Membrane materials are flexible and sensitive to temperature, and their mechanical properties and structural performance are closely related to the geometry. PV-integrated membrane structure buildings unify structural force and photovoltaic function, but the temperature increase of PV modules under sunlight radiation can impact power generation efficiency, mechanical properties of the materials, and overall force of the structure. When laminated with crystalline silicon solar cells, the close fit between the PV module and membrane structure materials can further affect the material properties and geometry of the membrane structure due to temperature changes brought about by solar radiation. To address this issue, this study designed a test system to evaluate the temperature distribution and changes, as well as stress relaxation of this new PV-integrated membrane structure under solar radiation.

The test system uses three common membrane materials, namely PVC, ETFE, and PTFE, to create composite membrane materials, which are tensioned and formed into a single-layer plane with a negative

Gaussian curvature surface. The PV modules occupy 20.4% of the membrane structure area and consist of 30 monolithic packages measuring 160mm × 40mm. Under standard laboratory test conditions (AM1.5, 25°C), the module has an open-circuit voltage of 19.5V, a short-circuit current of 2.54A, an operating voltage of 16.5V and operating current of 2.4A, meaning 40W output power.

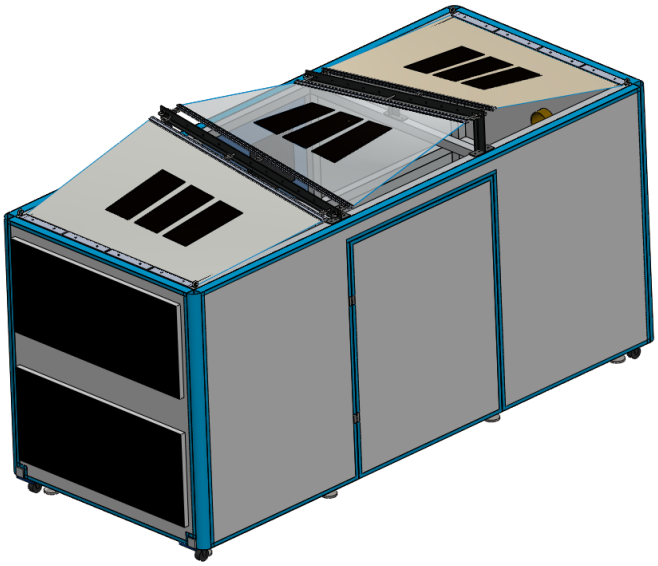

Figure 2. PV membrane testing mock-up

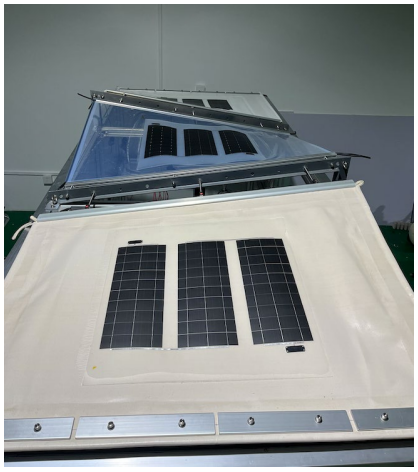

Figure 3. PV-PTFE/PV-ETFE/PV-PVC membrane roofs

Figure 4. Facade of mock-up

In the case of Shanghai 2022, the average daily solar radiation energy reaching the ground in August is 5.77kWh/m^2, which can be converted into approximately 791Wh of electricity through PV membrane structures. In January, the average daily solar radiation energy reaching the ground is 2.58kWh/m^2 due to heavy clouds and rainy weather, which can be converted into approximately 354Wh of electricity through PV membrane structures.

Since the membrane material has been compounded with the PV module before installation, this test system employs a planar tensioning process for the installation construction of the PV membrane structure. This process verifies the applicability of the planar forming process and ensures that the PV membrane structure is well tensioned after installation, with a smooth surface, uniform stress, and no damage to the PV modules. The results demonstrate the feasibility of planar tensioning and forming of PV integrated membrane structures and provide a reference for the application of planar tensioned membrane structures to building facades.

The test system can also evaluate the performance of the three membranes laminating the new flexible crystalline silicon photovoltaic modules. The photovoltaic power generation performance and the impact of temperature change on the membrane structure performance can be simultaneously examined, thereby verifying the structural suitability and energy efficiency of this flexible crystalline silicon photovoltaic integrated membrane structure for building roof and facade applications.

2.2. CdTe PV Glass

Tensioned membrane structures are typically used for roofing in membrane buildings, but building facades are also exposed to solar radiation and offer significant potential for the use of photovoltaic modules. While membrane facades are gaining attention from architects, glass remains the most used facade material. The primary method of integrating PV modules into glass facades involves using the glass as the base plate and panel, with the PV modules placed in the middle layer. However, the use of crystalline silicon solar cell arrays in these modules can negatively affect the transparency and aesthetics of the glass due to their thickness, as well as create challenges in waterproofing.

To address these issues, this test system employs chromium telluride (CdTe) material photovoltaic glass, which offers a solution to these problems. The sprayable nature of the chromium telluride photovoltaic material allows for customization of the transparency of the photovoltaic glass based on the spraying concentration. The resulting teal glass achieves both photovoltaic power generation and transparency, while also avoiding direct glare and other potential issues. The thickness of the chromium telluride photovoltaic modules is thin, and their coatings can be customized with patterns and colours to enhance the aesthetic appeal of the building. The temperature coefficient of CdTe cells is 0.20%/°C, which is lower than that of crystalline silicon (0.45%/°C), so that the output power of CdTe cells is not easily affected by temperature as Si cells.[20]

Table 2. Properties of CdTe PV modules

ASP-S1		
	P_m	105W
	V_{oc}	124V
	I_{sc}	1.28A
	V_m	92.9V
	I_m	1.13A
	Size	1200*600*6.8mm
	Weight	12kg

The test model presented in this paper features two chromium telluride photovoltaic glass modules installed on the south elevation. For instance, based on statistical data from the national meteorological station in Shanghai, the highest and lowest average daily solar radiation values are recorded in August and January, respectively, at 5.77kWh/m^2/day and 2.58kWh/m^2/day. Based on these values, the average daily power generation of the two PV modules in August and January can be calculated to be 1557Wh and 696Wh, respectively. The energy utilization rate of the PV modules is estimated to be around 18.7%.

The combination of chromium telluride photovoltaic modules and glass aligns with the current trend in the building market, which favours glass curtain walls that maximize the use of building facades for photovoltaic power generation, while also considering aspects such as light transmittance and aesthetics.

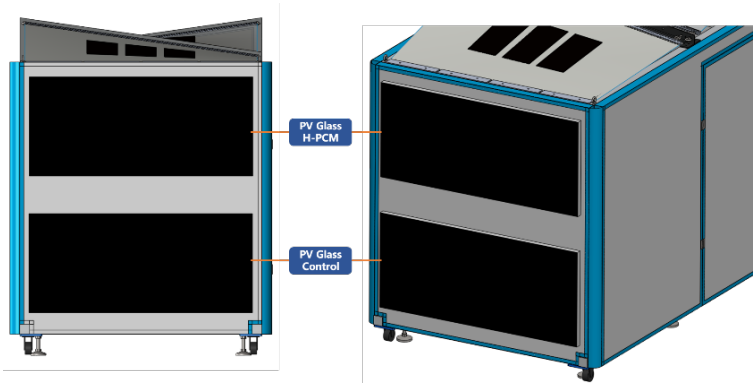

Figure 5. PV Glass module design

Figure 6. PV Glass Modules

3. Thermal regulation in membrane buildings

The indoor temperature is a crucial factor affecting human comfort. Traditionally, air conditioning and heating systems are used to regulate indoor temperature, which often results in significant energy consumption and reliance on fossil fuels. However, by incorporating solar power and heat storage systems, a significant portion of energy consumption can be reduced, resulting in a more sustainable and eco-friendly approach to regulating indoor temperature.

3.1. Semiconductor air conditioning

Summer presents a great opportunity to utilize solar air conditioners due to the high radiant sunlight energy during this period. The compressor, which uses Freon as its refrigerant, is the main component of conventional air conditioners. The release of Freon into the atmosphere contributes to ozone layer destruction. However, recent advancements in semiconductor materials have made it possible to develop eco-friendly air conditioners. Semiconductor cooling sheets create a significant temperature difference between the two sides when activated, which can be utilized to regulate room temperature. Although the effectiveness and energy efficiency ratio of semiconductor air conditioning in larger building spaces are yet to be proven, a small refrigerator has already been designed and produced using the idea of using semiconductors.

Figure 7. Semiconductor air conditioner

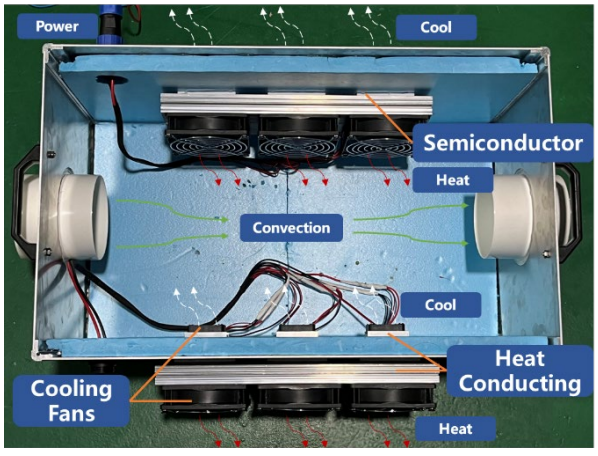

Figure 8. Configration of semiconductor air conditioner

This paper presents the design and construction of a semiconductor air conditioner that considers both cooling and heating. The semiconductor air conditioner consists of a semiconductor chip, a heat transfer chip, a cooling fan, a cabinet, and an extractor fan. Six semiconductor chips are used in this study, with

three forming a cooling group and another three forming a heating group. A single group has a power of 150W.

The semiconductor air conditioner has been tested and shown to meet the cooling and heating needs within 3.6m^2. Its advantage is that it consumes only electrical energy, produces no exhaust gas or pollution, and provides equal cooling and heating power. However, the inflow measures are not yet optimized, and temperature control is less efficient.

3.2. Phase change materials (PCM)

Besides air conditioning, thermal insulation is also crucial for maintaining a stable environment inside membrane buildings. While PV modules on the market have an efficiency of around 20%, which means only a fraction of the solar energy can be utilized for PV power generation, a significant portion of the radiant energy is converted into thermal energy, leading to a rise in the temperature of the PV modules. High temperatures can compromise both the lifetime of the PV modules and the comfort of the building's occupants in PV-integrated buildings.

To address this issue, phase change materials (PCM) with excellent thermal storage capacity, thanks to their special thermodynamic properties, can be added to the backside of PV modules. This addition not only reduces the peak temperature of the modules but also stores the thermal energy generated by the sunlight radiation for later use. Additionally, the adjustable phase change temperature of the PCM material allows for building insulation, providing a new way of thinking about building insulation and heating in the winter. During the day, solar energy is absorbed by the photovoltaic modules and stored in the phase change material. At night, when the temperature drops, the phase change material releases the stored heat to maintain a comfortable indoor temperature.

Table 3. Properties of PCM

Material	Temperature	Enthalpy	Heat conductivity	Density
PCM	Variable	220J/g	0.21W/(m K)	0.86g/cm3

As an example, a 10mm thick phase change material (PCM) weighs 8.6kg/m^2 and has a thermal storage capacity of 525Wh/m^2. PV glass modules can reach a maximum surface temperature of 80°C under solar radiation. Therefore, PCM materials with a higher phase change temperature can be used to reduce the high temperature zone and peak of PV modules. In contrast, the building facade can be made of PCM materials with a lower phase change temperature to achieve the building insulation effect of storing energy during the day and releasing it at night.

If a 10mm thick solid-solid PCM with a phase change temperature of 18°C is used as insulation for the building facade during winter, the energy utilization rate can reach 20.3% based on the enthalpy of the PCM material for heat storage.

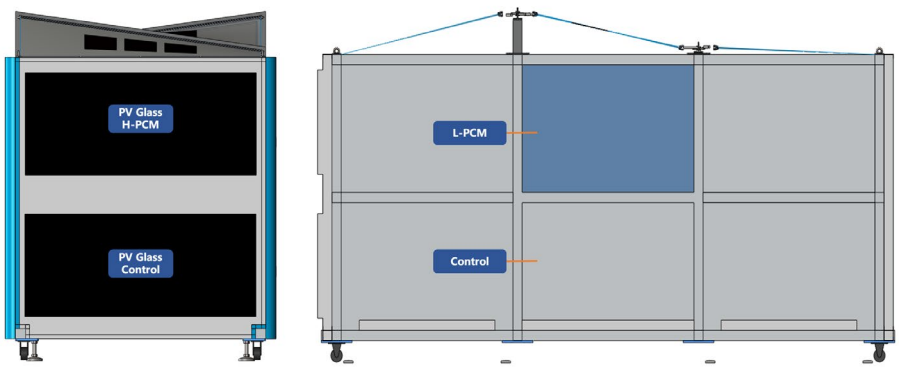

Figure 9. PCM in the mock-up design

Therefore, utilizing the remarkable energy storage capacity of phase change materials, incorporating PCM materials as insulation in buildings can provide numerous benefits. Firstly, using high-temperature PCM on the backside of PV modules can decrease the temperature peak of the modules, which protects them and prolongs their lifetime. Secondly, using low-temperature PCM on the building façade can help regulate the thermal environment inside the building and serve as a buffer when the temperature fluctuates, thereby decreasing the need for air conditioning or heating and saving energy.

4. Monitoring and control system for membrane buildings integrated PV

To achieve intelligent health testing of buildings and to verify the reliability and applicability of the low carbon technologies mentioned in long-term operations of large-span membrane structures, an integrated test system has been developed. This system addresses membrane structure safety, building energy efficiency, comfort, and intelligence. Equipped with a design control cabinet, the system enables health monitoring and control of the building structure, energy storage, and cloud data transmission. This integrated approach ensures a comprehensive and effective means of testing the performance of the low carbon technologies used in large-span membrane structures.

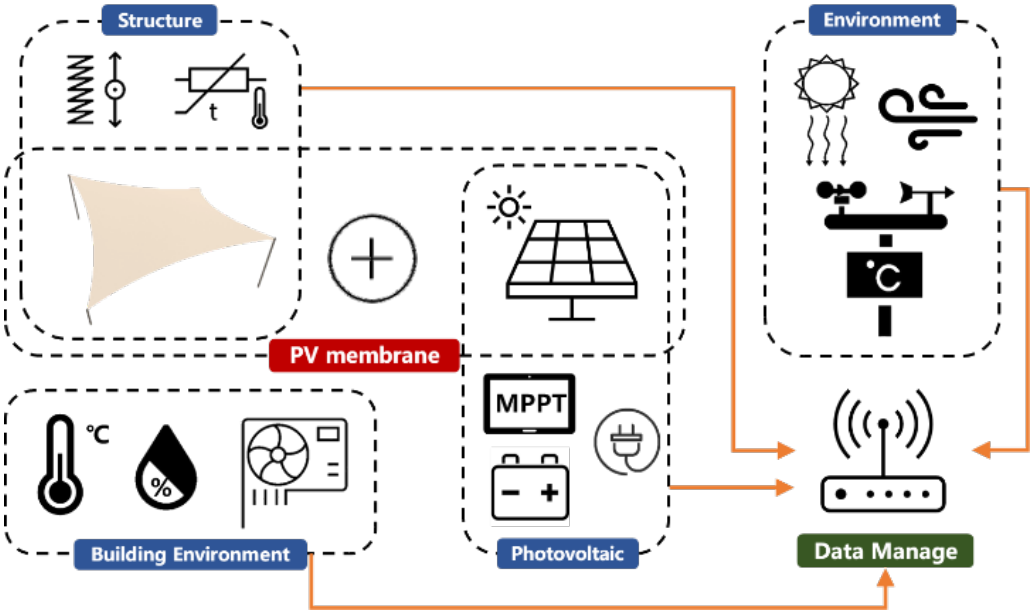

Figure 10. Data acquisition and management system

The structural monitoring system outlined above enables the monitoring of key indicators of photovoltaic membrane buildings over long periods of operation in natural environments. By assessing the economic efficiency of photovoltaic power generation, membrane structure relaxation, and thermal environment of the building, the feasibility and cost-effectiveness of various low-carbon technologies in membrane buildings can be evaluated. The monitoring system comprises five main components:

(1) Photovoltaic system, which includes monitoring of power generation from photovoltaic modules, battery storage, and load energy consumption.

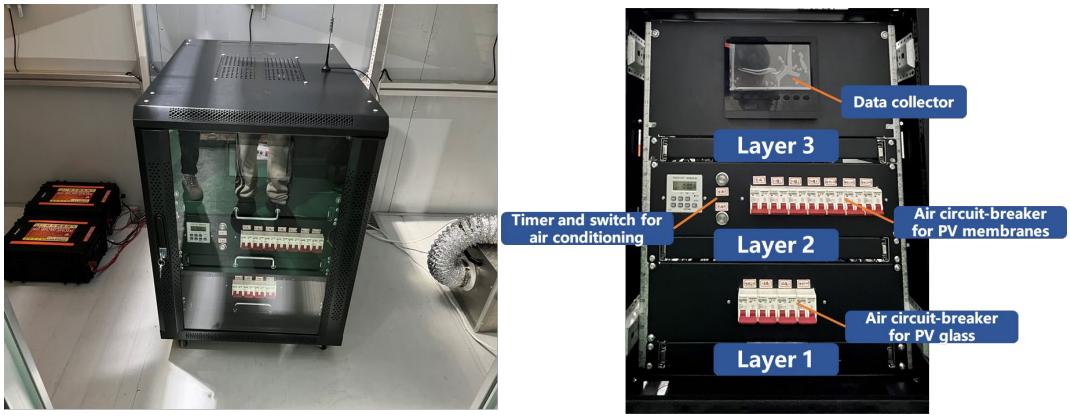
(2) Membrane system, which includes monitoring of tension in the PV membrane structure and temperature of the membrane surface.

(3) Building environment, which includes monitoring of temperature and humidity, as well as air conditioning control.

(4) External environment, which includes measurement of sunlight radiation intensity, wind speed, wind direction, ambient temperature, humidity, and other meteorological data.

(5) Data acquisition and transmission, which includes data acquisition and internet transmission modules.

To realize the above ideas, a monitoring cabinet for the test system is designed and built. The structural monitoring system is capable of monitoring the main indicators of photovoltaic membrane buildings for a prolonged period of time.



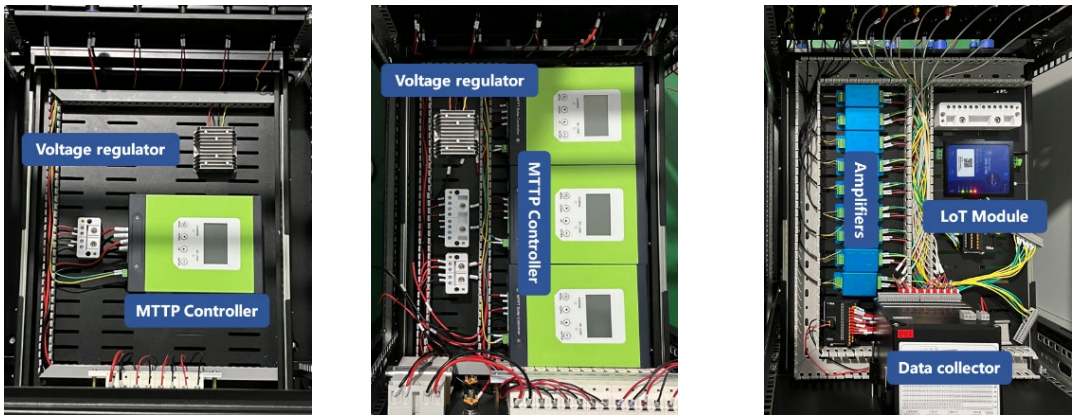


Figure 11. Monitoring and Control Cabinet

(a) Layer 1 Control of PV glass modules

(b) Layer 2 Control of PV membrane modules

(c) Layer 3 Data Collector and Internet modules

Figure 12. Layout of the control cabinet

The monitoring cabinet is equipped with data acquisition and internet cloud transmission capabilities, enabling the acquisition of various data types, including temperature, tension, current, voltage, and meteorological data such as solar radiation intensity and wind speed. By monitoring various aspects of the photovoltaic membrane building, including building safety, energy economy, and comfort, the applicability of a broad range of low-carbon membrane technologies can be verified.

Concerning building structural safety and reliability, the system collects data on membrane surface temperature, tension relaxation, and ambient wind speed to monitor the membrane's structural safety and to analyse the effect of temperature changes, wind pressure, and other factors on membrane tensioning.

For building energy and economy, the system monitors the generation, storage, and energy consumption of photovoltaic modules to achieve a balance between energy acquisition and consumption for the test installation's long-term operation and to reach carbon neutrality in the membrane structure.

Regarding building comfort, the system monitors ambient temperature and humidity and controls the switching time of air conditioning using energy from solar power storage to adjust the indoor environment.

In order to ensure the safety and stability of the test system while working outdoors for extended periods and to avoid any interference with the sensors, all devices within the monitoring cabinet, including sensors, data acquisition components, IoT modules, time control switches, and building loads, are powered by DC. Power is generated by the photovoltaic membrane structure and photovoltaic glass modules through solar energy and is stored in batteries. The batteries then power the test system and loads such as the air conditioning, enabling the test system to operate off-grid for long periods of time.

Table 4. Energy consumption of testing system

	Power/W	Amount	Energy consumption/(Wh/Day)
Data collector	8	1	192
Tensile sensor	0.3	9	2.7
Temperature sensor	0.1	3	0.3
MTTP	2	4	192
LoT Module	0.86	1	21
Time-controlled switch	1	1	1
SUM			409

According to the statistical monitoring of the test system's power consumption, the system requires a continuous energy supply that is obtained through the PV glass modules absorbing solar energy and converting it into electrical energy. The PV glass can supply a minimum of 696Wh per day, which is sufficient for the system's continuous operation, and any excess energy is stored in the battery. The air conditioner operates at a power of 150W, which is powered by the solar energy absorbed by the PV membrane structure. Throughout the year, the PV membrane structure generates a maximum of 791Wh per day and a minimum of 354Wh per day. This provides approximately 5 hours and 2.5 hours of power respectively for the air conditioner. A time-controlled switch can be used to turn the air conditioner on and off depending on the amount of solar radiation and the indoor temperature during different seasons.

In summary, this monitoring cabinet combines data monitoring, control, and transmission into a single unit, capable of collecting data and transmitting it to the cloud for the low-carbon membrane structure testing system. The monitoring system operates with long-term autonomous energy supply, effectively monitoring membrane structures' safety, economy, comfort, and energy efficiency, and assessing the applicability of low-carbon technologies across a broad range of membrane structures.

5. Conclusion

This paper presents four low-carbon building technologies that can be applied to large-span membrane structures and explains their characteristics.

Membrane structure integrated photovoltaic, which achieves an integrated structure of membrane and photovoltaic module, can convert solar energy into electricity through the photovoltaic module on the composite while ensuring the mechanical properties of the membrane material itself. The ultra-thin crystalline silicon flexible photovoltaic module used in the testing mock-up can reach a photoelectric conversion efficiency of 21%, with a measured 23.8%.

CdTe photovoltaic glass provides a new option for membrane structure building facades. Cadmium telluride photovoltaic material is sprayed onto the glass, forming photovoltaic modules. The spraying concentration can customize the transparency and pattern of photovoltaic glass, ensuring the

transparency of the glass while absorbing solar energy into electricity. Its photoelectric conversion efficiency is 19%, measured at 18.7%.

With the advance of semiconductor material, semiconductor air conditioning system is designed for membrane building. When a semiconductor cooling material is energized, a temperature difference is generated on both sides of the material. Using this temperature difference, equipped with a thermal conductor, cooling fan, and ventilation fan, it can play a simple air conditioning effect of cooling and heating. The process consumes only electrical energy and does not rely on refrigerants such as Freon, thus avoiding damage to the atmosphere.

Phase change material (PCM) has a good thermal storage effect due to the presence of a plateau section in the phase change process, whose phase change temperature can be adjusted according to demand. It can act as a buffer during temperature changes, and it can be used for high-temperature protection of photovoltaic modules and as an insulation material for building facades.

To test and verify these low-carbon technologies, a carbon neutral test system for long period off-grid operation has been designed and fabricated, which includes an integrated control cabinet that allows for long-term and all-weather monitoring of structural response, PV temperature, membrane surface temperature, indoor temperature and humidity, PV power generation, and other indicators. This testing system will provide a basis for the application and development of new low-carbon building technologies in large-span membrane structures.

Numerical and experimental modelling of pneumatic structures

Ruy Marcelo O. PAULETTI[a,*], Karina B. ROCHA[b]

Abstract

As other types of tensile structures, pneumatics rely on geometric stiffness for stability. However, pneumatic structures are also endowed with a 'pneumatic stiffness', which corresponds to a reluctance of the pressure envelope to change its volume. The higher the inside pressure, the more relevant this component can be. Most civil and architectural applications of pneumatic structures are low to moderate-energy systems, for which simplified material models may suffice, if a sound model to cope with membrane wrinkling is also considered. This paper presents a simple yet effective model to cope with the nonlinear analysis of pneumatic membranes under wind loads, incorporating an effective wrinkling criterion into a simple membrane element, and deriving new expressions for its pneumatic stiffness. The model was tested through an inexpensive experiment, comprising the compression of an exercise ball, which corroborated the importance of considering variable inside pressures for moderate-energy systems. The relevance reduces, however, as the dimensions of the structures increase, especially in the case of large, insufflate domes, which are also discussed in the paper.

Keywords: pneumatic structures, membranes, finite elements, nonlinear analysis, pneumatic stiffness, membrane wrinkling

1. Introduction

Pneumatic structures are paradigms of tension structures, since only in them it is possible to have all structural elements working exclusively in tension. Practical applications of pneumatic structures started at the beginnings of the 20th century, to become rather customary nowadays, in many distinct areas, as large stadia roofs, building façades, or everyday furniture, like sofas, boats and toys. Although the use of large, insufflated pneumatics for permanent applications has been superseded by other light structural systems in the last decades, the use of smaller inflated or insufflated domes, as well as inflated beams and cushions, combined with gridshells and other rigid systems, is becoming increasingly popular worldwide [1].

In this paper we present a simple model, of easy implementation and yet able to cope with a broad range of civil and architectural applications, which usually employ (almost) impermeable fabrics or films, whose material behaviors might be quite complex. Typical materials present nonlinear, anisotropic and hysteretic behaviors, very much dependent on the fabric internal structure and load history. The orientation of orthotropy directions in double curvatures surfaces is not a trivial matter, not least because fabric patterning usually aims to minimizing waste, a conflicting objective with optimizing the yarns lay-out. Consequently, industry strives to provide the market with fabrics the more isotropic and linear elastic as possible, and so follows design and analysis software. Furthermore, wind loads might induce

wrinkling on the pneumatic envelope, and practical strategies to cope with wrinkling supersede concerns about other types of nonlinear material behavior [2].

2. Nonlinear equilibrium

Upon discretization, the problem of *equilibrium of a membrane structure* can be expressed as finding *a displacement vector* $\boldsymbol{u}^*$ such that $\boldsymbol{g}(\boldsymbol{u}^*) = \boldsymbol{p}(\boldsymbol{u}^*) - \boldsymbol{f}(\boldsymbol{u}^*) = \boldsymbol{0}$, where $\boldsymbol{u} = \boldsymbol{x} - \boldsymbol{x}_r$ is the *global displacement vector* with respect to an initial configuration $\boldsymbol{x}_0$, $\boldsymbol{g}(\boldsymbol{u})$ is *a residual force vector*, $\boldsymbol{p}(\boldsymbol{u})$ is the *internal load vector* and $\boldsymbol{f}(\boldsymbol{u})$ is the *external load vector*, all of order n_{dof}, the number of degrees of freedom of the system. The equilibrium problem can be solved –within a vicinity of a solution $\boldsymbol{u}^*$– iterating Newton-Raphson's recurrence formula, $\boldsymbol{u}_{k+1} = \boldsymbol{u}_k - \left(\frac{\partial \boldsymbol{g}}{\partial \boldsymbol{u}}\Big|_{\boldsymbol{u}_k}\right)^{-1} \boldsymbol{g}(\boldsymbol{u}_k)$, where the *tangent stiffness matrix* is defined as $\boldsymbol{K} = \frac{\partial \boldsymbol{g}}{\partial \boldsymbol{u}}$. It is usual to assemble the global quantities from their elements' counterparts, with the element tangent stiffness given by $\boldsymbol{k}^e = \frac{\partial \boldsymbol{g}^e}{\partial \boldsymbol{u}^e}$, where $\boldsymbol{u}^e$ is the element displacement vector and $\boldsymbol{g}^e$ is the element residual vector.

Whenever analytical expressions for the tangent stiffness matrices are not at hand, a convenient option is given by *finite-difference approximations,* which achieve the same convergence rate and precision as the consistent tangent stiffness matrices, with acceptable extra computational cost, provided calculations are performed at the element level. Using a *central-difference* scheme, each column of the tangent stiffness matrix can be evaluated according to $\breve{\boldsymbol{k}}_j^e = \frac{1}{2h}\left[\boldsymbol{g}^e\left(\boldsymbol{u}^e + h\delta_j^e\right) - \boldsymbol{g}\left(\boldsymbol{u}^e - h\delta_j^e\right)\right]$, where $\pm h\delta_j^e$ are backward and forward perturbations of the j^{th} degree of freedom, which can be taken as small as allowed by the machine precision [3].

The *Newton-Raphson Method* (NRM) usually yields the best algorithm for the solution of non-linear static equilibrium of cable and membrane structures, since it then presents quadratic convergence rate, in a sufficiently narrow vicinity of the solution. However, cables and membranes have no bending stiffness and in the absence of a proper tension field, the structure's tangent stiffness matrix may become non-positive definite, leading to divergence of the method. In many cases, the *Dynamic Relaxation Method* (DRM) offers a convenient alternative, replacing the equilibrium problem by a pseudo-dynamic analysis, where fictitious mass and damping matrices are arbitrarily chosen to control the stability of the time integration process. The definition of an arbitrary damping matrix may be circumvented by the process of *kinetic damping*, whereby the undamped movement of the system, governed by $\boldsymbol{M}\ddot{\boldsymbol{u}} + \mathbf{g}(\boldsymbol{u}) = \boldsymbol{0}$, is followed until a maximum of the total kinetic energy is reached, whence all the velocity components are cancelled, and the analysis is restarted, until new kinetic energy maxima (usually smaller than the precedent ones) are found, and all velocities are zeroed again. Although DRM shows no advantage for small to medium sized problems, whenever NRM shows good convergence, there might be economy for large problems. Both methods have been implemented into a coherent computational framework named SATS – A System for the Analysis of Taut Structures, which has been applied to several problems involving the shape finding and analysis of cable and membrane structure. Details can be found in [4].

