Corporation (Figure.6).

5.2. Installation of floor panels and marking of leg bolts

The construction experiment was conducted indoors on March 25, 2023. The construction work was done by 15 people over a period of nine hours. First, a floating floor was created by lining the floor with a square timber and then lining it with 910 x 1820, 12 mm plywood. The coordinates of where the legs were to be fixed were marked, holes were drilled at the bolt locations on the plywood, and the bolts were temporarily placed from the downside.

5.3. Load of tensile force to the membrane material

In this experiment, the compression member was simultaneously fixed and tension was load by inserting the compression members into pockets pre-sewn on the membrane and hooking the end of the rods while stretching the pocket. The installation procedure was as follows.

(1) Bolt the 3D printed joint at the apex where the CFRP rod gathers on the membrane material.

(2) The CFRP rods are threaded through a pocket sewn on the membrane and then the tip is inserted into the hole in the joint.

(3) Pull the membrane material along the CFRP rods and hook the folded end of the pocket onto the opposite end of the CFRP rod, securing the membrane material with tensile force applied to it.

(4) (1) to (3) were performed sequentially from the centre of the membrane to the periphery (Figure.7).

Figure 6. (Left) 3D printed joints and legs. (Right) One flat membrane with pockets attached

Figure 7. (Top left) Bolt the 3D printed joint (Top right) insert CFRP rod to pocket on the membrane (Bottom left) Assembled joint by joint and stand vertices. (Bottom right) 3D printed joints and legs on membrane.

5.4. Fixing membrane to floor

After all joints and CFRP rods were installed, the membrane was inserted between the legs and the floor panel and bolted in the same manner as the joints, securing the membrane material to the floor panel. As with the joints, CFRP rods were inserted through the pockets and into the holes in the legs, and tensile forces were loaded by pulling the membrane and hooking the opposite end onto the fold of the membrane (Figure 8).

Figure 8. Self-supporting membrane tensegrity structure

Figure 9. (Left) Large deflected rod members (Right)Twisted and broken joint with rod protruding

6. Analysis of shape accuracy

6.1. Visual observation

Visual observation showed that the center of the rod deflected significantly and appeared to be more deformed than expected. In addition, some of the joints were found to be twisted and greatly deformed. Some of the joints were damaged and the rods were exposed through the joints, so the rods were reinforced to prevent further damage (Figure 9).

6.2. Measured by 3D laser distance-measuring machine

The 3D coordinates of the apex using a 3D laser distance-measuring machine. We used a fixed-type surveying instrument that can calculate the 3D coordinates and angles of any point on the measurement object's surface through laser irradiation. The distance error between each point on the specimen and the 3D model's apexes were then measured, and the accuracy of the sample's shape was analyzed . Figure 10 shows the amount and direction of deformation at each of the 27 vertices for the actual design model. The outward deformation is shown in red and the inward deformation in blue for the freeform dome shape. Of the 27 vertices, the vertex in the center of the span was highly deformed downward, dropping a maximum of 469 mm. On the other hand, the vertex in the second row from the perimeter had relatively small displacement from the design model and moved in the outward opening direction. In this range, the apexes were settled with a displacement of about 60-100 mm (maximum 161mm).

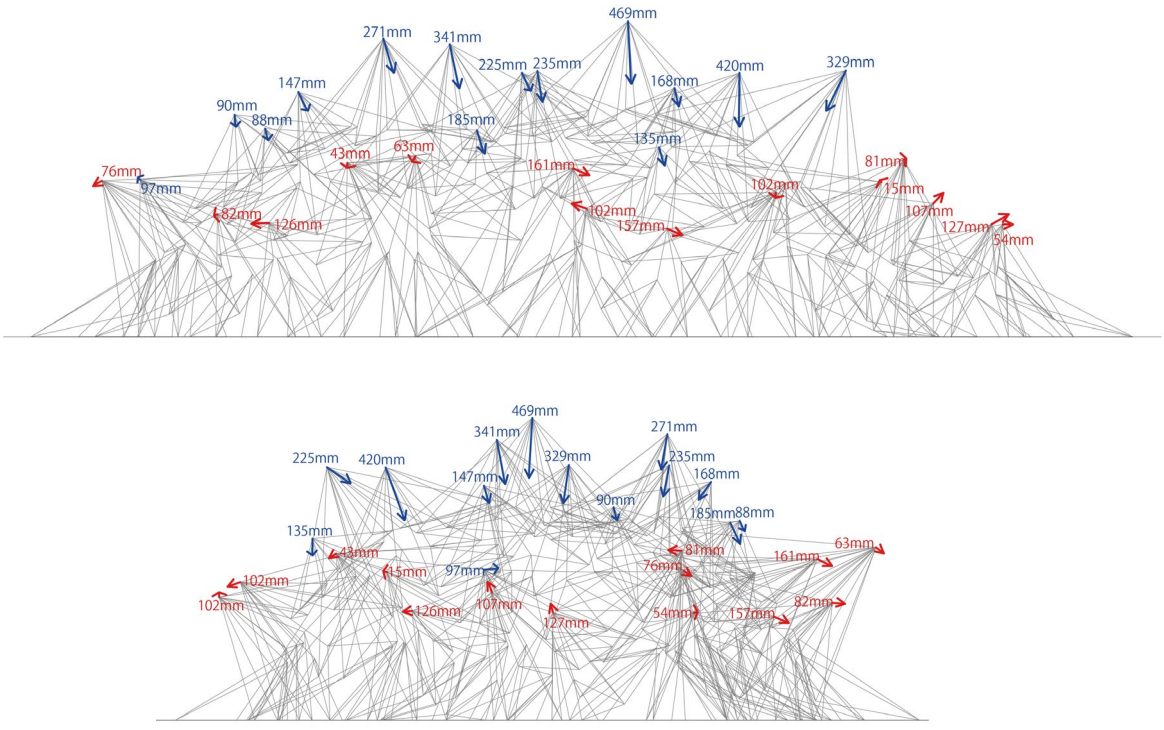

Figure 10. Error of each vertex in the design model and mock-up

7. Discussion and conclusion

This paper proposes a design method for membrane tensegrity structures by solving the inverse problem using freeform origami tessellations by generalizing Resch's patterns. Moreover, we demonstrated the feasibility of our method by constructing a full-scale mock-up. In constructing the structure, we sewed pockets, shorter in length than compression members, into the mountain fold lines and applied tensile force across the membrane by inserting CFRP rods as the compression members while pulling the membrane material. Furthermore, we measured the coordinates of each joint of the structure with a three-dimensional laser distance meter. Finally, we compared them with the design model to assess the reproducibility of its geometry. A comparison of the shape of the constructed mock-up and the model shows that the apex in the center of the span is much lower than in the model. In addition, observation of the test specimen showed that the compression material deflected significantly. Issues to be addressed include building a design model that considers the bending of the compression material and the stable sculpting of the 3D-printed joints.

Abstract

With the understanding of the mechanical behaviour of membrane materials, the popularity steadily increases. Membrane materials can be distinguished between technical (coated) textiles and technical foils, oftentimes ETFE foils. Recently, the final draft of the technical specification (TS) prCEN/TS 19102 has been submitted to CEN, which focuses on the design of tensioned membrane structures. Herein, rules for the design of textiles and foils are given, distinguishing between the Ultimate Limit State (ULS) and the Serviceability Limit State (SLS). For ETFE foils, the ULS and SLS design are based on uniaxially determined material properties. However, the majority of membrane structures exhibit biaxial stresses. Therefore, the material behaviour under biaxial tension is crucial. To evaluate the biaxial mechanical behaviour of membrane materials, generally biaxial tension tests on cruciform specimen are conducted. Yet, due to the cruciform geometry, a biaxial yield stress f_y cannot be determined. Bubble inflation tests can be performed to determine the biaxial stress-strain behaviour of ETFE foils especially after yielding. To determine the biaxial material behaviour of ETFE foils, bubble inflation tests are performed on materials from three different producers and one foil thickness. The evaluated data are presented and used to formulate design limits considering the material behaviour under biaxial tension up to the plastic deformation stage.

Keywords: ETFE foils, uniaxial, biaxial, bubble inflation test, mechanical behaviour, design, design limits

1. Introduction

With its first use of Ethylene/Tetrafluoroethylene (ETFE) foils as façade and cladding materials in the 1980ies, their convention in membrane structures steadily increased. Today, the building material ETFE is applied in cladding systems of prestigious buildings, such as stadiums, atriums or market halls. They are characterised by their low dead weight and transparency. All these membrane structures – technical textiles, technical foils – have in common, that they are usually built in synclastic or anticlastic shapes to activate their membrane stiffness. Generally, membranes are multiaxially prestressed and are exposed to multiaxial stresses due to external loads. Herein, the prestress can be applied either mechanically or pneumatically to form the anticlastic and synclastic shapes. Mechanical prestress is used to form anticlastic, single-layer shapes. To obtain synclastic shapes, oftentimes foil envelopes are produced and prestressed with an internal pressure, so that cushions are formed. Figure 1 illustrates two exemplary foil structures, which are mechanically (left) and pneumatically (right) prestressed. Comparing these two prestress application types, pneumatically prestressed multi-layer structures excel due to their capacity to compensate occurring plastic deformations by adjusting the internal air volume while keeping the pressure constant. Plastic deformation occurring in mechanically prestressed, single-layer structures leads to a loss in pretension and therefore to a loss of structural integrity.

Figure 1. Mechanically and pneumatically prestressed ETFE foil structures (left: Ruhr Park Bochum, Bochum, Germany, © Taiyo Europe GmbH; right: Nuova Sede Regione Puglia, Bari, Italy, © Taiyo Europe GmbH)

Regardless of the prestress application, all membrane structures must be designed in the Ultimate Limit State (ULS) and Serviceability Limit State (SLS) with external loads in mind. The newly developed final draft of the technical specification prCEN/TS 19102 [1] includes the design, execution and testing of membranes using the k-factor concept. With the use of the k-factor concept, which bases on the A-factor concept, see e. g. Minte [2], the strength characteristics of the used materials are divided by corresponding k-factors, which are chosen depending on the design condition, e. g. a slowly accumulating long-term load at T = 0 °C is taken into account for the load case "snow". For ETFE foil structures, decisive characteristics are the Young's Modulus E, the elastic limit f_{el}, which is defined by the first inflexion point f_{ip} in the stress-strain diagram, the yield point f_y, and the ultimate tensile strength f_u, which are highly dependent on the strain rate and temperature due to ETFE being a thermoplastic. To derive these material characteristics, typically uniaxial tensile tests or more rarely biaxial tensile tests are performed, simplifying the multiaxial stress states occurring in membrane structures into two principle stresses. Uniaxial tensile tests are carried out due to the ease of processing and the comparatively low costs. However, knowledge about material properties and characteristic values under multiaxial – or simplified biaxial – loading conditions are crucial. Under multiaxial tension, ETFE foils show a stiffer and at the same time stronger material behaviour compared to the material response under uniaxial tension. If the strains in the material directions are compared in uniaxial and biaxial/multiaxial stress conditions, higher forces and thus higher stresses result in equivalent material strains in the biaxial stress state.

In the ULS design of ETFE foils, according to the submitted final draft of prCEN/TS 19102 [1], no difference is made between the ultimate tensile strength of ETFE foils in uni- and biaxial stress states resulting in a k-factor of $k_{biax} = 1.0$. However, previous studies on the biaxial mechanical behaviour of ETFE foils in bubble inflation tests showed, that under biaxial tension, ETFE foils exhibit a stiffer material behaviour. Schiemann [3] performed bubble inflation tests on 200 µm ETFE foils revealing that the ultimate tensile strength of a ETFE foil in a bubble inflation test occurs at approx. 10 % to 12 % strain with a mean tensile strength of 29 MPa and a characteristic tensile strength of 26.6 MPa. Thus, according to Schiemann the k_{biax}-factor for the ULS as a quotient between the characteristic tensile strength of welded ETFE foils ($f_{uw,k,uni} = 30$ MPa) and the characteristic tensile strength in his welded bubble inflation tests ($f_{uw,k,bubble} = 26.6$ MPa) equals $k_{biax} = 30/26.6 \cong 1.15$. In SLS-design, Schiemann refers to the yield strength of ETFE foils, thus determining a factor of $k_{biax} = 1.0$. Moritz [4] suggested a factor to consider the biaxial tensile strength of ETFE foils of 1.2 for ULS-design and 1.4 for SLS-design. In uniaxial tensile tests on ETFE foils, the yield point occurs at approximately 18 % strain.

2. The tensile behaviour of ETFE foils

2.1. General

In the framework of the German DFG research project "Characterisation of the nonlinear viscoelastic material behaviour of ETFE- and ECTFE-foils for the use in building membrane structures" (STR482/6-

1), the mechanical behaviour of ETFE foils was analysed in short-term tensile tests as well as in long-term creep and relaxation tests, both in uniaxial and biaxial stress states. To evaluate the influence of the material thickness, two commonly used foil thicknesses were examined: 100 µm and 250 µm ETFE foils. Herein, 100 µm foils are usually applied as the middle layers of multi-chamber cushion systems. 250 µm foils typically form the envelope of those structures. Additionally, to investigate the producer's influence on the material behaviour, materials from three different producers were included in the project: Fluon ETFE Film 250NJ-1550NT and 100NJ-1550NT, Nowoflon ET 6235 Z in 250 µm and 100 µm, ETFE AG 250 µm and ETFE AG 100 µm. This order does not reflect the allocation of producers I, II, and III in the following, respectively. In this paper, the results achieved for the 250 µm foils are presented and discussed.

2.2. Uniaxial tensile behaviour

To derive the uniaxial mechanical behaviour of ETFE foils, uniaxial tensile tests were performed according to EN ISO 527-1 [5] and -3 [6]. Special provisions are mentioned in prCEN/TS 19102 [1] regarding the specimen's geometry, prestress application and the strain rate. According to prCEN/TS 19102, uniaxial tensile tests should be performed on strip specimens with an initial measuring length of 50 mm and a width to length ration of 1:5 with linear fixation at the top and bottom. The tensile test results include the recorded force F and elongation $\Delta L = L\text{-}L_0$ obtaining an engineering stress-engineering strain diagram (σ_{eng}-ε_{eng}-diagram), relating to the initial cross-section area A_0 and initial measuring length L_0 with $\sigma_{eng} = F/A_0$ [MPa] and $\varepsilon_{eng} = \Delta L/L_0$ [%].

Figure 2 represents a typical σ_{eng}-ε_{eng} diagram of 250 µm ETFE foils at room temperature and at $d\varepsilon/dt$ = 200 %/min from three different material producers I, II and III, featuring the material characterising parameters. In the left diagram, the overall uniaxial tensile behaviour up to the break is shown. For ETFE foils, the ultimate tensile strength f_u occurs at the rupture of the specimen. At the inflexion point f_{ip} as well as the yield point f_y, the material stiffness significantly decreases. These two points are commonly called first and second yield point, $f_{y,1}$ and $f_{y,2}$ respectively. However, EN ISO 527-1 defines the yield point as the σ_{eng}-ε_{eng} point, where the strain increases without any further increase in stress, so that the first inflexion point is called f_{ip} here. Simultaneously, f_{ip} and f_y divide the material behaviour of the thermoplastic ETFE into three different stages. The first stage represents the viscoelastic stage ranging up to the stress f_{ip} including elastic and viscoelastic deformations. After the stress f_y, ETFE foil is viscoplastic. The foil material yields and mainly plastic, viscous deformations are present. Between f_{ip} and f_y, the material is viscoelastic-plastic with significant viscoelastic and viscoplastic deformation.

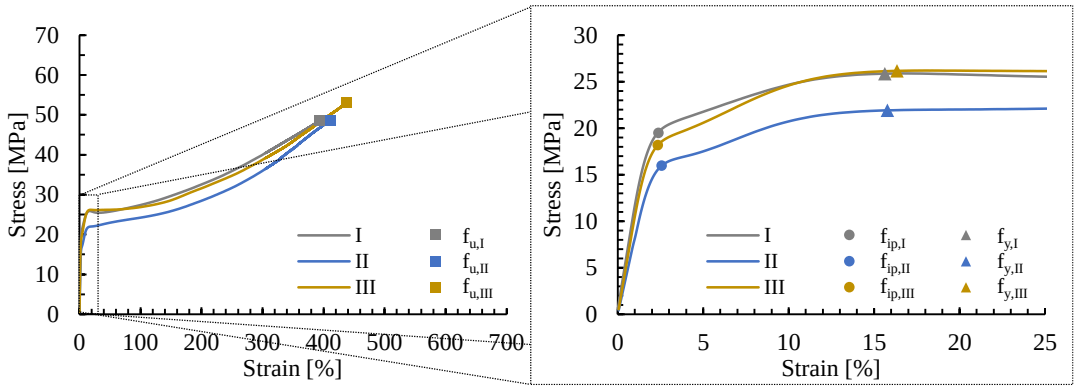

Figure 2. Engineering stress-engineering strain diagram of ETFE foil in ED under uniaxial tension for three different producers I, II and III (250 µm, 23 °C, 100 mm/min ≙ 200 %/min).

Additionally, Figure 2 shows the material producer dependency on the foil product. Material from producer II shows significantly lower strength values, even at the elastic and viscoelastic limit, which is

decisive for the design of ETFE foil structures. prCEN/TS 19102 defines the characteristic tensile strength of ETFE foil base material to $f_{u,k}$ = 40 MPa (T = 23 °C) for ULS design, and the elastic limit to f_{el23} = 15 MPa for SLS design. Figure 3 shows the temperature and strain-rate dependent material behaviour of ETFE foils. With an increase in the test temperature, the material shows a considerably weaker and slightly softer tensile behaviour. An equivalent response can be observed with a decrease in the strain-rate. For a detailed discussion on the temperature- and strain-rate dependent uniaxial material behaviour see Surholt et al. [7]. In the past several investigations into the strain rate and temperature dependent material behaviour of ETFE foils were conducted, e.g. by Moritz [4], Galliot and Luchsinger [8], Hu et al. [9], [10], Zhao and Chen [11], [12], Saxe [13], Sun et al. [14], and Lippke [15].

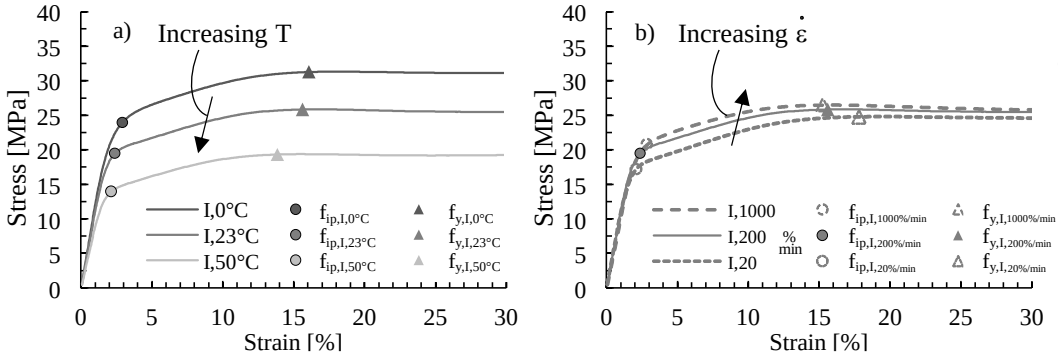

Figure 3. Section of an engineering stress-engineering strain diagram of ETFE foil in ED under uniaxial tension for producer I up to 30 % strain; a) 0 °C, 23 °C and 50 °C (250 µm, 100 mm/min ≙ 200 %/min); b) 10 mm/min ≙ 20 %/min, 100 mm/min ≙ 200 %/min and 500 mm/min ≙ 1000 %/min (250 µm, 23 °C).

To consider environmental effects on site, the previously mentioned design concept in prCEN/TS 19102 introduces additional k-factors to modify the material behaviour at T = 23 °C to the material behaviour under the considered design condition, e. g. $k_{temp,50\,°C}$ to consider the strength reducing effect of an environmental temperature of 50 °C on site on the foil surface or the surface of adjacent components like clamping profiles.

2.2. Biaxial tensile behaviour using cruciform specimens

Uniaxial stress states rarely occur in built membrane structures. The necessary prestress as well as the stresses due to external loads are multiaxially and transferred to the primary steel-, aluminium- or timber-structure. These multiaxial stresses can be simplified to biaxial stress states considering the principle stresses σ_1 and σ_2. Therefore, to design membrane structures overall and ETFE foil structures in particular, the load bearing behaviour in multiaxial stress states is crucial. To evaluate this material behaviour, biaxial tensile tests and bubble inflation tests were performed. Using plane cruciform specimens, defined loads can be applied via arms, which transfer the uniaxial stresses to a measuring field, which is thus biaxially loaded. Figure 4 illustrates such a plane cruciform specimen.