2.1. Argyris' membrane element

Figure 1(a) shows the Argyris' natural triangular membrane finite element defined in an initial configuration Ω_0, in which it is already under an initial stress field. A *reference configuration* Ω_r usually considers stress-free conditions but, for small strains, we assume $\Omega_r \equiv \Omega_0$. The element's *current configuration* is denoted by Ω. Element nodes and edges are numbered anticlockwise, with edges facing nodes of same number.

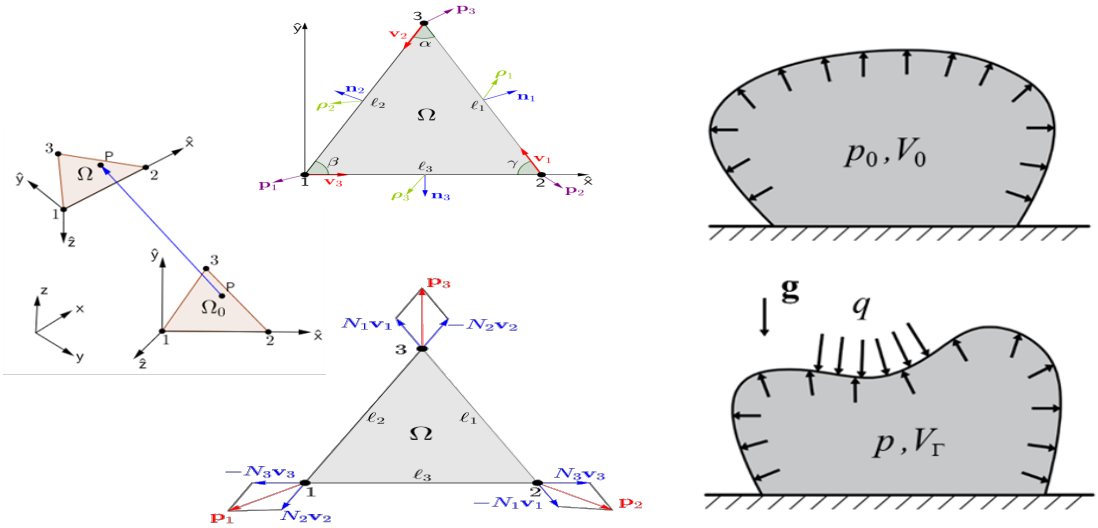

Figure 1. (a) definitions of Argyris membrane element quantities: An element is defined at a configuration Ω_0, which may also be used as reference configuration, i.e. $\Omega_r \equiv \Omega_0$; (b) initial and current configuration of a pneumatic envelope.

Nodal coordinates are referred to a global Cartesian system and at the current configuration are given by $\boldsymbol{x}_i = \boldsymbol{x}_i^0 + \boldsymbol{u}_i$ where $\boldsymbol{u}_i$ are the element's nodal displacements. The lengths of element edges are given by $\ell_i = \|\boldsymbol{\ell}_i\| = \|\boldsymbol{x}_k - \boldsymbol{x}_j\|$, with indexes $i,j,k = 1,2,3$ in cyclic permutation. Unit vectors parallel to the element edges are denoted by $\boldsymbol{v}_i = \boldsymbol{\ell}_i/\|\boldsymbol{\ell}_i\|$. At the current configuration Ω , side length ℓ_i and the unit vector $\boldsymbol{v}_i$, parallel to the nodes are shown in Figure 1, as well as the unit vector normal to the sides $\boldsymbol{n}_i$, and the resultant of the stress acting on each element side, $\boldsymbol{\rho}_i$. These results are added up to the nodal loads $\mathbf{p}_i$, which may be decomposed into natural load, i.e., components of loads parallel to the element sides see [2] and [4] for further details).

With these definitions, the *vector of internal nodal forces* can be decomposed into forces parallel to the element edges, according to

$$\boldsymbol{p}^e = \begin{bmatrix}\boldsymbol{p}_1\\ \boldsymbol{p}_2\\ \boldsymbol{p}_3\end{bmatrix} = \begin{bmatrix}N_2\boldsymbol{v}_2 - N_3\boldsymbol{v}_3\\ N_3\boldsymbol{v}_3 - N_1\boldsymbol{v}_1\\ N_1\boldsymbol{v}_1 - N_2\boldsymbol{v}_2\end{bmatrix} = \begin{bmatrix}\mathbf{0} & \boldsymbol{v}_2 & -\boldsymbol{v}_3\\ -\boldsymbol{v}_1 & \mathbf{0} & \boldsymbol{v}_3\\ \boldsymbol{v}_1 & -\boldsymbol{v}_2 & \mathbf{0}\end{bmatrix}\begin{bmatrix}N_1\\ N_2\\ N_3\end{bmatrix} = \boldsymbol{C}\boldsymbol{N}, \qquad (1)$$

where $\boldsymbol{C}$ is a *geometric operator*, which collects the unit vectors parallel to the element edges and $\boldsymbol{N} = [N_1 \quad N_2 \quad N_3]^T$ is the *vector of natural forces*.

We assume that the behavior of the element in taut conditions is linear elastic, thus a relationship exists, such that $\boldsymbol{N} = \boldsymbol{k}_n^0\boldsymbol{a} + \boldsymbol{N}_0$, where $\boldsymbol{a} = [\Delta\ell_1 \quad \Delta\ell_2 \quad \Delta\ell_3]^T$ is the *vector of natural displacements* (with $\Delta\ell_i = \ell_i - \ell_i^0$ and the *element natural stiffness* is a constant matrix given by

$$\boldsymbol{k}_n^0 = t_0 A_0 \boldsymbol{L}_0^{-1}\boldsymbol{T}_0^{-T}\widehat{\boldsymbol{D}}\boldsymbol{T}_0^{-1}\boldsymbol{L}_0^{-1}, \qquad (2)$$

where t_0A_0 is the element volume, $\boldsymbol{L}_0 = \mathrm{diag}\{\ell_i^0\}$, $\widehat{\boldsymbol{D}}$ collects the coefficients of Hooke's law for plane stresses, such that $\widehat{\boldsymbol{\sigma}} = \widehat{\boldsymbol{D}}\widehat{\boldsymbol{\varepsilon}}$, and $\widehat{\boldsymbol{T}}_0$ is a classical transformation matrix, relating the linear Green strains $\widehat{\boldsymbol{\varepsilon}}$ to the *natural strains , i.e.*, $\boldsymbol{\varepsilon}_n = \widehat{\boldsymbol{T}}_0\widehat{\boldsymbol{\varepsilon}}$, highlighting the fact that Argyris' natural membrane element is akin to a *strain gauge rosette*.

Since $\boldsymbol{k}_n^0$ has only six independent components, its storage is economic, reducing the number of operations required to calculate the internal loads and tangent stiffness, and thus the overall computing time. The vector of internal forces at each configuration is given by

$$\boldsymbol{p}^e = \boldsymbol{C}(\boldsymbol{k}_n^0 \boldsymbol{a} + \boldsymbol{N}_0). \qquad (3)$$

Assembling these loads into the global residual vector is all it takes to pose the equilibrium equation of a taut membrane structure via DRM or NRM, using finite differences. It is also a matter of simple derivation to obtain the *internal stiffness matrix of the taut membrane element*, given by:

$$\boldsymbol{k}_{int} = \boldsymbol{C}\boldsymbol{k}_n^0\boldsymbol{C}^T + \begin{bmatrix} \left(\frac{N_2}{\ell_2}\boldsymbol{M}_2 + \frac{N_3}{\ell_3}\boldsymbol{M}_3\right) & -\frac{N_3}{\ell_3}\boldsymbol{M}_3 & -\frac{N_2}{\ell_2}\boldsymbol{M}_2 \\ -\frac{N_3}{\ell_3}\boldsymbol{M}_3 & \left(\frac{N_1}{\ell 1}\boldsymbol{M}_1 + \frac{N_3}{\ell_3}\boldsymbol{M}_3\right) & -\frac{N_1}{\ell 1}\boldsymbol{M}_1 \\ -\frac{N_2}{\ell_2}\boldsymbol{M}_2 & -\frac{N_1}{\ell 1}\boldsymbol{M}_1 & \left(\frac{N_1}{\ell 1}\boldsymbol{M}_1 + \frac{N_2}{\ell_2}\boldsymbol{M}_2\right) \end{bmatrix}, \quad (4)$$

where, for brevity, we have defined some *projection matrices*, $\boldsymbol{M}_i = \boldsymbol{I}_3 - \boldsymbol{v}_i\boldsymbol{v}_i^T$. See details of the above formulation in [2] and [4].

2.2. External nodal loads and stiffness for pneumatic envelopes

We consider that the pressure envelope displayed in Figure 1(b) is under pressure on both sides. We denote the total *outside pressure* as q, and we strongly simplify the problem by assuming that its magnitude is not dependent on displacements. For the *inside* pressure p, we assume Boyle-Mariotte's law, for an ideal gas under adiabatic conditions, such that $p = p_0 V_0 / V_\Gamma$, where p_0 and p are the absolute values of the pressure acting inside the pneumatic envelope, at the initial and current configurations, of total volumes V_0 and V_Γ, respectively.

The total volume of the pneumatic envelope at some current configuration Γ can be calculated as $V_\Gamma = \frac{1}{3}\int_\Gamma (\boldsymbol{x}\cdot\boldsymbol{n})dA \simeq \frac{1}{3}\sum_{k=1}^{n_{el}} \boldsymbol{x}_1^k \cdot A_k \boldsymbol{n}_k$, where n_{el} is the number of elements of the mesh, A_k is the k^{th} element area, $\boldsymbol{n}_k$ its unit normal vector, and where we arbitrary picked $\boldsymbol{x}_1^k$ (the coordinates of node 1 of the element), but could have chosen $\boldsymbol{x}_2^k$ or $\boldsymbol{x}_3^k$ as well. If positive p acts parallel to $\boldsymbol{n}$, outwards the envelope, and outside pressure q is positive inwards, the external load vector acting on the element is given by

$$\boldsymbol{f} = \boldsymbol{f}_g + \boldsymbol{f}_p = \frac{\boldsymbol{m}}{3}\left[\boldsymbol{g}^T \,|\, \boldsymbol{g}^T \,|\, \boldsymbol{g}^T\right]^T + \frac{(p-q)A}{3}\left[\boldsymbol{n}^T \,|\, \boldsymbol{n}^T \,|\, \boldsymbol{n}^T\right]^T, \quad (5)$$

where $\boldsymbol{f}_g$ are forces due to self-weight, $\boldsymbol{f}_p$ are forces due to the transversal inside and pressures, $\boldsymbol{m}$ is the mass of the membrane element, $\boldsymbol{g}$ is the gravity acceleration vector. The awkward double transpositions were used to allow a single line notation.

Eq. (5) assembled for each element is all what is needed to include the external pressure loads on the equilibrium problem, solved through DRM or NRM, with finite-difference approximations $\widetilde{\boldsymbol{k}}_{ext}$. A somewhat lengthy derivation is required to arrive at the analytical expression for the external tangent stiffness under wind and pneumatic loads, given by:

$$\boldsymbol{k}_{ext} = \frac{q-p}{6}\begin{bmatrix} \boldsymbol{\Lambda}_1 & \boldsymbol{\Lambda}_2 & \boldsymbol{\Lambda}_3 \\ \boldsymbol{\Lambda}_1 & \boldsymbol{\Lambda}_2 & \boldsymbol{\Lambda}_3 \\ \boldsymbol{\Lambda}_1 & \boldsymbol{\Lambda}_2 & \boldsymbol{\Lambda}_3 \end{bmatrix} + \frac{pA}{18V_\Gamma}\begin{bmatrix} \boldsymbol{\Phi}_1 & \boldsymbol{\Phi}_2 & \boldsymbol{\Phi}_3 \\ \boldsymbol{\Phi}_1 & \boldsymbol{\Phi}_2 & \boldsymbol{\Phi}_3 \\ \boldsymbol{\Phi}_1 & \boldsymbol{\Phi}_2 & \boldsymbol{\Phi}_3 \end{bmatrix} = \boldsymbol{k}_\Lambda + \boldsymbol{k}_\Phi\,, \quad (6)$$

where $\boldsymbol{\Lambda}_i = skew(\boldsymbol{\ell}_i)$ are skew-symmetric matrices, whose axial vectors are given by $\boldsymbol{\ell}_i = \ell_i \boldsymbol{v}_i$ and where $\boldsymbol{\Phi}_i = \boldsymbol{n}\left(\boldsymbol{x}_j \times \boldsymbol{x}_k\right)^T$, with indices $i, j, k = 1,2,3$ in cyclic permutation. The Appendix provided in [2] presents the deduction of Eq. (6).

Several authors present alternative ways to handle pneumatic loads and stiffness [2], but there is limited exploration on the relative importance of the resulting terms. Especially in the case of insufflated structures, due to the envelope permeability and the limited power of the mechanical blowers, a constant inside pressure might be a more realistic assumption, in which case $\boldsymbol{k}_{ext} = \boldsymbol{k}_\Lambda$. Moreover, the examples explored in Section 3 suggest that the external stiffness can be approximated by $\widetilde{\boldsymbol{k}}_{ext} \cong \boldsymbol{k}_\Lambda$, alleviating computations without degrading convergence. We also remark that although $\boldsymbol{k}_{ext}$ is an asymmetric

matrix at the element level, if the boundary nodes are constrained, all the non-symmetric stiffness terms cancel out on the global external stiffness $\boldsymbol{K}_{\text{ext}}$, therefore the system is conservative. If, however, free borders exist, or pressure varies along the surface in a generic way, there is no guaranty on the symmetry of $\boldsymbol{K}_{ext}$.

2.3. A simple wrinkling model

Matrix $\boldsymbol{k}_n^0$ defined in (2) provides an efficient scheme to compute the internal loads and stiffness of a taut membrane, avoiding explicit calculation of strains or stresses, which may be evaluated at the postprocessing stage. However, before undergoing compressive stresses, a membrane becomes wrinkled or slack. When wrinkles ought to be accurately represented, a shell-like formulation is required, demanding relatively heavy computation. Nonetheless, in most civil and architectural applications, there is no exacting requirement for tautness, nor it is required the knowledge of the precise wrinkle patterns. What does is required is the knowledge of the basic load transfer mechanisms, which may be incorrectly assessed, if spurious compression is not averted. Moreover, if wrinkling or slackening are allowed, for some operational conditions, the resulting anchorage loads might be reduced, because smaller initial stresses are then required, and because larger displacements of the membrane usually contribute to a more favorable load distribution. Criteria for identification of the *status* of a membrane element (*taut*, *wrinkled,* or *slack*) require consideration of either stresses or strains, or both. When wrinkling or slackening are likely, equations (3) and (4) ought to be replaced for lengthier calculations. For isotropic materials, principal stress and strain directions are parallel, and stress, strain or mixed wrinkling criteria are equivalent. Herein, we choose a *pure stress criterion* and calculate the element stresses directly from the natural displacements.

In order to speed up calculations, we first decompose the element natural stiffness according to $\boldsymbol{k}_n^0 = \left(t_0 A_0 \boldsymbol{L}_0^{-1} \widehat{\boldsymbol{T}}_0^{-T}\right)\left(\widehat{\boldsymbol{D}}\widehat{\boldsymbol{T}}_0^{-1}\boldsymbol{L}_0^{-1}\right) = \boldsymbol{k}_\sigma^0 \boldsymbol{k}_a^0$, where we observe that $\boldsymbol{k}_\sigma^0$ and $\boldsymbol{k}_a^0$ are two constant matrices that can be conveniently stored during the pre-processing phase. Then stresses at any configuration can be evaluated according to $\widehat{\boldsymbol{\sigma}} = \boldsymbol{k}_a^0 \boldsymbol{a} + \boldsymbol{\sigma}_0$ and, after calculating the principal stresses (σ_1, σ_2) and the "principal angle" θ_1 (between the element local axis $\hat{x}$ and the σ_1 direction), we determine the element status, and whether it is necessary to modify stresses, according to the following *wrinkling criterion*:

$$\begin{cases} \sigma_2 > 0 & \Rightarrow \text{TAUT} & \Rightarrow & \tilde{\boldsymbol{\sigma}} = \widehat{\boldsymbol{\sigma}} \\ \sigma_1 > 0 \ \wedge \ \sigma_2 \leq 0 & \Rightarrow \text{WRINKLED} & \Rightarrow & \tilde{\boldsymbol{\sigma}} = \frac{\sigma_1}{2}[(1+\cos\theta_1) \quad (1-\cos\theta_1) \quad \sin(2\theta_1)]^T \\ \sigma_1 \leq 0 & \Rightarrow \text{SLACK} & \Rightarrow & \tilde{\boldsymbol{\sigma}} = \boldsymbol{0} \end{cases} \tag{7}$$

Thereafter, we consider a *modified element internal force vector* $\tilde{\boldsymbol{p}}^e = \boldsymbol{C}\boldsymbol{k}_\sigma^0 \tilde{\boldsymbol{\sigma}}$. A mixed stress-strain criterion could avoid the intermediate calculation of negative stresses, which have no physical meaning for membranes, but in our framework, we determine stresses and internal loads without the explicit calculation of strains. Once again, assembling the element internal load vectors into the global residual vector is all it takes to pose the equilibrium of a wrinkled membrane structure via DRM or NRM using finite differences. An analytical expression for the internal stiffness, according to the above criterion is still possible, as given in [5], but it is not as immediate as for the taut element, so we avoid bringing forth its consideration. Reference [6] details the above formulation.

3. Applications

We present in this section some selected problems to assess the performance of our simplified kinematic assumptions and the relevance of the pneumatic stiffness for modelling low to moderate-pressure systems. Initially experimental and numerical results of two small-scale pneumatics are compared, to assess the performance of the proposed membrane element, and the Boyle-Mariotte's Law. Then two pneumatic domes under inside and outside pressures are numerically modeled, one of moderate and another of large dimensions, under different hypothesis for the inside pressure. Results allow relevant conclusions about the importance of modeling the variation of inside pressure and considering the pneumatic stiffness term.

3.1. Henky's problem

We first consider Hencky's problem (1915), on the deformation of an initially flat, circular membrane fixed at the border and pressurized at one side. Bouzidi *et al*. [7] compared analytical solutions given by different authors with a numerical solution using an axisymmetric membrane element and considering large deformations and hyperelastic material. Figure 2(a) depicts the profiles assumed by a flat membrane with radius $R = 0.1425$ m, a product $Et = 311488\ Nm$, Poison ratio $\nu = 0$, under inflation pressures $100\ kPa$, $250\ kPa$ and $400\ kPa$. Up to moderate deformations, isotropic strains are approximately $\varepsilon \cong 2(\delta/r)^{2/3}$, thus, strains are about 3.5%, 7% and 10%, for these three pressures intensities. We modeled the same problem in SATS, considering the mesh shown in Figure 2(b). For each pressure intensity, our model took five NRM iteration to achieve equilibrium, for $\max(\|\boldsymbol{g}_i\|)/\max(\|\boldsymbol{g}_i^0\|) \leq 10^{-3}$, starting from a flat disc configuration. Our results, superimpose well with those provided in [7], with increasing, but small differences up to the maximum tested load, showing that our model is applicable to problems up to moderate deformations, which comprises a broad range of structural applications ((Figure 2(c)).

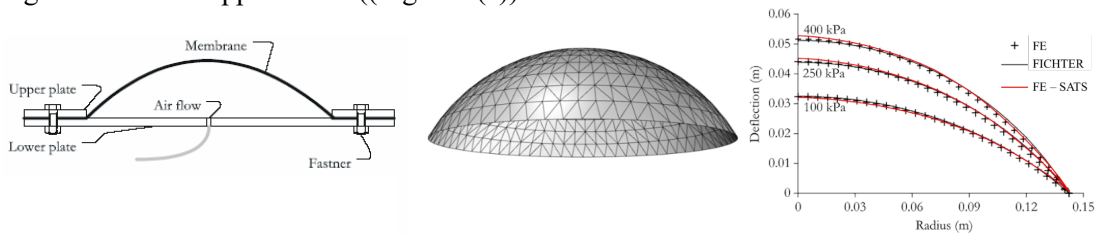

Figure 2. (a) experimental set up of an axisymmetric pressurized membrane; (b) SATS finite element model (flat initial configuration); (c) comparison between FE and theoretical results.

3.2. A Swiss ball experiment

The problem of the equilibrium of a spherical balloon under axisymmetric loads has become a benchmark for theoretical and numerical methods on the modelling of pneumatic membranes, and Swiss balls provide for ready and inexpensive experimental setups. In this section we compare the numerical modelling of a typical Swiss ball compressed between two parallel planes with experimental results. The test was freely inspired by Liu *et al.* [8], where a semi-analytical formulation was solved numerically, for different contact conditions, comparing numerical results with experimental ones.

We experimentally obtained an average elasticity modulus $E = 7.23$ MPa and a density $\rho = 0.88\ \mathrm{g/mm^3}$ for the ball's material, as well as an average membrane thickness $t = 1.3$mm. The tests were made according to ASTM D638-14. We started the experiment inflating the ball with an initial inside pressure $p_0 = 2.413$ kPa (0.35 psi). The precision of this measurement was limited by the low resolution of the available pressure gauge ($\Delta p = 0.01$psi). The initial inflated geometry was then measured with a digital ruler. Due to slight orthotropy of the material and the presence of some reinforcement rings, the inflated shape was a slightly prolate spheroid, of equatorial radius $R_{E,0} = 0.2775$ m and polar radius $R_{P,0} = 0.2800$ m, with an initial volume $V_0 = \pi R_E^2 R_P/3 = 9.0318 \times 10^{-2}$ m^3. The reinforcement rings were located at symmetrical distances, parallel to the equator and the air inlet was located at the lower pole. To connect the pressure gauge, the original PVC inlet was replaced by a metal valve stem.

We tested the ball for a vertical compression load, preserving the rotational symmetry of the problem. A gap was provided below a stiff base plate, to accommodate the pressure gauge, and the ball was pushed downward by the top plate. An ink layer was sprayed over the ball's top hemisphere, and a sheet of paper was glued to the lower face of the top plate, to obtain an imprint of the contact area. An initial vertical load of 50 N was required to stabilize the set, before a final vertical load $F = 535$ N could be applied, (encompassing both the applied external load and the weight of the top plate). The final pressure

measured by the pressure gauge was $p = 4.481$ kPa (0.65 psi). Thus, considering the BML, a final volume $V_{BM} = 4.8633 \times 10^{-2}$ m^3 was estimated.

Using a digital ruler, we measured the ball's final equatorial radius $R_{E,f} = 0.313$ m, equivalent to a radial displacement $\Delta R_E = 0.0355$ m. It was then possible to estimate the meridional stress $\sigma_\theta = \left(p\pi R_{E,f}^2 - F\right)/\left(2\pi R_{E,f} t\right) \cong 0.32$ MPa. The downward displacement of the top plate was $\Delta_{Z,NP} = 0.189$m. The vertical coordinate of the circular contact disc, with respect to ball equator, was $z_{DISC} = \left(R_{P,0} - \Delta_{Z,NP}\right)/2 = 0.1855$ m. The diameter of the imprint of the contact disc was also measured with a digital rule, resulting $D_{disc} = 0.39350$ m. Disregarding any bending stiffness of the ball, the coherence between these measurements can be verified by considering that the ratio of the measured vertical force by the measured inside pressure should equate the area of the contact imprint. That yields and estimated diameter $D'_{disc} = 0.38987\ m$, with a 0.92% error compared to the measured imprint diameter.

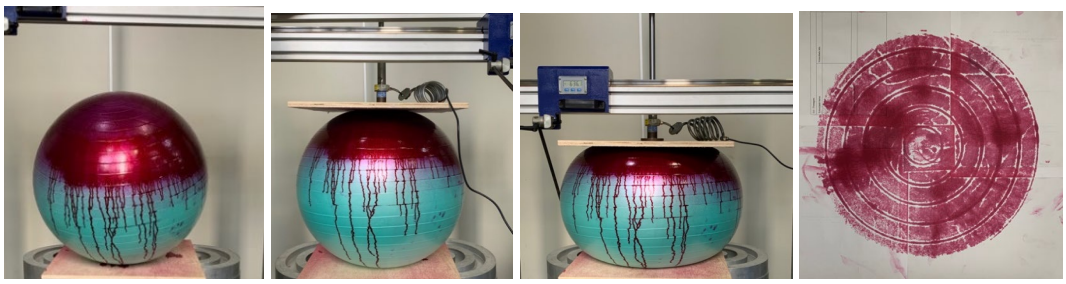

Figure 3. Several stages of the testing of the Swiss ball before, at the onset and at the end of the compression test and imprint of the contact área.

Figure 4(a) displays our numerical model, which considered the symmetry with respect to the equatorial plane. Boundary conditions avoided any rigid body movements and preserved the rotational symmetry. The volume of faceted approximation was $\tilde{V}_0 = 9.03690 \times 10^{-2}$ m^3, with an error of 0.39%, compared to the analytical volume of the spheroid. We assumed a membrane material with $E = 7.23$ MPa and a zero Poison ration, as well as a membrane thickness $t = 1.3$ mm.

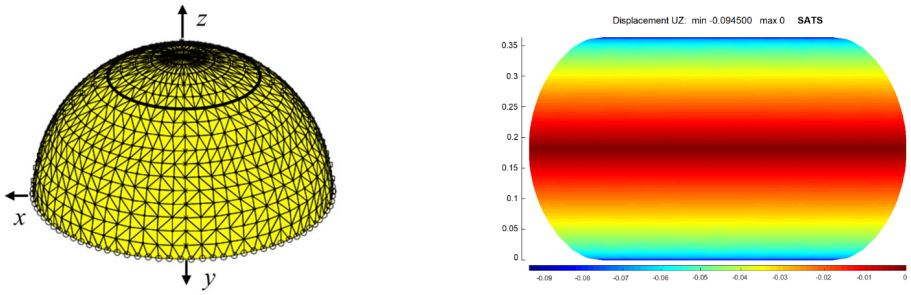

Figure 4. Numerical model: (a) discretization of the ball's top hemisphere; (b) Lateral view of the deformed numerical, reflect with respect to the equatorial plane.

We opted for controlling the vertical displacements of the nodes belonging to the spheroidal cap, which would become in contact with the top plate. To estimate the size of this cap, we assumed that both the sag of the cap and the material deformation were small, thus the cap perimeter could be approximated by the intersection of the spheroid with the plane $z = z_{cap} = R_{P,0} \times \cos\left(R_{disc}/R_{P,0}\right) = 0.2137$m. We enforced a set of nodes of our finite element mesh to conform to this perimeter, highlighted with a thicker parallel shown in Figure 4(a) . We then deformed the top cap into a flat disco, imposing vertical displacements such that the final vertical coordinates of the cap's nodes were all equal to $z_{disc} = 0.1855m$, as experimentally measured. Thus, the node located at the upper pole was displaced of $u_{z,P} =$

$z_{disc} - R_{P,0} = -0.0945m$, whilst the nodes at cap's perimeter were displaced of $u_z^{\partial cap} = z_{disc} - z_{cap} = -0.02817m$, with intermediate u_z values for the intermediate nodes. We remark that this procedure implies frictionless contact between the membrane and the compression plates. We considered that the reference experiment reported in [8] actually indicated that the effect should be relatively small, moreover because in our case the membrane was partially lubricated by the ink layer and because the contact occurred gradually, so that the contact disc would become stretched even for high friction conditions. Anyway, the validity of the frictionless assumption could be verified afterward, by inspecting the results of our model.

Figure 4(b) displays the resulting equilibrium shape. Although only the top hemisphere was modelled. For easier interpretation, the deformed geometry mirrored with respect to the equatorial plane. Colors indicate the magnitude of the vertical displacement. Only minor differences were observed using ether NRM and DRM. Moreover, equal values were obtained, through NRM, either with the analytical tangent stiffness or its finite-difference counterpart, requiring the same number of 6 iterations, with $\epsilon_{\boldsymbol{g}} \leq 10^{-3}$. The third column of Table 1 compares the NRM solution with respect to the experimental values. A discrepant error on maximum $\sigma_1$compared to the meridional stress estimated from the experimental results, may be associated to the coarseness of the mesh. Nonetheless, a maximum deformation $\varepsilon_{max} \approx max(\sigma_1)/E = 4.7\%$ is still within the applicable range of our simplified kinematic model.

Table 1. Results for the Swiss ball, $\boldsymbol{V_0 = 9.0318 \times 10^{-2}\, m^3}$, $\boldsymbol{p_0 = 2.4132\ kPa}$

Hypothesis on inside pressure:	BML: $p = p_0 V_0 / V_\Gamma$			$p = p_0$
Solution method:	NRM	Error NRM vs. expr.	DRM	NRM & FDM
$p\ [kPa]$:	4.4870	0.1%	4.4913	2.4132
$V_\Gamma\ [\times 10^{-2}\ m^3]$:	9.6980	0.3%	9.7494	13.1740
Equator displacement ΔR_E [cm]:	3.532	0.5%	3.553	5.5259
Total vertical reaction $\sum F_z$ [kN]:	0.5368	0.3%	0.5359	0.5364
max (σ_1) [MPa]:	0.3392	5.1%	0.3457	0.4748
min (σ_1) [MPa]:	1.9393	--	2.027	0.2644
max (σ_2) [MPa]:	2.4504	--	2.5739	3.2119
min (σ_2) [MPa]:	1.5894	--	1.8917	0.2143

To highlight the importance of considering the BML for this system, we repeated the analyses assuming a constant inside pressure $p_0 = 2.413$kPa. Results for this case are summarized at the fourth column of Table 1. Both NRM and DRM provides the same numerical results, requiring 4 iterations to achieve converge, for the same criterion as before. However, large errors are observed with respect to the experimental values, of about 32% for the final volume, 46% for the final pressure, 56% for the equator's displacements and 33% for the final maximum stress. The comparison between the numerical and experimental results indicates that the assumption of frictionless contact was acceptable, and that at the scale of a Swiss ball, compliance to BML is required to provide satisfactory results.

3.2. A hemispherical pneumatic dome under wind loads

As a further example, Figure **5**(a) shows a model of hemispherical pneumatic dome with radius $R = 10.0$ m, All the nodes at the base of model are constrained, and we assumed an elastic modulus $E = 0.5$ GPa, zero Poisson ratio, and membrane thickness $t = 0.5$ mm. An initial isotropic stress field $\sigma_0 = 0.2$ MPa was imposed, coherent to an initial inside pressure $p_0 = 0.2$ kPa. We considered two load cases, superimposed with the inside pressure: *(a)* a *low wind velocity* $v_a = 47$km/h , equivalent to a *low dynamic wind pressure* $q_a = 0.1$ kPa $< p_0$ and *(b)* a *high wind velocity* $v_b = 147$ km/h, equivalent to a *high dynamic wind pressure* $q_b = 1.0$ kPa $> p_0$, Figure **5**(b) shows the wind pressure

coefficients, determined using Ansys/Fluent software, considering a uniform inlet velocity profile. Positive pressures coefficients were obtained at both the weather and leeward sides, which is somewhat against common knowledge, but coherent with recent research [9]-[11], which indicate that for Reynold's numbers $Re > 10^6$ a separation region appears, where the flow detaches from the surface of the dome, leading to a recirculation area at leeward. Thus, for the current geometry and wind velocities, with $Re \approx 10^7$, compression at this region can indeed appear. The precise location of flow detachment depends not only on Re, but also on the turbulence intensity at boundary layer and the surface roughness.

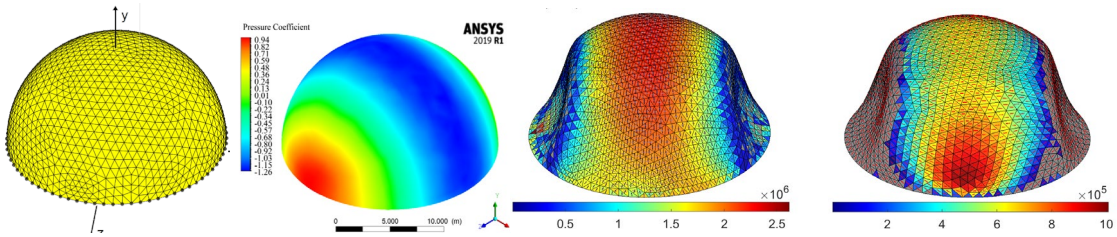

Figure 5. (a) FE model; (b) pressure coefficients determined using Ansys/fluent; (c/d) field of principal stresses $\boldsymbol{\sigma_1}$ and $\boldsymbol{\sigma_2}$, plotted over the deformed shape. Maximum values are given in Table 2.

Table 2 - Selected results for a hemispherical dome, $\boldsymbol{V_0 = 2.0892 \times 10^3\ m^3}$, $\boldsymbol{p_0 = 0.2\ kPa}$

Basic wind pressure	Hypothesis on inside pressure	BML: $p = p_0 V_0 / V_\Gamma$	Constant: $p = p_0$
$v_a = 47\ k$m/h $q_a = 0.1$ kPa	p (kPa):	0.1994	0.2000
	V_Γ ($\times 10^3$ m^3):	2.0898	2.0898
	$max\ (\sigma_1)$ (MPa):	0.4174	0.4175
	$min(\sigma_1)$ (MPa):	1.6841	1.6847
	$max\ (\sigma_2)$ (MPa):	0.2886	2.8887
	$min(\sigma_2)$ (MPa):	0.0262	0.0262
	$max\ (\|\boldsymbol{u}\|)\ (m)$:	0.0048	0.0048
$v_b = 147$ km/h $q_b = 1.0$ kPa	p (kPa):	0.2161	0.2000
	V_Γ ($\times 10^3$ m^3):	1.7987	1.9336
	$max\ (\sigma_1)$ (MPa):	2.6224	2.6846
	$min(\sigma_1)$ (MPa):	0	0
	$max\ (\sigma_2)$ (MPa):	1.0073	1.0115
	$min(\sigma_2)$ (MPa):	0	0
	$max\ (\|\boldsymbol{u}\|)\ (m)$:	2.2094	2.2660

For the low wind velocity case, the analysis converged in only 3 NRM iterations, with $\epsilon_u \leq 10^{-3}$. Very small displacements were observed, $\|\boldsymbol{u}\| < 5$ mm , with all elements in taut or marginally taut conditions. For the high wind velocity case, however, convergence by NRM becomes problematic, since large wrinkling areas developed over the membrane, with a ring of elements effectively becoming slack, at the transitions between the convex and concave regions of the membrane at the deformed configuration, as can be seen on the plotting of the σ_1 field (Figure **5**(c)). The onset of slackness renders the system's tangent stiffness $\boldsymbol{K}$ non-positive definite. To circumvent this nuisance using NRM, we have implemented a naïve, yet enough penalty method, simply adding artificial nodal stiffnesses $\bar{k}$ for every degree of freedom and gradually reducing it until artificial reactions becomes either null or small, if compared with the external forces $\boldsymbol{f}$ .Assuming as correct the results obtained using BML, shown at the 2nd column of Table 2 , we compare them with the results obtaining with constant inside pressure, shown at the 3rd column of Table 2. We find an error about 7.5% for the inside pressure and the final volume. The maximum displacement becomes 6 cm smaller, with an error about 2.6%. Maximum σ_1 and σ_2 principal stresses present errors of 2.32% e 0.41%. It is seen that in comparison to the Swiss ball experiment, the consideration of BML in this example is not as relevant, although not insignificant.

3.3. A large, insufflated dome reinforced by meridian cables

As a final example, we will consider the '*Megadome*', a large, inflated dome built for the 2022 Christmas and New Year's celebrations in the city of *Canela*, in the South of Brazil. Figure 6(a/b) depict the installed structure. Only the main dome, with a diameter of $D = 60\text{m}$ and a height $H = 30\text{m}$, was modeled. The pneumatic envelope is constituted by single layer of PVC-polyester fabric, reinforced with 40 meridian steel cables anchored to a perimeter concrete ring. The inside pressure was guaranteed by a set of fans with enough redundancy and capacity to vary the internal pressure for different operational scenarios.

Figure 6. The Canela's *Megadome*, Brazil (2022).

The meridian cables converge to a parallel upper cable ring, with a diameter of 5m. The spacing between the cables varies from 4.7m at the base of the dome to 0.40m at the top. Although a larger number of smaller diameter cables might be desirable to increase the rigidity of the dome and minimize the wrinkles of the membrane, they would also significantly increase the practical difficulties of detailing and assembling the structure. The internal surface of the Megadome was designed for cinematographic projections, and to avoid significant creases in the pneumatic envelope under normal operational conditions, the reinforcing cables should be installed with small initial loads, which should however suffice to prevent cable slippage, under normal operating conditions. Morover, the inside pressure under normal operational conditions should not be as high as to excessive, to avoid an excessiveley scaloped surface.

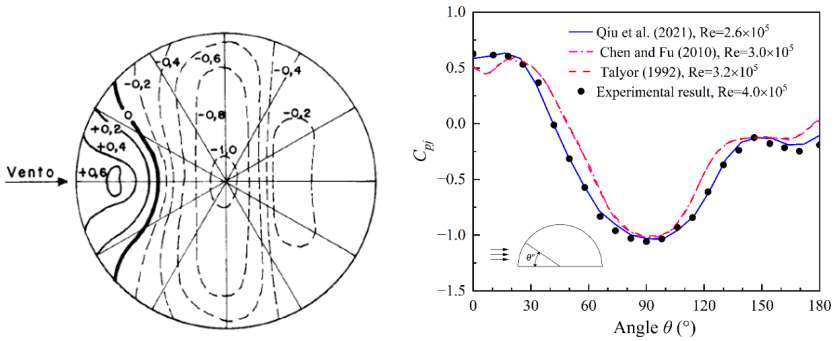

Figure 7. Wind pressure coefficients for a semispherical dome; (a) NBR-6123 standard; (b) reference [12].

Reference [12] lists some of the most notable spherical domes in the world. The dimensions of the Megadome place it among the largest pneumatic domes in the world, and while there are domes with larger diameters, those that reach its height and aspect ratio are rare. It is common for large spherical domes to be reinforced by cables, with the most frequent option being a meridian arrangement, although in some cases, cross-cable arrangements are also used. The option of pneumatic envelopes without reinforcement cables is less frequent, usually limited to domes with smaller diameters. Although the response of pneumatic domes to wind actions is a dynamic phenomenon, the consideration of equivalent

static analyses is reasonable for typical dimensions [12]. Moreover, in this case we considered constant inside pressure, since in [2] we concluded that this hypothesis suffices for large, insufflated domes.

Wind loads were defined considering Brazilian NBR6123 Standard. A characteristic wind speed $v_k = 37\text{m/s}$ = 133km/h was defined. The dome was classified as a temporary building, since public access is restricted for operational wind speeds $v_{op} > 30\text{m/s}$. A dynamic wind pressure $q = 0.613 v_k^2 = 0.85\text{kPa}$ was defined. The external pressure coefficients were assumed by considering an envelope of the coefficients provided by the NBR-6123 and [12], see Figure 7.

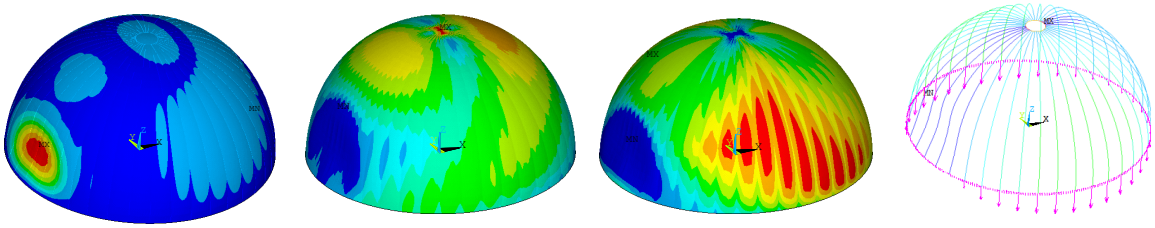

Figure 8. field distributions for Concern conditions: (a) norm of the displacements; (b/c) principal σ_1 and σ_2 stress fields; (d) normal loads on cables and achorages. Maximum values are given in Table 3 for different operational conditions.

Table 3. Some selected maximum results for different operational conditions (without partial safety factors)

Conditions	Beauford wind Scale	v_{op} $[km/h]$	p_0 [mmH2O]	Max. Membrane Displacements [m]	Max. Membrane stress [kN/m]	Max cable loads N_{max} [kN]

Assembling	--	0	30	0,03	4,7	0	0
Attention	Fresh Gales	70	30	0,36	11,4	23,4	37,6
Concern	Storms	100	30	2,02	18,0	47,4	87,9
Preservation	Violent Storms	134	40	2,70	25,0	87,8	196,6

The operational conditions of the Magadome are associated to daily wind forecasts. Several conditions have been considered, including Testing, Instalation, Maintenance, Normal Operation, Attention, Concern and Preservation. The *Concern* condition corresponds to 'Storms' on the Beaufort Scale and, in antecipation of that forescat, the structure must be closed to the public, with access allowed only to the maintenance team. In the *Preservation* conditions, corresponding to 'Violent Storms', the inside pressure must be increased to p_0=0.4kPa, the structure must be sealed, and access allowed only to tackle the envelope's jeopardy. We remark that even moderate winds can generate projectiles such as fallen tree branches [13], which might puncture the pnaumetic envelope, but with low probability of tearing the membrane, under normal operational conditions. At Conservation conditions, the membrane will be under high stresses, and tear progagation cannot be precluded.

Figure 8 shows the overal spatial distribution of main quantities for Concern condition. Maximum values, relevant to the design, are given in Table 3 for differet operational conditions. Since the direction of the wind can be any, all the cables and anchorages must be designed to withstand maximum loads.

4. Conclusions

We have presented a simple yet effective model to cope with the nonlinear static analysis of pneumatic membranes under wind loads, incorporating an effective wrinkling criterion into Argyris' triangular membrane element and deriving a new expression for its pneumatic stiffness, $\boldsymbol{k}_{ext} = \boldsymbol{k}_{\Lambda} + \boldsymbol{k}_{\Phi}$. The model was tested through an inexpensive experiment, comprising the compression of a typical exercise

ball, which corroborated the relevance of the variation of the inside pressure, for moderate-energy systems. However, further numerical explorations, on domes of realistic dimensions and pressure intensities, indicated that this relevance decreases, as the dimensions of the pressure envelopes increase. In the case of a large, insufflated dome, have found that although $\boldsymbol{k}_{\Phi}$ did complete $\boldsymbol{k}_{ext}$, its contribution did not improve convergence of NRM. On the other hand, when wrinkling occurs, $\boldsymbol{k}_{\Lambda}$ was required to guaranty converge, but it was not necessary while the pressure envelope was fully taut. The relative influence of these stiffness terms is an open subject, but our results indicate that, at least for low to moderate-energy pneumatic systems, the external stiffness is fairly approximated by $\widetilde{\boldsymbol{k}}_{ext} \cong \boldsymbol{k}_{\Lambda}$, without degrading convergence, while alleviating computations.

Abstract

In snowy and windy regions, snowdrift may lead to uneven snow distribution on the roofs. Uneven snow distribution cause snow sliding from the edge of roofs and frequent collapsing, which threatens people's lives and properties. With the rapid development of membrane structures, an increasing number of these structures have been built in cold regions at high latitudes and altitudes. In recent years, climate-related disasters including heavy snow on membrane structures for roofing have increased globally. Therefore, the snowdrift on membrane structures has received increasing attention. In this paper, based on the Euler-Euler method in multi-phase flow theory, the Mixture model using the secondary development method for commercial CFD software Fluent is adopted. Based on this simulation approach, the snowdrift on a long-span membrane structure is simulated under different wind velocities and wind directions.

Keywords: snowdrift, membrane structure, numerical simulation, mixture model

1. Introduction

With the rapid development of construction technology, an increasing number of membrane structures have been built in cold regions at high latitudes and altitudes. Considering the wind action, snowdrift may result in uneven snow distribution on the roofs which ultimately leads to structural collapse. Although the membrane structures have great advantages in unique shape and rapid construction, it has deficiencies in bearing the unbalanced snow loads. Thus, accurate prediction of snow distribution on the membrane roof is indispensable to membrane structure design.

In the investigation process of the snowdrift, there are three methods to estimate snowdrift namely field measurement, wind tunnel test, and numerical simulation. Based on the restrictions of uncontrollability of field measurements and similarity requirements of wind tunnel tests, Computational Fluid Dynamics (CFD) takes more attention from researchers. Uematsu[1] conducted a pioneering study suggesting a three-dimensional. numerical simulation for snowdrift and took saltation as well as suspension into consideration. Sundsbø[2] proposed a two-dimensional numerical model for the transient simulation of snow drift where snow transport by saltation and suspension is considered. Okaze[3] develop a new k–ε model that incorporates the effects of snow particles on a flow field. The spatial distributions of the mass flux of drifting snow, wind velocity, and turbulence were simultaneously measured under several different wind-speed conditions. Zhou[4] proposed a quasi-steady method to simulate the redistribution of snow on roofs, which is considered the calculated results of the change rate of snow depth in the previous phase.

On the account of the treatment of the snow phase, the numerical simulation method of CFD can be classified into two methods i.e. the Eulerian-Lagrangian method and the Eulerian-Eulerian method. The Eulerian-Lagrangian method is used to track each trace of snow particles while the snow is regarded as the continuous phase of the air phase in the Eulerian-Eulerian method. It makes the Eulerian-Eulerian method has high computational efficiency.

In recent years, with the rapid development of construction technology of membrane structures, the annual construction quantity of the membrane structure increases year by year. And there are few studies and relevant codes on snow distribution of membrane structures. In this paper, to investigate the snow distribution on membrane structure, a series of numerical simulations are conducted. Based on the Euler-Euler method in multi-phase flow theory, the Mixture model in FLUENT is adopted. Firstly, the governing equation, deposition and erosion, and turbulence model are briefly introduced. Then, the geometrical modelling and computational settings, which are used in the numerical simulation, are recommended. In the final section, the impacts of wind direction and velocity on snow distribution on the air-supported membrane structure are discussed.

2. Numerical modelling

2.1. Governing equations

Simulation methods for snow drifting progress on the roof include the Euler-Euler method and the Euler-Lagrangian method. In this simulation, the snow is taken as a continuous phase in the flow field with multiphase flow theory using the Euler-Euler method. On account of the Euler-Euler method, there are three typical models named the VOF model, the Mixture model and the Eulerian model, respectively. The Mixture model could take the speed difference between the snow and air phase into account, which has higher computational stability[7]. The governing equations consist of the mass continuity equation and momentum conservation equation as Eq.(1) and Eq.(2). The Mixture model is equivalent to one-way coupling, in which the snow phase has no impact on the mass continuity equation and momentum conservation equation of the air phase. The snowdrift simulation is done with the Computational Fluid Dynamics (CFD) software —— FLUENT.

$$\frac{\partial \rho_m}{\partial t} + \nabla\cdot\left(\rho_m u_m\right) = 0 \tag{1}$$

$$\frac{\partial\left(\rho_m \overrightarrow{v_m}\right)}{\partial t} + \nabla\cdot\left(\rho_m v_m \overrightarrow{v_m}\right) = -\nabla p + \nabla\cdot\left[\mu_m\left(\nabla\overrightarrow{v_m} + \nabla\overrightarrow{v_m}^T\right)\right] + \rho_m \vec{g} + \vec{F} \tag{2}$$

where ρ_{m} is the density of the mixture phase, v_{m} is the velocity of the mixture phase of air and snow, and μ_{m} is the mixture dynamic viscosity.

2.2. Deposition and erosion model

The wall shear stress is a significant parameter which can determine whether erosion and deposition occur. When the wall shear stress is more than the gravity and internal force of snow particles, deposition takes place. However, it is difficult to obtain the wall shear stress during snowdrift. In most of the previous studies on snow drifting, the wall shear stress is generally calculated from the friction velocity through logarithmic law. Hence the discriminant method of erosion and deposition is transformed to whether the friction velocity is larger than the threshold friction velocity or not.

The relationship between friction velocity and snow mass flux has been investigated. Beyers[8] indicated that snow erosion would occur on the occasion that the friction velocity exceeds the threshold friction velocity, as shown in Eq.(3).

$$q_s \begin{cases} q_{ero} = A_{ero}\left(u_*^2 - u_{*t}^2\right) & u_* > u_{*t} \\ q_{dep} = \rho_s f w_f \dfrac{u_{*t}^2 - u_*^2}{u_{*t}^2} & u_* \le u_{*t} \end{cases} \tag{3}$$

where f is the snow concentration, A_{ero} is the empirical constant which is set as 7.0×10^{-4}, and w_f is snowfall velocity.

2.3. Turbulence model

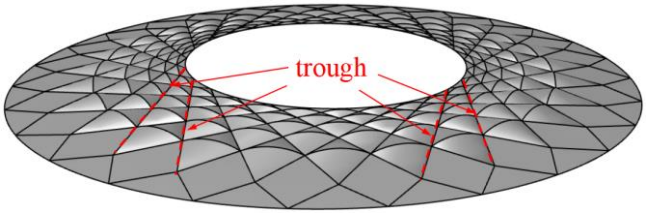
The turbulence model has been widely explored to predict complex turbulent flow fields around a bluff body and the validity of turbulence models has been verified. The turbulence model used for snow drifting includes the RSM model, SST *k-ε* model, *k-ε* model[8] and *k-kl-ω* mode[7]. And the results of the turbulence model mentioned above are in good agreement with filed observation data or test data. The model can effectively describe the transition from laminar to turbulent flow in the boundary layer, and the transition from saltation to suspension motion during snowdrift is similar to the transition from laminar to turbulent. Hence the model is suitable for simulating snowdrift on roofs. To better reproduce the movement of snow particles on the roof, an approach based on the Realizable *k-kl-ω* model is adopted in this study. Specifically, the turbulence equations are as follows.

$$\frac{Dk_T}{Dt} = P_{k_T} + R + R_{NAT} - wk_T - D_T + \frac{\partial}{\partial x_j}\left[\left(v + \frac{\alpha_T}{\alpha k}\right)\frac{\partial k_T}{\partial x_j}\right] \tag{4}$$

$$\frac{Dk_L}{Dt} = P_{k_L} - R - R_{NAT} - D_L + \frac{\partial}{\partial x_j}\left[v\frac{\partial k_L}{\partial x_j}\right] \tag{5}$$

$$\frac{D\omega}{Dt} = C_{\omega 1}\frac{\omega}{k_T}P_{k_T} + \left(\frac{C_\omega R}{f_\omega} - 1\right)(R + R_{NAT})\frac{\omega}{k_T} - C_{\omega 2}\omega^2 + C_{\omega 3} f_\omega \alpha_T f_\omega^2 \frac{\sqrt{k_T}}{d^3} + \frac{\partial}{\partial x_j}\left[\left(v + \frac{\alpha_T}{\alpha_k}\right)\frac{\partial k_T}{\partial x_j}\right] \tag{6}$$

where k_T is the turbulent kinetic energy, k_L is the laminar kinetic energy, ω is the inverse turbulent time scale, P_{kT} and P_{kL} are the production term of turbulence and laminar kinetic energy respectively. D_T and D_L are diffusion terms. $C_{\omega 1}$, $C_{\omega 2}$ and $C_{\omega 3}$ are constant terms.



3. Numerical simulation of snowdrift

3.1. Geometrical modelling

The membrane structure is located in Dalian, northeast China, a representative cold region with heavy snowfall. This cold region has a medium-latitude monsoon climate. Referring to meteorological history data, Dalian has an extremely high temperature of 35.3 °C extremely low temperature of -20.1 °C, and a maximum snow depth of 136 mm. This membrane structure adopts an oblique double-cable system, and the roof material is PVC-coated fabric, as shown in Figure1 (a). The span of the membrane structure is about 253 m with a covered area of 42994 m^2, and the highest point of the membrane part is about 54.25 m. Because the curvature of the membrane structure is small and it has fan-shaped bulges locally, snow stacks in the trough between the bulges (Figure1(b)). For safety, it was necessary to simulate the snow distribution on this membrane structure.

(a) photo of the long-span membrane structure

(b) Lateral view of membrane structure

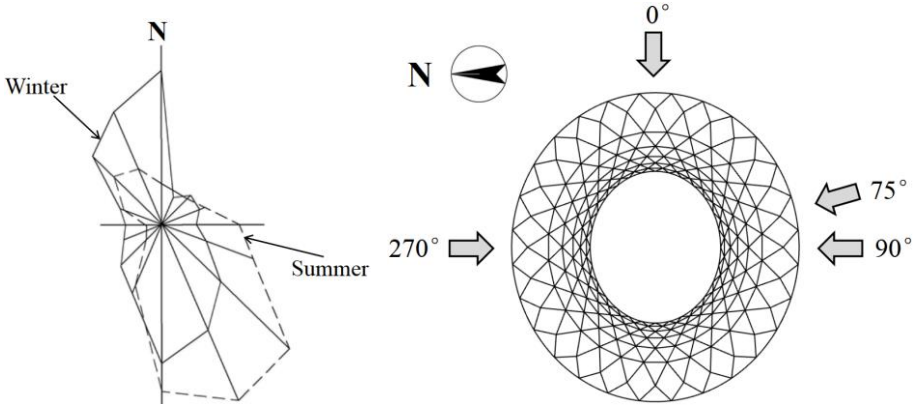


Figure 1. Membrane structure.

3.2. Computational settings

Figure 2 shows the wind rose map of Dalian and the orientation of the membrane structure. Because the dominant wind direction of Dalian in winter is north to south, we selected wind directions of 90 ° and 270 ° to simulate the snowdrift. Considering the symmetry of the structure, 0 ° is also a significant wind direction that affects snow distribution. This membrane structure was built on the seaside, and wind often blows from land to the ocean during the winter. Hence, a wind direction of 75 ° is the prevailing wind direction in the winter. Considering the asymmetry of the structure and the prevailing wind direction of Dalian in the winter, snowdrift under four wind directions was simulated. The wind directions were 0 ° , 75 ° , 90 ° , and 270 ° , as shown in Figure 2.

A full-scale model is established for the membrane structure in Figure 3. To ignore the impact of the boundary of the computational region, the size of the computational region of the numerical simulation is 10L(x)×21B(y)×7H(z). L, B, and H represent the length and width and height of the membrane structure, respectively. Considering the efficiently developed flow field, the model is placed at 7B from the entrance of the computational region. The computational domain and boundary conditions are summarized in figure 3. The total number of the unstructured mesh employed in this study is around 4.8 million cells and the growth factor of the grid is 1.2.

The SIMPLE algorithm is used to simulate the transportation of snow particles. Convergence is assumed to be obtained when all scaled residuals level off and reach a minimum of 10^{-7} for continuity, 10^{-7} for x velocity, y velocity, and z velocity. The height of the saltation layer is 0.05 m. The snow particle density is 150 kg/m^3, the snow particle diameter is 0.0005 m, and the threshold friction velocity is 0.2 m/s.

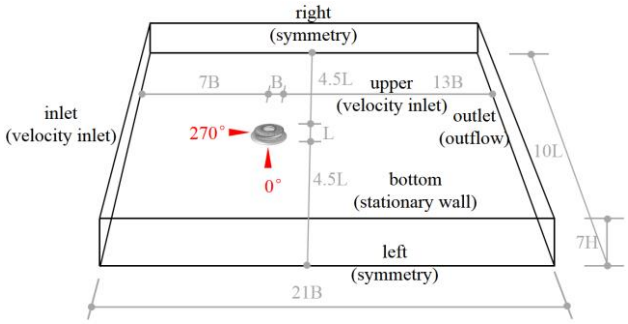
Figure 2. The schematic diagram of the wind rose map and wind direction.



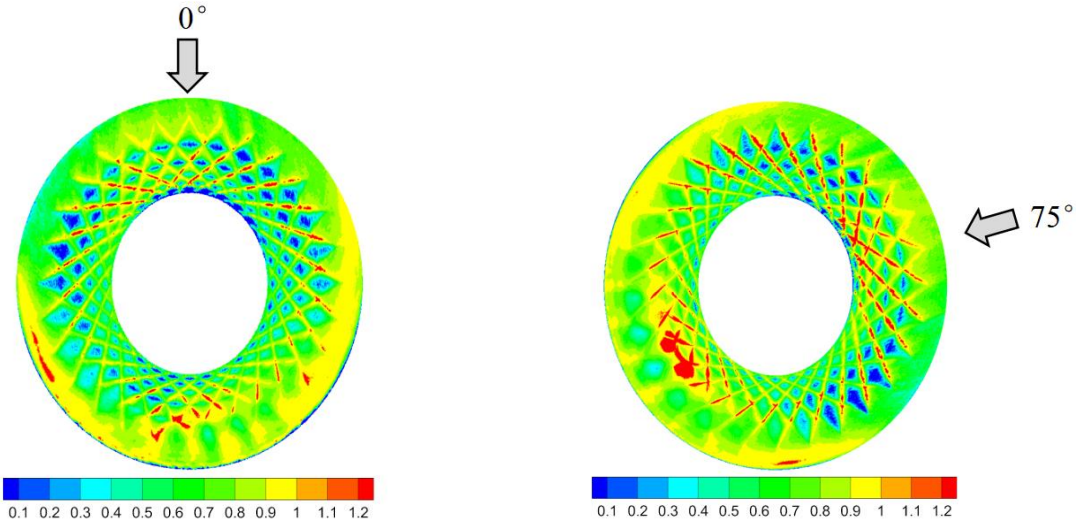


Figure 3. Computational domain and boundary conditions.

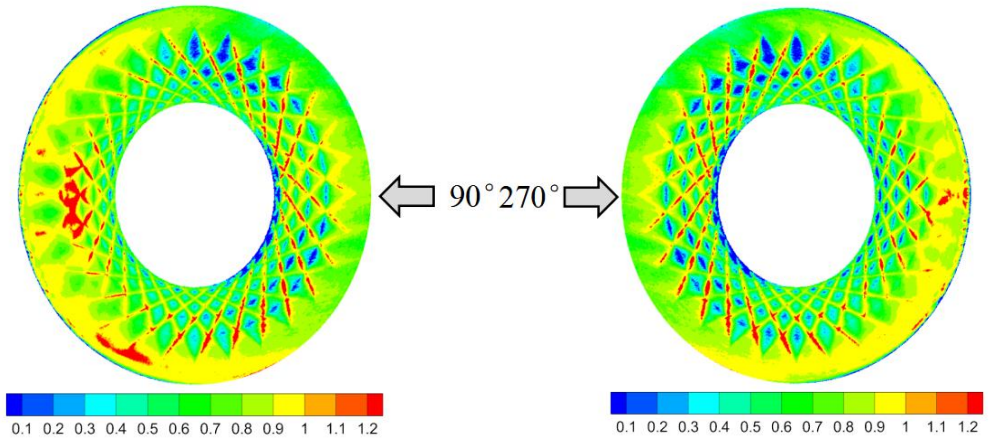
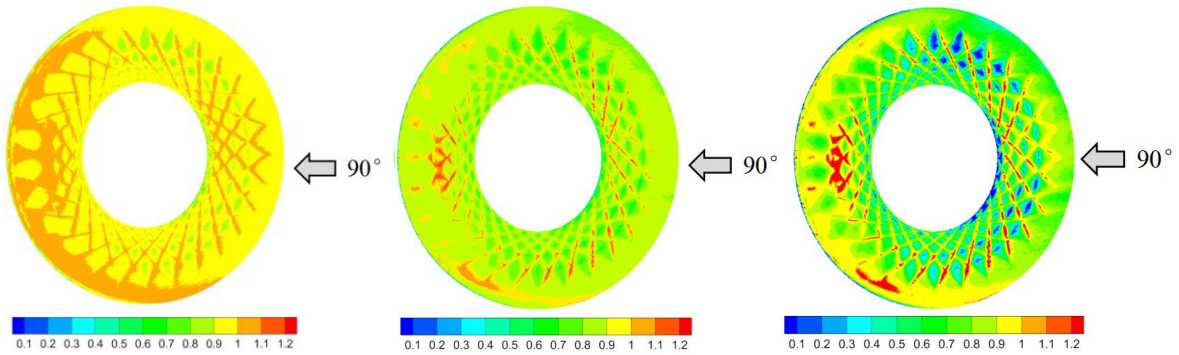


3.2. Results and discussion

3.2.1. Impact of wind direction

Wind direction is a dispensable parameter which influences the snow distribution on the air-supported membrane structure. That is attributed that wind direction has an impact on the flow field around the roof. Figure 7 shows the snow distribution on the air-supported membrane structure under the wind direction of 0, 75, 90, and 270° with the wind velocity of 10m/s, respectively. Under all wind directions, the windward section of the roof presents to be erosion. The value of the snow distribution trend is 0.4. The deposition occurs throughout the entire region of the leeward side. The maximum normalized dimensionless snow depth occurs in the trough between the bulges which reaches 1.2. In the leeward area, considering the flow separation, the snow particles blown away from the windward area reattach to the surface of the structure in the leeward area which leads to snow deposition in the leeward area and snow erosion in the windward area.

(a) 0° (b) 75°



(c) 90° (d) 270°

Figure 4. Snow distribution under different wind directions.