Figure 5 presents the response of biaxial tensile tests in stress ratio 1:1 (extrusion direction:transverse direction, short ED:TD) of ETFE foil material of the three different producers at room temperature. The tests were performed with a constant stress rate of 1.5 MPa/min, which equals an average strain rate of approximately 0.33 %/min. The stress rates refer to the first principal direction of stress (ED). The σ_{eng}-ε_{eng} diagram shows the stress-state dependent material behaviour of the ETFE foils investigated. It illustrates that for all three ETFE foil materials under biaxial tension, a stiffer mechanical response can be observed compared to uniaxial stress, cf. Figure 2. A distinct yield point f_y cannot be identified due to early specimen rupture. The specimen arms are loaded uniaxially as mentioned above. When they begin to yield, the biaxially loaded measuring field cannot be loaded further by the test machine and the test is terminated. All investigated ETFE foils show an isotropic material behaviour in a 1:1 stress ratio, and – compared to uniaxial behaviour – the three analysed materials stiffen, referring to the Young's modulus E and the hardening modulus E_{ve}. Moreover, they harden, referring to f_{ip} and f_y. Here, the

engineering stresses σ_{eng} are determined as a quotient of the measured forces F and the initial specimen area A_0: $\sigma_{eng} = F/A_0$ [MPa].

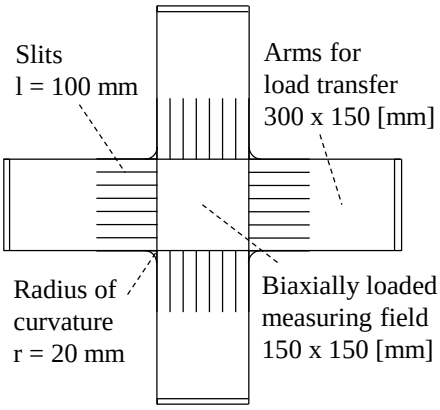

Figure 4. Used cruciform specimen geometry.

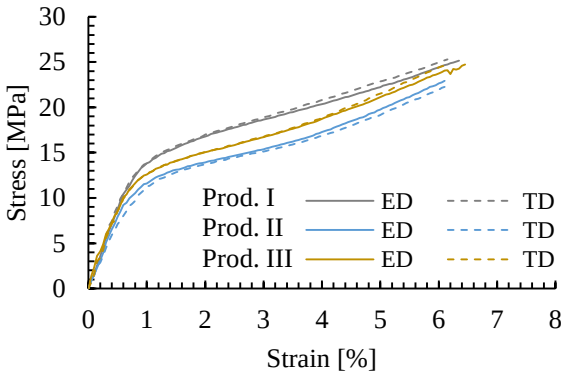

Figure 5. Biaxial mechanical behaviour of ETFE foils of three different producers under stress ratio 1:1 (mean value curves; 250 µm; $d\sigma/dt$ = 1.5 MPa/min ~ $d\varepsilon/dt \cong 0.33$ %/min).

2.3. Multiaxial tensile behaviour using bubble inflation specimens

To characterise ETFE foils in the viscoelastic-plastic as well as the viscoplastic material stages, bubble inflation tests are required. For this purpose, circular test specimens with a clear diameter of 500 mm were used. In bubble inflation tests, the forces F cannot be measured directly. In these tests, the specimens are loaded pneumatically, so only the internal pressure is known. In the performed tests, the inner pressure was constantly raised with a rate of dp_i/dt = 16.67 Pa/min to achieve a strain rate of approximately $d\varepsilon/dt \cong 0.33$ %/min. The strains were determined using a photogrammetric 3D deformation measurement system. To derive the stresses at the bubble peak in stress ratio 1:1 induced by the internal pressure, the Barlow's formula can be used. In the bubble inflation test, a rotationally symmetric shape is assumed. This leads to an identical stress in both material directions ED and TD:

$$\sigma_{eng,bubble,ED} = \sigma_{eng,bubble,TD} = \frac{p_i r_i}{2t_0} \tag{1}$$

with p_i being the internal pressure [MPa = N/mm^2], r_i the radius of curvature at the peak [mm], and t_0 the initial foil thickness [mm]. Schiemann [3] used Eq. 1 to derive the foil stresses in his bubble inflation tests. However, in bubble inflation tests, ETFE foils show an inhomogeneous material behaviour in its deformation after reaching the yield point. The specimen's peak elongates at first up to the point, when its mechanical capabilities are exhausted. To compensate the still increasing air volume in the pressure chamber and to allow for further elongation, material from further down the line is pulled in reducing the material's thickness at the locations from where it is drawn. Murphy [16] (cited in [17]) as well as Javořik and Dvořàk [18] performed bubble inflation tests on elastomers and calculated the stresses at the peak considering the occurring "stretch ratio" λ ($\lambda = \varepsilon+1 = L/L_0$ [-]). Under the assumption that ETFE foils are incompressible, the engineering stresses at the peak can be determined under the consideration of the stretches in ED (λ_{ED}) and TD (λ_{TD}):

$$\sigma_{eng,bubble,ED} = \frac{p_i r_i}{2t_0}\lambda_{ED} \tag{2}$$

$$\sigma_{eng,bubble,TD} = \frac{p_i r_i}{2t_0}\lambda_{TD} \tag{3}$$

In both cases, the radius at the pole r_i is determined evaluating the deformation in ED and TD axis using a polynomial fit of 6th degree ($f(x) = ax^6+bx^5+cx^4+dx^3+gx^2+hx+j$). As an example, Figure 6 illustrates

the deformation and strain along ED and TD of test no. BIT-II250-23_16,67-II (Bubble Inflation Test, producer II, t_0 = 250 µm, T = 23 °C, dp_i/dt = 16.67 Pa/min, test number II) at recording step 1 000 with an internal pressure of p_{1000} = 32 812 Pa, at the recording step 1 290 with the maximum internal pressure of $p_{i.max}$ = 42 150 Pa, and at the last recording step (1 305) with an internal pressure of p_{1305} = 33 620 Pa close before fracture. The tests were recorded with 0.5 Hz. Figure 6 illustrates the general good fit of the polynomial fit for the material from Producer II, 250 µm.

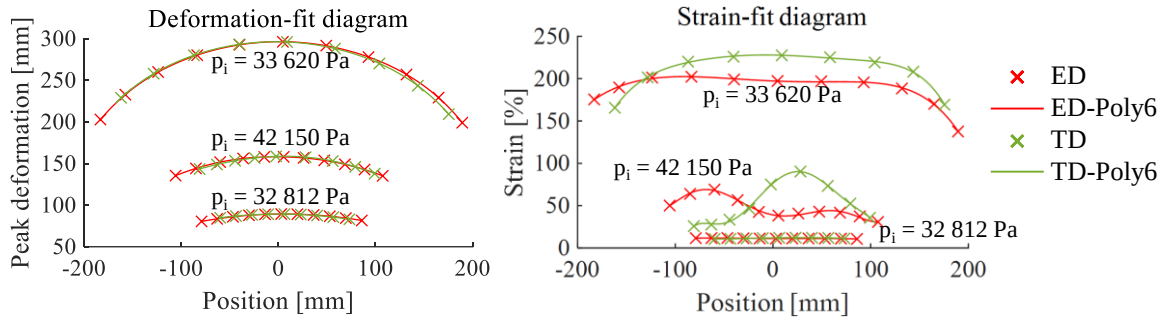

Figure 6. Comparison of the polynomial fit to the measured deformation stages (left) and strains (right) for the bubble inflation test BIT-II250-23_16,67-II at specific points X in both material directions at p_{1000} = 32 812 Pa, and at p_{1305} = 33 620 Pa.

Figure 7 illustrates the load-deformation curves of the performed bubble inflation tests for all three producers. In all tests, the internal pressure was constantly rising until the maximum internal pressure was reached. Reaching their individual maximum internal pressure, the specimen's volume increased drastically, so that the pressure system could not maintain the programmed pressure rate. This way, the internal pressure decreased until specimen fracture occurred.

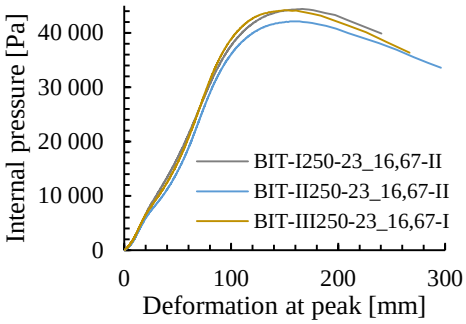

Figure 7. Load-deformation diagram of the performed bubble inflation tests.

Using the fitted curves (Poly6), the radius of curvature in each recording step, each point, in each direction and for each test can be calculated. Here, the radius of curvature was calculated at the peak deformation of the test specimen for ED and TD separately to derive the stresses of the ETFE foil in the two material directions using the following formula:

$$r = \frac{1}{\kappa} = \frac{\left(1+\left(\frac{df}{dx}\right)^2\right)^{\frac{3}{2}}}{\frac{d^2 f}{dx^2}} \tag{4}$$

In addition to the calculation of the radius, the strains in ED and TD were calculated at the peak. This does not mean that the highest strains must occur at the peak deformation, see Figure 6 (right). The occurring strains in ED and TD of the illustrated bubble inflation test demonstrate the anisotropic behaviour in the last recording stage close before rupture. Over a wide span of the test specimen, the

strains equalize, so that a strain "plateau" is observed. The specimen gathers material from the region closer to the clamps. During bubble inflation tests, the centre region around the peak exhibits the highest strains in both material directions. Approaching the maximum bearable inner pressure, the strain at the pole does not increase drastically anymore; the strains further away from the centre region raise while the strains in the centre region stay stable. In the present paper, the strains were calculated using the polynomial fit at the location with the highest peak deformation. As an example, for test BIT-II250-23_16,67-II, the strains were calculated at the centre of the peak which lays at position approximately 5 mm, see Figure 6.

To obtain the strains in both material directions, the specimens have to be prepared for the photogrammetric measurement system. The photogrammetric measurement system generates facets on the specimen surface based on a black and white stochastic pattern. Therefore, the transparent ETFE foils to be tested were primed white and then dabbed with black paint, cf. Figure 10. The photogrammetric measurement system then tracks the generated facets during the inflation test and calculates the distances of their centres from which the strains are obtained.

With the calculated parameters, which are mentioned above, a σ_{eng}-ε_{eng} diagram can be generated for the peak location on the bubble using Equations (2), (3) and (4). For the tests performed on the 250 µm ETFE foils of three different producers at room temperature, Figure 8 illustrates the determined σ_{eng}-ε_{eng} curves up to 200 % strain and in a cut-out up to 25 % strain.

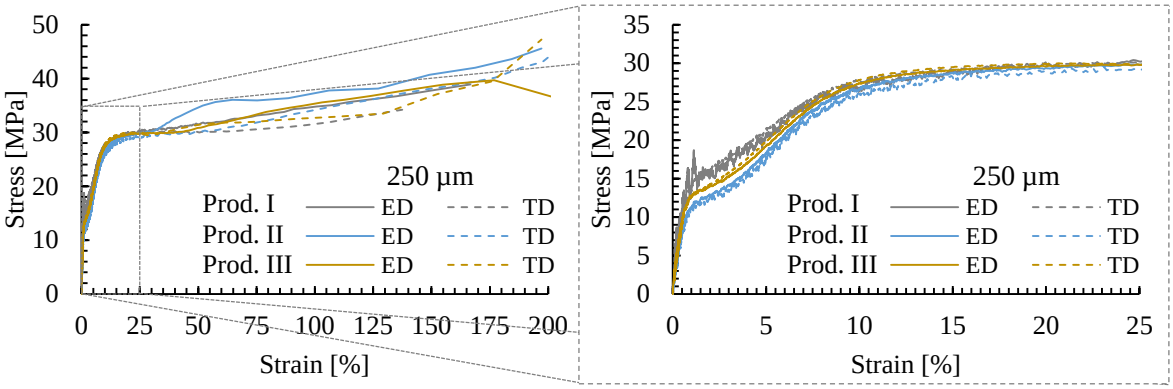

Figure 8. Calculated σ_{eng}-ε_{eng} curves of the bubble inflation tests performed on 250 µm ETFE foils from three different producers (T = 23 °C).

The results show the different material behaviour of the three foils already observed in the uniaxial and biaxial test results. Material from producer I exhibits the strongest characteristic first inflexion point f_{ip}, and material from producer II the weakest. Table 1 lists the measured breaking strains ε_u and calculated ultimate tensile stresses f_u as well as the material characterising strength points f_{ip} and f_y in addition to their strain values ε_{ip} and ε_y. The first inflexion point was determined by calculating the point where the slope of the σ_{eng}-ε_{eng} curves reaches 80 % of its initial slope calculated in the elastic material region, and f_y where the slope reaches less than 1.5 % of its initial slope, respectively. Reaching the second material characteristic f_y between 10 % to 15 % strain, depending on the material producer, the material shows a similar yielding stage as known from uniaxial tensile tests but with less pronounced hardening after yielding, cf. Figure 2. After reaching f_y, the strain rate drastically increases while the pressure regulator tries to maintain the programmed pressure rate. This effect was so strong that the pressure system could not reach the desired pressure rate in this stage. In the yielding process, an extremely high strain rate occurs, which leads to the recording of only a few measuring steps due to the fixed measuring rate of 0.5 Hz. After reaching the yield point f_y, hardening effects can be observed in the σ_{eng}-ε_{eng} curves. Finally, the ultimate tensile strength is reached at several hundred percent strain with stresses higher than the yield point, which again resembles the σ_{eng}-ε_{eng} curve of uniaxial tensile tests. After rupture, the nominal specimen thicknesses of 250 µm decreased to 40 µm, 39 µm, and 35 µm for producers I, II,

and III, at the pole, respectively. Ruptures occurred diagonally between ED and TD as well as in TD, with crack sizes between approximately 230 mm, 320 mm, and 285 mm for producers I, II, and III, respectively.

Table 1. Measured strains [%] and calculated tensile stresses [MPa] of the performed bubble inflation tests on 250 µm ETFE foil.

Test	BIT-I250-23_16,67_II		BIT-II250-23_16,67_II		BIT-III250-23_16,67_I

ε_u [%]	205	182	197	228	255	197

It should be noted that not every bubble inflation test specimen reached its theoretical maximum load bearing capacity due to the occurrence of early "small cracks" which appeared approximately in the middle between the pole and clamping region, see Figure 10. It is assumed that a small defect in the foil can lead to this type of crack/leakage in the specimen when the defected area is strongly strained and the thickness reduced. These small cracks, however, do not propagate further. As soon as there was such a crack/leakage in the specimen, the internal pressure dropped, so that the specimen could not be loaded further. In 1/3 of the tests, the full capability of the foils was not achieved because of such small cracks. In these tests, the crack occurred shortly after yielding at the pole region. It can be concluded for practical construction applications, that yielding of foils used in cushion structures under internal pressure should be strictly avoided. Figure 9 shows the derived σ_{eng}-ε_{eng} curve of a bubble inflation test (test BIT-I250-23_16,67-I), where a small crack occurred after reaching f_y. Figure 10 shows the plastic deformed specimen and the crack detail.

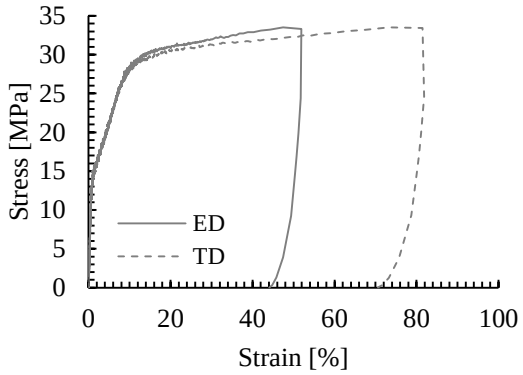

Figure 9. Calculated σ_{eng}-ε_{eng} curves of BIT-I250-23_16,67-I terminated early due to a small crack.

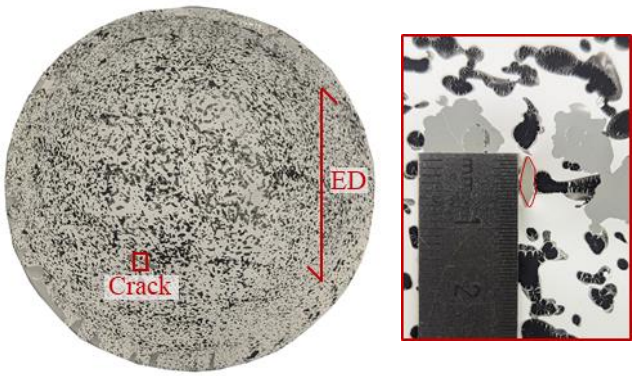

Figure 10. Small crack in the deformed test specimen BIT-I250-23_16,67-I leading to the termination of the test.

3. Comparison of the uniaxial and multiaxial/biaxial mechanical behaviour using strip, cruciform and bubble inflation specimens

Figure 11 shows the mechanical behaviour of ETFE foils in a uniaxial and two biaxial stress states using strip, cruciform and bubble inflation specimens, respectively. Additional information is presented in Table 2 regarding the derived material characteristics. Comparing the biaxial mechanical behaviour of the foils investigated using cruciform and bubble inflation specimens, the stress-strain diagrams show qualitatively equal stress-strain curves of ETFE foils independent of the stress state. In the stress range up to f_{ip} also quantities are comparable. Moreover, cruciform and bubble inflation specimens behave

similar up to the point where records for the cruciform specimens end. This verifies the applicability of bubble inflation tests for the determination of biaxial mechanical properties. Cruciform specimens exhibit slightly less strains at equal stress levels greater than f_{ip}. A biaxial yield stress f_y cannot be measured using these specimens. Even though a yield strength cannot be measured in this way, these specimens find application for the determination of the biaxial material behaviour for building purposes. According to prCEN/TS 19102 [1], single layer foil structures should not exhibit plastic deformation which can lead to a loss of prestress and thus to a loss of its load bearing capabilities. Thus, the elastic limit should be used for the SLS verification of single layer structures. Special provisions are mentioned for the SLS design of foil cushion structures. If no limitation is defined by contractual agreement, the plastic strain may be limited to 1.0 %, which opens the applicable stress to stresses higher than the elastic limit. Therefore, cruciform specimen can be used to determine the biaxial material behaviour with measurable strains of approximately 6 % to 7 %, cf. Figure 5.

Figure 11 and Table 2 show that under multiaxial tension, ETFE foils show a less ductile material behaviour than under uniaxial tension. Regarding strength characteristics, the different materials behave different, at least with regard to f_{ip}. It can be stated that at f_{ip} the material of producer I exhibits increased stresses while materials of producers II and III exhibit slight decreases in stresses in bubble inflation tests compared to uniaxial tests. The amount of differences are $((f_{ip,bubble}-f_{ip,uni})/f_{ip,uni} =)$ 5.9 %, -1.7 %, and -1.6 % in ED for producers I, II, and III, respectively. At f_y, these differences are $((f_{y,bubble}-f_{y,uni})/f_{y,uni} =)$ 14.0 %, 26.5 %, and 17.7 % also in ED for producers I, II, and III, respectively. In TD the differences in stresses equal 8.3 %, 0 %, and 5.0 % at f_{ip}, and 15.8 %, 28.3 %, and 22.8 % at f_y for producers I, II, and III, respectively. This shows that in the preliminary bubble inflation tests, small differences in the range between 8 % and -2 % are recorded for f_{ip}, while an increase of at least 10 % is observed for f_y. Regarding the ultimate tensile strength of the investigated materials, percentile deviations at f_u equal $((f_{u,bubble}-f_{u,uni})/f_{u,uni} =)$ 0.2 %, -4.2 %, and 12.2 % in ED and -13.1 %, 5.8 %, and -8.3 % in TD for producers I, II, and III, respectively. However, with only one bubble inflation test made per producer, statements about an increasing or a decreasing ultimate tensile strength due to multiaxial loading cannot be made keeping in mind that at f_u relatively high coefficients of variation (COV) are observed in the uniaxial tensile tests with 6.2 %, 8.0 %, and 17.5 % in ED and 3.9 %, 2.8 % and 3.5 % in TD for producers I, II, and III, respectively. While the breaking stresses roughly maintain their level, the breaking strains are approximately halved.