3.2.2. Impact of wind velocity

Wind velocity is the significant influential factor determining snow distribution. Figure 8 shows the snow distribution under wind velocity of 6, 8, and 10m/s with the wind direction of 90 ° . When the wind velocity is 6m/s, nearly no erosion and deposition occurs on the structure and the normalized dimensionless snow depth is around 1 in most areas of the air-supported membrane structure. A significant increase in snow deposition and erosion with the increase in wind velocity can be concluded from figure 5. Meanwhile, the difference in the region of the erosion area between different wind velocities may not be obvious. This is because the wind velocity does not affect the position of separation of the flow which influences whether snow particles are blown away or not. For the wind velocity of 6m/s, the normalized dimensionless snow depth in the snow erosion area reaches 0.83. Additionally, the minimum normalized dimensionless snow depth with the wind velocity of 8m/s and 10m/s is 0.41 and 0.19.

(a) 6m/s (b) 8m/s (c) 10m/s

Figure 5. Snow distribution under different wind velocities.

4. Conclusion: submission of contributions

The numerical simulation based on the Mixture multiphase model was conducted to analyse the relationship between the wind direction, wind velocity and normalized dimensionless snow depth. The snowpack is mainly eroded on the windward side and deposited on the leeward of the structure under

wind action. Meanwhile, it is noticed that the maximum and minimum normalized dimensionless snow depth has a positive correlation with wind velocity and the difference in the region of the erosion area between different wind velocities may not be obvious. The reason could be wind velocity does not affect the position of flow separation.

Abstract

This paper presents a unique application of tensile membrane as a shield for privacy protection purpose. The privacy protection membrane structure is located within the compound of National Palace in Kuala Lumpur Malaysia. The necessity for the privacy screen arises from the fact there are highrise condominium buildings surrounding the compound of National Palace and privacy protection of an outdoor private area within the palace is needed. The project was managed by Public Work Department of Malaysia. The final design of the privacy screen is a frame supported PTFE membrane structure. The height of the membrane screen structure is 11.36 m with cantilever parts of 8.53 m(front) and 3 m(back). The total length of the screen is about 25 m in plan. Several challenges were faced during the construction. First and foremost was the lack of information on the supporting RC structure. Rebound hammer, determination of reinforcement using ferroscan equipment and concrete coring were carried out. Other challenge was site accessibility for logistic and installation purpose which called for solution of using high capacity crane (120T) and smaller individual segments for the ease of steel frame structure erection. These challenges together with strict rules regarding working time and entry check for security reason into compound of National Palace are described in the paper.

Keywords: PTFE membrane, privacy screen structure

1. Introduction

Due to its lightweight and flexible characteristic, tensile membrane is suitable to be formed into surface with large area. Such large-surface-area membrane can be used in application such as outdoor screen, all-weather purpose cover over construction site, sunlight shields over surface of building etc. With proper form-finding and design, the membrane surface can be formed into anti-clastic surface which adds element of aesthetic apart from serving its intended function.

Figure 1 shows the National Place of Malaysia which is located in the city of Kuala Lumpur. The location of the National Palace is surrounded by highrise buildings as shown in Figure 2. Due to the necessity of privacy protection of an outdoor area within the compound of the palace, Public Works Department of Malaysia as project management consultant was tasked to design a privacy protection structure. The design called for a structure in the form of a privacy screen. Figure 3 shows the conceptual idea of the privacy screen.

This paper describes the planning work and construction of this unique application of tensioned fabric structure as a privacy screen. Challenges faced and solutions adopted are presented.

2. Structural system of the privacy screen

The final design of the privacy screen is a frame supported PTFE membrane structure. The height of the membrane screen structure is 11.36 m with cantilever parts of 8.53 m(front) and 3 m(back). The total length of the screen is about 25 m in plan. Figure 4 shows the overall structural system.

Figure 1. National Palace of Malaysia.

Figure 2. Highrise buildings surrounding National Palace Malaysia.

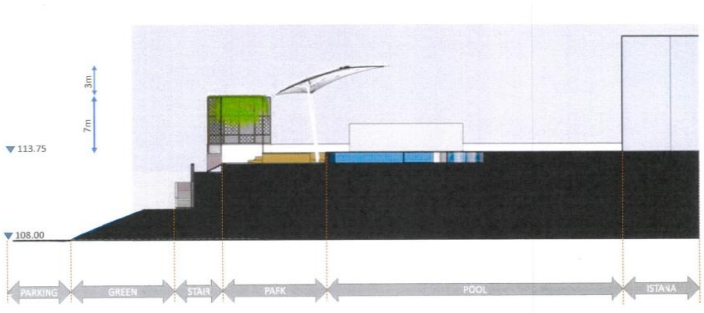

Figure 3. Conceptual idea of a privacy protection structure for a private area within National Palace Malaysia.

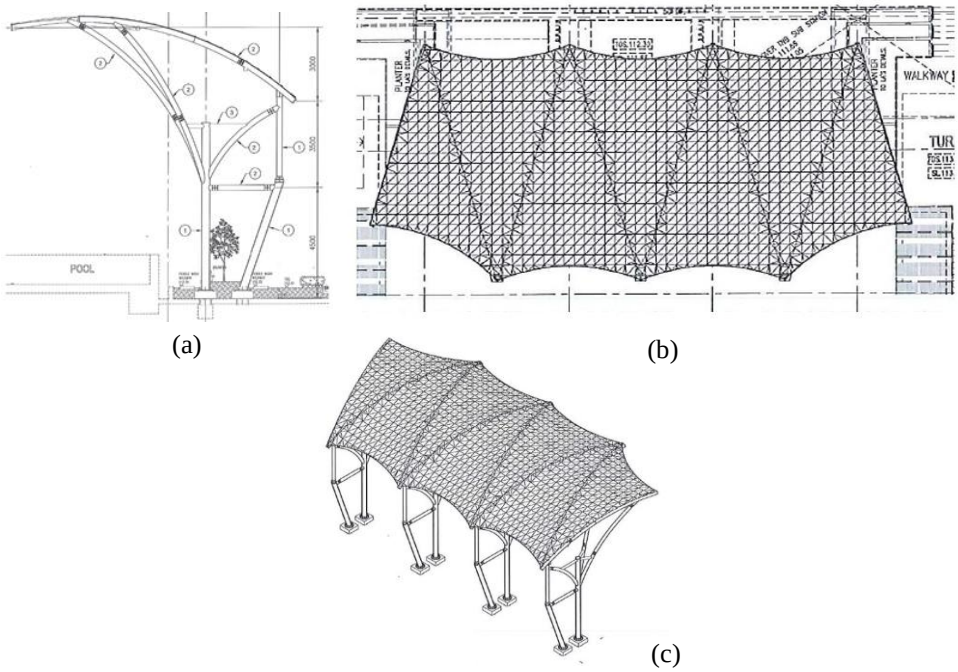

Figure 4. PTFE membrane privacy screen structure of National Palace Malaysia: (a) plan view, (b) site view and (c) 3D view.

The whole project took six month to complete. Several challenges were faced during the planning of the structure. First of foremost was the lack of information regarding the structural conditions of existing RC beams to be used as supporting or anchoring points of the tensioned fabric structure(see Figure 4a). Figure 5 shows another view of the RC beams where the frame of the privacy screen structure was to be supported. The support details is also shown.

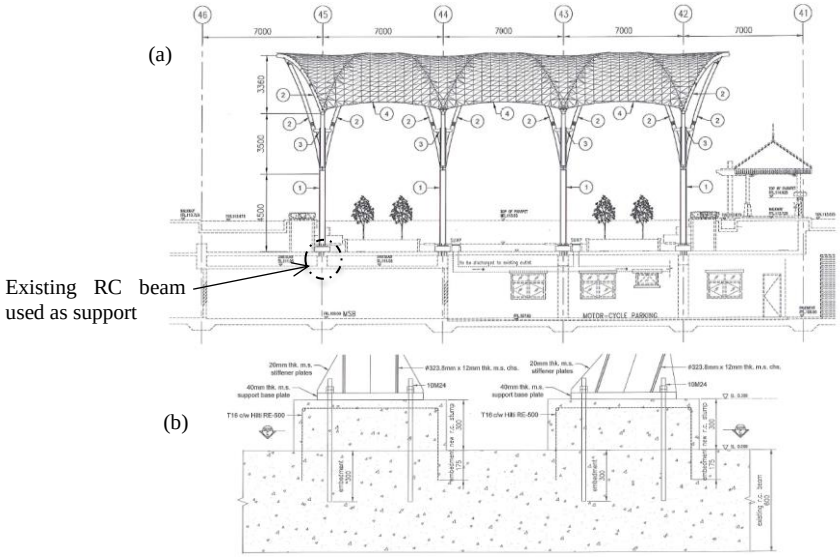

Figure 5. (a) Existing RC structure supporting the frame of privacy screen structure; (b) Details of the support.

Non-destructive tests such as rebound hammer test and ferroscan were carried out on existing structure to ascertain the strength and to obtain more information about the structures – e.g. location of reinforcement bars. Concrete coring was also carried out in order to further confirm the compressive capacity of concrete of the existing structure. Site accessibility and logistic were other problems faced. In order to overcome this problem, crane with capacity of 120 T was used for better reach purpose. At the same time, steel members were split into smaller individual components for ease of lifting during installation. Figure 6 shows the information about size of members used for the frame of the privacy screen structure. Details of fabric to frame connections are also shown.

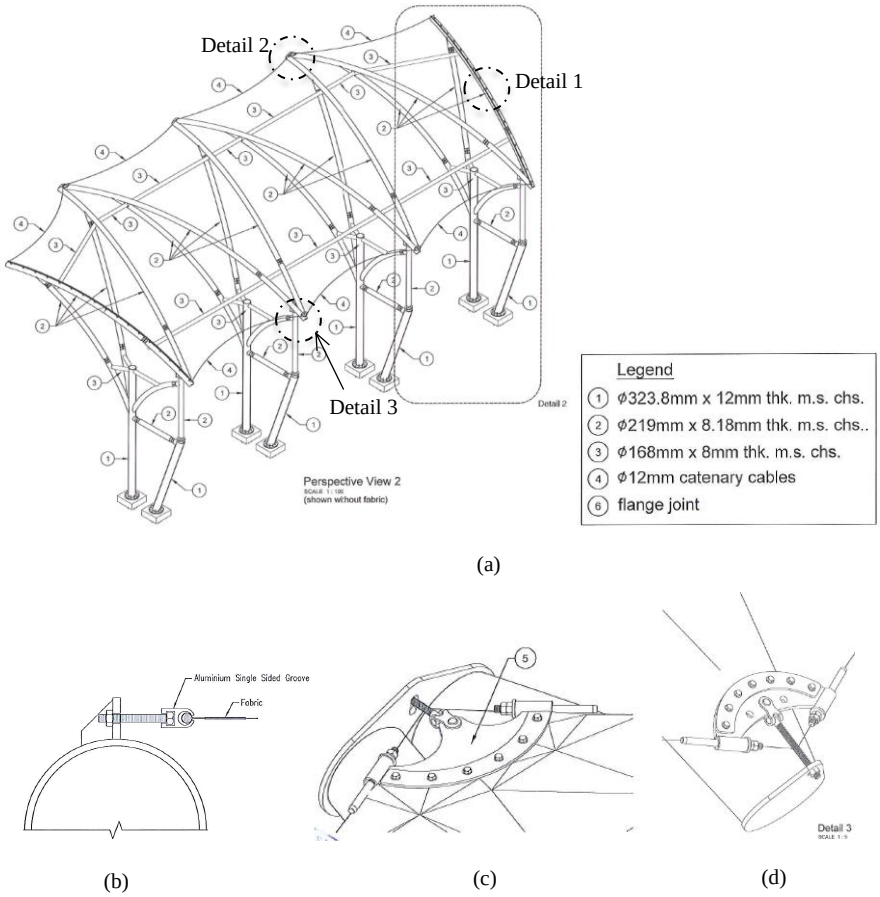

Figure 6. (a) Member sizes used for the different parts of the frame of the privacy screen structure; (b) Detail 1; (c) Detail 2; (d) Detail 3.

Apart from technical issues mentioned above, there was also problem due to strict working time according to requirements of National Palace which has resulted in longer project duration. Strict workers' background check prior to entering work site was another rule that has to be adhered to for security of National Palace.

4. Construction process

All components of the steel frames and fabrics were first fabricated in the factory and later transported to site (Figure 7). With the use of 120 T crane, the frame was first erected(Figure 8). After the completion of the frame, tensioned fabric was then installed on the frame structure(Figure 9). The final completed PTFE privacy screen tensioned fabric structure is shown in Figure 10.

Figure 7. Fabrication of components of steel frame.

Figure 8. Erection of steel frame at site.

Figure 9. Installation of tensioned fabric on the steel frame.

Figure 10. Completed PTFE privacy screen tensioned fabric structure.

5. Conclusion

The planning and construction of PTFE privacy screen tensioned fabric structure within the compound of National Palace Malaysia has been described. It can be considered as a unique application of tensioned fabric structure for privacy protection. It also showcases the diverse application of tensioned fabric structure – from large span roof structure to small scale flexible screen structure.

Abstract

Roofs of stadium buildings generally require a large opening in the center of the roof, and many examples of roof structures composed of radially arranged cables have been constructed in recent years in stadium buildings outside of Japan. This structure is a lightweight structure in which cables are radially arranged between the inner tension ring and the outer compression ring. In a previous report [1] considering this structure for Japan, the authors reported on wind tunnel tests and numerical analyses of a model with one tension ring and two compression rings. However, the wind tunnel tests in the previous papers used rigid models of the initial geometry, so the deformation of the roof surface was not taken into consideration in the wind load evaluation. In addition, with recent improvements in computer processing power, the use of computational fluid dynamics (CFD) analysis is expected to be utilized in the wind-resistant design of buildings. Therefore, in this paper, the authors proposed a convergence calculation to obtain the response after deformation of the roof based on CFD analysis and static analysis iterations to understand the effects of roof deformation on the wind pressure characteristics and structural behavior of this structure.

Keywords: lightweight structure, stadium, tension structure, cable, CFD analysis

1. Introduction

Roofs of stadium buildings generally require a large opening in the center of the roof, and many examples of roof structures composed of radially arranged cables have been constructed in recent years in stadium buildings outside of Japan. This structure is a lightweight structure in which cables are radially arranged between the inner tension ring and the outer compression ring. In previous papers [1, 2], the authors have investigated the structural behavior using wind tunnel tests and numerical analysis with a view to adopt this structure in Japan. In those previous papers, it was reported that the deformation of this structure under wind load is more than 1/100 of the cantilever length, which is large deformation. There are also some cases outside Japan where deformation of more than 1/20 of the cantilever length is allowed [3, 4]. On the other hand, the wind tunnel test in the previous paper [1] was conducted on a rigid model with initial geometry, so the deformation of the roof surface was not considered in the wind load evaluation.

Therefore, in this paper, the authors consider roof deformation from convergence calculations based on computational fluid dynamics (CFD) analysis and static analysis iterations to understand the effect of roof deformation on the wind pressure characteristics and structural behavior of this structure.

2. Study methodology and model overview

The study flow is shown in Figure 1. First, a CFD analysis (CFD-1; hereinafter, called CFD-*n*) is performed on the initial shaped roof model to determine the mean wind force coefficient C_f. The *n* in CFD-*n* indicates the number of iterations of the calculation. Next, a static numerical analysis (FEM-1; hereinafter, called FEM-*n*) is performed using the obtained C_f to determine the structural behavior. Then, CFD analysis (CFD-2) and static numerical analysis (FEM-2) are performed again using the deformed roof shape from FEM-1 as the model. This iteration was performed five times (*n*=1-5). Roof deformation is evaluated as a time-averaged value during the analysis time (equivalent to 10 minutes on a real scale). In this paper, the convergence calculation was judged to have converged when the displacement difference (δ_n-δ_{n-1}) between the displacements δ_n and δ_{n-1} obtained from the n^{th} and $(n\text{-}1)^{th}$ FEMs were less than 1/300 of the cantilever length 50 m.

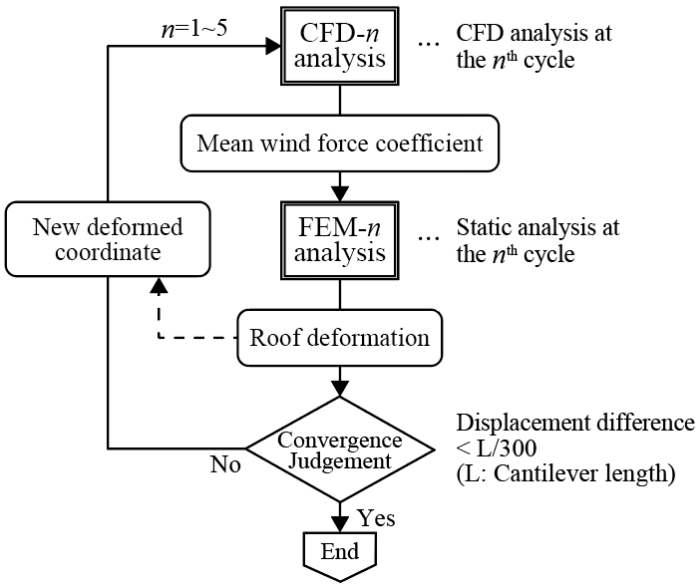

Figure 1. Consideration flowchart

The study model is shown in Figure 2. In this paper, only the roof structure is considered, and it is circular. Two roof configurations were used: Model A has one tension ring and two compression rings, and model B has two tension rings and one compression ring. The roof membrane material was attached to the lower radial cable in model A and to the upper radial cable in model B. The height of the roof surface was 24 m at the eaves.

3. Numerical analysis overview

3.1. CFD analysis overview

An overview of the CFD analysis is shown in Figure 3. The model for the CFD analysis is assumed to be 1/500 of the actual size, with a total length of 560 mm and a cantilever length of 100 mm. This scale was adjusted to the model of the wind tunnel test conducted separately. In addition, only the roof and stand were used to reduce the analysis load. The CFD analysis was performed using scFlow (ver. v2020) and the turbulence model is the Smagorinsky model of LES. The governing equations were the incompressible Navier-Stokes equations and the continuity equation. The lattice system is an unstructured lattice with polyhedral. The discretization method was the finite volume method, with a gamma scheme for the discretization of the spatial term and a second-order precision implicit method for the discretization of the time term. The inflow condition is a uniform flow simulating only the vertical profile of wind velocity in surface roughness category III in Japan. The outflow condition was static pressure = 0. The evaluation time was set to be equivalent to approximately 10 minutes on the real scale, and the time increments for the calculations were 1.3×10^{-3} seconds. The analysis area was 1.2 m x 0.9 m and 3 m in length. The boundary conditions were set as no-slip boundaries on the ground surface and model surface, and free-slip boundaries on the sky and sides. The number of elements is approximately 4 million.

3.2. Static numerical analysis overview

A static numerical analysis (FEM) overview is shown in Figure 4. The radial cable was modeled as an incompressible material and divided into eight sections. The suspension cables connecting the upper and lower radial cables were placed at equal intervals and were made of incompressible material. The boundary condition was pin support at the joints of the compression rings and radial cables. The wind load was calculated from a reference wind speed of 41 m/s at the roof eave height to a design velocity pressure of 1,000 N/m². In addition, considering the mean wind force coefficient and burden area, loads were placed as concentrated loads at eight nodes of the radial cable. The self-weight and the membrane weight of 20 N/m^2 are considered as the fixed load (long-term load). The self-weight is divided by 1.2 times the cable self-weight of the tension ring to account for the weight of the cable joint. The initial tension force was set at 2,000 kN and 4,000 kN, the sum of the upper and lower cable axial forces of the radial cable under long-term loading.

Figure 4. Static numerical analysis overview

4. Numerical analysis results

4.1. CFD analysis results

The mean wind force coefficient C_f obtained from the CFD analysis at an initial tension of 2,000 kN is shown in Figure 5. Focusing on model A, CFD-1 through CFD-2 showed properties with larger positive C_f on the windward side. This is thought to be due to deformation from the initial shape in FEM-1, creating areas where wind tends to stagnate on the roof surface. After CFD-2, C_f tended to increase at the points where there were no suspension cables (even points in Fig. 5). On the other hand, no significant changes were observed from CFD-1 on the leeward side. Focusing on model B, the positive C_f was larger in the center of the roof on the windward side. This is thought to be due to the loss of tension force in the suspension cables due to the windward blowdown load. On the other hand, on the leeward side, no significant changes were observed from CFD-1 as in model A. This suggests that the upward convex deformation shape has a small effect on the wind pressure characteristics.

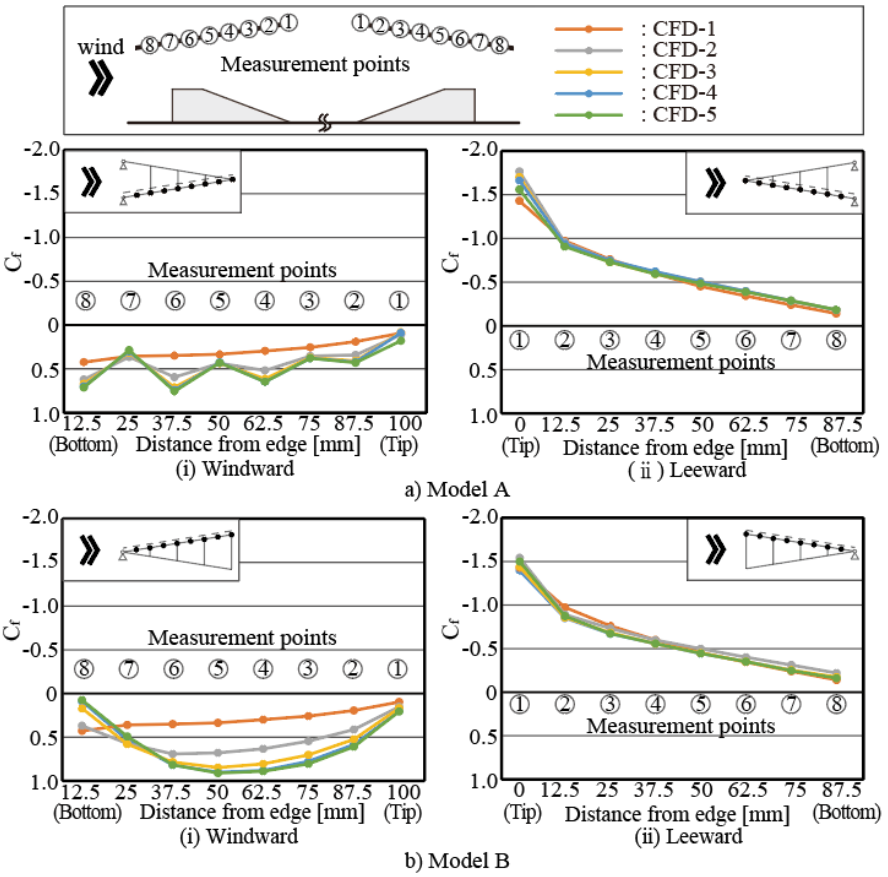

Figure 5. Mean wind force coefficient (Initial tension force 2,000 kN)

The convergence conditions of the displacements with the number of iterations are shown in Figure 6. For both models, the number of convergence calculations decreased as the initial tension increased. The displacement tended to decrease rapidly from FEM-1 to FEM-2.

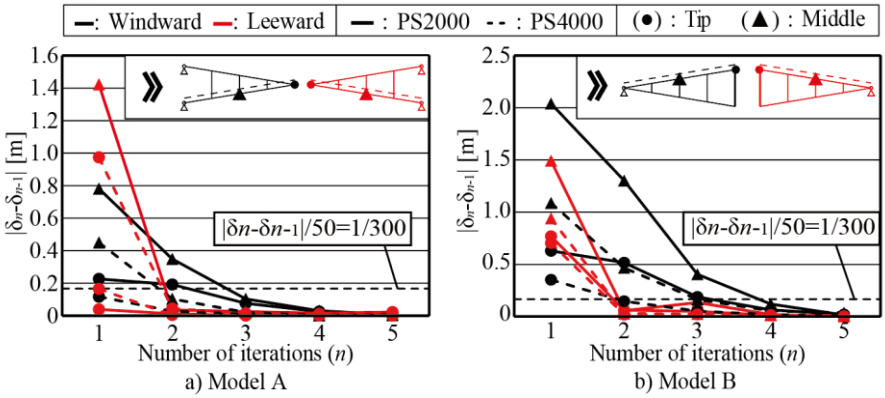

Figure 6. Convergence conditions of the displacements

Figures 7, 8 and Table 1 show that the roof deformation and the radial cable axial force after convergence increased from orthogonal to windward direction for both models A and B. No significant deformation changes were observed on the leeward side. The radial cable axial force showed an overall increasing trend with deformation.

Focusing on model A, the vertical displacement was 1.78 times the value at convergence compared with FEM-1 for an initial tension force of 2,000 kN at the windward tip. For the initial tension force of 4,000 kN, the windward tip was 1.12 times the initial tension force of 2,000 kN, and the rate of increase was smaller than for the initial tension force of 2,000 kN. For these roof deformations, the radial cable axial force increases by about 1.10 times the upper radial cable axial force for both windward and leeward sides at an initial tension force of 2,000 kN. On the other hand, at an initial tension force of 4,000 kN, the increase in axial force of the upper radial cable was less than 1.02 times.

Focusing on model B, the vertical displacement was 1.77 times the deformation at the windward tip at convergence compared with FEM-1 for an initial tension force of 2,000 kN, whereas for an initial tension force of 4,000 kN, the windward tip was 1.30 times the deformation. The radial cable axial force increases more than 1.12 times for the upper and 1.21 times and lower radial cable axial forces in all regions at an initial tension force of 2,000 kN. On the other hand, the increase in axial force at an initial tension force of 4,000 kN was less than 1.04 times for both the upper and lower radial cables.

The above results suggest the need for a wind load evaluation that takes deformation into account, since models with small initial tension force and initial deformation (FEM-1) of more than about 1/40 of the cantilever length for model A and more than about 1/20 of the cantilever length for model B may experience increased deformation and axial force due to repeated calculations. On the other hand, when the initial deformation (FEM-1) is less than about 1/60 of the cantilever length for model A and 1/40 of the cantilever length for model B, the wind load evaluation considering the deformation suggests that the deformation only affects the deformation.

		FEM-2	-0.255 (1.12)	-0.712 (1.17)	0.058 (1.07)	0.858 (1.05)	2,681 (1.02)	1,445 (0.97)	1,512 (0.98)	2,547 (1.02)
Model B	PS2,000	Long-term load	-0.375	-0.541	-0.375	-0.541	716	1,308	716	1,308
		FEM-1	-1.004	-2.581	0.395	0.952	893	1,560	1,380	1,001
		FEM-4	-1.774 (1.77)	-4.410 (1.71)	0.270 (0.68)	0.739 (0.78)	1,055 (1.18)	1,881 (1.21)	1,541 (1.12)	1,283 (1.28)
	PS4,000	Long-term load	-0.317	-0.304	-0.317	-0.304	1,737	2,263	1,737	2,263
		FEM-1	-0.671	-1.392	0.387	0.636	1,765	2,391	2,192	1,898
		FEM-3	-0.872 (1.30)	-2.023 (1.45)	0.383 (0.99)	0.640 (1.01)	1,764 (1.00)	2,491 (1.04)	2,229 (1.02)	1,942 (1.02)

4. Conclusion

In this paper, the effects of the roof deformation of this structure and wind response characteristics were investigated. The results suggest the need for wind load evaluation that takes deformation into account, since models with low initial tension force and large initial deformation may experience increased deformation and axial force due to repeated calculations. On the other hand, when the initial deformation (FEM-1) is less than about 1/60 of the cantilever length for model A and 1/40 of the cantilever length for model B, the wind load evaluation considering the deformation suggests that the deformation only affects the deformation.

Abstract

This study focuses on the temperature field analysis of air-supported membrane structures. A numerical model under various fire conditions of rectangular air-supported membrane structures for coal storage sheds was established using the Pyrosim field simulation software. An empirical formula for the relationship between the maximum temperature and the spatial position was proposed. This paper analysed flue gas emissions and construction. The influence of building height and the power of the fire source on the maximum temperature was also investigated.

This study shows that the R-squared for the maximum temperature curve obtained by the numerical simulation and the established mathematical model falls within 0.92-0.94, indicating that the proposed empirical formula correlates well with the simulation. The paper also discusses the relationship between the maximum temperature and the spatial position of the fire source in the combustion process. The power of the fire source is found to be the main factor affecting the maximum temperature. Under the same conditions, the maximum temperature is found to be inversely proportional to the building height. Results also indicated that the mechanical smoke extraction system has a specific cooling effect, but this effect is limited for the air-supported membrane structure coal storage shed with large space.

Keywords: space structure, air supported membrane structures, mathematical model, temperature field

1. Introduction

Over the past few years, the importance of environmental protection has significantly increased in China, leading to the closure of many coal yards in power plants. During this time, the use of air-supported membrane structures has become increasingly popular due to their flexible space, simple construction, and economic benefits. As these structures rely on inflation to provide a stable closed structure, understanding the temperature field during a fire is crucial. Domestic and foreign scholars have used relevant software to simulate fires in small and large-scale structures and analyze temperature field characteristics. For example, Li Guoqiang [1-2] et al. used a two-region model and temperature unsteady model to analyze the fire numerical analysis of large-span spatial structures and fitted an empirical temperature rise model for specific structures. However, this model is not universal and needs to be re-fitted for different projects. Other researchers [3] have used computational fluid dynamics software to simulate different fire scenarios in large space buildings, considering factors such as smoke exhaust systems. Xue Suduo[4-5] simulated fire scenes using the FDS program and established a mathematical model of the temperature field related to time, taking into account the influence of smoke emission on air temperature rise in large space building fires. Finally, other scholars [6-7] have studied the temperature distribution and smoke diffusion law of cylindrical inflatable membrane structures under fire using CFD numerical models, obtaining temperature distribution and smoke diffusion laws for membrane structures with different ignition points and smoke exhaust measures.

2. Fire model

2.1. Fire simulation parameters

In the context of closed renovation projects of coal yards in power plants, gas film structures are commonly used, particularly rectangular gas-supported membrane structures. Gas film coal storage sheds require fire-fighting equipment and a certain spray area. Experience has shown that the actual combustion area during a warehouse fire is generally between 10m2-20m2. Therefore, assuming a stable fire source, a cube of 4m × 4m × 1m with a combustion area of 16m2 is used to simulate a fire. Previous research on combustion tests and simulations have shown that adverse fire conditions mostly occur during the beginning and full combustion stages. However, the ignition and recession stages of fire are not typically considered. The heat release rate of a fire is proportional to the square of time, which is known as 't square fire'. The coal stored in these sheds tends to burn at a medium speed, and the simulation uses the fast fire coefficient with a growth coefficient α of 0.044kw/s2 to ensure the structure's safety. According to the technical standard of building smoke prevention and exhaust system [8] GB51251-2017, the heat release rate of the fire is determined to be 4MW and 20MW.

The coal shed is equipped with 6 evacuation doors, 16 air supply outlets, and 10 exhaust outlets. The door opening size is 1.5m × 2m, while the air inlet and outlet sizes are 1m × 1m and 0.85m × 0.85m, respectively. The setting of the supplementary air volume and exhaust air volume is based on the condition that the structure does not collapse due to air leakage without burning through. The pressure difference between the interior and exterior of the structure remains constant, and the parameters are established such that the intake air volume is equivalent to the total air leakage.

The mechanical smoke exhaust volume of the smoke outlet is determined using the calculation method provided in the American standard NFPA 92B [9]. It is important to note that the parameters for the intake air and exhaust air are determined with the safety of the structure in mind, such that it can withstand the air leakage without collapsing.

$$m_p = 0.071 Q_c^{1/3} Z^{5/3} + 0.0018 Q_c \tag{1}$$

$$V = m_p / \rho_0 + Q_c / \rho_0 T_0 C_p \tag{2}$$

In the formula: the mass flow rate of the plume, kg / s ; convective heat release rate (about 0.7 Q), KW ; is the height above the burning surface, m ; the volume flow rate of plume, smoke exhaust volume, m3 / s ;

ambient air density, kg / m3; for the ambient temperature (take 293K), K; is the specific heat capacity of air, 1.02KJ / (kg °C). The air leakage at the door opening is calculated according to the formula in the ' Air Membrane Structure Design and Construction Guide '[8] :

$$P = 1/2 \times \rho \times v^2 \tag{3}$$

In the formula: for the pressure difference between the inside and outside of the inflatable membrane, Pa ; for air velocity ; m / s ; the air density is 1.205kg / m3 at 20 °C.

The position of the air supply outlet is shown in Figure1. When the top surface exhausts, the fan is evenly arranged on the top surface of the membrane, and the size and number of the exhaust outlets are the same as the side wall exhaust. The setting of the air intake and exhaust volume of the fan is shown in table 1.

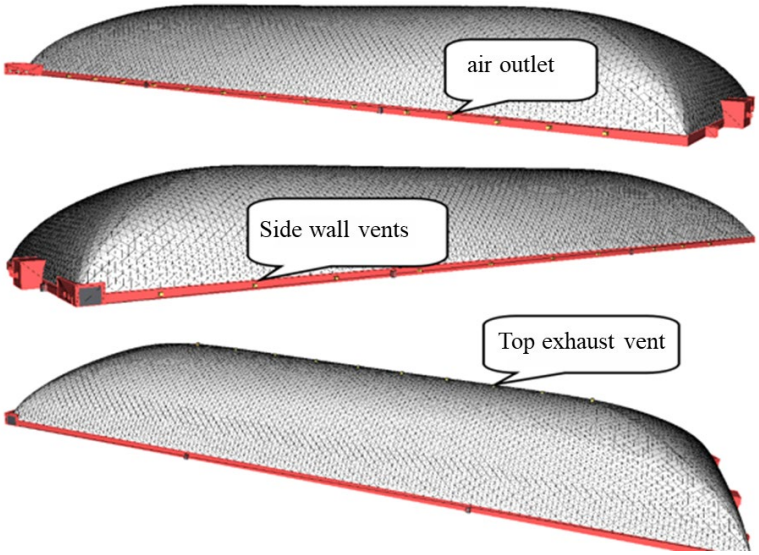

Figure1. Location of fan

Table 1. Fan inlet air volume and exhaust air volume setting

smoke exhaust mode	Leakage velocity of door opening(m^3/s)	inlet air velocity /(m^3/s)	Exhaust rate / (m^3/s)
Evacuation door smoke	251	15.68/each	
Side wall mechanical smoke exhaust	251	21/ each	8.5/ each
Top mechanical smoke exhaust	251	21/ each	8.5/ each

The model takes the grid as the minimum calculation unit. The finer the grid division, the more accurate the calculation results. Practice has proved that the influence of the grid on the calculation results will increase with the shortening of the distance from the fire source. Considering the running time and calculation accuracy of the computer, the model mesh is divided into four regions in the numerical simulation. The mesh size of the region with fire source is 1m × 1m × 1m, and the mesh size of other regions is 2m × 2m × 1m. The actual fire will burn completely within 15 minutes (experience). Considering the calculation running time, the combustion time is 2000 s.

2.2. Fire source location

The coal storage shed of the power plant divides the coal storage area into four areas], and a 10 m wide fire isolation belt is set between the coal piles. The partition is shown in Figure 2. Han Hongbin [10] studied the spontaneous combustion phenomenon of coal yard in thermal power plant. The results show that the flammable area of coal pile is the surrounding of the bottom layer of coal pile and the intersection of coal pile. Lyu Mu [11] and Gu Haijun [12] found that coal pile is easy to spontaneous combustion in the internal oxide layer of coal pile. Tang Zhong and Du Yunfeng [13] optimized the determination process of coal calorific value in the process of long-term coal storage on the basis of the study of the law of coal oxidation temperature rise in the field, and concluded that the flammable oxide layer of coal pile is located 1-3 meters below the coal surface. It is stipulated in the safety regulations of coal preparation plant [14] that the stacking height of coal pile should not exceed 6 meters. Based on the study of the stacking height of the coal pile in the ' Coal Preparation Plant Safety Regulations ' and the

flammable position of the oxide layer by Tang Zhong and Du Yunfeng, the ignition height of the oxide layer of the coal pile is roughly within 3-5 meters from the ground. After calculation and discrimination, the 10 m wide fire isolation belt can meet the safety needs. A pile of coal is on fire, and theoretically it will not ignite adjacent coal piles. This situation is not considered in the study. In summary, take two fire source points of fire source one and fire source two, and the plane position is shown in Figure2.

Based on the numerical simulation results of the previous foundation, the hot smoke in the center of the fire source rises vertically after the fire, and the top surface of the film directly above the fire source is directly impacted by the hot smoke airflow and is in a relatively unfavorable position. After the hot smoke flow rises to the top surface of the film, it gradually diffuses around the film and then decreases layer by layer. There are workers in the coal shed, and the limit temperature that the human body can tolerate is 60 °C. Inhalation of superheated smoke by the human body will cause heat stroke, skin burning or other injuries. The temperature of the smoke layer in the area affected by the evacuation of the researchers is particularly important for the safety of evacuation. NFPA 92B stipulates that the 2m high plane is a clear height plane, and the temperature of the smoke layer on this plane is studied to provide suggestions for the safe evacuation of personnel.

Second Fire source	4×4	4-5

2.3. Fire conditions

The building area and building height of the gas film structure coal storage shed in the existing power plant coal yard closed renovation project are summarized. The building area of the gas film structure coal storage shed of most power plants is 30000m2-40000m2, and the building height is 30m-40m. The building area is 30000m2,35000m2,40000m2, the building height is 30m, 35m, 40m, the fire power is 4MW, 20MW, the smoke exhaust methods are evacuation door smoke exhaust, side mechanical smoke exhaust and top mechanical smoke exhaust. The above different factors are arranged and combined to obtain 54 different fire conditions, see table 3. The following fire conditions were simulated for fire source one and fire source two.

Table.3 Fire condition

building area /m^2	building height /m	fire power /(MW)	smoke exhaust mode	working condition
30000	30	4	Evacuation door smoke	1
			Side wall mechanical smoke exhaust	2
			Top exhaust mechanical smoke	3
		20	Evacuation door smoke	4
40000	40	20	Top mechanical smoke exhaust	54

3. The relationship between maximum temperature and spatial location

3.1. The relationship between the highest position above the fire source center and the longitudinal height

The numerical simulation of the combined fire conditions was carried out. Through the collation and analysis of the data, the relationship curve between the maximum temperature and the longitudinal height above the fire source is shown in Fig.6. During the combustion process, the trend of the highest temperature at different heights is as follows : between 2m and 8m, the highest temperature at each position decreases very rapidly ; as the height increases, the temperature gradient at each position gradually decreases ; between 10 m and 14 m, the maximum temperature at each position is not much different, and the curve shows a smooth downward trend ; when the height is 16 m and above, the maximum temperature at each position basically shows a horizontal linear trend. When the ignition point is the second fire source, the characteristic trend of the relationship curve between the maximum temperature above the fire source and the longitudinal height is the same as above. The characteristic curve is shown in figure5: 6m to 20m, and the maximum temperature gradient at each position is large ; as the height increases, the maximum temperature gradient decreases and the curve tends to be gentle.

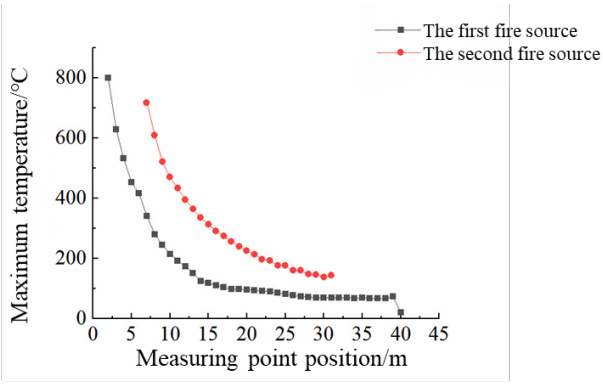

Figure5. Relationship between maximum temperature and vertical height

Figure 6 show the temperature cloud diagram on the center plane of the fire source under one of the fire conditions. It can be seen from the figure that the temperature of the flue gas layer above the fire source center has obvious stratification in the height range near the fire source point, and the temperature gradient is large. As the height increases, the temperature gradient difference decreases, and the stratification law is consistent with the previous curve characteristics.

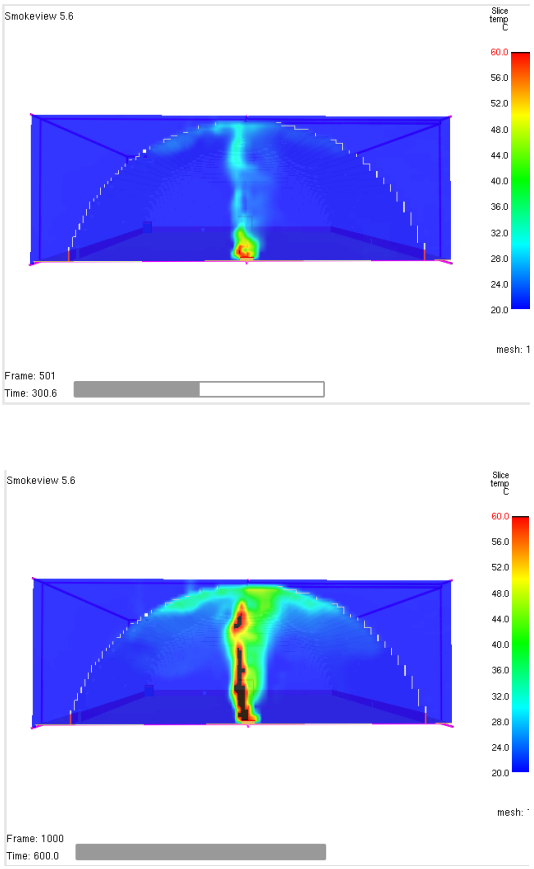

Figure6. Temperature nephogram of longitudinal section in the center of fire source (fire source 1)

The empirical formula of the relationship between the maximum temperature above the fire source and the longitudinal height is obtained by fitting the maximum temperature characteristic curve of each working condition, as shown in Equation 4 :

$$T_{\max} = \theta_1 \ln(h - z) + \theta_2 + T_0 \tag{4}$$

where : : the maximum temperature at the height of the fire source center ; °C Height of measuring point directly above the fire source ; m : the highest surface height of the fire source ; m The initial ambient temperature inside the structure ; 20 °C The height of the fire source surface of fire source 1 and fire source 2 is different. The parameters in the empirical formula are explained : see table 4.

Table.4 Fire condition

	z	h	$h-z$
First Fire source	1m	≤ height of film surface above fire source	≥1m
Second Fire source	5m	≤ height of film surface above fire source	≥1m

3.2. The relationship between the maximum temperature on the clear height plane and the transverse position

The fire numerical simulation of the combined fire conditions is carried out. Through the collation and analysis of the data, it is concluded that the relationship between the maximum temperature and the transverse position on the clear height plane of fire source one and fire source two is different. The characteristic curves are shown in Figure7 and Figure 8 respectively.

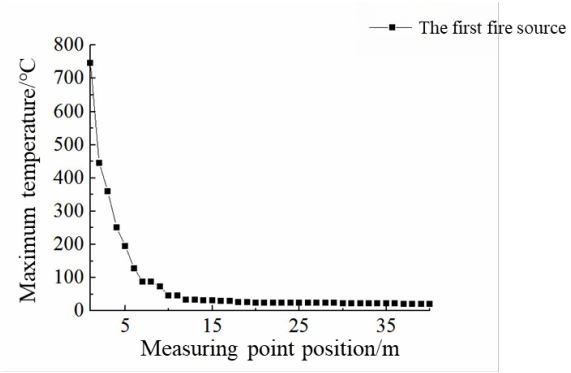

Figure7. Relationship between maximum temperature and transverse direction

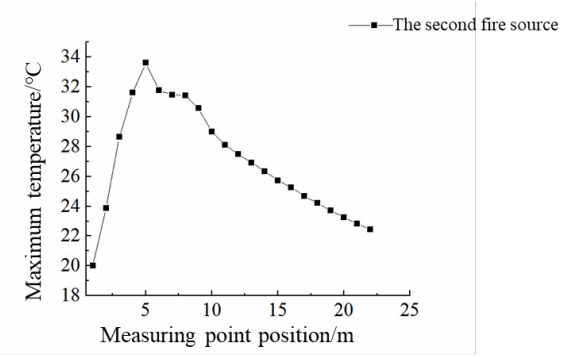

Figure8. Relationship between maximum temperature and transverse direction

When the ignition point is a fire source, the relationship between the maximum temperature on the clear height plane and the lateral position is roughly the following characteristics : in the range of 0-4m from the center of the fire source, the maximum temperature decreases rapidly with the increase of distance, and the curve almost shows a 90 ° downward trend ; in the range of 4m-10 m, the change of maximum temperature with distance is no longer obvious, especially after 12 m, the curve tends to be almost horizontal. When the ignition point is fire source two, the relationship between the maximum temperature and the lateral position on the clear height plane is roughly the following characteristics :

between 1m and 6m from the center of the fire source, the maximum temperature increases with the increase of distance ; the maximum temperature decreases with the increase of distance when the distance from the fire source center is greater than 6m. Basically at about 6m from the fire source, the temperature reached during the combustion process is the highest, roughly at 35 °C.

The study of the highest temperature on the clear height plane mainly considers the safety of personnel evacuation. When the ignition point is the second fire source, the highest temperature within the measuring point range under each working condition does not reach the human tolerance limit temperature of 60 °C, and its highest temperature will not affect the evacuation of personnel. The relationship between the maximum temperature and the transverse position when the ignition point is the fire source is studied in detail. The empirical formula of the relationship between the maximum temperature and the lateral position on the clear height plane is obtained by fitting the characteristic curves of each working condition, as shown in Formula 5.

$$T_{\max} = \theta_1 \times r^{\theta_2} + \mathrm{T}_0 \tag{5}$$

Where : Maximum temperature, °C Room temperature, 20 °C : Distance from the fire center ($1 \leq \leq 50$), m

It is determined according to different fire conditions, which is related to building area, building height, fire power and smoke exhaust mode. The practical verification of the formula and the determination of the parameters are shown in Chapter 4.

4. Effects of different factors on the maximum temperature above the fire center

The effects of building height, smoke exhaust mode and fire source power on the maximum temperature above the fire source center of rectangular air-supported membrane structure coal shed in super large space were studied. Due to too many working conditions, the paper is limited in space. Only some of the working conditions are listed for analysis and explanation, and the remaining results are essentially the same as the listed results.

4.1. Effect of building height

Figure 9 is the comparison of the highest temperature data when the fire source power is 20MW, the building area is 30,000m2, the smoke exhaust mode is evacuation door smoke exhaust, and the building height is 30m, 35m and 40m respectively. It can be seen from Fig.11 that within the height range of 0m-8m, the maximum temperature does not show a clear characteristic relationship with the height due to the instability of the fire source power near the fire source. When the height of the position rises, roughly from 8m, the relationship between the maximum temperature and the height shows regularity, that is, under the same other conditions, the higher the building height, the lower the maximum temperature at each height of the fire source center.

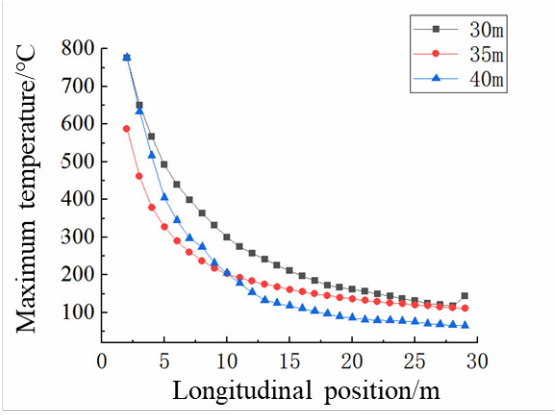

Figure9. Comparison of building height impact

4.2. Impact of smoke exhaust methods

Table 5 is the comparison of data results when the fire source power is 20MW, the building height is 40m, the building area is 40,000m2, and the smoke exhaust methods are evacuation door smoke exhaust, side wall mechanical smoke exhaust, and top surface mechanical smoke exhaust (working condition 1). Table 6 is the comparison of the data results of the fire source power of 20 MW, the building height of 30 m, and the building area of 40,000 m2. The smoke exhaust methods are evacuation door smoke exhaust, side wall mechanical smoke exhaust, and top surface mechanical smoke exhaust (working condition 2). From Table 5 and Table 6, it can be seen that the highest temperature obtained by different smoke exhaust methods is slightly different under the same building area, the same building height and the same fire source power. Compared with the evacuation door exhaust method, the mechanical exhaust method has a slight cooling effect, and the cooling effect of the top mechanical exhaust method is slightly better than that of the side mechanical exhaust method. However, the actual cooling of the two smoke exhaust methods is not much. At the same position, the side wall mechanical smoke exhaust is about 5 ° C lower than the evacuation door smoke exhaust, and the top surface smoke exhaust is about 10 ° C lower than the evacuation door smoke exhaust. In practical engineering, the smoke exhaust method is not an efficient cooling solution.

Table.5 Situation (1)

	8m	16m	24m
Evacuation door smoke	369.90℃	235.46℃	173.79℃
Side wall mechanical smoke exhaust	357.92℃	228.40℃	169.93℃
Top mechanical smoke exhaust	354.19℃	215.84℃	154.01℃

Table.6 Situation (2)

	8m	16m	24m
Evacuation door smoke	355.80℃	232.52℃	171.77℃
Side wall mechanical smoke exhaust	358.17℃	226.20℃	166.57℃
Top mechanical smoke exhaust	355.79℃	221.25℃	160.20℃

4.3. Effect of fire power

Figure 10 shows the data comparison diagram when the building area is 30000m2, the building height is 30m, the smoke exhaust mode is evacuation door, and the fire source power is 4MW and 20MW respectively. It can be seen from Fig.12 that the fire source power has a great influence on the maximum temperature compared with the influence of the smoke exhaust mode on the temperature. The maximum temperature difference under different fire power at the same position reaches about 400 °C. The closer to the fire source point, the greater the temperature difference. As the position increases, the difference becomes smaller, but even close to the height of the top surface of the film, the temperature difference reaches about 50 °C. The fire power is the main factor affecting the maximum temperature at different heights of the fire center.

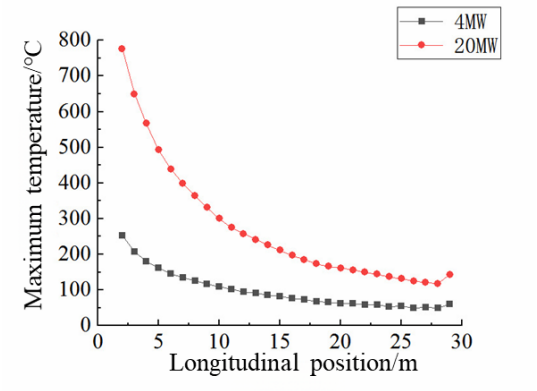

Figure10. Comparison chart of fire source power influence

5. Practical verification of empirical formula

Chapter 3 analyzes the influence of different factors on the maximum temperature. From chapter 3, it can be seen that the higher the building height, the greater the fire source power, the smoke exhaust mode is the evacuation door smoke exhaust, that is, the fire condition is the building height of 30 m, the fire source power is 20 MW, and the smoke exhaust mode is the evacuation door smoke exhaust. The coefficients of each working condition are summarized, and the coefficients of the highest temperature empirical formula of the following three most unfavorable working conditions are described in detail. The highest temperature calculated by the empirical formula is compared with the highest temperature obtained by numerical simulation to verify the practicability of the empirical formula.

5.1. Practicability verification of empirical formula for the relationship between maximum temperature and longitudinal height

The empirical formula coefficients, evaluation function R2 and corresponding empirical formulas of the relationship between the maximum temperature and the longitudinal height of the three working conditions are summarized in Tables 7 and 8.

Table 7 Working conditions

Condition	building area /m^2	building height /m	smoke exhaust mode	fire power /KW
The first condition	30000	30	Evacuation door smoke	20
The Second condition	35000	30		20
The Third condition	40000	30		20

Table 8. Fire source

		θ_1	θ_2	R^2
First Fire source	The first condition	-203.90	747.12	0.98
	The Second condition	-190.70	653.54	0.97
	The Third condition	-174.5	692.08	0.99
Second Fire source	The first condition	-160.80	527.56	0.94
	The Second condition	-211.90	788.68	0.99
	The Third condition	-208.70	746.18	0.99

The maximum temperature results obtained by numerical simulation are compared with the maximum temperature results calculated by empirical formula to verify the reliability of empirical formula, see table 9.

Table 9. Results comparison table

		Loaction/m	Numerical simulation of the highest temperature /℃	Empirical formula to calculate the highest temperature /℃
First Fire source	The first condition	8	364.16	370.35
		16	197.22	214.95
		24	137.20	127.79
	The Second condition	8	293.78	302.46
		16	159.10	157.12
		24	114.68	77.00
	The Third condition	8	355.80	372.52
		16	232.52	239.53
		24	171.77	164.94
Second Fire source	The first condition	8	369.36	370.94
		16	137.53	161.96
		24	80.93	74.16
	The Second condition	8	576.42	576.01
		16	284.61	300.54
		24	180.18	184.85
	The Third condition	8	550.90	537.03
		16	263.48	201.02
		24	181.34	151.76

6. Conclusion

According to the numerical simulation results and analysis results, the conclusions are as follows:

(1) The characteristic curve of the relationship between the maximum temperature and the spatial position was obtained, and the empirical formula was fitted. The evaluation function R2 was above 0.92, which indicated that the formula was simple and practical.

(2) When other conditions are the same, the higher the building height, the lower the maximum temperature above the fire center.

(3) For the large space rectangular air-supported membrane structure coal storage shed, the cooling effect of mechanical smoke exhaust is not obvious. In practical engineering, smoke exhaust is not an efficient cooling method.

(4) The fire power is the main factor affecting the maximum temperature. The higher the fire power, the higher the maximum temperature.

Abstract

STFE membrane material is a new kind of building material developed these years, it combines the high transparency of fluoropolymer film as ETFE, and the high strength of coated fabric membrane materials as PVC and PTFE, which makes it a high-strength transparent roof material for membrane structures. However, the constitutive model of STFE material has not been studied yet. In this paper, uniaxial tensile test and biaxial tensile test in different load scales between warp and weft directions (with 1:1,1:2,2:1,1:0,0:1) were carried out, gaining the stress-strain relationship curve of warp and weft directions. Resulting from the structure of the fabrics, the stress-strain curve in weft direction are approximately linear, while the curve in warp direction are non-linear. An in-plane orthotropic anisotropy linear constitutive model is established, calibrating the elastic modulus and Poisson's ratio for two directions, furthermore, a non-linear biaxial constitutive model is proposed, which has a higher accuracy for the description of stress-strain relationship.

Keywords: tensioned membrane structures, STFE membrane materials, uniaxial tensile test, biaxial tensile test, constitutive model

1. Introduction

Membrane structure is an important type of spatial tensile flexible structure, which is lightweight in appearance and easy to construct. They have been widely used in various types of architectures such as public buildings and transportation facilities [1]. The emergence of structural systems is closely related to the invention of building materials. The promotion and application of membrane structures are developed from the invention of architecture membrane materials. After decades of development, two different types of membrane structures have gradually emerged based on different membrane materials: coated fabric membrane structures and polymer membrane structures, which correspond to coated fabric membrane materials and polymer membrane materials, respectively.

Coated fabric membrane materials are made of high-strength fibers woven into a base cloth, covered and protected by a polymer coating. According to the type of the fibers that bear the tension, they are generally divided into polyester fiber fabric and glass fiber fabric, corresponding to P-type membrane materials and G-type membrane materials, respectively. Depending on the type that polymer coating used, they can be classified as PVC membrane materials, PVDF membrane materials, PTFE membrane materials, etc. The thickness of coated fabric membrane materials are generally in the range of 0.3mm-1.5mm, and are characterized by high strength, easy welding, and resistance to high tensile and tear forces, making them suitable for use in large-span tensile membrane structures, such as the Shanghai Hongkou Stadium and other buildings (Figure 1).

Figure 1. The coated fabric membrane structure: Hongkou Stadium

The most commonly used polymer membrane material in membrane structures is ETFE membrane material, which has strong light transmission and is suitable for use in various types of buildings that require transparency, particularly the famous National Aquatics Center "Water Cube" in Beijing (Figure 2). The thickness of ETFE membrane material is generally between 0.05mm and 0.3mm, much thinner than coated fabric membrane materials, and its strength is far lower than that of coated fabric membrane materials. For ETFE membrane materials, tearing strength is generally not considered, making it difficult to use for large-span tensile membrane structures. Generally, it is attached to the rigid or other tensile building facade in the form of air cushions.

Figure 2. The polymer membrane structure: National Aquatics Center "Water Cube"

In order to meet the demands of large-span tension and transparency in membrane structures, Serge Ferrari Company has developed a new type of transparent tensile membrane material called STFE, which stands for Structural, Transparent, Fluorinated, Envelope. The material composition of this membrane is polyarylate structural mesh with high tenacity yarn and Transparent hybrid fluoropolymer film. Due to the high strength of the fibers, which is higher than that of general polyester fibers and glass fibers, sparse fiber arrangement can be adopted on the membrane surface, leaving a large area of transparent film uncovered, thus keep a certain degree of translucency of the membrane material (see Figure 3). It has been measured that the light transmittance of STFE membrane material can reach more than 50%, which is less than the high light transmittance of ETFE membrane material (usually above

90%). Since the fibers are relatively thick (about 1mm in diameter), the fibers on the membrane surface can be clearly seen from close distance. However, at a distance of more than 5m from the membrane surface, the fibers are basically invisible and difficult to see clearly, and the effect of viewing the membrane surface from a distance is very similar to that of transparent membrane materials(as Figure 4 shows).

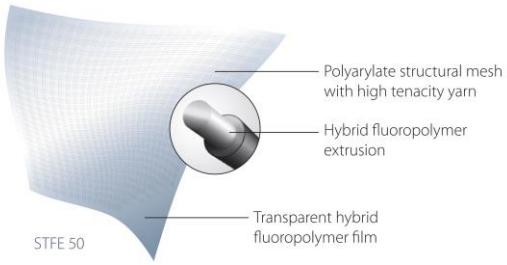

Figure 3. The composition of STFE

Figure 4. Transparent view effect from different distance

2. The constitutive model of traditional membrane

In the design and calculation of membrane structures, the stress-strain relationship of materials is the most important mechanical model, which forms the basis for calculating the displacement of membrane structures under various loads. For traditional coated fabric membrane materials and polymer membrane materials, there are already many mechanical models that describe their stress-strain relationships.

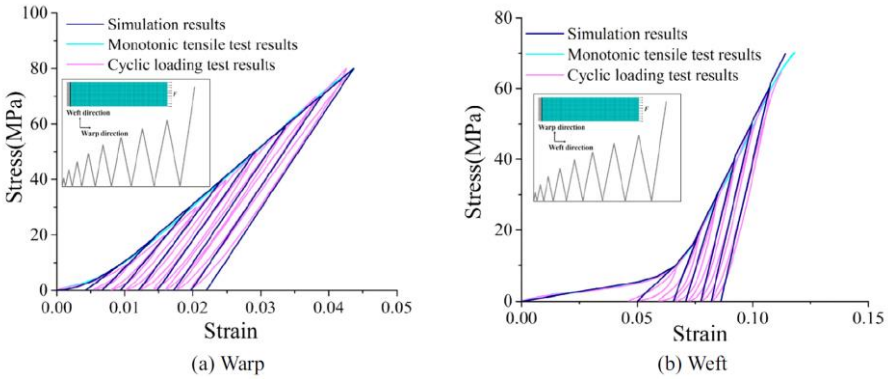

Figure 5. Comparison between the stress-strain curve of warp and weft directions [3]

The stress-strain relationship of coated fabric membrane materials is influenced by their material composition. The base fabric of this type of membrane is woven from high-strength fibers that intersect in two perpendicular directions, the warp and weft directions, resulting in two material principal axes that correspond to the mechanical properties in the warp and weft directions. In various codes/standards, the orthogonal anisotropic model of linear elasticity is commonly used to describe the mechanical properties of coated fabric membrane materials, but this model cannot reflect the nonlinear stress-strain relationship of the membrane material. As a result, other nonlinear models have been developed, such as nonlinear orthotropic material model [2], segmented model [3], hyperelastic model [4], and models

that consider the crimp interchange of the warp and weft directions [5]. These models to some extent reflect the differences in stress-strain relationships between the warp and weft directions and the nonlinearity of the two direction curves (as shown in Figure 5). To determine the stress-strain curves in the warp and weft directions, biaxial tests are usually performed by applying different proportions of loads in the warp and weft directions to obtain the curves of the membrane material under different stress states [6].

The stress-strain relationship of ETFE membrane material is generally considered to be isotropic, although it is greatly influenced by temperature. Under certain temperatures, the membrane material can be approximately regarded as a homogeneous material in-plane, and described using a fixed constitutive model [7]. At room temperature, a three-segment model shown in Figure 6 is commonly used to describe the stress-strain relationship of ETFE membrane material, which has two characteristic points on the curve representing the first and second yield strengths of the material. It is generally believed that ETFE material is elastic only on the curve before the first yield strength.

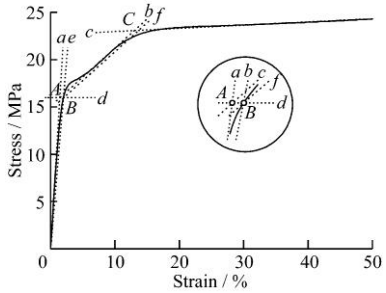

Figure 6. The stress-strain curve of ETFE [7]

3. The uniaxial tensile test and biaxial tensile test

To obtain the stress-strain relationship of STFE membrane material, uniaxial and biaxial tests of the membrane material must be performed. Since the main tension component of STFE membrane material is its fibers, similar to coated fabric membrane materials, the test specimen processing method of coated fabric membrane materials is used when testing STFE membrane materials.