The findings in these preliminary experiments that f_u does not change noticeably in a uniform biaxial stress state indicates that the current modification factor $k_{biax} = 1.0$ considering biaxial/multiaxial stresses is justified in the ULS design. For SLS design, the current modification factor $k_{biax} = 1.0$ is applicable for $f_{ip,uni}$. For safety reasons, $f_{y,bubble}$ should not be used in SLS design, due to the possibility of occurring small cracks in the specimens at stresses slightly higher than $f_{y,bubble}$ and at strains of approximately three times $\varepsilon_{y,bubble}$. With other words, when the yield point $f_{y,uni}$, is used for the stress verification of cushion structures, the current modification factor $k_{biax} = 1.0$ should still be used and not reduced to reflect $f_{y,bubble}$. By this way, a safety margin towards the chance of occurring small cracks after yielding of at least 10 % remains, when using $f_{y,uni}$ in combination with $k_{biax} = 1.0$. Additionally, the usage of $f_{y,uni}$ in SLS design leads to huge strains in cushion structures, which are generally not desired. In the performed bubble inflation tests, strains of approximately 7 % are measured at stresses equal to the uniaxially determined yield strengths $f_{y,uni}$ for all the analysed materials from producers I, II, and III. These values align with the maximum strains measured in the biaxial tensile tests using cruciform specimens.

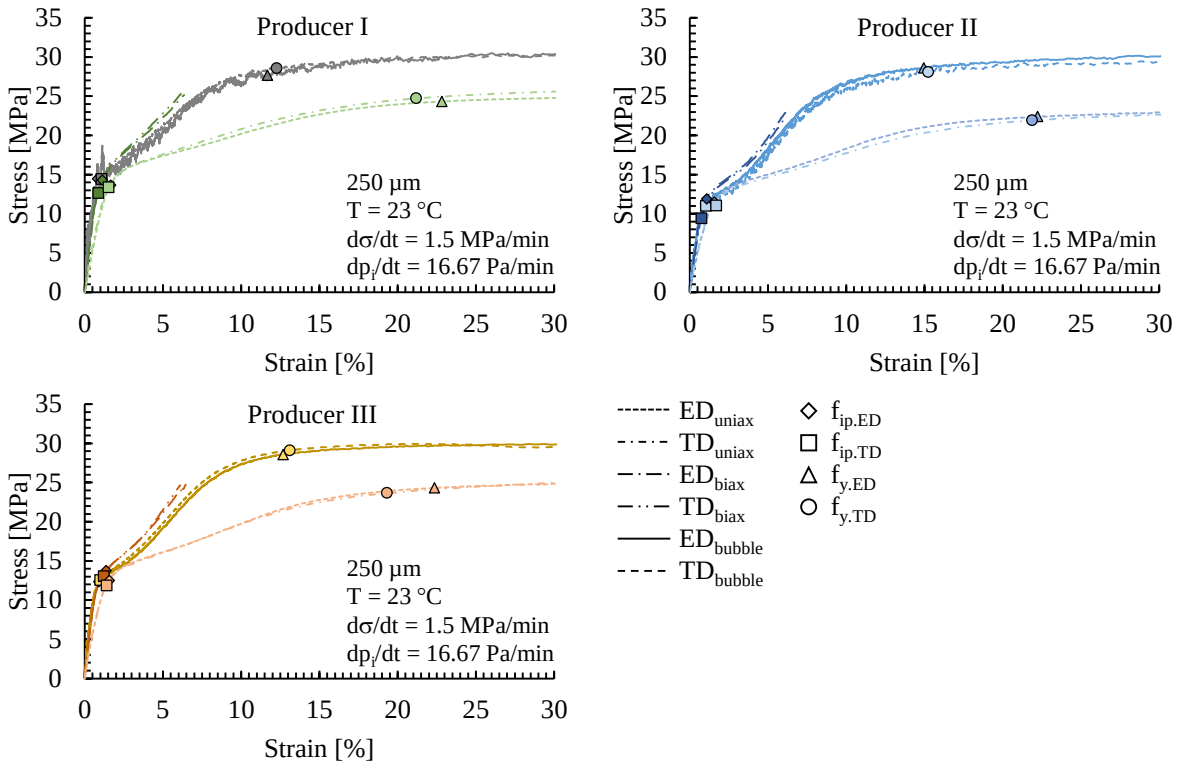

Figure 11. Comparison of the mechanical behaviour of ETFE foils derived in uniaxial, biaxial and multiaxial tensile tests using strip, cruciform and bubble inflation specimens of producers I, II, and III.

Table 2. Comparison of ETFE foils' tensile behaviour using different types of specimens in a uniaxial (1.5 MPa/min), biaxial (1.5 MPa/min) and multiaxial (16.67 Pa/min) stress state (250 µm, T = 23 °C).

Extensive research is demanded, characterising the strength effects caused by multiaxial loading to formulate more accurate k-factors for the ULS and SLS design. Herein, additional parameters influencing the mechanical behaviour such as the strain rate and test temperature have to be analysed simultaneously. A design method should be developed that allows the use of increasing strengths and

load bearing capabilities of ETFE foils due to multiaxial loading derived in bubble inflation tests, while maintaining safety against small cracks.

4. Conclusions

In the draft technical specification prCEN/TS 19102 [1] just recently submitted to the standardisation body, ETFE foil structures have to be designed in the ultimate limit state (ULS) and the serviceability limit state (SLS). In these design situations, different mechanical properties are required, which are typically determined in uniaxial tensile tests. To consider various effects such as multiaxial stresses occurring in ETFE foil structures, the k-factor concept is introduced, which is based on the A-factor concept, see e. g. Minte [2]. In prCEN/TS 19102, the modification factor considering biaxial/multiaxial stresses k_{biax} is set to 1.0 for ULS and SLS. In the frame of this contribution, a comparison is conducted between the mechanical behaviour of ETFE foils under uniaxial and biaxial/multiaxial tension using strip, cruciform and bubble inflation specimens. The tests performed reveal that the derived stress-strain diagrams show qualitatively equal stress-strain curves of ETFE foils independent of the stress state with three decisive strength characteristics, f_{ip}, f_y, and f_u.

ETFE foils exhibit a higher strength and stiffness under biaxial/multiaxial tension in comparison to the behaviour under uniaxial tension regarding the first and second inflexion point, f_{ip} and f_y. In the bubble inflation tests performed, specimen rupture occurred at several hundred percent strain with an average of 219 % strain in ED and 202 % strain in TD at stresses higher than f_y with average ultimate tensile stresses f_u of 47 MPa in ED and 45 MPa in TD. As the numbers of f_u are similar to those measured in uniaxial tensile tests, these preliminary tests confirm the current assumption of a k-factor considering biaxial/multiaxial stresses of $k_{biax} = 1.0$ for ULS design. In SLS design, the modification factor of $k_{biax} = 1.0$ is applicable for the first strength characteristic f_{ip}. The test series revealed that small damages/cracks can lead to leakages in the specimen. This occurred in 1/3 of the tests, each time shortly after reaching the yield point ε_y/f_y. With the occurrence of a leakage, the pressure system could not maintain the internal pressure, so that the internal pressure decreased to 0 Pa leading to a loss of prestress and thus to a loss of the load bearing capabilities of the specimen. It was concluded for practical structural applications that the yield stress should not be exceeded to avoid this type of failure. To ensure stresses not reaching the yield strength determined in bubble inflation tests, the modification factor for the uniaxially determined yield strength $f_{y,uni}$ is also proposed as $k_{biax} = 1.0$. By this way, the strength increase of at least 10 % at the yield strength under multiaxial loading compared to uniaxial is used as a safety margin to avoid the risk of appearance of small cracks.

To specify the modification factor k_{biax} more reliably, more bubble inflation tests are required. Simultaneously, influencing parameters such as the temperature and strain rate as well as different stress ratios should be investigated leading into a design method considering the strength increasing effects due to multiaxial loading.

Abstract

PVC coated polyester fibre membrane is one of the most widely used materials since its good mechanical properties and durability. In this paper, the strength of PVC coated polyester fibre membrane under different temperature were studied. The results showed the strength and stiffness decreased significantly with the increasement of test temperatures, which may be the cause of stress relaxation and wrinkles of the membrane structure. This study can provide reference for fire safety design, as well as for product design of material manufacturers.

Keywords: fabric membrane, temperature, strength, stiffness

1. Introduction

The architectural membrane structure has flourished, not only widely used in stadiums, transportation hubs, commercial exhibitions, but also in special application such as shelter hospitals, stockyards, logistics centres, and so on. However, with the expansion of application scenarios and the increase of fire risk factors faced during the service life of architectural membrane structures, fire prevention of architectural membrane structures becomes more and more important.

The key to fire protection in architectural membrane structures is the mechanical properties of the fabric membrane under high temperature, especially the strength and stiffness have an important impact on structural safety. Inevitably, the strength of the membrane material decreases under fire, and this drastic decrease in strength can lead to structural damage as it is difficult to maintain the original load-bearing capacity in a fire environment. The high temperature of fire also causes softening of the fabric membrane, making it difficult to maintain the original structural shape due to the loss of membrane surface pretension.

Ambroziak et al. [1] conducted uniaxial tensile tests at different temperatures and determined the variation of nonlinear elastic parameters with temperature in the range of -30°C to +70°C, which is far from the fire temperature. Ma [2] studied the tensile strength and elongation at break of PVC and PTFE coated fabrics by uniaxial tensile tests at different temperatures; PVC coated fabrics showed a 44% ~ 52.5% reduction in strength at 170°C and an increase in elongation at break of more than 20%; PTFE coated fabrics showed a 17.5% to 19.1% reduction in strength at 220°C and an increase in elongation at break of 6% to 11%. Sun et al. [3] conducted an experimental study of four kinds of PVC coated fabrics with uniaxial loading from 23°C to 250°C. The results showed that the elastic modulus at 230°C was only 1/10 of that at room temperature, and the ultimate tensile strength (UTS) at 200°C was about 1/2 of that at room temperature. Thus, both PVC and PTFE coated fabrics shown significant elastic modulus and strength reduction problems at high temperatures.

In this paper, the mechanical properties of PVC coated fabrics and weld seam at high temperature was tested in uniaxial tensile test method, and the test temperature was gradually increased from room

temperature (20℃). The mechanical properties of coated fabrics and weld seam at high temperature were obtained in this study. The weld was more prone to damage in fire damage since the strength of the weld at high temperatures is lower than the strength of coated fabrics.

2. Specimen

In this case, rectangular specimens with twisted clamp were used to avoid breakings at the gripped ends [28]. The rectangular specimen with a length of 1 m and width of 50 mm, and the lap length was 50 mm in weld specimen. The longer specimen was for an extra loop at the twisted clamping to prevent slippage caused by melting coating. The detailed dimensions of the two specimens were illustrated in Fig. 1. The material in this study was two kinds of PVC coated fabrics, JD5500 from Zhejiang Jinda New Material Co., Ltd and the basic parameters of materials was shown in Table 1.

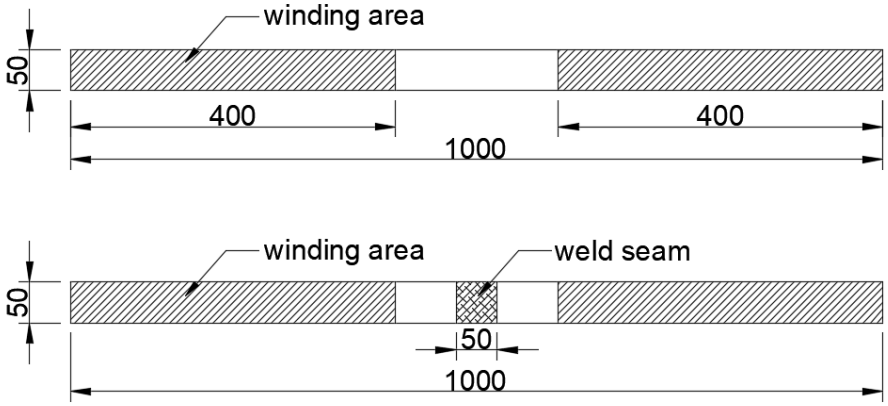

Figure 1. Dimensions of rectangular specimen

Table 1. Basic parameters of materials

Material	JD5500
Total thickness	0.84 mm
Total mass	1055 g/m^2
Tensile strength (warp/filling)	110/105 N/mm
Tear strength (warp/filling)	780/770 N

3. Test method

Mechanical tests were carried out on a single axis servo-hydraulic test machine UTM 400 with computer control and acquisition. Specimens were twisted at the twisted clamps and were preloaded with 1.0 N in order to ensure the removal of slack just prior to the tests. The displacements were measured between two ends of the rectangular specimens and load was measured by a standard force transducer. After mounting the retangular specimen, the target temperature was reached in 15 minutes and maintained for 15 minutes. Then apply tensile force to the specimen until failure, and record the tensile force and fixture displacement

The temperature chamber used for the test was shown in Fig. 2. Four electric heating tubes were placed inside the environmental chamber to directly heat the specimen, and the maximum temperature can reach 300°C. The temperature was controlled by PID control strategy with a control accuracy of ±2°C. The clamp was located outside the temperature chamber, and the hole of temperature chamber was sealed with asbestos to prevent heat escape. The thermocouple was lightly attached to the specimen to collecte the temperature, and the value of temperature was sent to temperature control system.

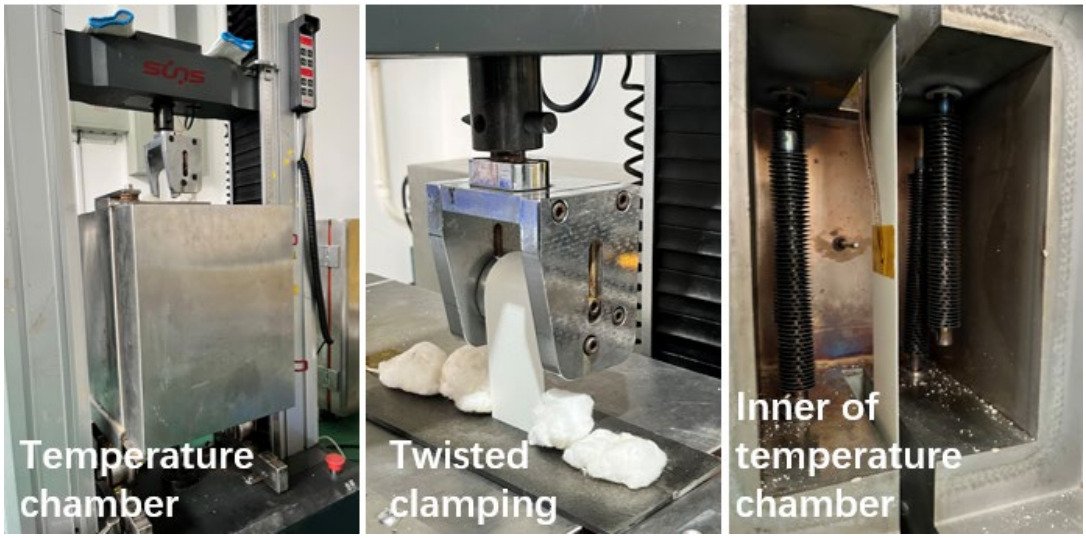

Figure 2. Temperature chamber and specimen installation method

4. Test result

4.1 Failure form

All of the specimens were broken in the middle of the test piece, except that no valid data was obtained at 80 °C since the coating of PVC partially softened and on the twisted clamping. The fracture pattern of the warp specimen at different temperatures were shown in Fig. 3. The fracture was relatively smooth at 20 °C, while the port flatness decreased with the increase in temperature and the yarn peeling phenomenon became more serious. When the temperature was between 20 °C and 60 °C, the apparent quality of the specimen did not change significantly. Further increasing the temperature, the surface color of the specimen to deepen, which was accompanied by the emission of white smoke and a pungent odor. The specimen became charred black and exhibited complete loss of strength at 250 °C.

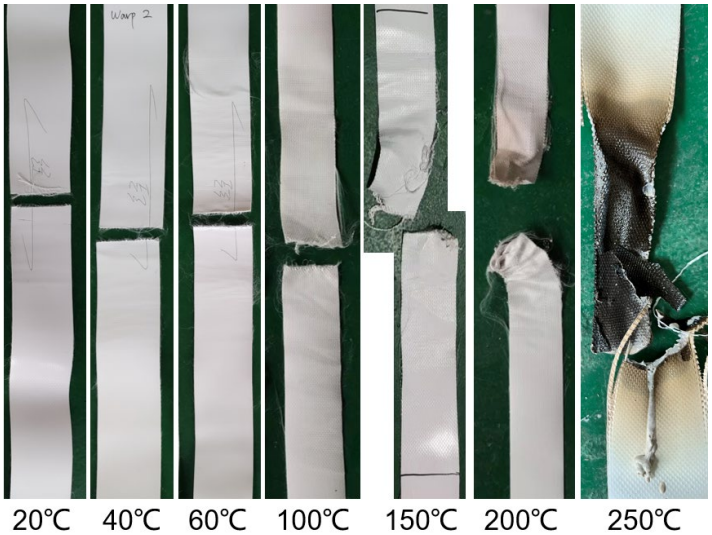

Figure 3. Fracture pattern of warp specimens at each temperature

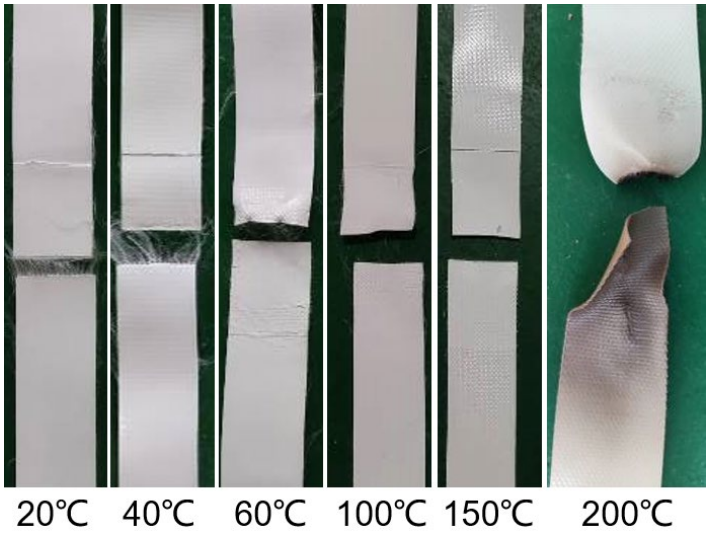
The fracture pattern of the welded specimens was shown in Fig. 4. The fractures were flush and occurred in the same direction as the weld. At 20℃ and 40℃, the fracture were located at the intersection of the

weld and the membrane and the weld joint remaining intact. The strength at edge of the weld was reduced due to the high temperature of the welding knife. The weld specimens were damaged in the form of joint separation from 60℃, and the weld strength was gradually reduced. Weld joint were separated and the surface of the specimens were blackened at 200℃。



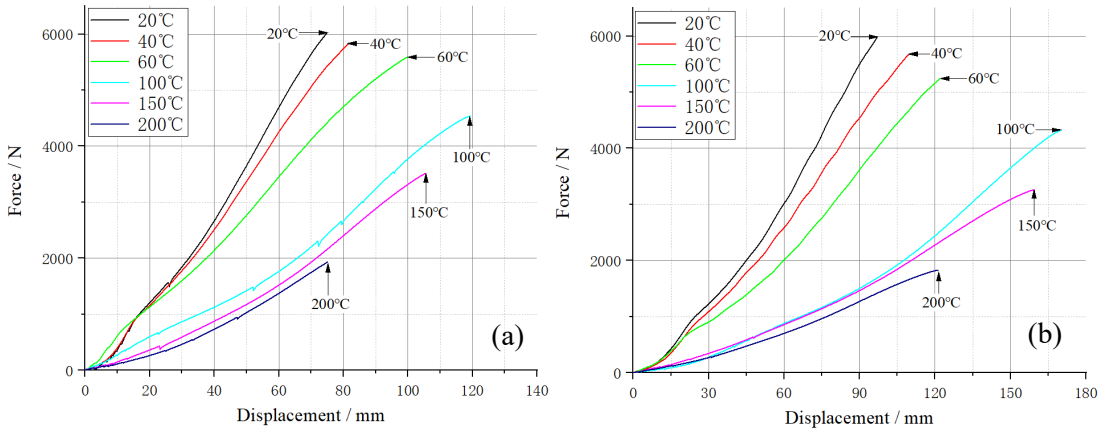


Figure 4. Fracture pattern of weld specmens at each temperature

4.2 Force-displacement curves

The weld joint failed at 200℃, while the fabric underwent charring at 250℃. Tensile tests were performed on the specimens in both the warp and weft directions, ranging from 20 ℃ to 200℃, as well as on the weld joint specimens, ranging from 20 ℃ to 150℃.