The uniaxial test of STFE membrane material use the clamping test method, and the specimen uses a rectangular strip specimen with a length of 300mm and a width of 50mm, cut from warp and weft directions. The clamping area at both ends is 50mm long, and the strain elongation area in the middle is 200mm long, as shown in Figure 7. The uniaxial test is carried out on an electronic universal testing machine, and the clamping end of the specimen is clamped with a clamping fixture at a loading speed of 10mm/min, as shown in Figure 8.

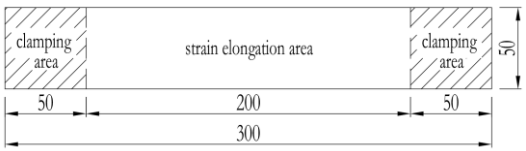

Figure 7. The size of uniaxial specimen

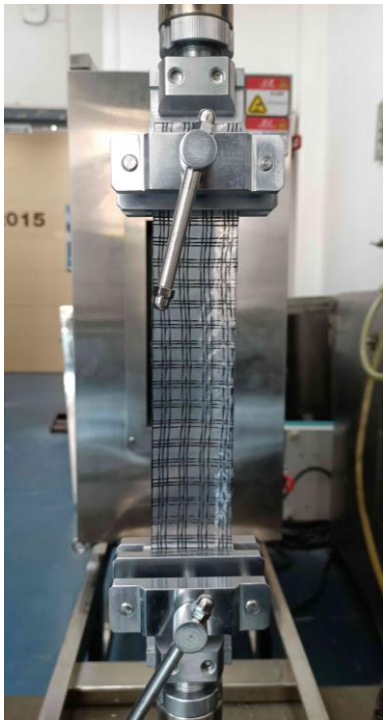

Figure 8. Uniaxial test

The biaxial test of STFE membrane uses a cross-shaped biaxial specimen with a core area of 160mm×160mm. The strain in the core area is measured by digital image correlation (DIC), and the tensile force of the warp and weft arms is measured in the clamping area to obtain the biaxial stress-strain curve. The biaxial test adopts a reciprocating loading system and performs five different ratios of longitudinal to transverse loading in turn: 1:1, 2:1, 1:2, 1:0, and 0:1. Before each loading, three 1:1 reciprocating loading cycle are conducted to eliminate strain. The stress and core area displacement field are measured and recorded in each formal loading. The loading speed of the high-stress side in the test is 10mm/min.

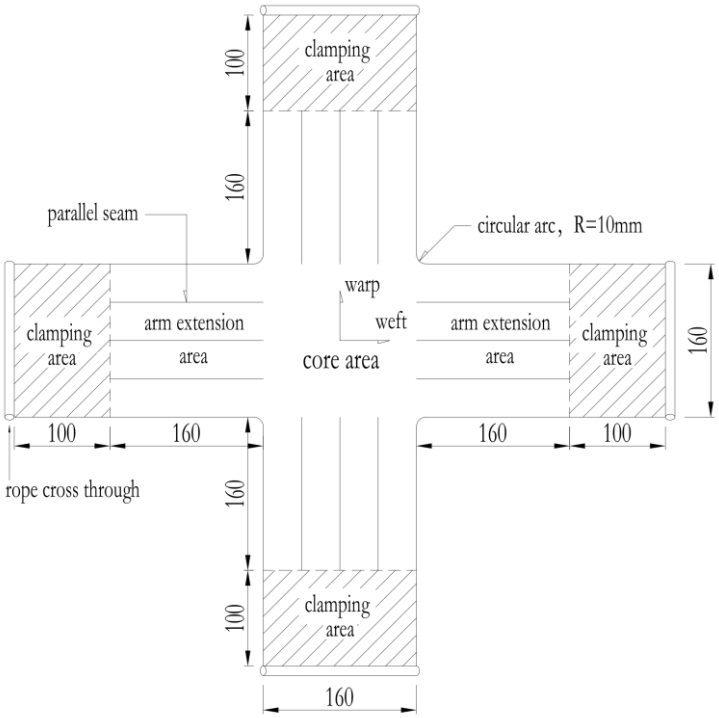

Figure 9. The size of biaxial specimen

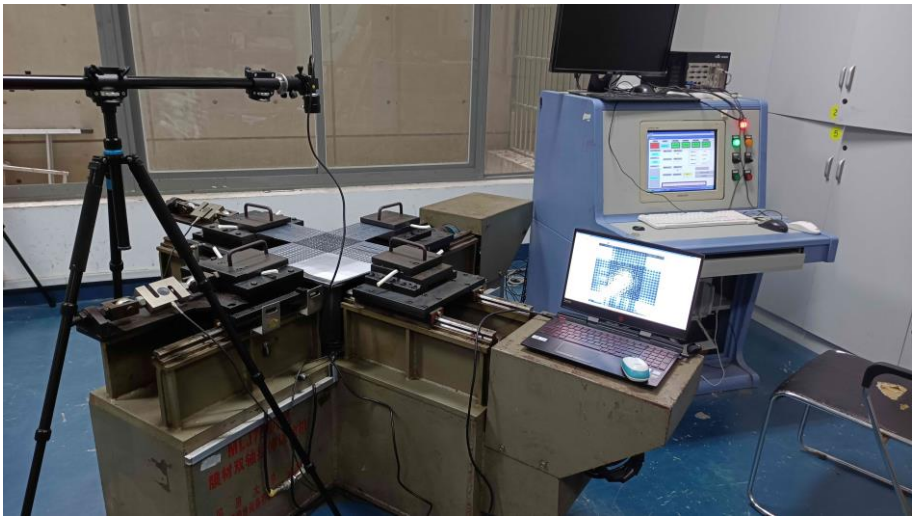

Figure 10. Biaxial test

4. The constitutive model of STFE

4.1 The uniaxial stress-strain model

From the uniaxial test, the uniaxial stress-strain curves of STFE membrane in the warp and weft directions can be obtained, as shown in Figure 11. The stress-strain curve in the warp direction is nonlinear, while that in the weft direction is linear. They are fitted with a quadratic polynomial and a linear function, respectively, as shown in equation (1), in the equation, σ_X is the stress in warp direction, σ_Y is the stress in weft direction, ε_X is the strain in warp direction, ε_Y is the strain in weft direction. In the stress-strain relationship in the warp direction, there are two material parameters a_1, a_2, while in the stress-strain relationship in the weft direction, there is only one linear material parameter b_1, These material parameters can be calibrated according to the test data, the fitting parameters are shown in table 1, and the fitted curves are also shown in Figure 11. It can be seen that the constitutive models of the quadratic function in the warp direction and the linear function in the weft direction have high fitting accuracy to the test results.

$$\begin{aligned} \sigma_X &= a_1 \cdot \varepsilon_X + a_2 \cdot \varepsilon_X^2 \\ \sigma_Y &= b_1 \cdot \varepsilon_Y \end{aligned} \tag{1}$$

4.2 The linear biaxial stress-strain model

According to the current membrane structural design standards/specifications of most countries, the most commonly used mechanical model for coated fabric membrane materials is the in-plane orthotropic linear constitutive model. This mechanical model describes the biaxial stress-strain relationship in the warp and weft directions through the elastic modulus and Poisson's ratio in the warp and weft directions,

as well as their mutual influence under different stress ratios. The general formula for this type of mechanical model is shown in equation (2), where E_X denotes the warp elastic modulus, E_Y denotes the weft elastic modulus, v_X denotes the warp Poisson's ratio, v_Y denotes the weft Poisson's ratio, and the Poisson's ratio in the warp and weft directions satisfies the relationship in equation (3). By calculating the sum of squared strain residuals for the five curves, the biaxial mechanical model parameters (elastic moduli and Poisson's ratio) of the membrane material can be determined using the least squares method. The calibrated parameters are shown in table 2. The biaxial stress-strain test data in the warp and weft directions at various stress ratios are plotted on the same graph with the fitted curves, as shown in Figure 12 and 13. It can be seen that the weft test data is approximately linear and fits the mechanical model well, while the warp test data is nonlinear and has some deviation from the mechanical model.

$$\varepsilon_X = \frac{\sigma_X}{E_X} - \frac{\sigma_Y}{E_Y} v_Y \qquad (2)$$

$$\varepsilon_Y = \frac{\sigma_Y}{E_Y} - \frac{\sigma_X}{E_X} v_X$$

$$\frac{v_X}{E_X} = \frac{v_Y}{E_Y} \qquad (3)$$

Table 2. The material parameters of biaxial linear model

Direction	Elastic modulus (E_X, E_Y) (kN/m)	Poisson's ratio (v_X, v_Y)
Warp	1510	0.13
Weft	2350	0.20

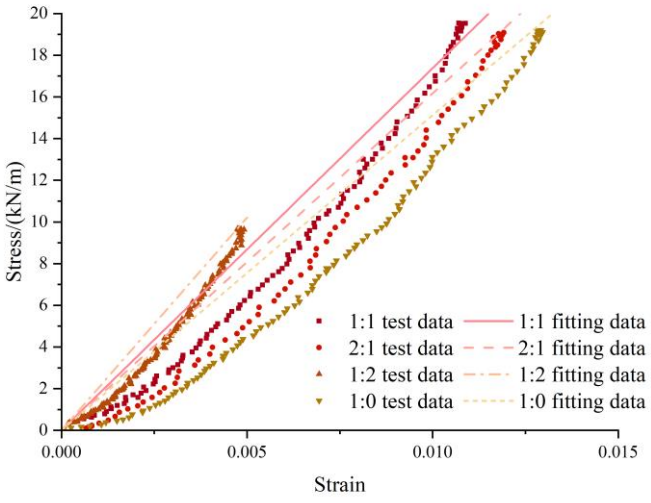

Figure 12. Biaxial stress-strain curve in warp direction with linear model

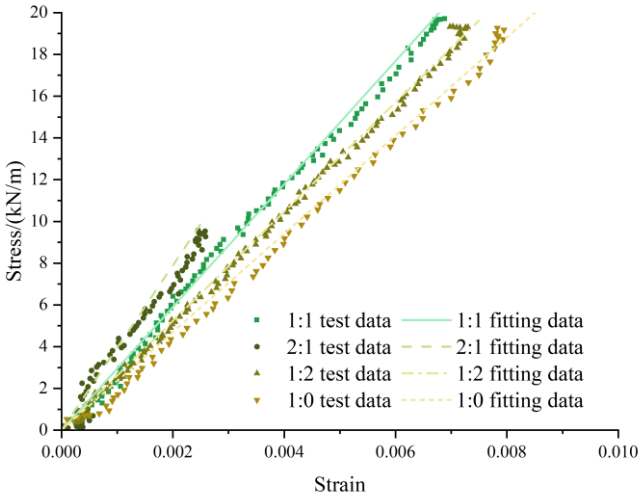

Figure 13. Biaxial stress-strain curve in weft direction with linear model

4.3 The non-linear biaxial stress-strain model

As mentioned in the previous section, the axial stress-strain curve of STFE membrane material is nonlinear at various loading ratios. In order to improve the model accuracy, a second-order term is introduced based on the linear orthogonal anisotropic constitutive model to describe the nonlinearity of the warp axial curve, as shown in equation (4). This mechanical model expresses stress as a function of strain, with material parameters (C values with subscripts) having the same unit as elastic modulus. The warp direction includes three material parameters: linear parameters C_{11}, C_{12} and nonlinear parameter C_{111}, while the weft direction includes two material parameters: C_{22} and C_{21}. By calculating the sum of the squared stress residuals for each curve and using the least squares method to calibrate the material parameters in the formula, the resulting data is recorded in Table 3. When the experimental data is plotted against the fitted curves in Figures 14 and 15, it can be seen that the nonlinear model fits the axial curve much more accurately than the linear model.

$$\begin{aligned} \sigma_X &= C_{11}\varepsilon_X + C_{12}\varepsilon_Y + C_{111}\varepsilon_X^2 \\ \sigma_Y &= C_{22}\varepsilon_Y + C_{21}\varepsilon_X \end{aligned} \tag{2}$$

Table 3. The material parameters of biaxial non-linear model

Direction	Parameter this side (C_{11}, C_{22}) (kN/m)	Parameter opposite side (C_{12}, C_{21}) (kN/m)	Second order Parameter (C_{111}) (kN/m)
Warp	693	572	65670
Weft	2352	251	——

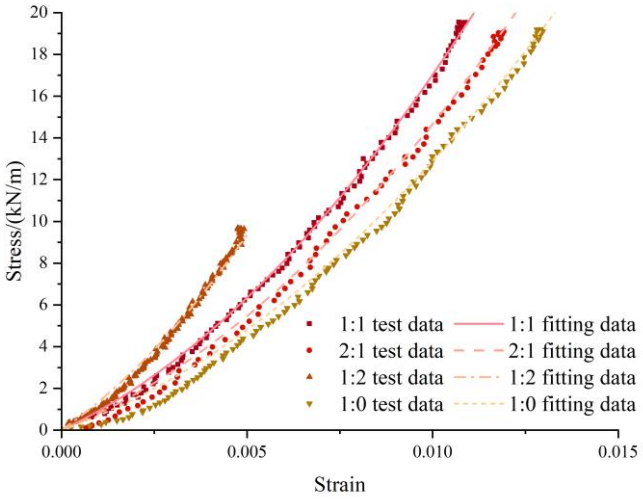

Figure 14. Biaxial stress-strain curve in warp direction with non-linear model

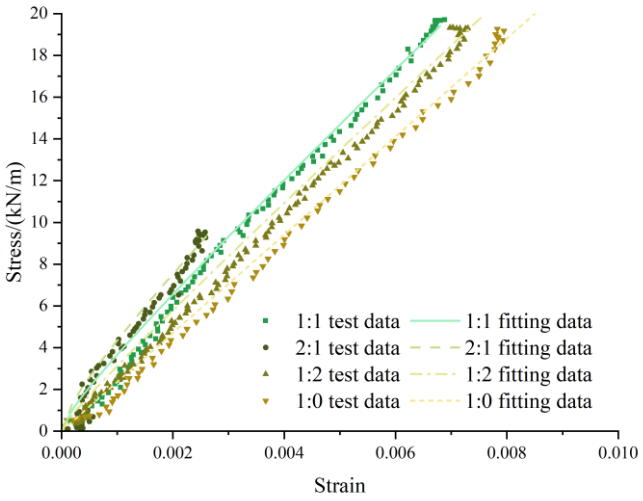

Figure 15. Biaxial stress-strain curve in weft direction with non-linear model

5. Comparison of elastic modulus between STFE and traditional membrane materials

As the most important parameter of the linear orthogonal anisotropic model, the elastic modulus approximately represents the ability of the membrane material to resist deformation in the warp and weft directions. A comparison of the elastic moduli of STFE membrane material with traditional membrane materials, including PVC, PTFE, ETFE, etc., is shown in Table 4. It can be seen that the elastic modulus of polyester fiber fabric membrane material is relatively low, while that of glass fiber fabric membrane material is relatively high. The elastic modulus of STFE membrane material is higher than these two, and the data for ETFE membrane material is taken as its tangent modulus. Compared with other materials, its elastic modulus is the lowest, less than 15% of that of STFE.

Table 4. The elastic modulus of different membrane materials

Direction	PVC membrane [2] (kN/m)	PTFE membrane [8] (kN/m)	STFE membrane (kN/m)	ETFE membrane [7] (kN/m)
Warp	730-917	1270	1510	223
Weft	565-714	866	2350	223

Compared with traditional building membrane materials, STFE membrane material has a higher elastic modulus, stronger in-plane resistance to deformation, a simpler form of stress-strain curve, and is more convenient to calculate in design, which is determined by the sparse arrangement and high strength characteristics of its fibers.

6. Conclusion:

This article conducted uniaxial and biaxial tensile tests on STFE membrane material, measuring the stress-strain curves in the warp and weft directions under uniaxial loading, and the stress-strain curves at different loading ratios under biaxial loading. Based on the test data, the uniaxial and biaxial constitutive mechanical models of STFE membrane material were established, and the parameters in the models were calibrated.

The test results showed that the stress-strain relationship in the warp direction of the STFE membrane material was nonlinear, while that in the weft direction was linear. The material had a high elastic modulus and good resistance to in-plane deformation, making it suitable for use in large-span tension membrane structures.

Abstract

STFE studied in this paper is a new kind of building membrane material, which is composed of polyarylate structural mesh with high tenacity yarn and transparent hybrid fluoropolymer film. Compared with fabric membrane materials, its non-tightly woven mesh makes STFE have better light transmission performance (53%); Compared with ETFE, the high tenacity polyester yarn grid provides a higher structural strength for STFE, making it suitable for tensile membrane structure. At present, there is no systematic experimental study on the mechanical properties of STFE membrane. In this paper, four mechanical properties of STFE are studied: The tensile strength of STFE membrane was measured by uniaxial tensile test based on winding method; The tearing strength of STFE membrane was measured by trapezoidal tearing method; The connection strength of STFE was measured by uniaxial tensile test; The creep of STFE within 24h was measured by uniaxial tensile test. On the basis of the above test data, STFE membrane materials are compared with traditional membrane materials, and the following conclusions are obtained: The tensile strength of STFE membrane is between that of traditional fabric material and ETFE material, while the tearing strength is higher than that of the above two types of materials; The butt joint of STFE is covered by black film. The connection strength is higher than the strength of base material. Therefore, the connection reliability is better than traditional membrane materials; The creep of STFE membrane is lower than that of the traditional membrane materials. This study shows that STFE membrane material has superior mechanical properties and can be an alternative material for membrane structure. Meanwhile, Material parameters given in this paper can provide reference for the design and application of membrane structure made of STFE.

Keywords: STFE, uniaxial tensile test, mechanical properties

1. Introduction

As a kind of spatial structure, membrane structure is favored by many architects and structural engineers due to its graceful architectural appearance and reliable structural system. Nowadays membrane structure is frequently used in large-scale public building such as stadiums, museums, airport terminals and railroad stations as shown in the Figure 1. Meanwhile, the development of membrane structure is inseparable from the innovation of membrane materials. There are two main categories of common membrane materials: one is coated fabric materials (e.g. PVC, PTFE, PVDF materials), which consist of bi-woven fibre substrate and self-cleaning coating; the other is polymeric membrane materials (e.g. ETFE materials). In terms of architectural performance, because of the poor light transmission performance of coated fabric materials, they do not meet the requirements of some building facades. In contrast, the light transmission rate of ETFE material is greater than 90%, which can meet the architects' requirements for light and landscape. However, ETFE is a single-layer polymer film, and its in-surface strength is much lower than that of coated fabric materials, so it is only applicable to inflatable membrane structures.

Figure 1. Famous membrane structures

As shown in Figure 2. STFE membrane material (Structural Transparent Fluorinated Envelope) is a new type of architectural membrane material produced by Serge Ferrari, which is composed of polyarylate structural mesh with high tenacity yarn and transparent hybrid fluoropolymer film. Specifically, the structural mesh of STFE is made in groups of three fibres, with each group of fibres staggered along both warp and weft directions. The fibres are arranged symmetrically along the warp direction and anti-symmetrically along the weft direction which is shown in Figure 3. The center distance between two adjacent fibre groups is about 12.5mm, and the fibre spacing within the group is about 2mm.

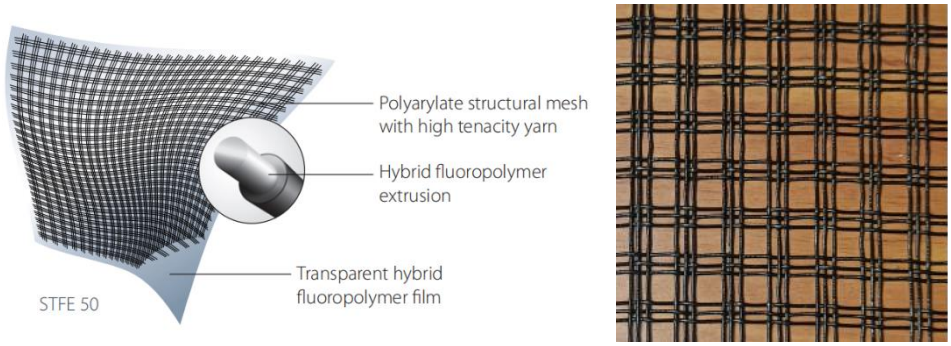

Figure 2. STFE membrane material

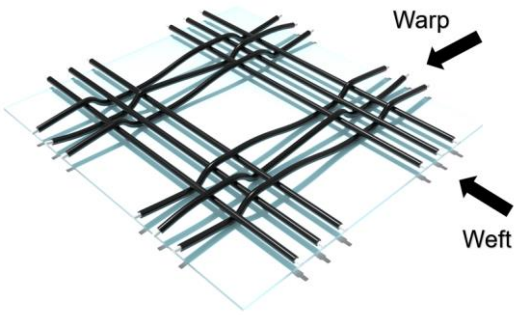

Figure 3. Microstructure diagram of STFE

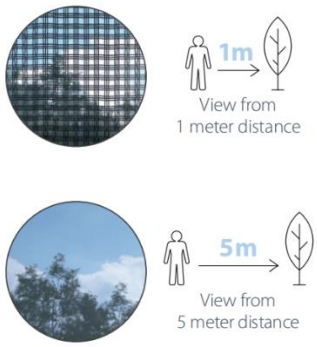

Figure 4. Visual performance of STFE

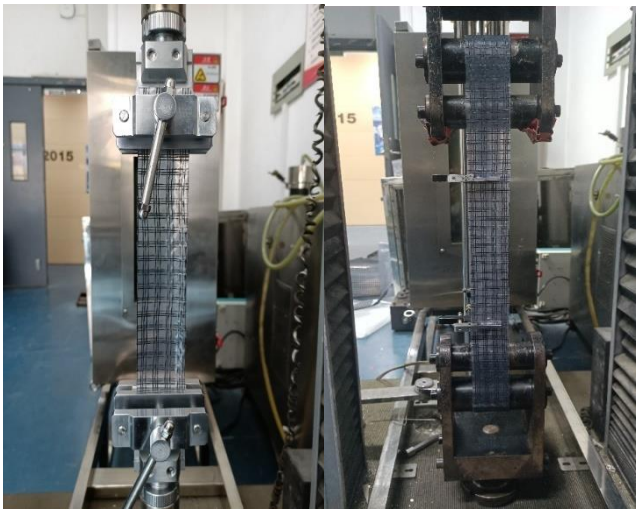
STFE uses non-tightly woven mesh instead of the dense weave of traditional coated fabric material. However, the strength of its single fibre is high enough, the global in-plane strength is sufficient to

ensure its application in tensioned membrane structures. In the light transmission performance test, the light transmission rate of STFE membrane is greater than 53%, which is a significant improvement compared to traditional coated fabric membrane materials. At the same time, though the black fiber groups on the surface of the STFE can be seen from a distance of 1m, this blocking field of view no longer occurs when the distance is extended to 5m and above as shown in Figure 4. In terms of structural and architectural performance, STFE is a new type of membrane material with superior performance. At present, STFE has been applied in some projects. As shown in Figure 5, the outer courtyard of the Royal Orthopaedic Hospital and the crosswalks of Istanbul Airport both use STFE as the membrane structure material.

(a) Royal Orthopaedic Hospital (b) The crosswalks of Istanbul Airport

Figure 5. Application projects of STFE



Nowadays, numerous test methods have been proposed for fabric and polymeric membrane materials. However, the mechanical properties of STFE membranes have not yet been systematically studied by scholars in the field of membrane structures. It is essential to provide standard test methods and material mechanical parameters for projects designed with STFE. Therefore, in this paper, four mechanical properties of STFE and the parameters are investigated: 1) tensile strength of STFE 2) tearing strength of STFE 3) connection strength of STFE 4) creep properties of STFE. The test method in this paper is based on the traditional test method for coated fabric membrane materials in Standard for inspection of membrane structures (DG/TJ08-2019), with some improvements to the sampling and test method based on the unique characteristics of STFE material. The test data are obtained under the adjusted test methods, different test methods may lead to some deviations from the test results.

2. Tensile strength

Tensile strength is an important parameter of the in-plane strength of membrane materials. Uniaxial tensile tests are commonly used to determine the tensile strength of traditional fabric and ETFE membrane materials [1–3]. Some scholars also proposed the use of biaxial tensile test to determine the tensile strength of membrane materials. Even though the biaxial tensile test reflects the actual force conditions of membrane materials in engineering better, the failure usually occurs at the edge of the cross specimens, so the accuracy of biaxial test is lower [4].

In this paper, the uniaxial tensile test method is used to determine the tensile strength of STFE. As shown in Figure 6, there are two different test method according to the types of holders: winding method and clamping method. The winding method fixes the specimen on the uniaxial tensile apparatus by the friction between the specimen and the holders, while the clamping method fixes the specimen by the gripping force of the holders. The advantages of the clamping method are easy operation and low material consumption. However, due to the stress concentration effect, specimen fracture often occurs at the edge of holders, so that the tensile strength of the material is underestimated. On the contrary, the stress of specimen fixed by winding holders is more uniform, which leads to more accurate tensile strength of the material. The disadvantage of winding method is the high material consumption and is

more complicated to operate. On balance, the winding method was chosen for the study to guarantee the accuracy of test results.

(a) clamping method (b) winding method

Figure 6. Uniaxial tensile strength test

For traditional coated fabric membrane materials, the tensile strength is mostly tested on long specimens of 50±0.5mm width and 300±1mm length (50mm on both sides of the gripper zone + 200mm in the core measurement zone), while for ETFE membrane materials, in consideration of the effect of stress concentration in the gripper, dumbbell-shaped specimens are often used. The strength of STFE membranes is mainly provided by the structural mesh with high tenacity yarn, from which the fibre groups should not be cut through during sampling to compromise the membrane strength. Therefore, it is necessary to ensure that the specimen has enough intact fibre groups during the sampling process. In the actual sampling, 4 groups of fibres are taken in the width direction and the width of the specimen is 50±0.5mm. Due to the selection of winding method, enough length need to be left at both sides to ensure that the size of the friction surface is sufficient to fix the specimen in the test, and the actual length was taken as 1200±5mm (500mm on both sides + 200mm in the core measurement zone). The specimen of tensile strength test is shown in Figure 7.

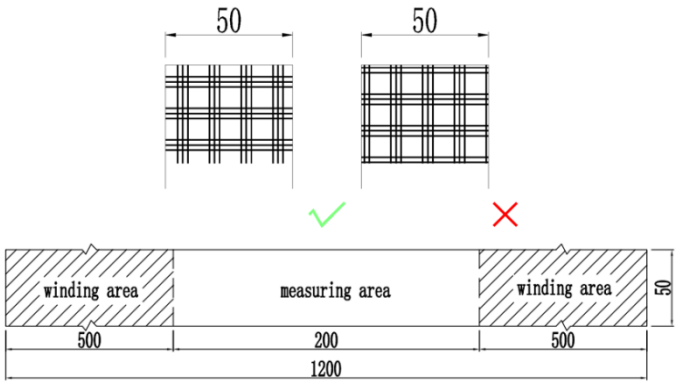


Figure 7. Specimen of tensile strength test

The experiments were carried out at a temperature of (20±2) ℃ and a relative humidity of (65±4) %. A uniaxial tensile test machine and an extensometer was used for recording the load and displacement

of the specimen. At the beginning of the experiment, the specimen was first tensioned to a pre-tension of 10N, and then stretched at a constant rate of 100mm/min until the specimen fractured. When the specimen fractures, if the fracture position is in the middle of the specimen, it is regarded as a valid result. If the specimen slips or the fracture does not occur in the core measurement area during the loading process, it is regarded as an invalid result and the test value of the specimen is discarded. In this test, five valid values were obtained in the warp and weft directions for the calculation of tensile strength. The elongation after fracture was determined based on the deformation of the core area measured by the extensometer.

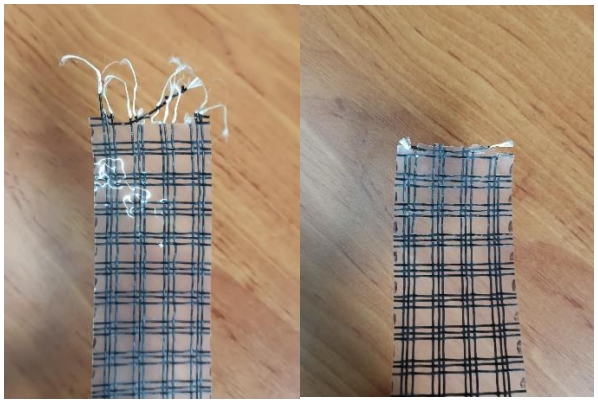

Figure 8. Two damage modes of STFE tensile test

According to the Figure 8, two damage modes were shown in the test of STFE: one is the longitudinal fibre fracture with a relatively straight fracture surface, which occurs relatively quickly and belongs to the brittle damage; under the other condition, firstly the longitudinal fluoropolymer coating yarn is pulled out from the black fibre shell, then the fracture of yarn leads to the damage of material, in which damage process is relatively slow. The main reason for the occurrence of the two damage modes may depend on whether the internal yarn is reliably connected with the fibre shell.

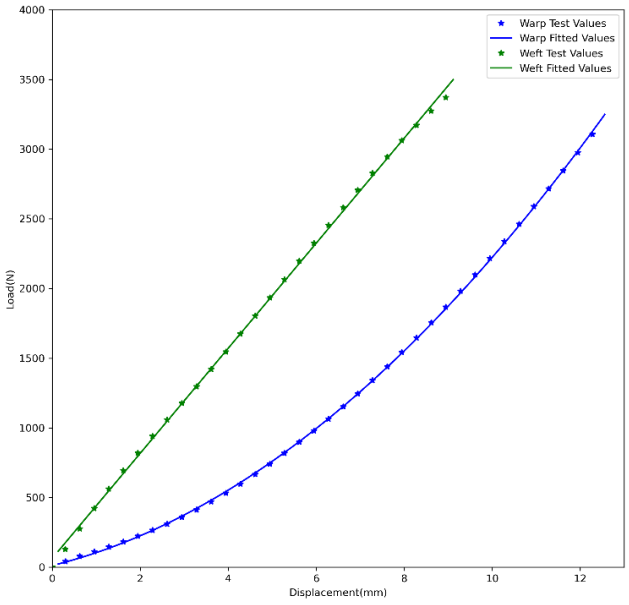

Figure 9. Uniaxial load-displacement curves of STFE

The uniaxial load-displacement curves of STFE in both warp and weft directions were obtained in this test. As shown in the Figure 9, STFE material is anisotropic. Nonlinear performance is obvious in the

warp direction under lower loads. With the loading process, the stiffness gradually increases and nonlinearity gradually decreases; while the material shows linear performance in the weft direction.

After calculation, the tensile strength of STFE is about 3136.42N/5cm in the warp direction and 4243.31N/5cm in the weft direction. The elongation rate after fracture is about 3.5%-4% in the warp direction and 3.0%-3.5% in the weft direction. The tensile strength of STFE in the weft direction is significantly higher than that of the warp direction, while the elongation rate after fracture in the weft direction is lower than that of the warp direction.

Compared with traditional materials, the tensile strength of STFE is slightly lower than that of coated fabric membrane materials such as PVC, PTFE, while higher than that of ETFE materials. The elongation rate after fracture is much lower than that of traditional coated fabric and ETFE materials. The data is shown in the Table 2, PVC material of Ferrari 1202T2, Ferrari 1002T are tested by Yang Li [5], PTFE material is tested by Tengfei Wang [6], and the data of ETFE is provided by Minger Wu [7].

Table 1. Results of STFE tensile strength test

Tensile strength (warp) N/5cm	3318.07	3159.35	3242.43	2868.33	3093.91

Elongation rate (warp)	4.01%	3.46%	3.81%	3.75%	3.46%
Elongation rate (weft)	3.17%	3.34%	3.19%	3.32%	3.28%

Table 2. Comparison of tensile strength among different membrane materials

Material	STFE	PVC (1202T2)	PVC (1002T)	PTFE	ETFE
Tensile strength (warp) N/5cm	3136.42	5269	4125	5231.50	600-900
Tensile strength (weft) N/5cm	4243.31	5174	4485	4127.50	600-900
Elongation rate (warp)	3.70	22.41	20.91	5.86	400
Elongation rate (weft)	3.26	23.06	20.59	7.92	400

3. Tearing strength

Tearing failure is a common damage mode of membrane structure. At present, there are several test methods for tearing performance of membrane material based on previous research: single tongue tearing method, double tongue tearing method, trapezoidal tearing method, center tearing method. The tearing strength obtained by the trapezoidal tear method are more stable, so the trapezoidal tear method was used in this study to determine the tearing strength of STFE membrane materials.

As shown in Figure 10, the size of the specimens and the crack are based on the Standard for inspection of membrane structures (DG/TJ08-2019). The specimens are in the form of long strips, and the length direction of the cut specimens should be parallel to the warp or weft direction of the membrane. The width of each specimen is (50±0.5) mm and the length is (180±1) mm, in which the middle tearing area is isosceles trapezoid, the upper bottom is 50 mm wide, the two waists are clamping lines, and the angle between the clamping lines and the length direction is 75°. The incision starts from the center of the upper bottom and the length of the incision is (25 ± 0.5) mm. In order to ensure the stable of the tearing experiment, the end of the incision should be required in the position of the film instead of the middle of a group of fibres, Also, the lower part of the incision should be left with two groups of parallel fibres.

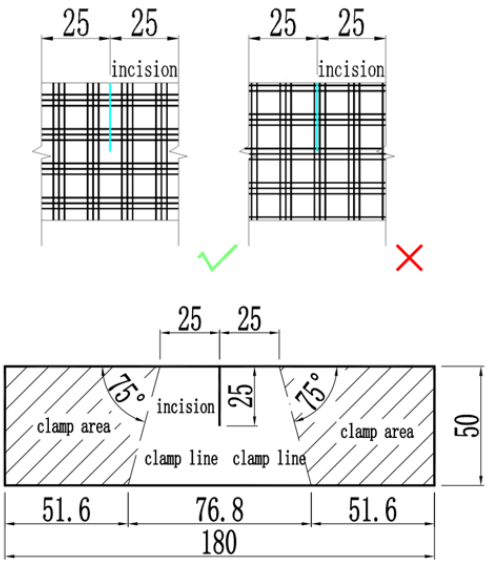

Figure 10. Specimen of tearing strength test

The experiment was carried out at the temperature of (20±2) ℃ and the relative humidity of (65±4) %. Before the test begins, keeping the short side of the trapezoid tensioned and the long side in a creased state, as shown in Figure 11. After the test begins, the specimen is stretched at a constant rate of 100 mm/min. If the specimen is torn along the middle incision direction, it is regarded as a valid result, while the specimen is not torn along the middle incision direction or slipped out of the jaws, it is regarded as an invalid result and the test value of the specimen is discarded. The processing of the test is shown in Figure 11.

(a) Before the test begins (b) After the test begins

Figure 11. The processing of tearing strength test

The processing of tearing failure starts with the film tearing along the incision line, then the crack quickly spreads to the fibre nearest to the incision. With the fibre gradually stressed, it slowly fractures

or its yarn is extracted. The tearing of film continues and spreads to the next fibres until all fibres are destroyed. Below the incision line, there are two intact fibre groups, each containing three fibres. Therefore, during the tearing process, six fibres are damaged in sequence. As shown in Figure 12, the tearing load-displacement curve shows a six-wave peak pattern in two regions.

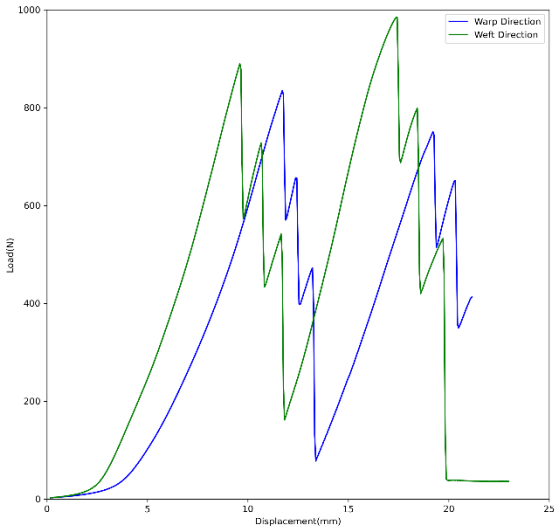

Figure 12. Tearing load-displacement curves of STFE

Based on the load-displacement curves of STFE specimens, this paper suggests using the mean value of six peaks to characterize the tearing strength of STFE. Seven groups in the warp direction and six groups in the weft direction are obtained. The tearing strength is 645.68 N in the warp direction and 754.96 N in the weft direction. The tearing strength in the warp direction was slightly lower than that in the weft direction, which is consistent with the conclusion of tensile strength.

Table 3. Results of STFE tearing strength test

Tearing strength (warp) N/5cm	629.64	623.78	695.42	616.13	640.70
	637.58	676.50			
Tearing strength (weft) N/5cm	714.73	760.25	745.69	772.12	707.28
	829.71				

Table 4. Comparison of tearing strength among different membrane materials

Material	STFE	PVC	PTFE (FGT-800)
Tearing strength (warp) N/5cm	645.68	552	418
Tearing strength (weft) N/5cm	754.96	540	407

From the Table 4, it can be seen that the tearing strength of STFE is higher than that of traditional coated fabric material. This result is reasonable since the tearing strength depends mainly on the local strength of individual fibres rather than the global strength of the material. The high tenacity polyarylate yarn used in STFE is stronger than glass fibre or polyester fibre used in traditional coated fabric material.

Compared to ETFE, the local tearing strength of its single-layer polymer structure is much lower than that of STFE. The data of PVC is provided by Han Bao [8] and PTFE is provided by Yaqin Wang [9].

4. Connection strength

Due to the limitation of material processing size, multiple pieces of STFE should be spliced together for membrane structures. A reliable connection strength is necessary for the construction of membrane structures. In this study, the connection strength of butt-joint of STFE is investigated experimentally. The STFE butt-joint are constructed by welding the fibre at both ends with a black covering film added, as shown in Figure 13, which can effectively protect the connection nodes, enhance the durability and make the appearance more attractive.

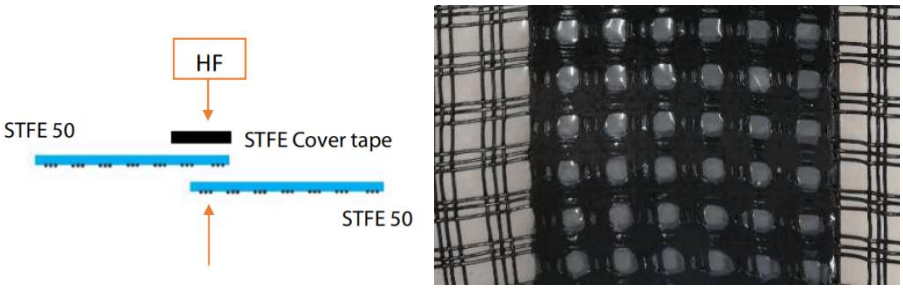

Figure 13. Butt-joint of STFE

The experiment was carried out at the temperature of (20±2)℃ and the relative humidity of (65±4)%. Samples are taken in long strips as shown in Fig. 14. Each specimen consists of two short samples. The width of short samples is (50 ± 0.5) mm and the length is (175 ± 1.0) mm. The length of connection area is (50 ± 0.5) mm and the total length of the specimen is (300 ± 1.0) mm. The samples should be cut parallel to the warp direction and through the center of the two adjacent groups of fibres.

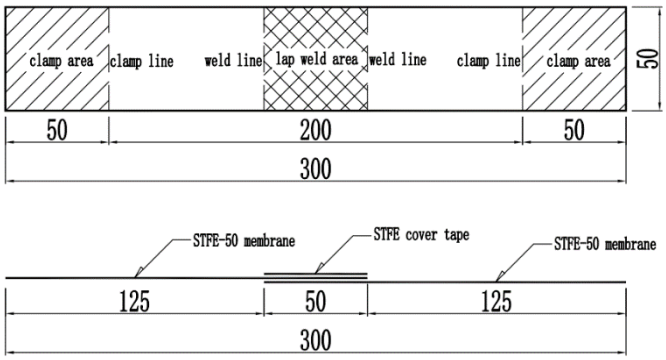

Figure 14. Specimen of connection strength test

After the test begins, the specimen is stretched at a constant rate of 100 mm/min. As a matter of fact, the failure of the specimen takes place in the junction of welding and non-welding area shown in Figure 15, which means the connection strength of STFE is higher than tensile strength. The conclusion is also confirmed by the test data which is shown in Table 5. The calculation check is unnecessary for the design of membrane structures made of STFE.

Table 5. Results of STFE connection strength test

Connection strength (warp) N/5cm	3744.67	3680.38	3288.26	3155.44	3423.01
	3423.01	3129.42	3414.35	2932.75	2688.90

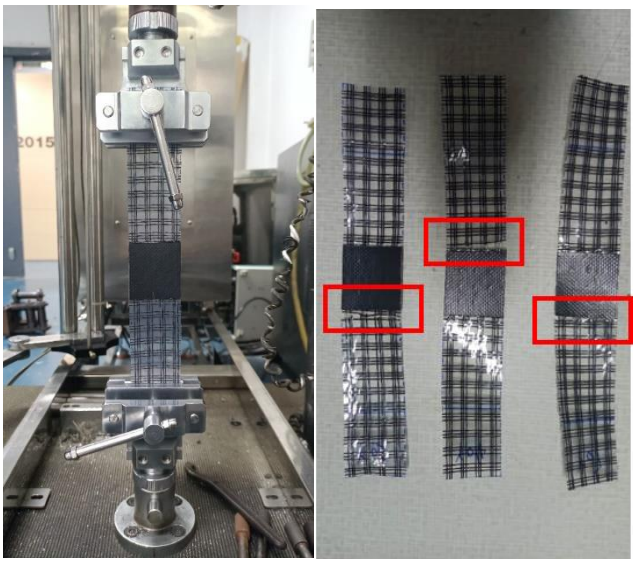

Figure 15. The connection strength test

5. Creep performance

The creep of membrane materials refers that the deformation of membrane materials gradually increases while the holding force remains constant over a long period of time. In project applications, the creep of membrane materials may lead to slackening or deformation of the membrane surface, so it is necessary to determine the creep elongation of membrane materials. Both traditional coated fabric materials and ETFE have the effect of creep. In general, the creep elongation of ETFE membranes is greater than that of coated fabric materials. The main influencing factors of creep include the type of material, temperature, holding force, etc. In this paper, based on the Standard for inspection of membrane structures (DG/TJ08-2019), the creep performance of STFE material at room temperature for 24h at 1/4 tensile strength is tested.

The size of specimen is exactly the same as the specimen for tearing strength test without incision. The experiments were conducted under the conditions of temperature (20±2) ℃ and relative humidity (65 ±4) %. After the experiment started, the specimen was stretched to 1/4 tensile strength at a stretching rate of 100 mm/min, after which the constant tension was maintained for 24 h. The distance between the two clamps at the beginning of the application of constant tension and at the end of the application is recorded. The creep elongation is calculated following the formula shown below:

$$\varepsilon_{cf} = \frac{L_2 - L_1}{L_0} \tag{1.}$$

L_2: Distance between two clamps at the end of constant tension application (mm).

L_1: Distance between two clamps at the beginning of constant tension application (mm).

L_0: Length of spacing, $L_0 = 200mm$.

ε_{cf}: Creep elongation.

As shown in Fig. 16, the creep time-strain curve indicates that the warp creep elongation is slightly higher than the weft creep elongation, which is consistent with the results of the fracture elongation rate. The test data is shown in Table 6, the absolute creep elongation in the warp direction is 0.85%, and the creep in the weft direction is 0.73%.

Compared to traditional coated fabric materials, the creep elongation of STFE is close to that of PVC in the warp direction (the higher creep elongation of STFE in the Table 7 is due to the higher stress), while

lower than PVC in the weft direction. Compared to ETFE, STFE has a much lower creep elongation in both directions than ETFE. In conclusion, STFE has better creep performance than traditional membrane materials. The data of PVC is provided by Yucong Yin [10] and the data of ETFE is provided by Minger Wu [11].

Table 6. Results of STFE creep test

Creep elongation (warp)	L_1 (mm)	4.72	4.51	4.56	4.78	5.30
	L_2 (mm)	6.47	6.07	6.30	6.37	7.14
	ε_{cf}	0.88%	0.78%	0.87%	0.80%	0.92%
Creep elongation (weft)	L_1 (mm)	3.52	3.87	3.49	3.68	3.81
	L_2 (mm)	5.00	5.29	5.10	5.17	5.14
	ε_{cf}	0.74%	0.71%	0.80%	0.75%	0.67%

Table 7. Comparison of creep elongation among different membrane materials

Material	STFE (20kN/m)	PVC (12kN/m)	ETFE (2.7kN/m)
Creep elongation (warp)	0.85%	0.38%	2.24%
Creep elongation (weft)	0.73%	1.30%	2.24%

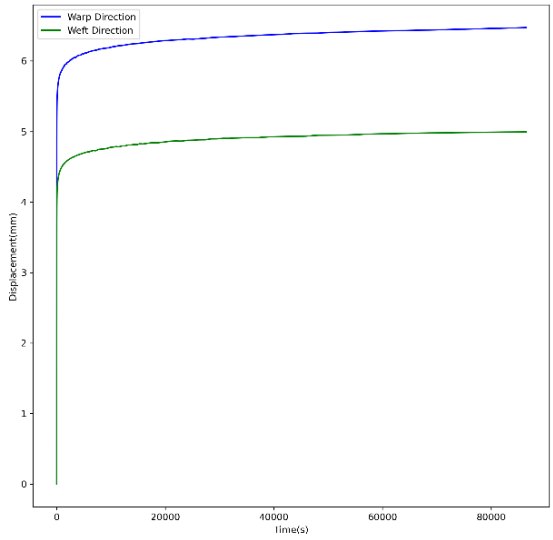

Fig. 16. Creep time-displacement curves of STFE

6. Conclusion

1) The tensile strength of STFE membrane is between that of traditional coated fabric material and ETFE material, while the tearing strength is higher than that of the above two types of materials.

2) The butt-joint connection strength of STFE is higher than the strength of base material. Therefore, the connection reliability is better than traditional membrane materials.

3) STFE has better creep performance than traditional membrane materials.

Abstract

The professional football stadium of Chengdu Phoenix Mountain Sports Center will host the 31st World University Games in 2023. The number of seats designed for professional football stadiums has reached 60000. The stadium roof is about 279 meters long in the north-south direction and 234 meters long in the east-west direction. The maximum overhanging length of the roof is 64 meters. The roof covering material is ETFE membrane material in the inner circle area and metal material in the outer circle area. An attempt was made to use a cable dome structure in a non enclosed roof in a football stadium. By using an inner ring steel truss at the edge of the central large opening, the weakening of the stiffness and integrity of the cable dome structure due to the large opening is compensated, ensuring the effective transmission of the force system of the tension structure. The practice of this project has expanded the application scope of cable dome structures to achieve lightweight and unique architectural effects. This article introduces the selection of the roof structure in detail, explains how the structure can be efficiently, economically, and aesthetically implemented, and ultimately completes the structural expression of the architectural form.

Keywords: large opening, rigid inner ring, cable dome, parametric analysis, anti-continuous collapse

1. Project overview

The Chengdu Phoenix Mountain Sports Center project was designed in 2019 and completed in February 2021. The project includes a 60000 seat football stadium and a 18000 seat comprehensive stadium. The project is located in the northern new city of Jinniu District, Chengdu, China, about 12 kilometers from the center of Chengdu.

The professional football stadium is located on the south side of the base, with a two-storey grandstand and a one-storey box, which can host large-scale football matches and large-scale performance activities. The total aboveground construction area of football stadium is 123500 square meters, and the total height of the building is 64.000 meters; The comprehensive stadium is located on the north side of the base, with a two-storey grandstand and a two-storey box. It can host different types of competitions such as basketball, ice hockey, badminton, gymnastics, and meet functional requirements such as performing arts, conferences, and exhibitions. The total aboveground building area of the building is 83200 square meters, and the total building height is 51.4m.

(a) (b)

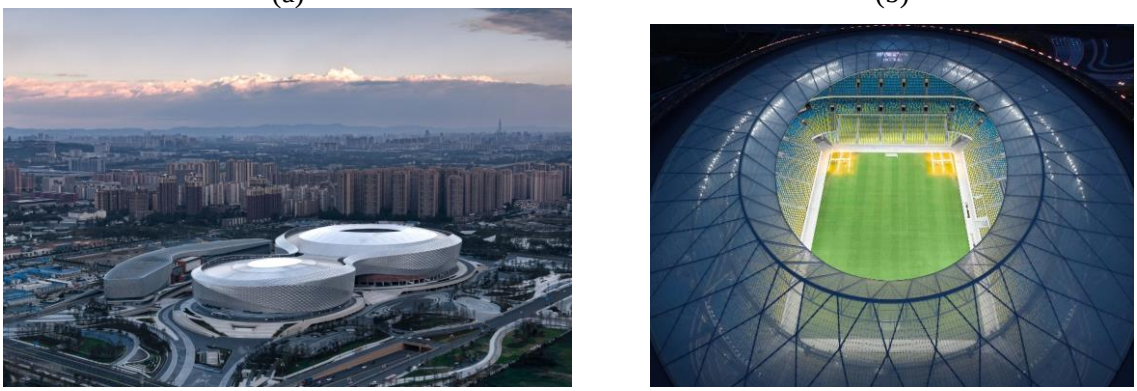

Figure 1. Chengdu Phoenix Mountain Sports Center: (a) aerial view of completed project, (b) night view of football stadium

Through two structural seams, the professional football stadium, the comprehensive stadium, and the Tianfu Club, which connects the football field and the stadium, are divided into three independent structural seismic units above the ground, ensuring that each part of the structure has reasonable dynamic characteristics and seismic capacity, while reducing the impact of temperature on the structure. After dividing the structural units, the structural units of the professional football stadium have a total length of 202m in the east-west direction and a total width of 242m in the north-south direction above the 7m platform. A typical structural layout plan is shown in Figure 2(a); The overall length of the comprehensive stadium structural unit above the 7m platform from east to west is 142m, and the total width in the north-south direction is 167m. The typical structural layout plan is shown in Figure 2(b).

2. Architectural characteristics

2.1. Irregular shape of the roof

For structural design, concise and symmetrical shapes tend to be more uniformly stressed, and have better static and dynamic performance. Especially for large span spatial structures, the symmetrical shape allows the structure to adopt a symmetrical layout, simplifying the design difficulty of the main structure. The architectural design scheme of this project is novel. The overall shape of the roof is inclined, with a north-south inclination and an angle of about 2.5 ° with the horizontal plane. The projection of the roof shape is oval like, symmetrical from east to west, but asymmetric from north to south. The overall shape is high in the north and low in the south, with a gradient shape. The irregular shape has brought certain difficulties to the structural design of the project.

(a) (b)

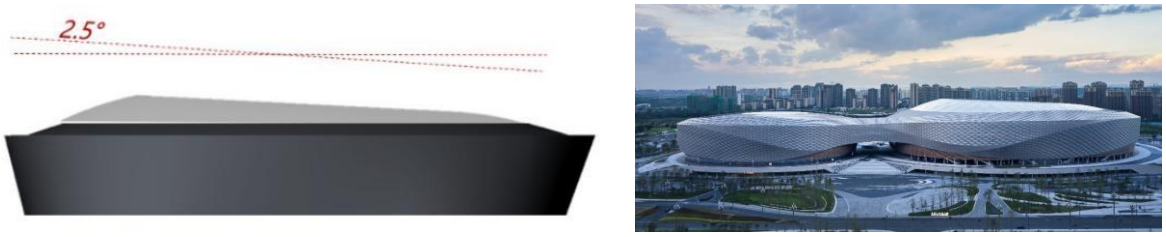

Figure 4. roof form: (a) schematic diagram of the north-south inclination of the football field roof, (b) elevation drawing of building project

2.2. Various roof covering materials

When designing the covering material for the roof, the architect chose two materials, one is traditional metal covering material, and the other is membrane material with high permeability. Choosing a transparent and lightweight membrane material as the covering material not only reduces the load and reduces the impact on the main structure, but also facilitates the maintenance and maintenance of high-quality lawns with a transparent and lightweight roof. Combined with the metal roof on the periphery, it can completely illuminate the lawn surface while avoiding the main stand from being exposed to sunlight, ensuring the audience's watching experience. Due to the different characteristics of the covering materials, it will have an impact on the selection of the main structure. Metal roof construction is convenient, with strong modeling ability and rich colors, but the overall load is large and cannot adapt to the large deformation of the main structure. Therefore, the main structure often adopts rigid systems, such as rigid trusses. The construction of membrane roofing is relatively difficult and its modeling ability is not strong, but the overall load is small and can adapt to large deformation of the main structure. Therefore, flexible systems such as cable trusses or rigid systems such as trusses can be selected for the main structure. The construction of this project adopts metal roofing and membrane roofing, which puts forward higher requirements for structural selection. Whether to adopt a simple rigid system, a flexible structural system, or a hybrid system of rigidity and flexibility is a question that needs to be considered in the design phase of the structure.

(a) (b)

Figure 5. Roof covering membrane material: (a) sunlight transmission film material, (b) interior drawing of construction project

2.3. Non enclosed roof

Unlike buildings such as stadiums and natatoriums, football stadiums often have large openings in the middle of the roof due to their architectural functions and audience line of sight. The size of the openings is close to or even exceeds half the length or width of the structure. How to give full play to the spatial performance of the structure with large openings is also a problem that structural engineers need to consider at the beginning of the scheme. At the same time, the project has designed 60000 audience seats. In order to meet the seating requirements, the overhang length of the roof has finally reached 64m. How to achieve the overhang economically and efficiently poses a challenge for structural engineers.

(a) (b)

Figure 6. Non enclosed roof: (a) top view of building project, (b) roof opening size

2.4. The position of the column grid does not correspond to the shape of the roof

The grandstand design of this project not only meets the requirements of FIFA, but also combines with China's security operation strategy, and tries to shorten the distance between the grandstand and the stadium to improve the proportion of high-quality grandstands. The grandstand design of the project is in a square and rounded shape, so the column network of the structure is closely related to the circumferential shape of the grandstand, and has an equidistant offset relationship with the edge line of the grandstand. However, the projection of the project roof shape is similar to an oval shape (red line in Figure 7), resulting in a problem of inconsistency between the structure column grid connection line (blue line in Figure 7) and the roof structure shape.

(a) (b)

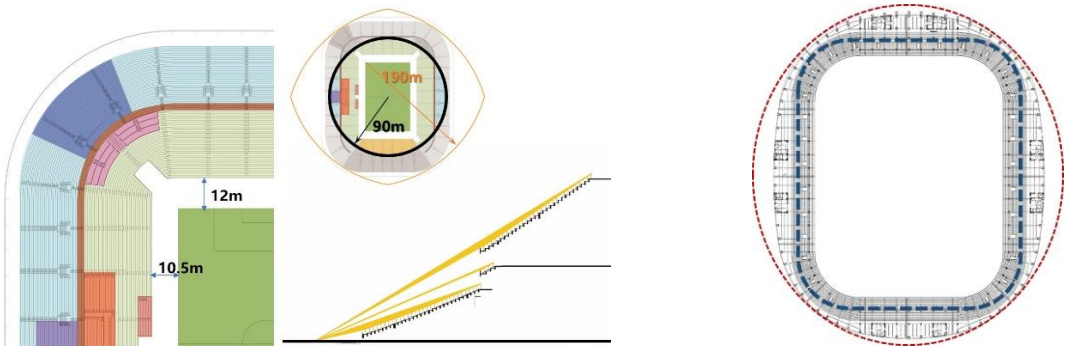

Figure 7. Stand column network relationship: (a) stand form, (b) column grid and roof form

3. Roof structure selection

Based on the architectural characteristics of the project, the roof structure system of the project should meet the requirements of safety, rationality, aesthetics, applicability, and economy. When seeing that

the roof covering material of the building roof is membrane material, the first thought of structural engineers is to use a flexible cable structure system. The most classic of cable structure system is the large opening spoke cable truss structure system[1]. The upper and lower inner ring steel cables of this structural system connect the radially arranged open web cable trusses together (as shown in Figure 8). The structural system has the following characteristics: 1) The planar cable truss is connected as a whole through inner ring cables to form a spatial stable system; 2) There are few structural members and a large number of members are tension cables, while a small number of members are compression members; 3) Structural stiffness is provided by prestress[2]; 4) The structure has a mechanical displacement mode, but can become a geometrically stable system under the action of prestress. However, with the increase of the cantilever length, in order to ensure the structural stress efficiency, the distance between the upper and lower chords at the cantilever end of the cable truss increases, and the height of the compression brace is high, causing certain design difficulties and easily affecting the audience's visual field. Especially in this project, as the structural overhang reaches 64m, if a cable truss structure is adopted, it will affect the audience's view of the game (as shown in Figure 8(b)).

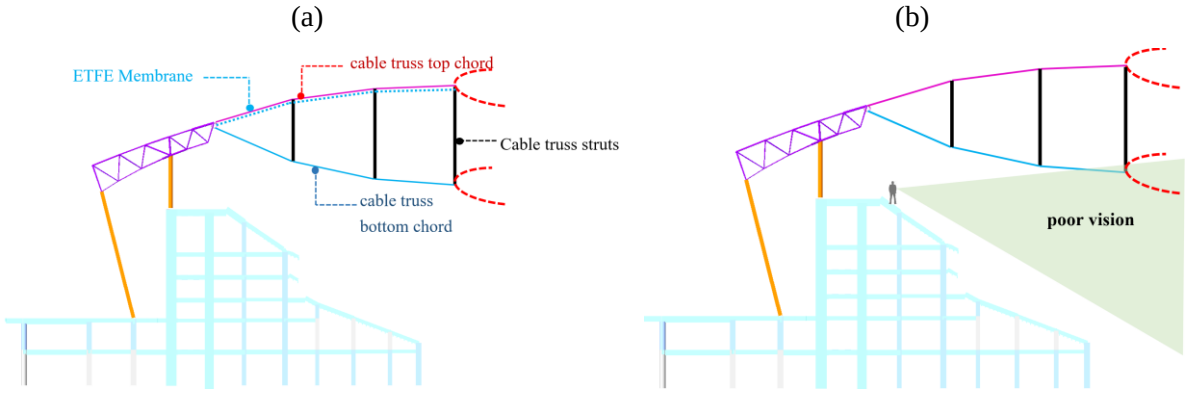

Figure 8. Cable truss structure: (a) cable truss structure composition, (b) audience ;ine of sight analysis

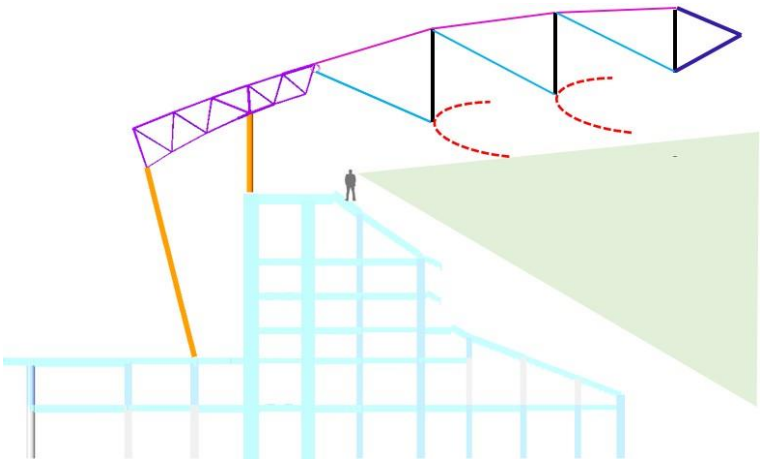
At this time, it is considered to lift the lower stay cable up while reducing the height of the strut. In order to ensure the transmission of force flow, the stay cable is arranged circumferentially at the end of the lower stay cable. At this time, the structural force is transmitted step by step from the inside to the outside. The height of the strut at each level of the structure is limited, and combined with a flexible lightweight membrane roof, not only the structural force is efficient and reasonable, especially suitable for large span spaces, but also can solve many adverse effects caused by the high height of the innermost ring strut, Improve the visual effect within the audience. This structural system is a cable dome structure[3] (see Figure 9).



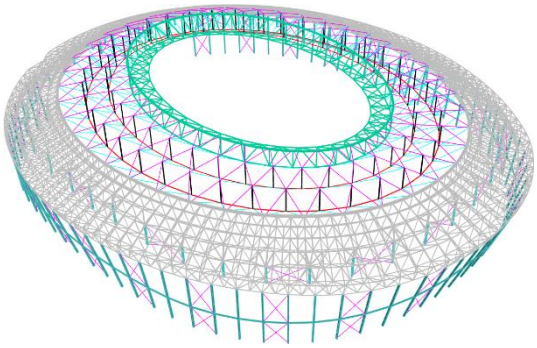


Figure 9. Cable dome structure

A rigid pull ring is arranging in the center of the closed tension cable dome structure, but the size of the pull ring opening is relatively small compared to the overall size of the structure. Generally, it is designed according to ordinary components, which can ensure the effective transmission of tension in the structural system; However, compared to the overall size of the structure, the size of the inner pull ring opening in the central large opening non closed tension cable dome structure cannot be ignored. The large opening significantly weakens the overall stiffness of the structure, and the inner pull ring needs to have sufficient stiffness to ensure effective transmission of tensile force. Therefore, an inner ring steel truss with good stiffness is provided at the edge of the large opening to solve the problem of weakening the overall structure and transmission of tensile force by the large opening.