The curves in Fig. 5 exhibited non-linear behaviour, with stiffness gradually decreasing. Chen et al. [4] described non-linear concave-convex changes in the tensile behaviour of the yarns in the membrane material, which were also observed below 60℃. However, at temperatures exceeding 100℃, the initial portion of the curve exhibited concave behaviour, with a subsequent trend towards convex behaviour, without the concave-convex behaviour observed at temperatures below 60℃.

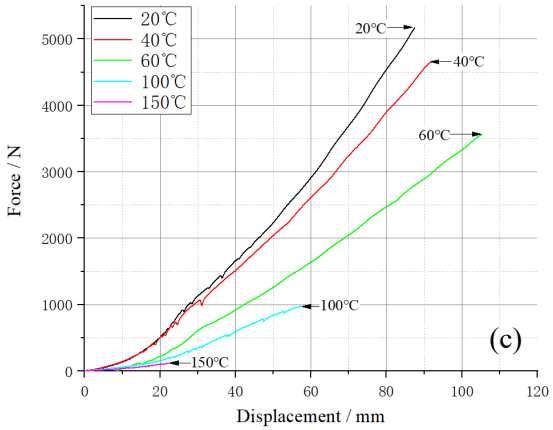

Figure 5. Force-displacement curves: (a) warp, (b) weft, (c) weld.

4.3 Uniaxial tensile strength

The tensile force at the time of fracture was recorded, and the uniaxial tensile strength of specimens at each temperatures were listed in Table 2 and Fig. 6. The strength of both the fabric and the weld was significantly reduced.

Table 2. The uniaxial tensile strength of specimens at each temperatures

Temperature (°C)	Warp		Weft		Weld joint	
	Strength (N/mm)	Percentage of 20 °C strength	Strength (N/mm)	Percentage of 20 °C strength	Strength (N/mm)	Percentage of 20 °C strength
20	118.11	100%	117.20	100%	101.26	100%
40	114.06	97%	111.35	95%	90.94	90%
60	109.63	93%	102.74	88%	70.46	70%
100	88.90	75%	84.70	72%	18.77	19%
150	68.93	58%	66.02	56%	2.28	2%
200	37.87	32%	35.84	31%	Separated	-
250	Burned	-	Burned	-		

Temperature has a significant effect on the strength of the membrane. When the temperature was below 60°C, the specimen was able to maintain 90% of its initial strength, but only about 30% of strength remaining at 200°C. When higher than 250 °C, the specimens were burned out. Ma [2] studied that the tensile strength of PVC coated fabircs in the warp and weft directions decreased 44% and 52.5% of its initial strength at 170°C respectively, which was similar to the results of this test.

The strength of the weld joint was found to be more sensitive to temperature, with a 30% reduction in strength observed when the temperature increased from 20°C to 60°C. At a temperature of 150°C, the strength decreased to only 2%, rendering it unable to withstand the pre-tension of the membrane structure. The weld joint failed completely at 200°C.

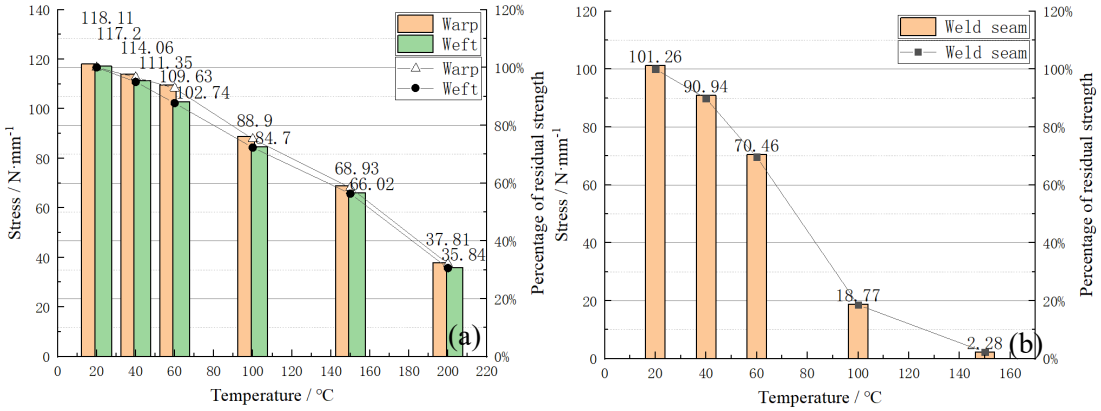

Figure 6. Uniaxial tensile strength and the percentage of residual strength: (a) warp and weft, (b) weld.

5. Conclusions

Temperature plays a crucial role in the strength of the specimen. This study provides important insights into the thermal behaviour of PVC coated fabrics and has potential applications in the field of fire performance analysis of membrane structures. PVC coating exhibited a softening phenomenon at a temperature of 80℃, resulting in slippage of the membrane material during the tensile testing process. The strength reduction of the weld was significantly greater than that of fabric membrane, so more attention needs to be paid to weld damage during fires

Abstract

Membrane structures have become popular in public, civil, and industrial buildings due to their diverse appearance, adaptability, low cost, and durability. However, the application of membrane structures and the precise assessment of their structural qualities are constrained by the fact that only a small number of studies have been conducted on them using experimentally obtained response data and environmental factors of models or actual structures. An effective method for analyzing the properties of membrane structures involves directly obtaining response data or environmental characteristics from a model or building. This method can also aid in the advancement of theoretical studies and simulation techniques, as well as the implementation of specifications. This paper provides a thorough discussion of the mechanical, thermal, and energy performance of membrane structures, as well as the deployment and deflation of inflatable varieties. The composition of the structure is the most essential component influencing its performance, and appropriate design can lead to improvements in mechanical characteristics, thermal environment, and energy consumption. The advantages and challenges of the current literature are also discussed.

Keywords: membrane, performance, thermal environment, energy, deployment, deflation

1. Introduction

Membrane structures have gained significant attention in recent decades due to their versatility in appearance and their ability to be constructed quickly as permanent or semi-permanent buildings [1]. They are also highly portable and adaptable for use in temporary construction projects [2]. In recent years, there has been a significant increase in the use of membrane structures, which can be attributed to the advancements in architectural membrane materials and improvements in construction technology.

The significant deformation of the membrane under external loads is a distinctive feature. Consequently, the mechanical performance of the membrane structure has become a major concern. The building sector is responsible for 40% of primary energy consumption, highlighting the importance of energy efficiency in construction [3]. As green concepts become increasingly prevalent, achieving a balance between energy consumption and maintaining a comfortable internal temperature environment is a key focus in the advancement of membrane buildings. Additionally, the deployment efficiency and safe deflation of inflatable membrane structures have been analyzed in recent studies [4, 5].

Membrane structures possess unique properties that distinguish them from traditional building materials, resulting in challenges when determining their architectural performance through conventional research methods [5]. Due to the significant geometric nonlinearity caused by the lightweight and flexible nature of membrane structures [6], precise structural analysis is vital for the formulation of design principles and the successful implementation of these structures [7]. Theoretical studies and numerical simulations

have shed some light on the structural properties of membrane structures. However, the reliability of the results may be impacted by the simplification of structural aspects or the application of models during the analysis process, raising concerns about the accuracy of the findings [8]. Understanding the structural performance of membrane structures can be improved by examining data gathered from models or real structures. This procedure also contributes in the improvement of finite element models and the verification of theoretical equations.

In this paper, a systematic review of the performance of membrane structures is conducted from five perspectives: mechanics, thermotics, energy, deployment, and deflation. A comprehensive understanding of these topics is crucial for the development of membrane structure specifications and for promoting their application in a wide range of fields.

2. Application of membrane structure

Polyvinylchloride (PVC), polyvinylidene fluoride (PVDF), ethylene tetrafluoroethylene (ETFE), and polytetrafluoroethylene (PTFE) are among the commonly used membrane materials in construction [9, 10]. Different combinations of materials result in various membrane types with distinct characteristics. Although there is a broad selection of membrane materials to choose from, a few dominant production types have dominated the market, accounting for 90% of membrane structures used in building construction [11]. As illustrated in Figure 1, the purpose of a building plays a significant role in determining the choice of membrane material. Membranes are more commonly utilized in enclosed permanent buildings than in other structures.

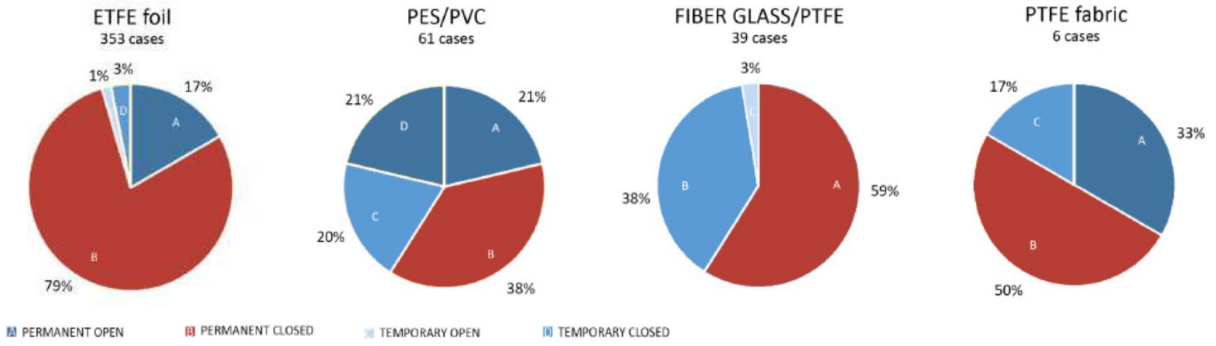

Figure 1. The utilization of membrane materials [11].

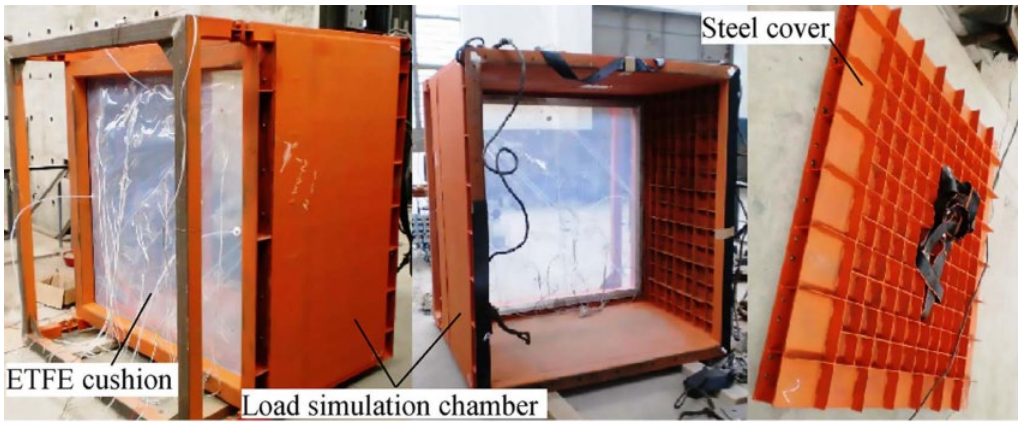
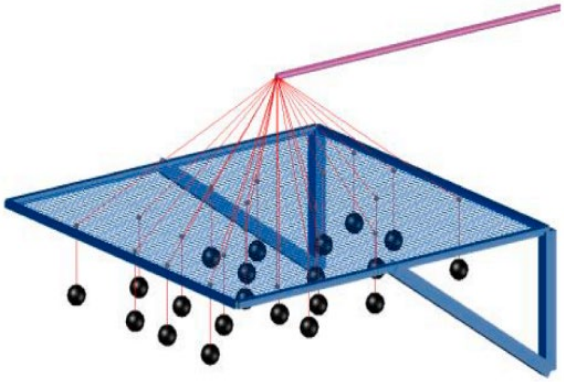


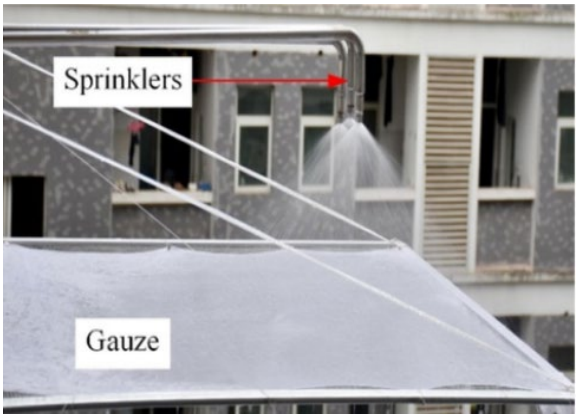
Depending on the building shape and supporting conditions, membrane structures are classified into tensioned, skeleton, cable membrane, and inflatable structures in the engineering field [12]. Engineers have also developed various derivative structures to cater to specific service requirements [13, 14].

3. Mechanical performance



The mechanical behavior of membrane structures can be primarily determined by analyzing their response to external loads. Membrane structures are subjected to external loads, which can be caused by natural phenomena (for actual buildings) or induced by human activities (for test models). The progress in technology has made it achievable to mimic the external loads that membrane structures might confront in actual environments under controlled laboratory conditions. Several load simulation devices are depicted in Figure 2, which are utilized for replicating external loads on membrane structures.

The unique properties of membrane materials necessitate consideration of load distribution across the structural elements, as variations in loads can greatly affect the load-carrying capacity of the structure [15]. One method to address this is by adding an auxiliary structure to the exterior of the membrane, which can improve load-bearing performance while also retaining the flexibility and other desirable characteristics of the membrane structure [16]. The stiffness of a membrane structure is closely linked



to the magnitude of prestress or internal pressure. However, the relationship between these factors is non-linear, and as the prestress or internal pressure increases, the corresponding increase in stiffness gradually decreases [17]. The long-term stress on membrane structures during regular use can result in a creeping phenomenon, which causes the material to experience increased deformation and reduced maximum structural stress over time [18, 19]. The welds that connect the membranes function as local reinforcement for the structure, but the distribution of stresses is not significantly affected by them [20]. Due to the significant impact of shear stress, the deformation of an air beam under external load is best calculated using the Timoshenko beam theory rather than the Bernoulli beam theory [21].

Figure 2. Experimental devices [22-24].

The oscillation of the structure during wind-induced vibration is affected by the alteration of the surrounding airflow pattern, resulting in a lower frequency of oscillation than in a vacuum, referred to as added mass [25, 26]. As the wind speed increases, the added mass also increases, significantly influencing the structure's displacement [27]. Wind-induced vibration can excite multiple vibration modes, and the amplitude and damping ratio are positively correlated with wind speed [28]. In the case of aeroelastic instability in tension membranes due to vortex-induced resonance, only one vibration mode is excited and leads to periodic destabilization [29]. Flutter occurs when the membrane deflects in a divergent direction and takes on the shape of standing waves [30]. The deformation of the structure was more prominent in the lateral and vertical directions along the airflow than in the longitudinal direction [8]. The membrane structure has different failure modes when subject to wind pressure and suction. Edge tearing is the primary cause of failure under wind pressure, while holes in the weld are the main cause of failure under excessive wind suction [31]. Wind tunnel is one of the most common experimental devices used for wind response of membrane structures. The deformation behavior of the

membrane structure under external loads makes it inappropriate to use a rigid model with an undeformed construction shape, as this may result in considerable discrepancies between the measured data and the actual state of the structure.

The properties of impact loads on the structure in nature are unknown, resulting in stochastic vibration and deformation [32]. Large deformations may cause the structural pretension to decrease, making the structure unserviceable when exposed to wind loads below the design value [23]. Moreover, structures with a low tear strength in the membrane are susceptible to scratches and punctures from impact objects [33]. The interaction of incident and reflected waves from the boundary triggered high-frequency vibrations during the early stages of vibration caused by an impact.

Wrinkling is a common issue that arises when compressive or shear stresses are applied to membranes, and it occurs locally when the maximum stress exceeds a critical threshold [34]. This phenomenon, which is a form of localized buckling, can significantly compromise the structural stability and performance. The prediction of the buckling behavior through theoretical and numerical methods is complicated by the complex wrinkling effect. Therefore, it is crucial to consider the wrinkling effect in the design and analysis of membrane structures. The creation of new wrinkles is driven by the local buckling of pre-existing wrinkles, in addition to changes in local modes [35]. The distribution of wrinkles is greatly influenced by the initial imperfections in membrane thickness, and the shapes of wrinkles cannot be uniquely determined when the membrane undergoes repeated deformations under identical conditions [36]. Wrinkles in the membrane affect its vibration modes and create areas of high stress at the wave peaks. The critical wrinkle strain can be calculated using the membrane's out-of-plane displacement and in-plane stress, with the mean principal stress increasing as shear displacement increases [37, 38].

4. Thermal environment

The thinness and high transparency of membrane structures make them less thermally insulated than traditional structures, with limited temperature inertia. Consequently, membrane structures rely heavily on temperature influences and usually have poor thermal comfort [39, 40]. Onsite measurements are the most appropriate method for acquiring building performance due to the solid space- and time-dependent characteristics of the structural temperature environment [41].

The temperature distribution in non-enclosed areas is affected by wind speed and direction, solar radiation, and the convective heat transfer coefficient on the membrane surface. As a result, the temperature inside the building is primarily dependent on the outdoor temperature and indoor heat sources. For enclosed spaces, the temperature is positively correlated with height and varies depending on the horizontal position, while the peak temperature occurs later as height decreases [42, 43]. Under natural ventilation conditions, the temperature distribution in a room is more influenced by solar irradiation than by airflow, given that the latter remains mostly stationary. Temperature fluctuations within membrane structures are significantly impacted by periodic changes in outdoor temperatures, with indoor air temperatures exhibiting a delay of less than 60 minutes compared to outdoor air temperatures [44, 45]. The correlation between the indoor and outdoor temperatures of an industrial membrane warehouse over time is visualized in Figure 3. Changes in outside temperature can cause more dramatic temperature fluctuations inside the building.

The temperature inside and outside of membrane structures plays a crucial role in their functionality and serviceability. In multilayer structures, the temperature on the side facing hot or cold air undergoes drastic variations, while the other side experiences minor differences due to the low thermal conductivity of the material and air between the membranes [4, 46]. A decrease in temperature reduces the degree of deformation in a structure under external loads, but the load-carrying capacity does not vary significantly [4]. The temperature difference has a significant impact on the internal pressure. Furthermore, a drop-in temperature leads to a decrease in the natural frequency of the structure and the internal force of the cable, affecting their performance and stability [47, 48]. Attaching elements comprised of insulating

materials to the structure is one way to lessen the effect of temperature on membrane systems. Despite the poor heat resistance of membrane materials, the use of retractable membrane structures can be a viable solution for improving the temperature conditions within pre-existing buildings.

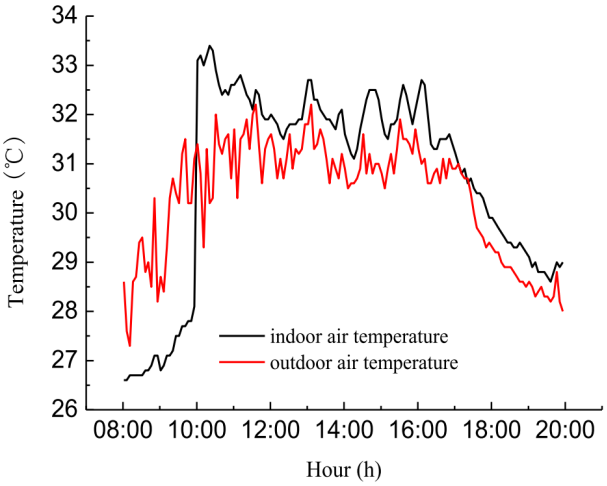

Figure 3. Indoor and outdoor temperature variation time course [45].

5. Energy performance

The numbers reveal that the building industry uses up almost a third of the world's energy resources [49]. With the increasing focus on energy conservation, it is becoming increasingly popular to enhance the energy efficiency of buildings. Energy performance in buildings is largely determined by the building's design. Natural lighting through the light transmission of membrane material can help lower the energy needed for artificial lighting, which is a key factor in improving energy efficiency in buildings. Additionally, the use of energy-efficient heating, ventilation and air conditioning (HVAC) systems, such as geothermal or solar-powered systems, can also significantly reduce energy consumption. A comparison of three membrane structure designs - single-layer, double-layer with cushions, and double-layer with a continuous air gap - showed differences in energy consumption. The energy savings achieved by the second and third designs were 11% and 18% respectively, in comparison to the single-layer design. Nonetheless, the same results as the single-layer design can be achieved by reducing infiltration losses or adding a low-emissivity coating [40]. The addition of photovoltaic (PV) panels to membrane structures allows for the conversion of solar energy to electrical energy, which can be harnessed to power the membrane, reduce the reliance on external energy sources, and promote sustainability.

6. Deployment and deflation

Inflatable structures, such as arches and tubes, have the potential to be rapidly deployed and provide temporary shelter in emergency situations, such as natural disasters or refugee camps [15]. The quick setup time is crucial in these scenarios, as it allows for immediate relief efforts to take place. Geometric configuration and ground placement prior to inflation are crucial for the successful deployment of inflatable arches. A larger diameter and lower height of the arch can facilitate easier deployment and lower peak pressures during inflation. In-plane deployment is more challenging than out-of-plane, and self-erection without external support can be problematic [4]. The location of wrinkles during inflation is variable and can differ between subsequent inflations. Assistance during the deployment phase, such as the use of elevation or other methods, can be beneficial in enhancing the efficiency of structural deployment.

Unlike traditional buildings that rely on rigid components for stability, inflatable membrane structures depend on internal pressure to provide adequate stiffness. Consequently, deflation-induced loss of load-

bearing capacity can lead to the complete collapse of the entire structure. Thus, the evacuation of occupants must be considered during the assessment of the dynamic deflation of the structure. The internal pressure of inflatable arches and tubes during deflation is typically lower than during deployment, due to a hysteresis effect that occurs when they reach a similar deformation state [50]. The internal pressure of the inflatable membrane structure undergoes a nonlinear shift, initially exhibiting a sharp decrease and then stabilizing as the deflation time increases. This leads to the structural displacement exhibiting a nonlinear increase followed by stabilization into a linear trend. Although the internal pressure of the structure drops rapidly during the early stages of deflation, the change in volume of the structure is negligible, as depicted in Figure 4. If a certain level of positive pressure is maintained within the structure, its shape can be largely retained, providing enough time for personnel to evacuate during an emergency. Wrinkling of the membrane usually initiates at the corners of the structure and subsequently propagates across the surface. n the case of sudden deflation, the membrane deformation around the entrance/exit area occurs faster, which may decrease the visibility of emergency access [51]. The appearance of wrinkles in the inflatable structure is directly influenced by the distribution of the load, which is an important factor in determining the residual pressure needed for the structure to maintain its deflated form [52].

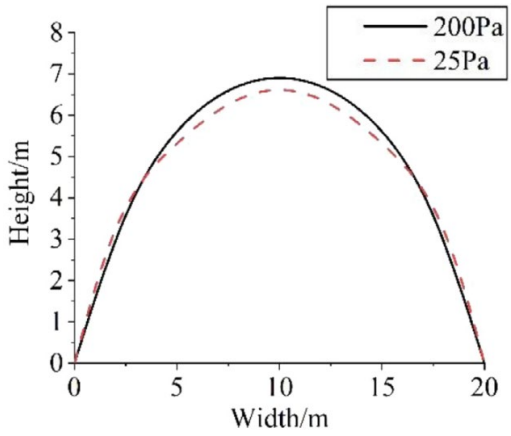

Figure 4. The structural profile at the beginning of deflation [51].

7. Measurement devices

Traditional contact measuring methods are no longer appropriate for measuring membrane structures, given their thinness and lightness, which may be influenced by the weight of the instrument. Instead, non-contact measuring instruments, such as lasers, cameras, and 3D scanners, have clear advantages when it comes to measuring membrane structures. Laser sensors can provide data on the stress and pre-stress of the membrane structure, among other factors relevant to the structure's performance by measuring the deformation of the membrane surface at a specific point. The structural pretension level can be estimated accurately using a laser sensor, which measures the maximum response amplitude of the membrane under impact load excitation. The accuracy of the estimation is directly proportional to the actual pretension magnitude. The excitation process using steel pellets results in higher accuracy than using glass and plastic pellets [53]. Devices such as 3D scanners, laser scanners, and cameras are capable of measuring multiple points at the same time, enabling the determination of the displacement field for the entire structure. This feature proves advantageous for accurately assessing the response of structures with considerable deformation and flexibility. Measuring the dynamic shape of small buildings can be achieved using 3D scanners. Laser scanning is capable of providing highly precise static profiles of structures regardless of their size. By adjusting the number of cameras, different structural data can be obtained. A static shape of the structure is obtained with a one-camera system, whereas a dynamic shape is obtained with a multi-camera system. The system's accuracy is constrained by systematic and statistical errors, although calibration algorithms based on MATLAB or OpenCV can

be utilized to reduce system errors. To reduce potential inaccuracies in data acquisition and fault detection, increasing the number of cameras and applying the least-squares method are recommended [54, 55].

The advancement of sensing technology, computing, and structural control methods has enabled the more extensive adoption of structural health monitoring (SHM) in recent years [56], but there is still a shortage of SHM applications in membrane structures, particularly in large-span ones. The monitoring system comprised of a sensor system, data acquisition and transmission system, data management system, and early warning system. The selection of measurement points is dependent on the economic and practical constraints, as well as the influence of each building component on structural safety. The key to realizing early warning of structural anomalies in the monitoring system is to achieve simultaneous processing of multiple signals from various sensors. Two approaches are used to identify anomalies in the structure: comparing the monitored data magnitude with prescribed upper limits and analyzing the structural modalities and correlation between variables [57]. The structural health monitoring system framework for a large-span membrane structure is depicted in Figure 5.

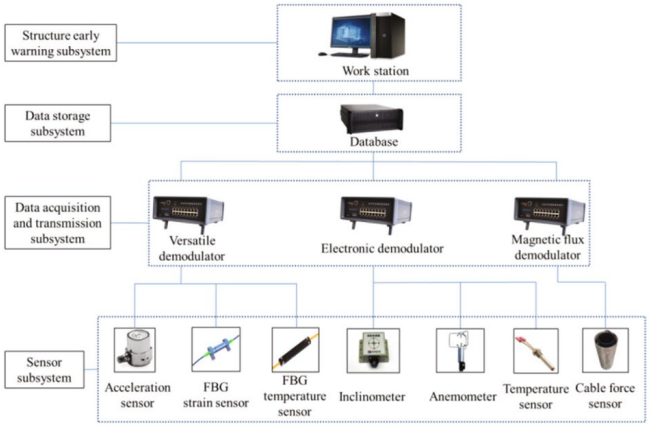

Figure 5. The framework of the SHM system for a membrane structure [57].

8. Conclusions

This paper provided an overview of the performance of membrane structures and measuring tools, which can be summed up as follows:

1) The mechanical behavior of membrane structures is closely related to their specific structural forms. Failure of membrane structures under external loads is mainly caused by damage to the joints between the membrane and the rigid boundary, as well as the seams between the membranes. The most effective approach to improving the mechanical performance of the structure is through proper design of the building configuration.

2) Optimal placement of uninflated inflatable membrane structures and assisted lifting during inflation can greatly enhance the efficiency of deployment.

3) Structural design and natural light utilization are passive methods that effectively alter the thermal environment within the building and decrease energy consumption, while ventilation systems and retractable devices are active methods that achieve similar results.

4) Contactless sensors that do not interfere with the membrane are more appropriate, and utilizing tools like cameras permit low-cost multi-point measurements.

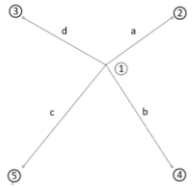
Abstract

We present FDMremote [1], an interactive inverse form-finding tool based on the force density method for the design of tensile networks by non-specialist users in the fields of art and architecture. We use gradient-based optimization to find force density distributions that best satisfy given objectives and automatic differentiation (AD) tools are deployed to provide exact gradients with respect to objective functions. This functionality is wrapped with a graphical interface built as a plugin for Grasshopper for real-time design and optimization of tensile structures. We review the functionality of our tool, demonstrate our workflow for optimization of a single objective and the composition of multiple design optimization objectives. We conclude with a case study demonstrating the use of FDMremote to develop a structure from design to fabrication during a short workshop.

Keywords: form-finding, force density method, inverse design, optimization, tensile structures, cable nets, interactive design tools

1. Introduction

Cable and rope net structures are lightweight structures that are designed to carry loads with only tensile forces and cannot resist compression or bending. This means that the entire cross section of the material is used efficiently, resulting in materially efficient structures that can be constructed from a variety of modern materials (wire rope, steel cables, UHMWPE rope, composites, etc.) which have high tensile strength-to-weight ratios. They have found applications in both art and architecture due to their visual lightness and they offer opportunities for transparency when combined with membranes or other cladding systems. Additionally, they can span large distances without intermediate supports which is often desirable in architecture and infrastructure. Key examples of note include the work of architect Frei Otto (e.g. the Munich Olympic Stadium)[2] and contemporary artist Janet Echelman (e.g. As If It Were Already Here, Boston, MA)[3].



Despite their advantages, tensile structures are difficult to model and manipulate in design. Their form cannot be directly imposed since an arbitrary geometry is not necessarily guaranteed to be in tensile equilibrium. Instead, a process of *form-finding* must be used to discover an appropriate shape that can work structurally in pure tension.

Prior to the 1970s, physical models were the primary tool for form-finding explorations. However, these models were difficult to adjust and not accurate enough for the engineering of large scale structures[2]. To address these issues, computational methods for form-finding were developed. The applicable methods can be grouped into three major categories: stiffness matrix methods, geometric stiffness methods, and dynamic equilibrium methods[4]. Within the category of geometric stiffness methods is an approach called the Force Density Method (FDM) which is well suited for the form-finding of tensile

structures [5]. Unlike other methods, it does not require iteration to find an equilibrium configuration of a tensile network, instead using a single linear solve, which makes it very computationally efficient.

This paper works with the original force density method proposed by Linkwitz and Schek (1971)[6]. The formulation is as follows: To solve for an equilibrium configuration of nodes using the force density method, it is required to build a branch-node connectivity matrix of the network [C] where each edge start is indicated with -1 and edge end is 1. Once assembled, each bar can be assigned a force density value, *q*, which is defined as the bar's force divided by length in the final equilibrium configuration. Various designs in tensile equilibrium can be found by varying the distributions of *q* values throughout the network (or by changing boundary conditions, which is not considered in this paper but could be included in future work). The branch-node matrix for a simple network is shown here:

$$C = \begin{bmatrix} -1 & 1 & 0 & 0 & 0 \\ -1 & 0 & 0 & 0 & 1 \\ -1 & 0 & 0 & 1 & 0 \\ -1 & 0 & 1 & 0 & 0 \end{bmatrix} \begin{matrix} a \\ b \\ c \\ d \end{matrix} \quad (1)$$

Then it is possible to solve:

$$\boldsymbol{XYZ_{free}} = \left(\boldsymbol{C_{free}^T\, Q\, C_{free}}\right)^{-1}\left(\boldsymbol{p_{free}} - \boldsymbol{C_{free}^T\, Q\, C_{fixed}\, XYZ_{fixed}}\right) \quad (2)$$

Where:

$\mathbf{C} = [\boldsymbol{C_{free}}\ \boldsymbol{C_{fixed}}]$
$\boldsymbol{XYZ_{free}}$ is a matrix of free node coordinates to be found
$\boldsymbol{XYZ_{fixed}}$ is a matrix of fixed node coordinates
$\boldsymbol{C_{free}}$ is a matrix with only the free nodes in C
$\boldsymbol{C_{fixed}}$ is a matrix with only the fixed nodes in C
$\boldsymbol{Q}$ is a diagonal matrix of force densities (*q*) with one value for each edge in the network
$\boldsymbol{p_{free}}$ is a matrix of force vectors acting on the free nodes in the network

Once the $\boldsymbol{XYZ_{free}}$ positions have been found, the network can be redrawn using the same connectivity. Additionally, since *q* = force/length, the force in each edge can be found by $q *$ length = force.

Although FDM provides a direct method for finding a single equilibrium solution, it does not provide a means for adjusting the structure after the initial form-finding. Due to the nonlinear relationships of the force density values *q*, it is not clear how one should redistribute them to achieve a modified network structure in a directed manner towards a particular desired outcome, such as the best fit of a target surface or force and length constraints based on fabrication requirements. This describes an inverse problem where the approximate goal outcome is known and can be defined as some objective to minimize, but the exact parameters to achieve this are unknown. Optimization techniques can be used to find a suitable set of force densities which do move an entire network towards some directed objective or compound objective [7]; however in practice, these techniques are largely inaccessible to designers who wish to work with form-found structures. A key to working with such techniques in an interactive manner is the ability to use gradient-based optimization techniques with accurate, fast evaluations of the gradient of the goal objective (i.e. matching a target shape) with respect to the design variables (i.e. the force densities).

To increase the accessibility the inverse design of tensile structures, we propose FDMremote, which abstracts away the technical implementation of the optimization of form-found networks, integrates fast and accurate gradients, and provides a user interface using Rhino/Grasshopper that allows for intuitive

network topology specification, node-based objective assignment and composition, and visualization of form-found networks for interactive iteration and fabrication.

2. Prior work

There are a variety of existing tools and approaches that can be used to approach the inverse form-finding problem for tensile structures. Notable non-FDM approaches include the use of the commercial Kangaroo2 tool for Grasshopper, which adapts techniques from the ShapeOp physics solver and constrained-optimization tool to provide a fast and robust design tool for a variety of physical simulation scenarios [8]. It implements its physics solver within the visual programming environment, Grasshopper and allows assignment of geometric and force goals in an intuitive manner. Although it can be used for form-finding, it does not ensure that the solutions reached are funicular, which can lead to physically impossible results. Additionally, finding a best fit funicular shape to an approximate target shape is not feasible since static equilibrium cannot be established as a hard constraint in the problem construction. Another technique, Thrust Network Analysis [9], was developed primarily for the design of compression-only structures, but can also be applied to the inverse form-finding of tensile structures [10]. This approach works by projecting the form network onto a horizontal plane and then modifying the reciprocal force diagram with an optimization loop to adjust the 3D form network. Authors of this work note several key restrictions: loads may only be applied vertically, and nodes are only allowed to move vertically during the form-finding process.

In contrast to these techniques, inverse form-finding with FDM is especially attractive because of the convenient parameterization via the force density q values, which indeed was originally noted by Schek in his 1974 overview of FDM (he called inverse form-finding via nested loops "a nonlinear [method]") [5]. However, it has only recently been demonstrated how to implement this approach with fast gradient evaluations. Cuvilliers et al. apply inverse design with FDM for the form-finding of compression structures that match target shapes using gradient-based optimization [11]. In this work, the authors derive the gradient and Hessian analytically for a single objective, but in doing this also demonstrate the complexity and challenges of including additional objectives.

The inclusion of additional objectives is necessary to enable more sophisticated design explorations and to deal with fabrication constraints. Fortunately, due to the rise of machine learning and the requirement of computing gradients of complex computational graphs, there are several software libraries that enable the easy implementation of automatic differentiation (AD), which allows for the computation of exact derivatives of arbitrary functions by breaking them down into elementary mathematical operations and composing them using the chain rule.

There are two primary modes that AD can operate in: *forward* and *reverse*. In forward mode, as a program is evaluated its directional partial derivatives with respect to a single input is also computed simultaneously. The decomposition of a function into its basic constituent parts can be represented as a directed acyclic graph also called the trace. If there are multiple inputs, then a forward evaluation pass is required for each input variable. For some function $f : \mathrm{R}^n \rightarrow \mathrm{R}^m$ where $n \leq m$, forward-mode will be the most efficient method. Reverse-mode, also referred to as adjoint mode, requires an initial forward evaluation pass. Then the gradient (if the output of the function is a scalar) can be computed in a single traversal of the graph in the opposite direction of forward mode. In general, if $m >> n$ then reverse-mode will be more efficient. For the optimization of a large vector of force densities with a scalar loss function output, reverse-mode is the most appropriate method to use [12].

In more recent work from 2020, Cuvilliers utilized the AD library *autograd* [13] written for the python programming language to extend the set of objective functions for use in conjunction with FDM as a core form-finding method[7]. He demonstrated a number of examples where multiple objectives, expressed only in code, were composed and returned a single scalar objective score that could be efficiently minimized using a general-purpose gradient-based optimization algorithm since the gradients of the functions were automatically computed by the *autograd* library. Most recently, an open-source

implementation called JAX FDM [14] takes a similar approach using the JAX [15] library for automatic differentiation and provides an API for inverse form-finding using gradient-based optimization written in python.

While an API approach to tool development does enable exploration and experimentation by advanced users, its reach to a more general user base is limited. A programming-based approach to geometric modelling also can hinder rapid user iteration in an uninterrupted flow state or creative expression of design intent. In contrast, this paper proposes a tool and design workflow that are integrated into a GUI-based 3D modelling environment, allowing the inverse form-finding process to respond to designer input in a rapid and natural manner.

3. Interactive Inverse Design

FDMremote is algorithmically structured as a triple nested loop. It integrates the intuitive problem setup style of Kangaroo2 with the fast form-finding and efficient optimization of multiple objectives possible with FDM and automatic differentiation.

The outer loop is where the user interacts with FDMremote and specifies their network topology, anchor locations, applied loading, and any objectives they wish to incorporate into their form-finding process. Then, a middle loop automatically sets up the optimization problem and iteratively and efficiently searches for the combination of design variables (force density q values for each bar) that minimize the defined objective. At each iteration of the middle loop, an inner loop is executed where updated force densities are used to form find a network and a new objective value is computed with respect to the updated network configuration.

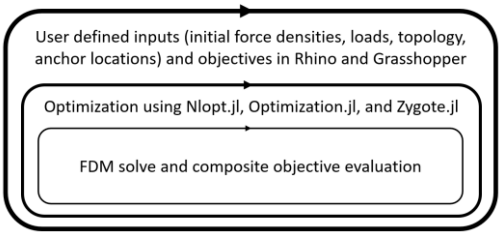

Figure 1. Triple nested loop program structure.

FDMremote implements a client-server model where the client (Rhino/Grasshopper) provides the graphical user interface (GUI) for the definition of objective, constraints, and network topology. This information is formatted into a single JSON message which can be passed via WebSocket messaging protocol to a server running the optimization loop and FDM form-finding. This separation is implemented out of necessity since Rhino 7 and Grasshopper do not have native support for high-performance linear algebra and automatic differentiation, which are essential features to provide a near-real-time workflow.

Figure 2: Client-Server program model

We chose to develop the server side of FDMremote using Julia [16]. Julia is an open-source, high-performance general purpose programming language with libraries that support automatic differentiation of sparse matrix operations. This allows for more efficient execution of the inner FDM solve, which is typically a very sparse problem. The library Nlopt.jl [17] is utilized for its L-BFGS optimization algorithm implementation, Optimization.jl [18] for optimization problem setup, and

Zygote.jl [19] for automatic differentiation. We used HTTP.jl to set up the WebSocket protocol for efficient inter-program communication. Since FDMremote utilizes a standard network protocol, the more computationally intensive part of the program can be run on a remote machine with more computational power if required.

3.1 User defined topology, anchor locations, and initial force densities

The first step in using the tool is the definition of a connected bar network on the client side in Rhino 7 and Grasshopper. A network in this context is a set of nodes which can either be fixed or free and a set of edges (lines) which connect pairs of nodes (points). Note that the topology (or connectivity) of the network remains constant in this paper's approach.

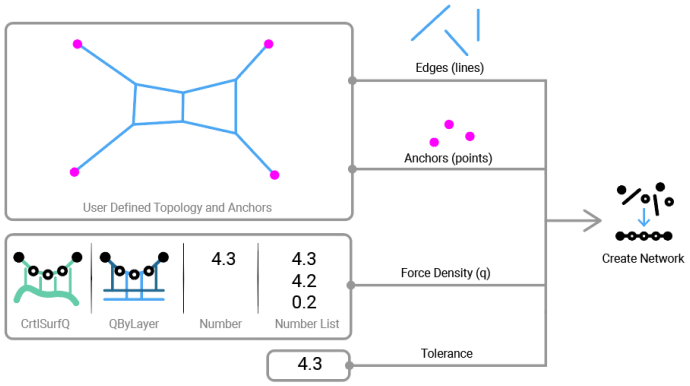

Figure 3. Creating a network

A network is defined using the inputs outlined in Figure 3. A user draws a set of lines which may share some end points. These lines may be drawn in the 3D modeling environment of Rhino or generated programmatically within Grasshopper. Once these lines are input to the *Create* component, endpoints closer than a specified tolerance will be fused together and become a node. Lines that connect nodes become edges.

The boundary conditions for the problem are points that will remain fixed during the form-finding process. A set of points to be used as anchors are input into the *Create* component. The closest points in the set of nodes generated from the lines input to *Create* will be flagged as fixed points. A minimum of two anchors are required to prevent the FDM problem from collapsing all points to a single location, however a minimum of three anchor points is recommended. A network with no anchor points is not well defined and is not permitted by FDMremote.

The initial force densities can be specified in multiple ways. If no objectives are provided, these assigned force densities will be used directly for FDM form finding. If objectives are provided, then these will be the initial variable values for the optimization. *CtrlSurfQ* is a component which allows the use of a control surface to spatially vary the initial force densities. *QByLayer* is another component that allows assignment of force densities to lines which are grouped by drawing them on separate layers in Rhino. If a single value is provided, the force densities for all edges will be set to the same value. If a list of values (matching the number of edges in the network) is provided, each edge will have a unique force density value.

The *Create* component will convert the lines, anchors, and force densities (q) into a description in suitable for the form-finding process.

3.2 User defined objectives and optimizer settings

To specify objectives and settings for the optimization algorithm there are a set of components. These are broken down into a set of 8 objective components and one *Params* component.

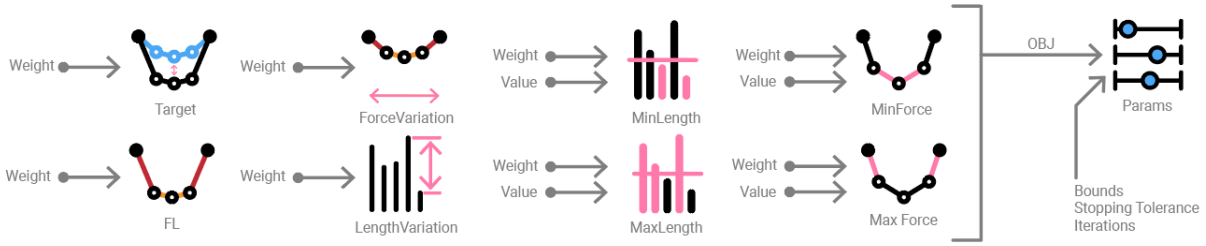

Figure 4: Optimizer settings and objective assignment

For each objective function available in FDMremote there is a corresponding objective function component. Each objective component has a *weight* input that can be used to scale the relative importance of an objective in the optimization process. The min/max force and length components have an additional *value* input used to specify a cutoff threshold above or below which the objective will be penalized. To compose multiple objective functions the output of each objective component is simply added to the *OBJ* input of the *Params* component. Because the objective values are not normalized, the weighting may require some experimentation to find a range where the influence of different objectives are relatively balanced. The current objectives include the following functions to minimize:

Table 1. Objectives for minimization in FDMremote.

Force Variation	$OBJ = \max(\boldsymbol{F}) - \min(\boldsymbol{F})$
Length Variation	$OBJ = \max(\boldsymbol{L}) - \min(\boldsymbol{L})$
Maximum Force	$\boldsymbol{t} = [F_i - v]\ \forall\ i\ ,\ OBJ = \sum(t_i + \lvert t_i \rvert)$
Minimum Force	$\boldsymbol{t} = [v - F_i]\ \forall\ i\ ,\ OBJ = \sum t_i + \lvert t_i \rvert$
Maximum Length	$\boldsymbol{t} = [L_i - v]\ \forall\ i\ ,\ OBJ = \sum t_i + \lvert t_i \rvert$
Minimum Length	$\boldsymbol{t} = [v - L_i]\ \forall\ i\ ,\ OBJ = \sum t_i + \lvert t_i \rvert$
Structural Performance	$OBJ = \sum_{i=1}^{N_e} (\lvert F_i \rvert L_i)$
Target	$OBJ = \lVert \boldsymbol{XYZ_0} - \boldsymbol{XYZ_f} \rVert$

Where:

$\boldsymbol{F}$ is a vector of edge forces for all edges in the network
$\boldsymbol{L}$ is a vector of lengths for all edges in the network
v is a thresholding value for min/max force or length objectives
N_e is the number of edges in the network
$\boldsymbol{XYZ_0}$ is a matrix of initial nodal coordinates from the user specified topology drawing (target shape)
$\boldsymbol{XYZ_f}$ is a matrix of nodal coordinates after an FDM solve

Additional settings for the optimization algorithm can also be specified in the *Params* component. These include upper and lower bounds for allowable force densities, stopping tolerance for the optimizer, and number of iterations before the optimization halts. In general, it is best to rely on relative improvement of the loss function between optimization steps falling below a threshold and not on the objective value falling below an absolute threshold since many of the objectives will not be able to reach zero and will instead simply cease to improve.

3.3 Full problem assembly for sending to the server for form-finding and optimization\

Once network creation and parameter specification have been completed, these components, along with any loads to be applied to the free nodes can be assembled with the *FDMsend* component in Figure 5. The loads can be applied in multiple ways, similarly to the force densities. The *CtrlSurfP* component can be used to assign varying loads controlled by a parameterized surface. Additionally, a single force vector or list of force vectors matching the number of free nodes can be applied to the network. The *FDMsend* component handles compiling all the inputs into a single JSON message to send via WebSocket protocol to the server in Julia.

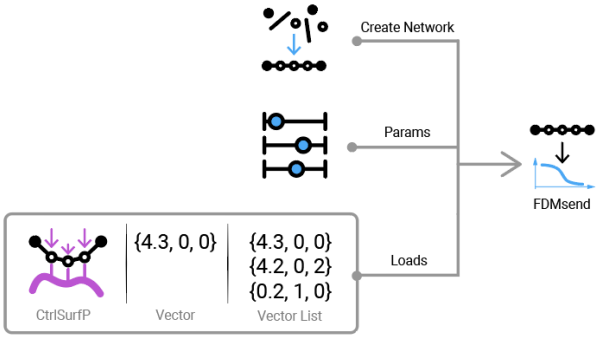

Figure 5. Assembly of inputs to send to be form-found using FDMremote

3.4 Optimization in Julia

In Julia once a new message is received the form-finding and optimization is performed. If no objectives are provided then a single FDM solve using user provided force density values is performed using equation (2) and the form found nodal positions are returned to grasshopper.

If objectives are provided, then a minimization problem is set up in the form:

$$\min_{\boldsymbol{x}} f(\boldsymbol{x}) \tag{3}$$

$$s.t.\ \boldsymbol{lb} \leq \boldsymbol{x} \leq \boldsymbol{ub}$$

Where:

$\boldsymbol{x}$ is a vector of force densities (q) which are the variables in the optimization
$f(\boldsymbol{x})$ is a composite objective function $\sum_{i=1}^{N_{OBJ}} w_i\ OBJ_i(\boldsymbol{x})$
OBJ is the set of user defined objectives to minimize
w are the corresponding user defined weights for each objective
lb is a vector of lower bounds for the force densities (always at least 0)
ub is a vector of upper bounds for the force densities

When the stopping criteria specified in the *Params* component are met the optimization will halt and the final nodal coordinates, final $\boldsymbol{x}$ force density values, final objective value, and the history of the objective values during the optimization are sent back to Grasshopper.

3.5 Visualization and fabrication of a form-found network

Once a form-found network is returned to Grasshopper, a user has a few options for proceeding. There are a set of utility functions outlined in Figure 5 to assist with iteration, documentation, and fabrication.

Figure 6. Utility Functions for Extracting Additional Information, Saving Networks, and Fabrication

To view the form-found network, the *Visualize* component can be used and different display modes are available to investigate force and force density distributions visually. *Info* will provide additional information about the form-found network.

If further design iteration is desired, the *Update* component can be used to match lines drawn in Rhino with their new form-found position. This is a very rapid way to iteratively form-find and then make incremental adjustments to a target shape. The *Freeze* and *Load* components are used to save a form-found network for later use or to save an option during a design session. *Tagger* and *Make* provide different ways of viewing additional information about a form-found network such as element forces (these are relative values dependent on the units of the rhino model), element lengths (accounting for expected elongation during installation), node names, and edge names required to fabricate a form-found network.

4. Results

The simplest form-finding possible with FDMremote is to directly use FDM to find an equilibrium configuration. In this situation, no optimization is required. The force densities for each edge are set manually and a network form-found using those values is returned.

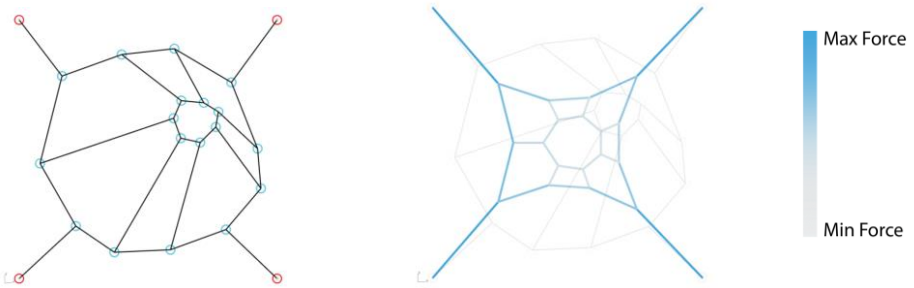

Figure 7. A simple network topology (left) with fixed (red) and free (cyan) nodes highlighted, and a form-found solution using equal force density values for all edges (right).

In the initial network specification in Figure 7, all the anchor points and free nodes lie on the XY plane. The initial locations of free nodes in the network topology diagram have no impact on the form-found solution on the right. Also note that even though the force densities prescribed for each edge are all equal, in the form-found solution the forces vary throughout the network.

4.1 Single-objective optimization

In Figure 8, a minimum length objective has been introduced. Now the optimization loop is required. In this case there is a feasible minimum solution where all edge lengths are longer than the prescribed

minimum length. After five steps the objective value reached zero and the network (right) was returned for visualization in Rhino/Grasshopper.

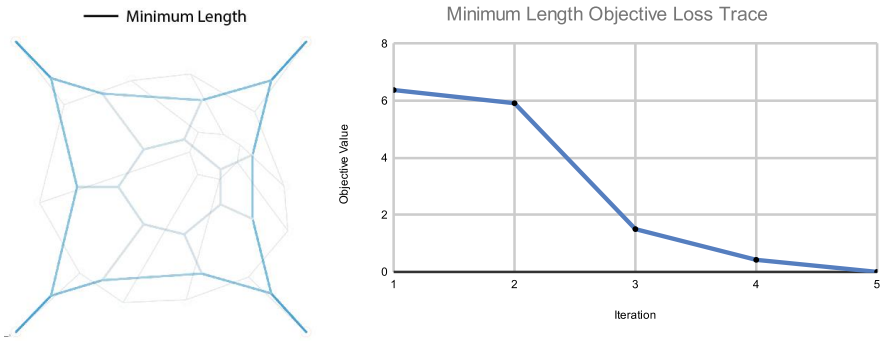

Figure 8. Use of a minimum length objective.

In Figure 9, a target objective has been used. In this example the optimized form-found network is trying to match nodal locations of the topological diagram while also ensuring that all the edges are in tension. Some of the node locations are impossible to reach if the edges are only in tension, which results in a slow convergence at the end of the optimization process.

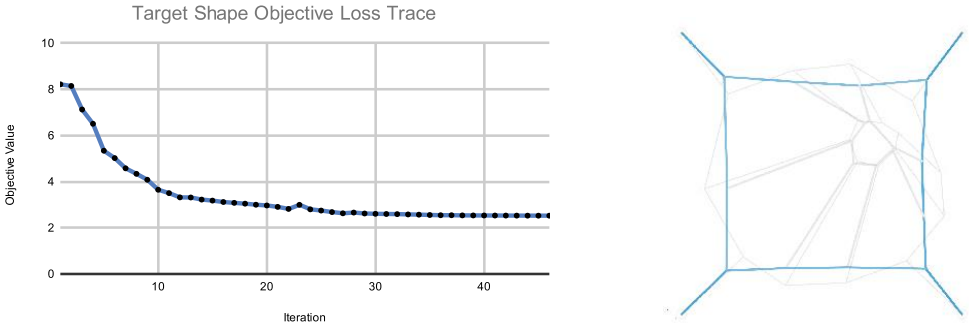

Figure 9. Use of a target shape objective.

4.2 Composite objective optimization

It is also possible to combine multiple objectives and to interpolate between them, using the objective weights to influence the relative importance of each objective. This provides a unique way to explore a large spectrum of design options. The form-found solutions are guaranteed to be in tensile equilibrium since the force densities have been restricted to be strictly positive; however, the visual outcome and force density distributions can vary across an infinite spectrum. In Figure 10 a more complex initial network has been defined and a tensile equilibrium solution using uniform force densities is shown.

Figure 10. An initial network constructed from the outline of the letter A (left) and its form-found shape with uniform force densities (right). This network has 588 edges, 8 fixed nodes, and 410 free nodes.

This generates an interesting form, however if a form-found shape which is shares more visual similarity to the initial input network is desired, additional objectives can be added to drive the form towards a different shape.

In Figure 11 multiple objectives are introduced to adjust the form-found network shape. In 11(a) two objectives (minimum length and maximum length) have been added to limit the extension or collapse of edges. In 11(e) only a structural performance objective is used. Alone, this objective results in form visually similar to the FDM only solution with uniform force densities. In 11(b-d) all three objectives are used, however in 11(b) the structural performance component has a weight of 1 while the min and max length components have weights of 16 and 8, respectively. In 11(c) the weight of the structural performance objective has been raised to 5 while the other weights remain constant. In 11(d) it is raised again to 10 at which point it dominates the optimization. In this example all optimization loops are initialized with uniform force densities and after a change is made by a user in Grasshopper the initial force densities are re-initialized as a uniform set.

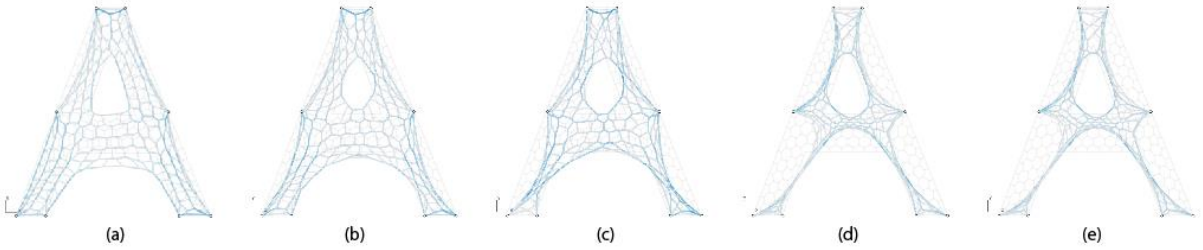

Figure 11. A range of alternative form found shapes can be explored using multiple objectives and their relative weights to interpolate between objective importance

4.3 Complex 3D Tensile Forms

Previous examples have explored tensile form-finding in 2D, however FDMremote can also be used for the exploration of 3D tensile forms. In Figure 12 a structural performance objective and target shape objective were used to drive the shape generation. The shown form is the result of performing multiple iterations, updating the target geometry using the *Update* component to set a new target geometry and making incremental adjustments to anchor locations and topology (deleting or adding edges before performing another form-finding and optimization pass). In Figure 13 a minimum edge length and target shape objective were used. The target geometry (left) was generated in a hybrid fashion between Rhino (black lines) and Grasshopper (red lines) to allow for direct control over some aspects of the structure, but also allowing for parametric control over others (such as number of subdivisions from end to end) all integrated into a single workflow.

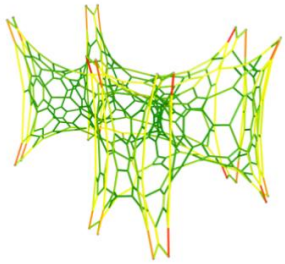

Figure 12. Structure with 814 edges

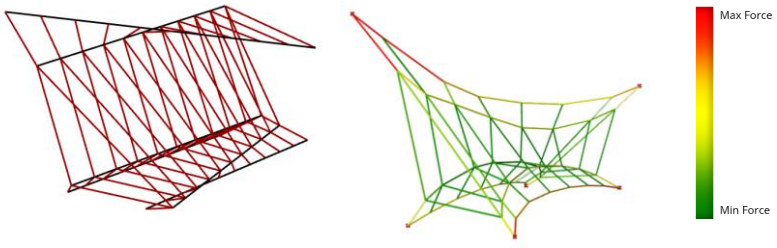

Figure 13. Structure with 90 edges - Target (left) and form-found (right)

4.4 Workshop participant designs and tensile network fabrication

In January 2023, we conducted an academic workshop, called *In Tension*, to introduce new users to FDMremote and to explore its use for the development of tensile sculptural works. The workshop took place over four half-day sessions. Participants first explored form-finding using physical models, and then worked with FDMremote to develop digitally form-found tensile structures.

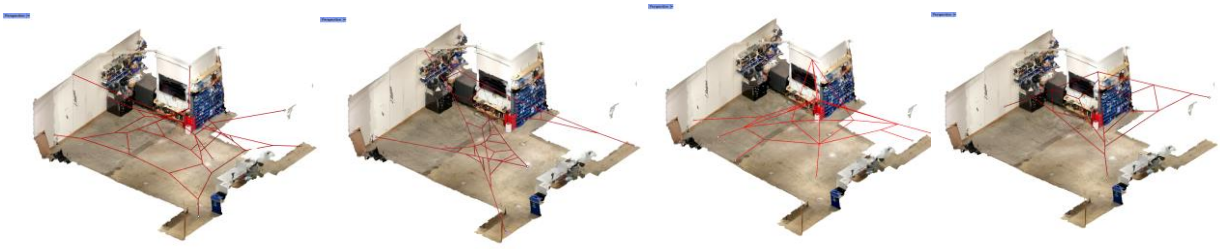

Figure 14. A selection of digital designs from the workshop.

Figure 15. Design selected for fabrication (left), students splicing (center), and installation of the structure (right)

The final design charette was to develop a site-specific tensile network structure. The participants were limited to eight anchor points and asked to consider the range of forces, number of nodes, and total length of rope when developing their designs (Figure 14). One design was selected by the group for fabrication (Figure 15, left) and installation in a teaching space on the MIT campus. Student participants were able to use the tool to design and construct a large-scale tensile sculpture in 24 hours, and worked collaboratively as a group to build the final piece. Students worked with traditional hand-splicing techniques (Figure 15, center) to translate the design from the computational environment to built reality (Figure 15, right), with minimal errors. The results showed that the FDMremote tool can be used by designers (including novices) to interactively explore buildable, lightweight structures in tensile equilibrium with a high diversity of possible outcomes.

5. Conclusion: Summary of contributions

In this paper, we reviewed the computational methods that enabled the development of FDMremote, an interactive tool for the inverse form-finding of cable structures. We showed the optimization of a simple network with a single objective. We then showed the composition of multiple objective functions on a more complex network and form-found solutions that interpolate between them through user adjustment of weighting parameters. Finally, we showed designs by non-specialist workshop participants and the physicalized outcome of one form-found design. Future work will focus on the assignment of objectives to subsets of the network, optimization of the boundary conditions, and the development of additional objective functions. We believe that this physically informed inverse design process can be a powerful tool for non-specialists to explore the design of form-found funicular structures.

Acknowledgements

We would like to thank the workshop participants Adam Snowdon, Albertine Van Marcke, Bernardo Gonzalez, Bill McKenna, Doris Duanmu, Gabrielle Moore, Harris Chowdhary, Jenny Zhang,

Jeonghyun Yoon, Karl-Johan Soerensen, Leon Kamp, Lingyi Qiu, Manavi Dixit, Morgan Johnson Quamina, Susan Williams, Tananya Prankprakma, and Thomas King for testing our tool and collaborating with us to design and fabricate a tensile structure. Additionally, we would like to thank Alessandro Beghini and Nicole Wang from SOM for their feedback on the development of our form-finding tool and contribution of time to the *In Tension* workshop, and MIT CAST staff, including Katherine Higgins and Leila Kinney, for their support of the workshop.

Abstract

In this study, we explore a method for form-finding in tensegrity-membrane structures by substituting membrane materials with truss elements, and we propose a technique for estimating the structure's behavior under external forces in a simple and accurate manner. We employ the dynamic relaxation method, a numerical analysis technique commonly utilized in form-finding for tensegrity structures. The analysis model is generated by replacing the membrane material with truss elements, referred to as equivalent membrane elements, based on the physical model. However, determining the properties and cross-sectional dimensions of the equivalent membrane elements solely from the physical model observation proves to be challenging. Consequently, we perform form-finding using the load-strain relationship obtained from tension tests on the membrane material. By comparing the experimental measurements from the physical model with the form-finding outcomes, we evaluate the efficacy of the analysis method presented in this study.

Keywords: tensegrity, membrane structures, form-finding, dynamic relaxation method, Hangai Prize applicant

1. Introduction

A tensegrity structure comprises continuous tension forces and discontinuous compressive forces. This structure can be composed solely of small members without using large members like conventional building materials. As a result, tensegrity structures offer the benefits of lightweight construction and efficient material utilization. Furthermore, their discontinuous compressive materials create a unique and captivating spatial experience. Nevertheless, achieving equilibrium states and predicting behavior under external forces can be challenging. A recent study introduced a method for obtaining equilibrium states through the dynamic relaxation method [1]. Additionally, tensegrity structures are difficult to use in structures like walls or roofs due to their low rigidity and large displacement.

To address this issue, several projects have explored tensegrity-membrane structures, where multiple tension elements are replaced with a single membrane material. A notable example is the "MOOM Pavilion" designed by C+A [2]. This design demonstrates advantages such as lightweight construction, straightforward assembly, and compact storage for transport. However, assessing tension stress and stiffness quantitatively is difficult because the membrane members do not form minimal surfaces, and there is significant variation in tension stress on the membrane. Consequently, tensegrity-membrane structures inherently present challenges in analyzing their equilibrium states and accurately evaluating their behavior under external forces. While numerous studies have investigated the form-finding and stability of membrane tensegrity structures [2]-[4], few have quantitatively assessed their behavior against external forces. To actualize tensegrity-membrane structures, it is essential to develop an analysis method that accurately evaluates their stiffness. As such, we conducted research aimed at

Copyright © 2023 by Yohei NAGANO and Takuo NAGAI. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

establishing a simple and precise analysis method for assessing the stiffness of tensegrity-membrane structures by substituting membrane materials with truss elements. In this study, we created a physical model of a tensegrity-membrane structure to examine its mechanical properties. Form-finding was executed using the dynamic relaxation method, and the results were compared with actual phenomena. We also discussed the evaluation method for the stiffness of tensegrity-membrane structures.

2. Physical model creating method

Fig. 1 illustrates the physical model created for this study. To investigate the fundamentals of tensegrity-membrane structures, we conducted experiments and analyses using a simplified model with as few members as possible. The model depicted in the figure is referred to as a "planar arch model." The compression materials employed were 3 mm diameter aluminium rods, and the membrane material consisted of highly elastic fabric.

Figure 1. Photos of the physical model (planar arch model).

Fig. 2 presents the process of creating the physical model. To produce a natural condition view of the membrane material, a 3D model (initial form) was generated based on geometric rules, as demonstrated in Fig. 2(a). The position of the compression members was determined by the sides of the regular polygon, and their lengths were calculated by extending each side of the regular polygon based on the angle θ at the center. The initial form was then flattened to create a rectangular development view, as displayed in Fig. 2(b), and a natural condition view was generated by scaling down the development view using a similarity factor of 0.65. The X direction of the natural condition view corresponded to the warp direction of the membrane material, the Y direction to the weft direction, and the compression members were parallel to the X direction. The compression members were fabricated to the same length as the initial form, and the membrane material was made according to the natural condition view. Finally, the compression members were inserted into the cut membrane, and tension was applied to the membrane by pulling both ends until the span of the column base in the initial form was reached, as illustrated in Fig. 2(c).

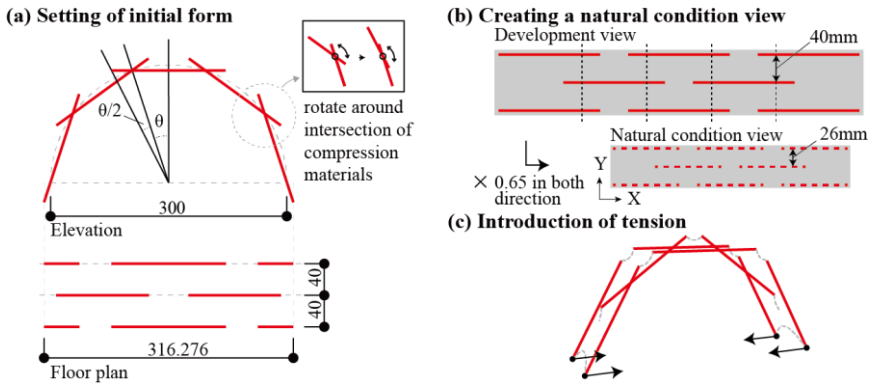

Figure 2. Creating method of physical model.

3. Modeling and analysis method

3.1. Modeling of tensegrity-membrane structures

Typically, in the analysis of tensegrity-membrane structures, the modeling of membrane materials is conducted by dividing the membrane surfaces into triangular meshes [5]. However, estimating the stiffness of the replaced membrane elements is difficult due to the anisotropic nature of the membrane materials and the complex stress distribution in the tensegrity-membrane structure. In tensegrity-membrane structures with scattered discontinuous compression members, dividing the membrane material into meshes necessitates a considerable amount of computational time due to the large number of elements, rendering it impractical for use in actual architectural design. Consequently, we focused on simplifying the modeling of membrane materials by referring to the physical model. The membrane materials are replaced with truss elements placed on parts of the membrane material where tension is particularly strong with straight lines, as illustrated in Fig. 3. The blue lines in the figure represent the equivalent membrane elements (EME).

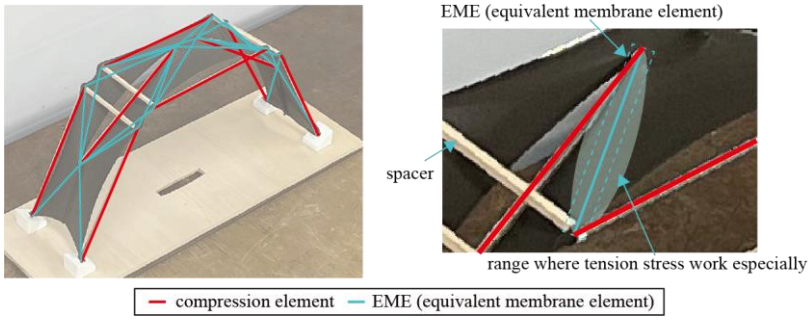

Figure 3. Method of replacing the tensioned membrane with EMEs (equivalent truss elements).

Fig. 4 displays a plan view of the analysis model used for form-finding, illustrating the element numbers and boundary conditions. Elements 1 to 3 in the figure represent compression elements (red lines), while the others are EMEs (blue lines). In accordance with the physical model, the compression elements are assumed to be 3 mm diameter aluminum rods with a Young's modulus set to 70,000 N/mm². Conversely, since the EMEs' properties cannot be determined solely based on the physical model's appearance, they were examined through tension tests. The boundary conditions include pin-supports at four points of the column bases, and to maintain the model's width of 80 mm, the Y-axis movement is constrained at eight points, as shown in the figure.

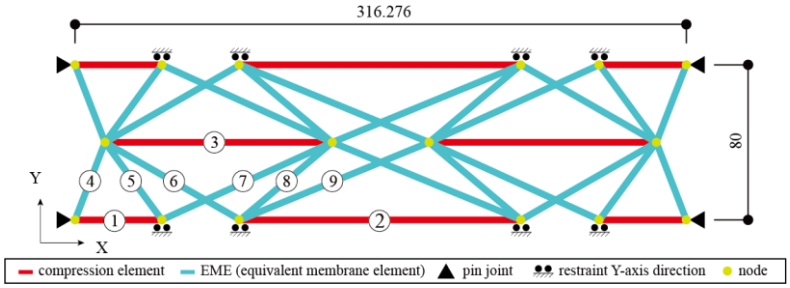

Figure 4. Plan view of numerical model: index of elements and boundary conditions.

3.2. Dynamic relaxation method (DRM)

In this study, form-finding using the dynamic relaxation method (DRM) was performed. DRM transforms a static equilibrium problem into a pseudo-dynamic problem and solves the original static problem by artificially damping the dynamic system to achieve a steady state [1]. Numerous studies have been conducted on form-finding and stress analysis using DRM [1], [6]-[8].

The following outlines the detailed calculation process for form-finding of tensegrity-membrane structures using DRM in this study. First, Eq. (1) is formulated based on Newton's second law of motion and is transformed into Eq. (2). Then, the accelerations $\boldsymbol{a}(\mathrm{t}+\Delta\mathrm{t})$ at time $\mathrm{t}+\Delta\mathrm{t}$ are obtained from the velocities $\boldsymbol{v}(\mathrm{t})$ and the out-of-balance forces $\boldsymbol{f}(\mathrm{t})$ at time t.

$$-\boldsymbol{D}\boldsymbol{v}-\boldsymbol{f}=\boldsymbol{M}\boldsymbol{a} \tag{1}$$

$$\boldsymbol{a}(\mathrm{t}+\Delta\mathrm{t})=-\boldsymbol{M}^{-1}\left(\boldsymbol{D}\boldsymbol{v}(\mathrm{t})+\boldsymbol{f}(\mathrm{t})\right) \tag{2}$$

Here, $\boldsymbol{D}$ represents the viscous damping matrix, $\boldsymbol{M}$ denotes the mass matrix, and $\Delta\mathrm{t}$ signifies the analysis time interval. Although these values have little connection with the analysis result, they are closely related to the calculation's convergence rate. Thus, we search for values that increase the convergence speed and utilize them. The out-of-balance forces $\boldsymbol{f}(\mathrm{t})$ at time t are obtained from the axial force $s(\mathrm{t})$ acting on each element. The axial force s acting on each element can be determined from the change in length of the elements. The axial force $s_{\mathrm{c}}(\mathrm{t})$ acting on the compression elements at time t can be expressed as Eq. (3). However, the membrane materials used in this study exhibit strongly nonlinear characteristics, necessitating their consideration when determining the axial force of the EMEs. Consequently, the axial force of the EMEs was calculated using the load-strain relationship expressions shown in Eq. (8)-(11), which are obtained in the following chapter, and the analysis was conducted using the EMEs as nonlinear springs.

$$s_{\mathrm{c}}(\mathrm{t})=\mathrm{EA}\varepsilon_{\mathrm{c}}(\mathrm{t}) \tag{3}$$

$$\varepsilon_{\mathrm{c}}(\mathrm{t})=\frac{\mathrm{L_c}(\mathrm{t})-\mathrm{L_{N,c}}}{\mathrm{L_{N,c}}} \tag{4}$$

Here, E represents Young's modulus, A denotes the cross-sectional area, and $\mathrm{L_c}(\mathrm{t})$ is the length of the compression elements at the t step, and $\mathrm{L_{N,c}}$ is the natural length of the compression elements. Fig. 5 illustrates the definition of the length of elements. $\mathrm{L_E}(0)$ is the initial length of the EMEs, $\mathrm{L_{N,E}}$ is the natural length of the EMEs, $\mathrm{L_c}(0)$ is the initial length of the compression elements. The natural condition view is obtained, similar to the creation method of the physical model. The length of the compression elements, $\mathrm{L_c}(0)$, are set to equal $\mathrm{L_{N,c}}$ in the initial form.

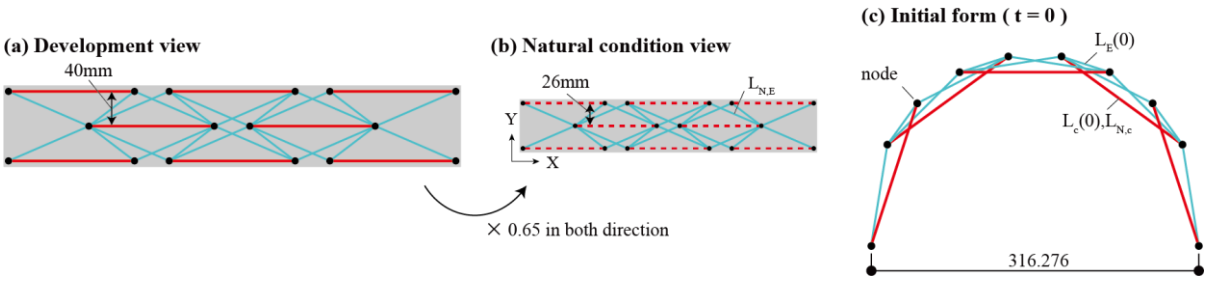

Figure 5. Definition of the length of elements and initial condition for form-finding analysis.

Utilizing the obtained acceleration $\boldsymbol{a}(\mathrm{t}+\Delta\mathrm{t})$ we can calculate the velocity $\boldsymbol{v}(\mathrm{t}+\Delta\mathrm{t})$ and displacement $\boldsymbol{\delta}(\mathrm{t}+\Delta\mathrm{t})$ simultaneously from Eq. (5) and (6). These calculations are repeated until the out-of-balance forces approach zero. The convergence condition for this iterative calculation is set as shown in Eq. (7). Here, R represents the convergence value, and n refers to the number of nodal degrees of freedom.

$$\boldsymbol{v}(\mathrm{t}+\Delta\mathrm{t})=\boldsymbol{v}(\mathrm{t})+\boldsymbol{a}(\mathrm{t}+\Delta\mathrm{t})\Delta\mathrm{t} \tag{5}$$

$$\boldsymbol{\delta}(\mathrm{t}+\Delta\mathrm{t})=\boldsymbol{\delta}(\mathrm{t})+\boldsymbol{v}(\mathrm{t}+\Delta\mathrm{t})\Delta t \tag{6}$$

$$\mathrm{R}\leq\sqrt{\boldsymbol{f}^{\mathrm{T}}\boldsymbol{f}/\mathrm{n}} \tag{7}$$

In addition, kinetic damping is employed alongside viscous damping. When the kinetic energy reaches a maximum value at a certain step, the calculation continues with the value of velocity at all nodes set to zero at the next time step.

3.3. Parameter setting of DRM analysis

The values employed in the numerical analysis were based on a mass matrix $\boldsymbol{M}$ that was 0.2 times the identity matrix, meaning that the mass of each point was taken to be 0.2 kg. The viscous damping matrix $\boldsymbol{D}$ was 1.0×10^{-5} times the identity matrix, and since the period was 1.2×10^{4} seconds, this value corresponds to a damping constant of 4.8% when interpreted as mass-proportional damping. The time interval for the analysis, Δt, was set to 2.0×10^{-4} seconds, and the convergence criterion was set to $R = 1.0 \times 10^{-3}$.

4. Tension test of membrane materials

4.1. Uniaxial tension test

In the modeling of the EMEs, there is an issue that it is difficult to estimate the properties and cross-section by only observing the physical model. Therefore, we conducted tests by pulling both ends of the membrane material under the same conditions as the EMEs in the structure. Fig. 6(a) shows the specific method for preparing the test pieces. The test pieces were cut in the directions of angles θ_A and θ_B, with the test pieces in the direction of angle θ_A denoted as test piece A1 and the test pieces in the direction of angle θ_B denoted as test piece B1 (θ_A is 23.3 degrees relative to the X-axis and θ_B is 37.2 degrees). The length of each test piece was set to 50 mm. The adhesive area between the membrane material and the compression members in the physical model was circular with a 5 mm diameter, as shown in Fig. 6(b). To create the same boundary conditions as the physical model, jigs with a 5 mm diameter were attached to each test piece. Additionally, since it was expected that the stiffness would differ depending on the width of the test pieces, even with the same boundary conditions, three types of test pieces were created with widths of 5, 10, and 15 mm. Test pieces were also prepared in the X-Y direction under the same conditions and were denoted as test piece X and test piece Y, respectively.

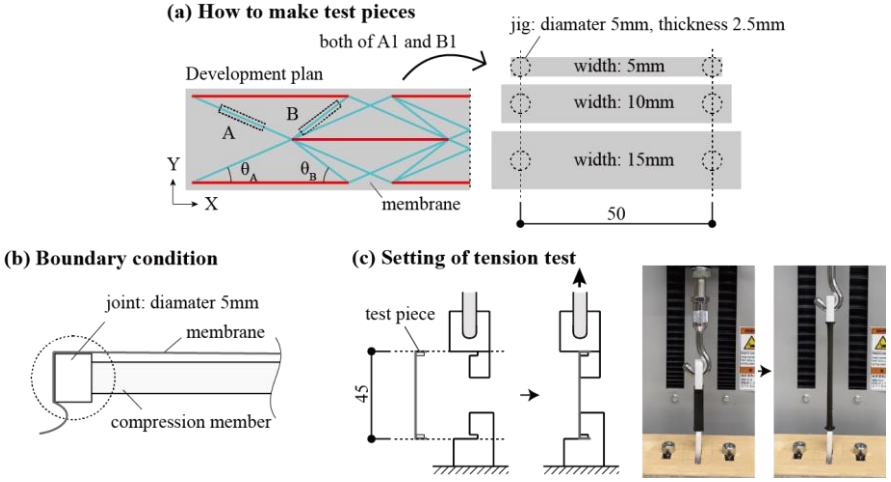

Figure 6. Uniaxial tension test of membrane materials used in the physical model.

Fig. 7 shows the results of the tension tests. The points represent the measured data, and the solid lines represent the curve obtained by the least squares method using the measured data. Here, the strain is calculated as linear strain that is obtained by dividing the displacement by 45 mm. From the graphs (a) and (b), it can be seen that the membrane material used in this study has a large difference in stiffness

between the X and Y directions. In addition, from the graphs (c) and (d), both test pieces A1 and B1 tended to be similar to the results of test piece X.

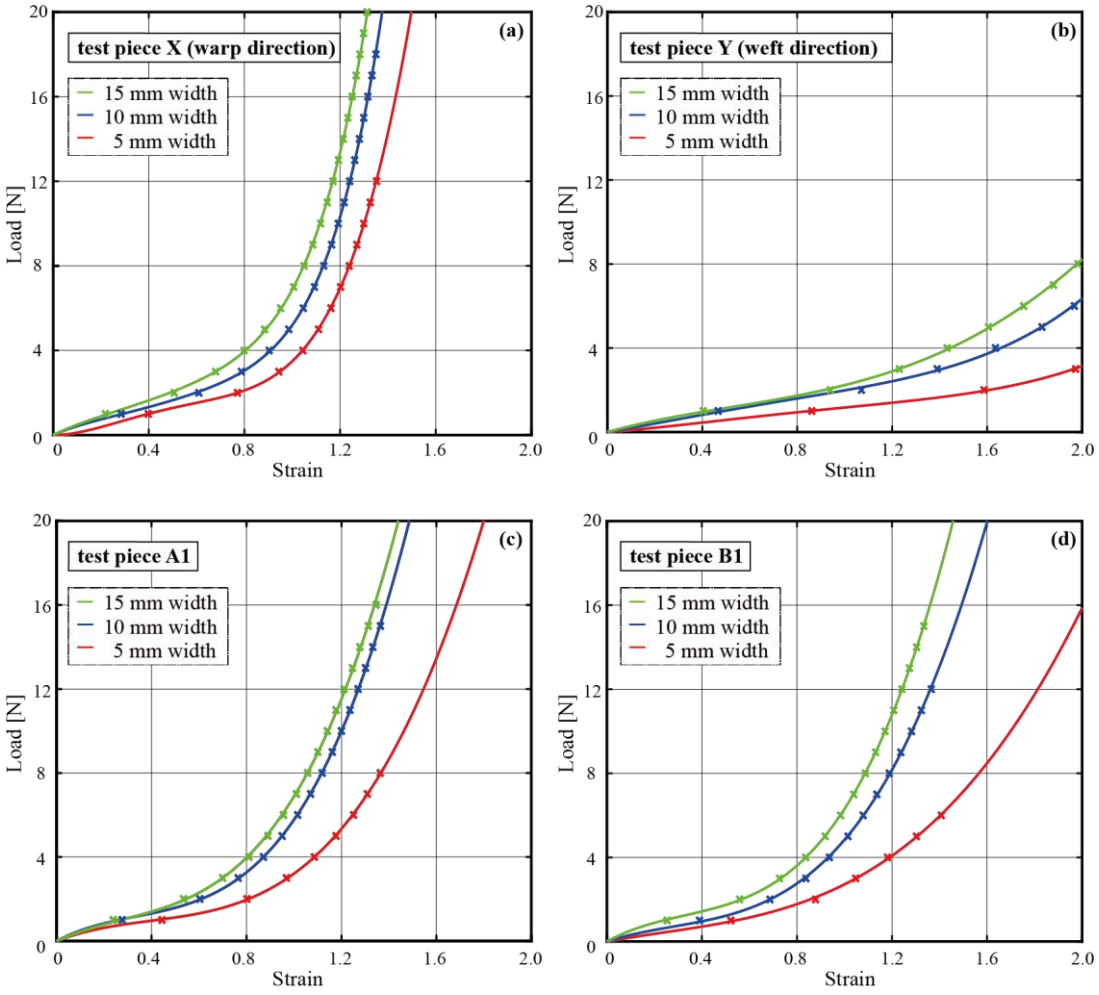

Figure 7. Results of uniaxial tension test.

As a general trend, the greater the width of test pieces, the greater the stiffness, and the differences in stiffness due to differences in width can be seen to be smaller for 10 mm and 15 mm compared to 5 mm and 10 mm. From these observations, it can be anticipated that even if the width of the test pieces exceeds 15 mm, load-strain relationships are unlikely to change significantly. Therefore, it is considered that the test results of the test pieces with a width of 15 mm best represent the properties of the EMEs. Eq. (8) is the load-strain relationship expression of test piece A1 (EME-A) obtained from the measurement data by the least squares method, and Eq. (9) is that of test piece B1 (EME-B).

$$s_{\mathrm{A1}}(\varepsilon) = 9.9\varepsilon^3 - 8.2\varepsilon^2 + 5.2\varepsilon \quad [\mathrm{N}] \tag{8}$$

$$s_{\mathrm{B1}}(\varepsilon) = 11.0\varepsilon^3 - 10.9\varepsilon^2 + 6.2\varepsilon \quad [\mathrm{N}] \tag{9}$$

4.2. Repeated uniaxial tension test

Since there is a possibility that the stiffness may change due to residual deformation occurring when the membrane material used in this study undergoes a large strain, we conducted the repeated loading-unloading test for the test pieces A1 and B1 within a range of strain up to 1.0 using the same testing

method as in the previous section. Fig. 8 shows the results of the tests. It is difficult to accurately grasp how much the stiffness changes because it is not possible to quantitatively grasp the range of strain for the EMEs in the structure, but it can be seen that the stiffness of both test pieces decreases from the graphs (a) and (b).

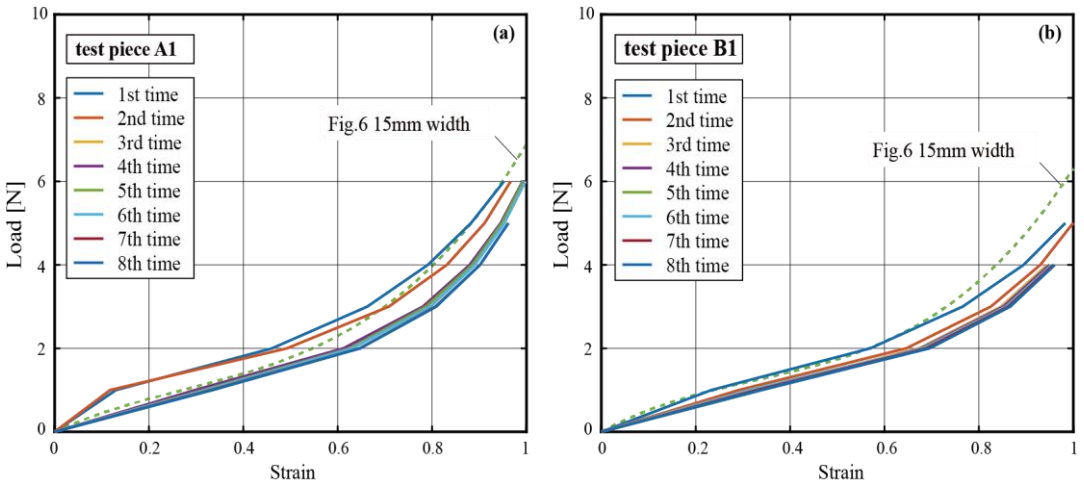

Figure 8. Result of repeated uniaxial tension test.

4.3. Biaxial tension test

In the equilibrium state of tensegrity-membrane structures, the membrane material is subjected to tension forces in various directions, not just in a single direction. As a result, it is uncertain whether the stiffness of the EME can be accurately estimated using only the load-strain relationship expressions derived from the uniaxial test in the previous section. To address this issue, a biaxial tension test was conducted, which involved applying tension forces in orthogonal directions to the EME-A and B. The change in stiffness was then compared to the results from the previous section. Test pieces were prepared by cutting the membrane material as shown in Fig. 6(a) and inserting a compression rod vertically into the test pieces, as illustrated in Fig. 9(a). It can be predicted that the stiffness of membrane will change depending on the length of the rod, but it is difficult to predict how much tension will act in the orthogonal direction of the EME in the actual model. Therefore, the length of the rod was set according to the same method of making the physical model as shown in the figure. By doing that, a test piece was thoght to be created in which the orthogonal tension force of roughly the same as the physical model. The test piece cut to match the EME-A is referred to as test piece A2, while the test piece cut to match the EME-B is referred to as test piece B2.

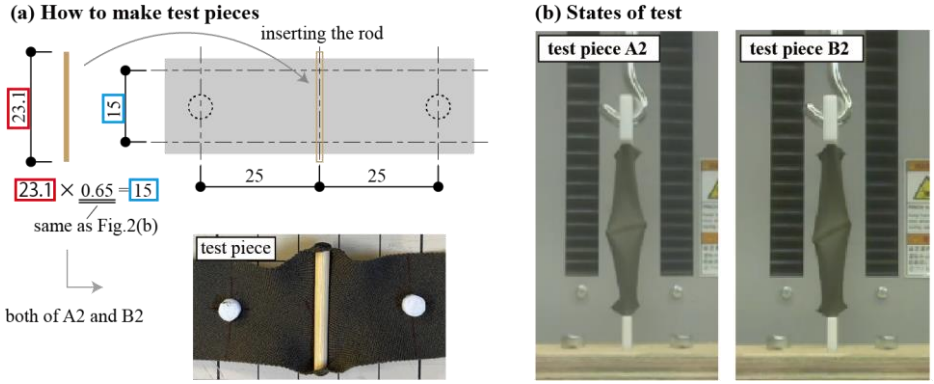

Figure 9. Biaxial tension test of membrane.

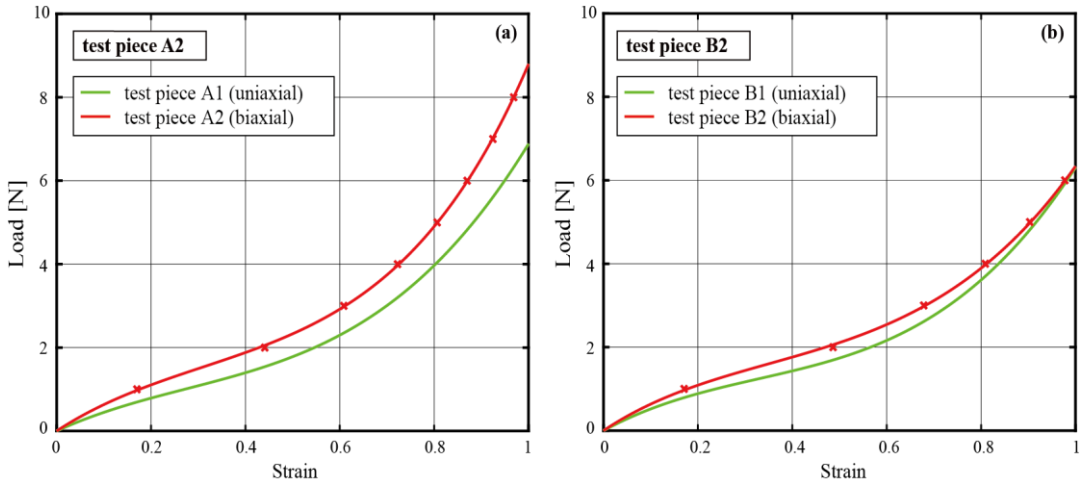

Figure 10. Results of biaxial tension test.

The graph comparing the results of the test and the Eq. (8) and (9) obtained in the previous section is shown in Fig. 10. Eq. (10) represents the load-strain relationship expression for test piece A2 (EME-A), obtained from the measured data using the least squares method, while Eq. (11) represents the load-strain relationship expression for test piece B2 (EME-B). From graphs (a) and (b), it can be observed that both test pieces exhibit higher stiffness than the results obtained in the previous section. This finding suggests that to accurately estimate the stiffness of the EME, it is crucial to consider the tension forces acting in directions other than the member axis and to understand the load-strain relationship accordingly.

$$s_{A2}(\varepsilon) = 5.4\varepsilon^5 - 8.6\varepsilon^4 + 17.3\varepsilon^3 - 12.7\varepsilon^2 + 7.4\varepsilon \quad [\mathrm{N}] \tag{10}$$

$$s_{B2}(\varepsilon) = 3.4\varepsilon^5 - 8.4\varepsilon^4 + 17.6\varepsilon^3 - 13.8\varepsilon^2 + 7.6\varepsilon \quad [\mathrm{N}] \tag{11}$$

5. Form-finding and structural analysis against external forces

5.1. Comparison of equilibrium states

Fig. 11 presents a comparison of the equilibrium state obtained from the form-finding using DRM and the physical model. Model-1 employs Eq. (8) and (9) as the load-strain relationship for the EME-A and B, while Model-2 utilizes Eq. (10) and (11). Both results are in good agreement with the physical model; however, it was found that the maximum height value of Model-2 is slightly closer to the value of the physical model form.

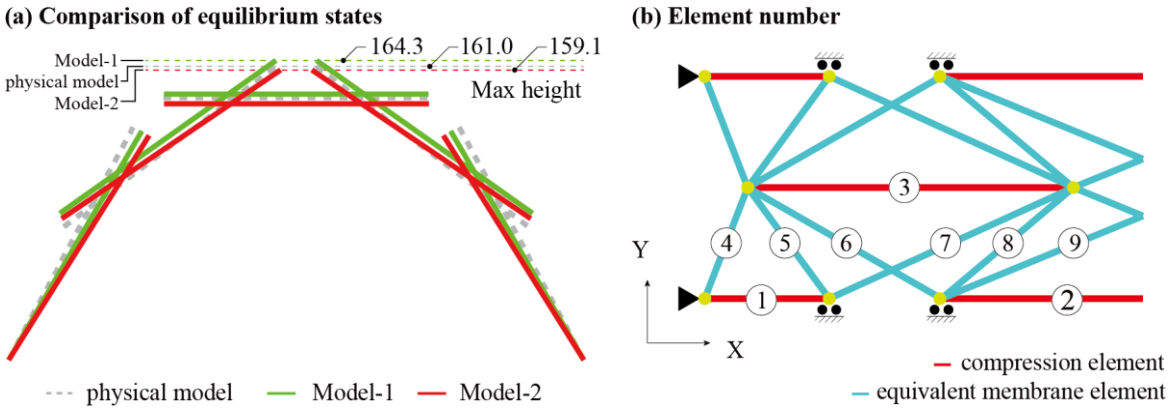

Figure 11. Comparison of equilibrium states and axial forces in the members.

Table 1 displays the axial force and strain acting on each element in the equilibrium state of Model-1 and Model-2. It is observed that the tension forces acting on the EMEs in the equilibrium state are greater in Model-2 than in Model-1.

Table 1. The axial force and strain in each element.

	Model-1		Model-2	
Element number	axial force[N]	strain	axial force[N]	strain
1 (compression element)	-1.50	0	-1.88	0
2 (compression element)	-3.05	0	-3.77	0
3 (compression element)	-5.86	0	-7.28	0
4 (EME-A)	1.52	0.43	1.89	0.40
5 (EME-B)	3.16	0.75	3.90	0.80
6 (EME-A)	1.60	0.46	1.98	0.42
7 (EME-A)	1.42	0.41	1.77	0.37
8 (EME-B)	3.24	0.76	3.98	0.81
9 (EME-A)	1.55	0.44	1.92	0.41

5.2. Comparison of behaviour against external force

The behavior of Model-2 under applied external forces is investigated using DRM, and the results are compared with the physical model experiment. Fig. 12(a) presents the comparison of the deformed forms between the physical experiment and the numerical result when an external force was applied in the vertically downward direction, as shown in the figure. The photos demonstrate that both forms during deformation match well.

Fig. 12(b) displays the relationship between the load and vertical downward displacement at the loading point. In the physical experiment, the first test was conducted approximately 5 months after the physical model was completed, followed by the second test about 15 months later. Both tests used the average of multiple trial results. It can be observed that the stiffness of the second result has decreased compared to the first result. This is considered to be due to the loss of tension in the membrane material from maintaining it under tension for an extended period, resulting in a decrease in stiffness. Therefore, it is highly likely that the stiffness of the first test result has decreased compared to just after the completion of the physical model. In fact, when comparing the analysis results of Model-2, assuming it was just after the physical model's completion, and the physical model experiment results, the analysis results exhibit a higher stiffness than the experimental results.

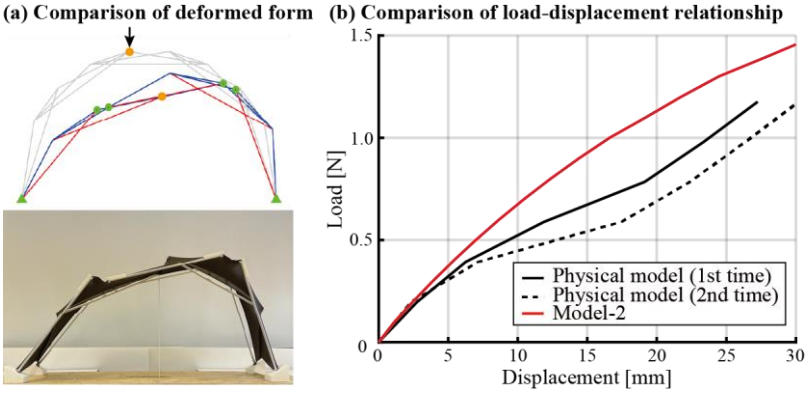

Figure 12. Results of experiment and numerical analysis applying external force

6. Conclusion

In this paper, we investigated the modeling and form-finding method for simple tensegrity-membrane structures. It was determined that the equilibrium state of the planar arch model could be accurately identified by performing form-finding using DRM through the replacement of equivalent membrane elements (EMEs) and tension testing of membrane materials.

On the other hand, due to the overall stiffness of the tensegrity-membrane structure decreasing over time, it was found that the behavior against external forces could not be accurately predicted using the analysis method that assumes the condition just after the completion of the physical model. As discussed above, it was discovered that the stiffness of the EME increases or decreases due to various factors. Therefore, it is essential to investigate the mechanism of stiffness change in membrane materials to determine the load-strain relationship for the EMEs.

Acknowledgements

A portion of this research was conducted with the support of a research grant from the Nohmura Foundation for Membrane Structure's Technology. We also received valuable advice and collaboration from Dr. Masaaki MIKI (The University of Tokyo), Kenji OHYA and Tatsushi HEGURI (Taiyo Kogyo). We would like to express our sincere gratitude here to all those involved.

Abstract

Membrane structure has encountered some problems in the development of photovoltaic integration, and its engineering practicability has not been well verified, such as low energy conversion efficiency, and the integration of photovoltaic modules and structural system. A membrane structure system integrated photovoltaic is designed and manufactured to verify the practical engineering applicability of these new green building technologies. The system consists of roof, facade, insulation, semiconductor air conditioner and monitoring cabinet. The photovoltaic membrane structures made of three kinds of building membrane materials (PTFE\ETFE\PVC) are used as the roof. The south facade is a photovoltaic glass curtain wall made of CdTe cells. The indoor wall is equipped with PCM materials to achieve heat storage and insulation. The indoor temperature is controlled through the air conditioning made of semiconductor chips. The monitoring cabinet is used to monitor the structural performance, photovoltaic temperature, membrane film temperature, indoor air temperature and humidity, solar energy generation and other indicators all day for a long period continuously. Through the testing system, the engineering feasibility and economy of a variety of new photovoltaic integrated building technologies can be verified, providing a basis for the promotion of new technologies and the development of new membrane buildings integrated photovoltaic.

1. Introduction

Membrane structures have become increasingly popular for large-span public buildings due to their lightweight, high efficiency, and aesthetically pleasing architectural shapes.[1] With global energy scarcity and climate change, green buildings have gained significant attention. large-span public buildings with membrane structures[2] typically consume a substantial amount of energy in human activities, such as lighting and regulating the thermal environment of the building due to their size, facing significant energy pressure and having great potential for low-carbon optimization.

Moreover, the large roof area of membrane buildings presents a significant potential for laying photovoltaic (PV) modules, although the curved shape of membrane structures creates significant resistance to the installation of PV modules.[3] In addition to photovoltaic energy storage measures, low-carbon solutions can also be sought in building energy consumption, such as building thermal insulation and regulating the thermal environment within the building. Currently, new low carbon technologies for membrane building are emerging, but their engineering feasibility has not yet been fully verified.

Many studies have researched the new technologies that porperbily can be used in large span membrane structures, such as flexible thin-film solar cells composites with different substrates. Weerasinghe *et al.*[4] studied the fabrication process and electrical properties of flexible thin-film solar cells with plastic

substrates. Chenni *et al*.[5] studied the photoelectric performance of photovoltaic cells. Armstrong *et al*.[6] analyzed the photothermal performance of photovoltaic cells under different conditions, which proves that flexible photovoltaic cells can be used in high temperature condition and can be integrated into building surfaces. Fukushige[7] analyzed the change law of temperature of OPV cells. Asano *et al*.[8] studied the electrochemical properties of flexible thin-film solar cells with PSE films as substrates. Zhao *et al*.[9] Concern the field experiments and numerical modeling on the temperature characteristics and temperature value of the a-Si PV integrated in a double-layer ETFE cushion structure. Zhou *et al*.[10] gained the force-electrical properties of flexible thin-film solar cells during uniaxial stretching. Hu[11] developed the heat transfer model and carried out experimental verification. Xu *et al*.[12] measured the force-electrical properties of flexible thin-film solar cells laminated with polyvinylidene fluoride film materials. Yin *et al*.[13] conducted an experimental study on the electro-thermal-mechanical properties of the composition of flexible organic thin-film solar cells with ETFE foils. Geng *et al*.[14] studied the heat transfer performance of photovoltaic cells under different environments through modeling and simulation. M. Gloeckler et al.[15] showed that laboratory conversion efficiencies up to 22.1% have been achieved for CdTe solar cells, and large-area module efficiencies of 19% have been achieved. Corina Stetiu et al.[16] conducted a study on the energy-saving effect of phase change materials through numerical simulations and experiments, showing that the use of a cooling system with phase change materials can achieve an average energy saving of about 30%, regardless of the location or climate in the U.S. A.K. Athienitis[17] also conducted a study on phase change gypsum board and found through experiments that it can reduce energy consumption by storing solar energy during the heating period. Similarly, Dariusz Heim et al.[18] conducted research on phase change gypsum board and confirmed its energy-saving capabilities.

This study aims to design and fabricate a PV-integrated membrane structure system that validates the practical engineering utility of new PV building technologies, including various PV membrane structures, CdTe PV glass, phase change materials (PCM), and semiconductor air conditioner, in line with the trend of the development of the current low-carbon membrane structure concept. The system comprises a roof cover, facade, insulation, interior regulation, and monitoring cabinet, with the latter offering long-term, all-weather monitoring of structural response, temperature of membrane surface and PV modules, indoor temperature and humidity, PV power generation, and other critical parameters to evaluate the engineering practicality and economy of each new green building technology.

2. Membrane structure integrated innovation PV

Membrane structures are a popular choice for the roofs of large-span public buildings [19] as they offer ample space for PV utilization, with PV modules mainly installed on the roof and façade, while the curved shape of these structures presents challenges for PV module arrangement.

In recent years, glass curtain wall designs have become commonplace, and membrane curtain walls are gaining traction among architects. Fabric curtain walls and ETFE tensioned grids offer several advantages, including lightweight, transparency, and aesthetic appeal, making them a potential replacement for glass of the architectural curtain wall.

2.1. New flexible PV membrane structure

Membrane roofs are typically curved, making it challenging to lay rigid supports for PV modules. As a result, coordinating the flexible PV modules with the membrane structure's geometric shape is crucial. However, the low photoelectric conversion efficiency of the current flexible OPV modules is a major obstacle that hinders the development and promotion of the integration of PV module and membrane structure.

Unlike the approach of attaching PV modules to the structure after the membrane structure construction is completed, material integration design is considered more reasonable. Using crystalline silicon solar cells made via an ultra-thin cutting process, the PV modules are flexible due to their ultra-thin thickness

while maintaining high photovoltaic conversion rates. Before the structure is formed, the PV modules are integrated into the membrane structure materials, such as ETFE, PVC, and PTFE, which are commonly used for membrane architecture, creating a flexible surface that ensures the mechanical reliability of membrane structures while allowing the solar energy to be converted into electricity through the composite PV modules.

The composite material is consisting of a laminated structure comprising three layers, from top to bottom: encapsulation film, cell layer, and base film. The encapsulation film is 25μm thick ETFE film with excellent light transmission, while the base film is made of ETFE, PVC, and PTFE, which are common building film materials. The cell layer is 140μm thick monocrystalline silicon cell.

Table 1. Properties of each layer of PV membrane materials

	Material	Thickness(μm)	Features
cover	ETFE	25	
PV	a-Si	140	0.4V×2.5A，conversion efficiency 21%
substrate	PVC	780	Fabric film 120kN/m
	PTFE	800	Fabric film 140kN/m
	ETFE	250	Polymer film 12kN/m