The plane of the roof of the Chengdu Phoenix Mountain Sports Center is elliptical, with a length of about 279 meters in the north-south direction (long axis) and 234 meters in the east-west direction (short axis). The highest point of the roof is about 64 meters high. The maximum overhang length of the roof roof is 64m, and the minimum overhang length is 55m. In the outer metal material area, a double layer grid structure is adopted, which simultaneously serves as the edge member of the cable dome. The average width of the grid is 27m, and the width of the cable dome is 46m. The cable dome structure in the inner membrane area is provided with two loops of cables, each loop being provided with 40 support rods, with a maximum height of about 14m. The outer ring of the cable dome structure is connected to a steel grid as a compression ring, and the inner ring is provided with a triangular three-dimensional pull ring truss. The lower end of the steel column supporting the roof is hinged to the concrete grandstand structure. The lower end of the outer ring facade steel column is hinged on a 7m elevation concrete structure. The composition of the roof structural system is shown below.

4. Calculation and analysis of roof structure

4.1. Static analysis

Establish a finite element analysis model in Midas Gen analysis software and conduct static analysis considering geometric nonlinearity. The analysis results show that gravity load and temperature play a major control role. The maximum vertical displacement of the large opening inner ring truss cable dome structure under 1.0 times the dead load and 1.0 times the live load is -388mm, and the maximum vertical displacement under 1.0 times the dead load and 1.0 times the wind load is 323mm. The calculation results show that the structure has good stiffness. The maximum stress of the cable in the roof structure is less than 0.5 times the breaking force, and the stress ratio of the main steel members is less than 0.75. The roof cable dome structure has sufficient safety.

The cross-sectional dimensions of the main steel structure components are: the maximum radial cable is a sealing cable with a diameter of 92 mm, and the maximum circumferential cable is a sealing cable with a diameter of 4 pieces of 125 mm; The maximum cross section of the support rod is a circular tube with a diameter of 426mm.

4.2. Stability analysis

Stability performance is the focus of attention for large span spatial structures. The stability performance of the structure under various operating conditions such as 1.0 dead load+1.0 live load, 1.0 dead load+1.0 half span live load was calculated and analyzed in Ansys finite element software through a full process analysis considering both geometric and material nonlinearities of the structure. The analysis shows that due to the use of a sunflower shaped cable dome structure, the structure has a high stiffness out of plane and is insensitive to defects. The ultimate bearing capacity state is controlled by strength. The most unfavorable working condition for stability analysis is 1.0 dead load+1.0 live load, and the safety factor for ultimate bearing capacity is 2.6.

(a) (b)

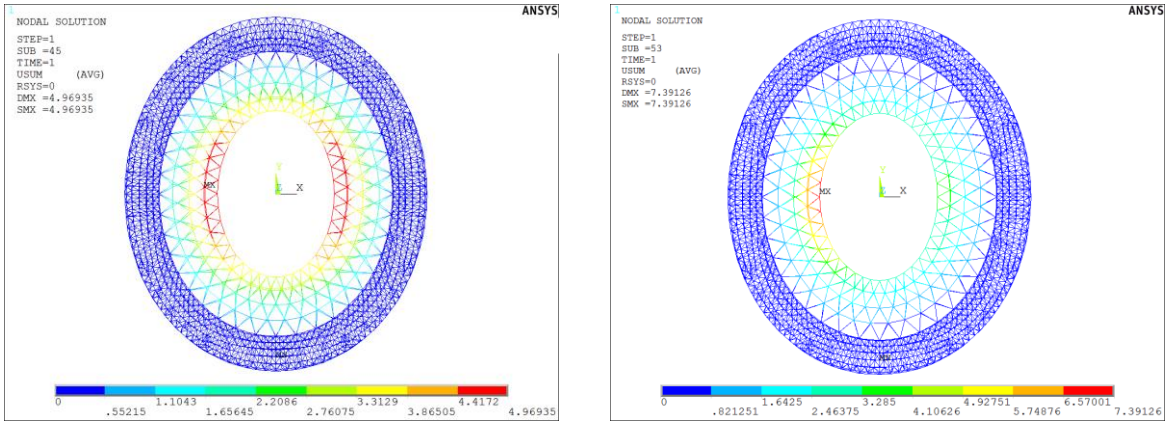

Figure 11. Structural stability analysis: (a) Instability mode under 1.0 dead load+1.0 live load condition, (b) Instability mode under 1.0 dead load+1.0 half span live load condition

4.3. Node analysis

This project has carried out detailed analysis and design on various types of key nodes to ensure reliable force transmission of the nodes. Due to limitations, only the connection nodes between the upper end of the strut and the notochord are listed.

The calculation results are shown in Figure 14. From Figure 13, it can be seen that the ultimate bearing capacity of this node is approximately 2.6 times the control case load, indicating that this node has sufficient safety reserves. As can be seen from Figure 14, under the control working condition, the node is in an elastic state, with the stress in most areas below 200Mpa, and the maximum stress value of 296Mpa appears at the side wall of the pin hole.

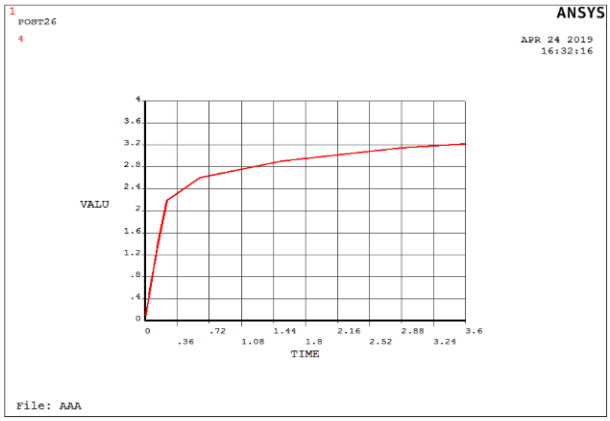

Figure 13. Node load displacement curve

(a) (b)

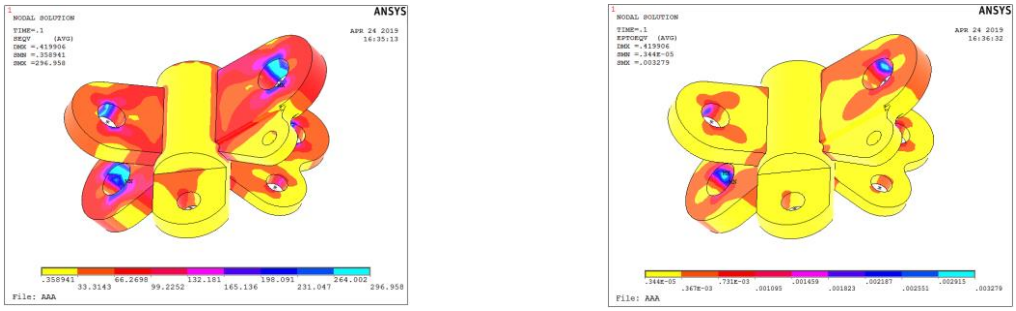

Figure 14. Node analysis results: (a) node stress diagram under 1 time control condition, and (b) node strain diagram under 1 time control condition

4.4. Analysis of resistance to continuous collapse

The cables of the football stadium roof structure play an important role in the entire structural system. If any one of the cables fails and causes the structure to collapse, it will bring serious consequences. Therefore, ANSYS finite element software is used to analyse the collapse resistance of the structure under the condition of broken cables using the transient analysis method of removed components. The location of structural cable breaks is shown in Figure 15.

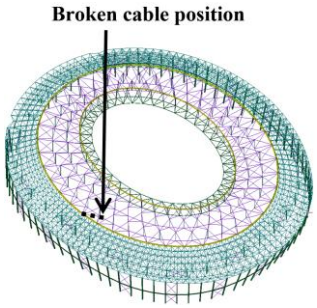

Figure 15. Broken cable position

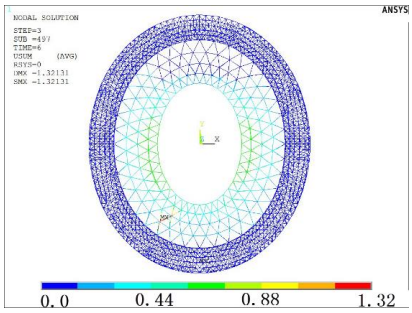

Figure 16. Cloud map of the maximum deformation of the notochord structure on the southwestern side of the fault /m

The fracture of the upper spinal cord on the southwest side was calculated and analysed. As can be seen from Figure 17, after one upper spine cable was broken in the southwest, a large horizontal deformation occurred in the local cable dome in the horizontal direction. After the vibration stopped, the maximum horizontal deformation of the structure was 1.5m, and the maximum stress during the radial cable breaking process of the adjacent upper spine cable was 463MPa, which was less than the cable breaking stress of 1670MPa. During the process of cable breakage, the internal force of the brace decreases and the internal force of the loop cable remains basically unchanged.

5. Conclusion

The professional football stadium of Chengdu Phoenix Mountain Sports Center will host the 31st World University Games in 2023. In the structural design of football stadiums, cable dome structures are used in non enclosed roof, and a large opening inner ring steel truss cable dome structure is proposed, expanding the application range of cable dome structures. The project compensates for the weakening of the stiffness and integrity of the cable dome structure due to the large opening by arraging an inner ring steel truss at the edge of the middle large opening; By adopting a sunflower shaped cable dome structure and conducting force finding analysis and applying reasonable prestress, the problem of uneven structural stress caused by structural asymmetry, oblique placement of the overall structure, and complex boundaries has been solved. At the same time, according to the building covering materials, the grid structure system was adopted, solving the contradiction between the boundary requirements of the column grid and the tensioning structure, achieving the architect's plan efficiently, economically, and aesthetically, and ultimately completing the structural expression of the architectural form.

Abstract

The Zhengzhou Olympic Center Sports Stadium has 60000 seats. The steel structure of the Stadium roof is 291.5m in the north-south direction, 311.6m in the east-west direction and the maximum length of cantilever is 54.1m. The steel structure of roof is composed of four components: the canopy of large-opening spoke-wheel-type cable-supported grid structure with the largest cantilever length in the world, the double-layer grid roof, plane truss and the spatial corridor of triangular mega truss with largest span in China. In order to optimize the large opening spoke-wheel-type cable supported grid structure, 8 main influencing factors on static performance are studied by parametric analysis. The rigid inner ring members is identified as the stable sensitive area of the structure by elastoplastic nonlinear whole process analysis. The load case of snow under extreme climate is considered to ensure the safety of the structure. The ability of the structure to resist progressive collapse is studied by alternative path analysis. Based on the time-varying of construction process and BIM technology, the integrated technology of design and construction is achieved. The seismic performance of the Stadium steel structure is investigated by using the assembly model, and the results show that the steel structure can keep elasticity under the action of frequently occurred earthquakes or precautionary earthquakes, and can achieve the objective of performance about non-yielding under the action of rarely occurred earthquakes.

Keywords: spoke-wheel-type cable-supported grid structure, static performance, influencing factor, nonlinear analysis, progressive collapse, integration, seismic design

1. Introduction

The project of Zhengzhou Olympic Sports Center, which includes Stadium, Gymnasium, Natatorium, and Commercial Facilities, is located in the core region of Zhengxi New District, Zhengzhou City, Henan Province, China (Figure 1). The Stadium has 50000 fixed seats and 10000 movable seats. It is a large-scale Grade A Stadium with a total construction area of 138,500 square meters. The plane size of the concrete structure is about 330m×362m and the roof is about 292m×311m. There are 11 floors above the ground, and the total building height is 54.390m. The standard track and field are located in the middle of the Stadium, which can host football matches and track and field competitions. There are badminton and table tennis courts on the west side of the west stand. The badminton and basketball training courts are located in the northern underground of the north stand. There is an hotel with eight-storey on the east side of the east stand, which is a complex and comprehensive multi-functional Stadium.

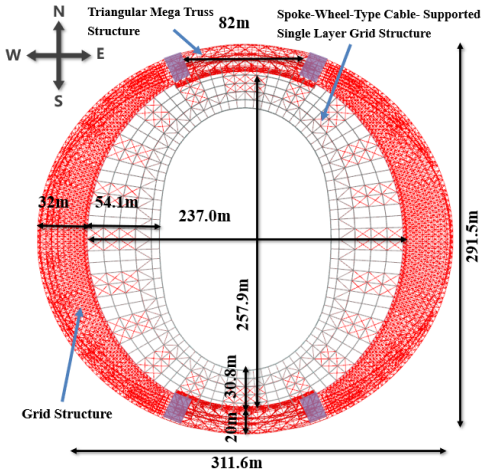
Figure 1. Aerial view of Zhengzhou Olympic Sports Center.

The steel structure of the Stadium roof is about 291.5m long in the north-south direction and 311.6m in the east-west direction, and the plane shape is approximately circular. The cantilever length of the stand canopy is 54.1m in the east-west direction and 30.8m in the north-south direction. The plane shape is approximately elliptical (Figure 2).



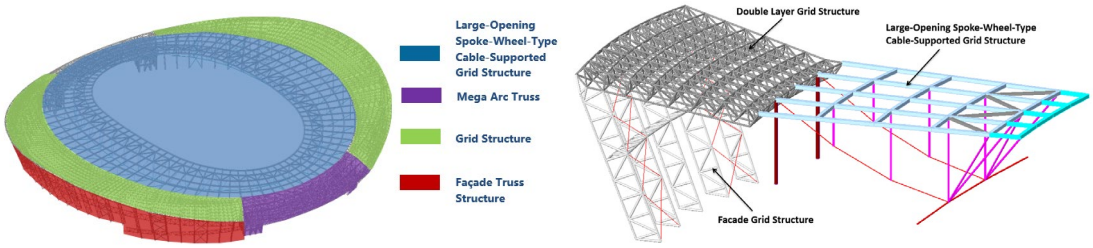


Figure 2. Plan of the Stadium roof.

2. Analysis and research of design

2.1. Structural system and layout

The roof steel structure consists of 4 components (Figure 3a). 1) The stand canopy of Stadium adopts the large opening spoke-wheel-type cable-supported grid structure. 2) The outer roof of Stadium adopts the square pyramid double layer grid structure, which is placed on the outer edge of the roof in the ring shape, and the width is 20m-32m. 3) The spatial corridors adopt the triangular mega truss structure at the north and south ends of the Stadium. 4) The façade adopts the plane truss structure. As shown in Figure 3b, the stand canopy is supported by the steel columns around the stands and the triangular mega truss at the north and south ends. One end of the grid structure is supported on the steel column, and the other end is supported on the facade truss. the lower end of the facade truss is hinged and placed on the

concrete structure with the elevations of 7m and 43.9m. The large opening spoke-wheel-type cable-supported grid structure is adopted for canopy, which is the self-balancing tension structural system [1]. The high-strength material characteristics of the cables are fully utilized, and the impacts on the main structure is also greatly reduced. It can economically and effectively realize the application of large spans, and at the same time obtain the simple design of architecture. The grid structure, as the outer roof of Stadium, also acts as the ring of external compression for cable-supported grid structure. The functional requirements of the building are satisfied by the layout of the facade truss structure and triangular mega truss structure, making the structural selection and architectural requirements harmonious and unified.

(a) (b)

Figure 3. Composition diagram of Stadium steel structure.

The main loads acting on the structure: 1) Self-weight, which should be considered according to the actual weight; 2) The additional dead load of the metal roof is 0.8kN/m^2, sunlight roofing sheets is 0.5kN/m^2， façade system is 1.5kN/m^2; 3) The reference wind pressure is 0.5kN/m^2 (100-year return period). The terrain roughness is Class B. The factor of height is determined according to the code for design. The shape factor and wind vibration factor are determined according to the results of wind tunnel test; 4) The reference snow pressure is 0.45kN/m^2 (100-year return period); 5) The temperatures are considered to be ±35; 6) The live load shall be selected according to the load code based on the building function of the specific location; 7) The seismic precautionary intensity is 7 degrees. The design basic acceleration of ground motion is 0.15g. The group of seismic design is the second group. And the category of seismic precaution is the key precautionary category. The load combination considers the combination of the normal service limit state and the combination of bearing capacity limit state.

According to the importance and distribution of members， the steel structural members of the Stadium are divided into key members (Table 1) and general members, and the indicators of stress control are developed respectively as shown in Table 2 and 3. The control criterions of displacement are simultaneously developed.

2.2. Canopy design of large opening spoke-wheel-type cable-supported grid Structure

2.2.1. Structural system

The shape of the canopy in the Stadium stand area is saddle-shaped, high in the east-west direction and low in the north-south direction. It adopts the large opening spoke-wheel-type cable-supported grid structure with internal ring trusses. The large opening spoke-wheel-type cable-supported grid structure reference to the mechanical characteristics of spoke-wheel-type tensioned cable truss structure [3] and beam-string structure [4-6], which is the new type of self-balancing and rigid-flexible composite structure. As shown in Figure 4, the upper chord of the structural system is the rigid single-layer grid, and the lower chord is the tensioned cable-strut system in the spoke-wheel-type layout; Diagonal web members connecting the ring cable and the upper chord single-layer grid are arranged along the ring cable to form the stereoscopic inner ring truss; Based on the combination of the requirement by architectural daylighting, the innermost ring is set with the cantilevered grid; The entire structural system is supported on the stand columns and the north-south triangular mega truss. The upper chord rigid grid of this project is arranged in the ribbed ring type, with 6 ring beams and 84 radial beams in total. Diagonal web members are set between the two ring beams corresponding to the inner truss. 1 ring cable and 42 radial cables are set in the lower chord cable-strut system, and 3 vertical struts on the upper side of each radial cable.

The mechanism of the structural system: By tensioning the lower chord cable, the upward support force is generated in the strut and elastic support for the upper single layer grid; The wide compressed ring is formed by the upper chord single layer grid, and the external compressed ring is formed by the

grid outside the stand and the north-south triangular mega truss, which further increases the horizontal stiffness and effectively resists the horizontal force caused by radial cables. This is the self-balancing structural system.

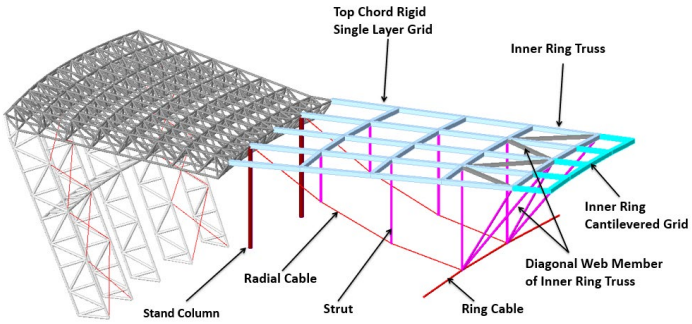

Figure 4. Composition diagram of large opening spoke-wheel-type cable-supported grid structure.

2.2.2. Statics analysis

Through a series of analysis and research on the static force influencing factors of the large opening spoke-wheel-type cable-supported grid structure, the mechanical characteristics under the static force are grasped. According to the basic principle of structural mechanism, there are two aspects by analysis about the influencing factors of structural static performance:

1) For the cable-strut system (Figure 5): Pretension is the necessary element in cable-strut system. Therefore, the magnitude of pretension was set as the analysis parameter; The support of the cable-strut to the rigid grid is mainly provided by the radial cables, and the stiffness of the radial cables is related to the inclination angle of the cables. Therefore, the height of the struts that characterizes the inclination angle of the radial cables was set as the analysis parameter; The function of the ring cable is balancing the horizontal force of the radial cable in the inner ring, and adjustment of the internal force distribution of the cable-strut system. Therefore, the shape of the inner ring cable was set as the analysis parameter; The form-finding of the cable system depends on the layout of the boundary. Therefore, the height difference of the outer ring beam at the boundary of the rigid grid was set as the analysis parameter.

2) For rigid grid: As the upper chord rigid member of the structural system and the “compressed ring” of the lower chord cable system, the rigid grid provides the certain stiffness and bearing capacity. Therefore, the height of the rigid grid surface and the rigid grid form were set as the main analysis parameters (Figure 6). At the same time, the influence of the height difference which about the inner ring of the rigid grid and the curvature of the ribbed beam on the structural performance were analysed.

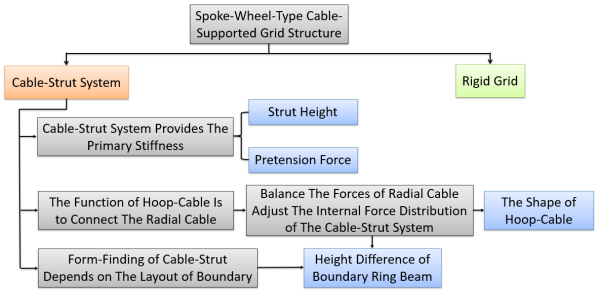

Figure 5. Parameter setting according to cable-strut system.

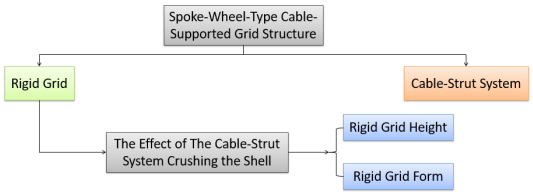

Figure 6. Parameter setting according to rigid grid.

Through the study of the factors which affecting the static performance, the principle of structural optimum design was obtained [2]. Therefore, based on the satisfaction of architectural requirements, the optimized parameters could be used to design and analyse the large opening spoke-wheel-type cable-supported grid structure roof of Zhengzhou Olympic Sports Center Stadium.

Through the modelling of the finite element analysis in Midas Gen analysis software, considered the influence of geometric nonlinearity, and analysed the static performance of the structure. The gravity load and temperature are the major controlling as shown in analysis results. The maximum vertical deformation of the cable-supported grid structure under displacement control conditions (1.0 dead love+ 1.0 live load+ 0.6 temperature reduction) is -427.4mm. The deflection-span ratio is 1/126 less than the limitation of 1/125 in design code. The maximum vertical deformation is occurred at the edge of the east-west inner ring of the cable-supported grid (Figure 7). The stress ratios of all members meet the requirements of Table 2 and Table 3.

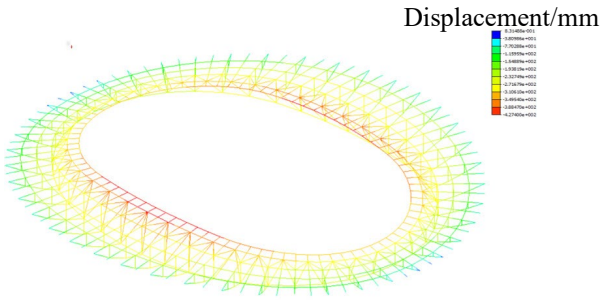

Figure 7. Displacement distribution of large opening spoke-wheel-type cable supported grid structure.

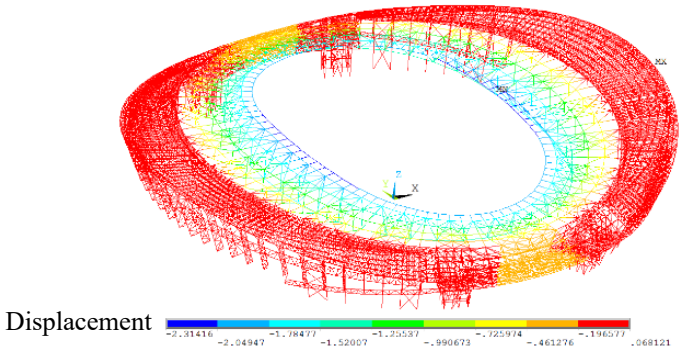
The cross-sectional dimensions of the main steel structural members are shown in Table 5. The maximum radial cable is 2×Φ119 of vanadium cable，and the ring cable is 8×Φ130 full locked coil rope; The maximum cross-section of the radial member is □750×500×20×20 and the ring member is □750×700×30×30 in upper chord grid; The maximum cross-section of the strut is Φ500×25.

Table 5. Sectional dimension of main steel members.

Function		Section Type	Section specification
Cable-Supported Grid Roof	Radial Cable	Round	Φ116、Φ140、2×Φ119
	Radial Cable	Round	8×Φ130
	Rigid Grid Radial Member	Rectangular Tube	□750×400×16×16、□750×500×20×20 etc.
	Rigid Grid Radial Member	Rectangular Tube	□750×450×20×20、□750×700×30×30 etc.
	Strut	Circular Tube	Φ315×16、Φ426×16、Φ500×16、Φ500×25
Roof Support Column		Circular Tube	Φ800×35

2.2.3. Stability analysis

Stability is the focus of the large-span space structure. In the Ansys software, the stability of the structure was studied by analysing the whole process of geometry and double-nonlinear analysis of material, and examined the load-displacement curve of the whole process. The stability of the structure was considered under various working conditions, such as 1.0 dead load + 1.0 live load, 1.0 dead load + 1.0 half-span live load, 1.0 dead load + 1.0 wind load, 1.0 dead load + 1.0 temperature rise and 1.0 dead load + 1.0 temperature reduction performance. Analysis shows that the stability of the structure is better, insensitive to defects, and control by strength. Due to the large axial pressure and weak out-of-plane stiffness of the inner ring beam, it is the sensitive area for stability and loses stability first (Figure 8). The most unfavourable working condition for stability analysis is 1.0 dead load + 1.0 live load, and the safety factor of ultimate bearing capacity is 2.6.



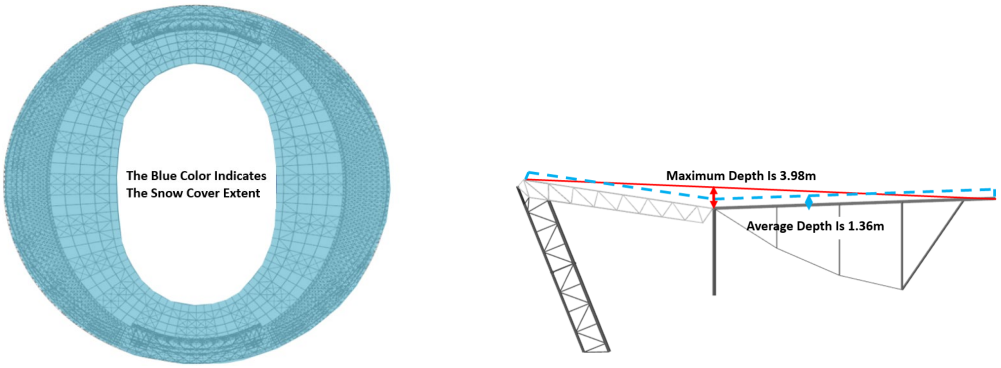


Figure 8. Buckling mode based on the load case of 1.0 dead load+1.0 live load.

2.2.4. Analysis of snow load in extreme climate

The elevation of the outer ring beam of the spoke-wheel-type cable-supported grid roof is lower than the outer edge of the grid and the inner edge of the cable-supported roof. Therefore, it is easy to cause the snow accumulation near the position. Based on the importance of the Stadium, the unfavourable condition of snow accumulation was considered in the extreme climate. In Midas Gen, the nonlinear finite element method was used to conduct static analysis on the structure. The snow accumulation range during the calculation is shown in Figure 9. According to the maximum snow accumulation, the average depth of snow accumulation is about 1.36m after calculation, and the snow load is 3.4kN/m^2.

（a）Plane　　（b）Section

Figure 9. Snow Distribution Range

The accidental combinations were considered of dead load, snow accumulation and temperature reduction conditions. The maximum stress of the ring cable is 575MPa and the radial cable is 675MPa. And the maximum stress ratio is 0.48, which is less than the limit value of 0.5 in Table 3. The stress ratios of the upper chord rigid grid also meet the requirements of Table 2. It can be seen from the analysis results that the structure can still guarantee the safety under the consideration of snow load in extreme climate.

2.2.5. Progressive collapse resistance analysis

The Stadium is the Densely populated place, and reliable measures should be taken in the design to avoid the progressive collapse of the structure due to the failure of local members. The spoke-wheel-type cable-supported grid structure resists external loads by applying of prestress to the cables. Therefore, the cables play a vital role in the entire structural system, and it is necessary to avoid the progressive collapse of the structure caused by the failure of the cables. The method of removing members (alternate load path method) can analyse the response of the structure after partial members

failure, to ensure that after partial members failure, the remaining members can redistribute internal forces and resist external loads without progressive collapse. Therefore, the member removal method was adopted, and the dynamic elastoplastic time-history analysis was used in Ansys software to study the progressive collapse resistance of the structure under the condition of broken cables [7-9].

The ring cable is the most important load bearing cable. This project guarantees the safety by controlling the stress ratio to be less than 0.4, and 8 parallel sub-cables are adopted to form the ring cable in structure. Assuming that the sub-cables of the 5 ring cables are damaged, the remaining 3 sub-cables bear the total force of the original 8 sub-cables. The stress ratio is 0.4/（3/8）=1.06, which just exceeds the breaking force. Therefore, when less than 5 sub-cables are broken, the ring cable will not be damaged as a whole, and the safety of margin is high.

Radial cables consist of single or double cables and are relatively easier to be damaged. Therefore, one and two radial cables are broken respectively at the maximum cantilever and tension to examine the progressive collapse resistance of the structure. The case where the cable breaks at the maximum cantilever as an example in Table 6. The stability value in the Table is after the dynamic impact effect of the broken cable disappears and the structure is stable; The peak value is the maximum value during the dynamic process of breaking the cable; The amplification factor is the ratio of the stable value, the peak value and the value before the broken cable. It can be seen that after the radial cable is broken, the displacement of the broken cable and the internal force of the adjacent radial cable will increase significantly, and the increased rate of breaking two radial cables is greater than one radial cable. Due to the dynamic effect, the maximum increasing of the adjacent cable force is 2.82 times when two radial cables are broken, and 2.23 times after stabilization. The maximum increasing in displacement is 7.7 times, and 5.0 times after stabilization. However, the internal force of the cable is still smaller than the breaking force, and the structure will not be progressive collapse.

Table 6. Results of alternative path analysis.

Condition	One Cable Broken				Two Cable Broken			
	Vertical Displacement		Stress of Radial Cable		Vertical Displacement		Stress of Radial Cable	
	Value/ m	Amplification Coefficient	Value/ MPa	Amplification Coefficient	Value/ m	Amplification Coefficient	Value/ MPa	Amplification Coefficient
Before Breaking the Cable	0.170	-	221	-	0.170	-	221	-
After Breaking the Cable (Stable Value)	0.250	1.47	327	1.47	0.857	5.0	501	2.23
After Breaking the Cable (Stable Value)	0.320	1.89	449	2.03	1.310	7.7	623	2.82

2.3. Integration technology of design and construction

The engineering project has two main stages from start to finish, design and construction. The construction stage includes the processing state, construction and installation state and forming state; The design stage includes the forming state and the working state; The forming state, as the junction between the design and construction stages, is the end of the construction stage and the start of the design stage (Figure 10).

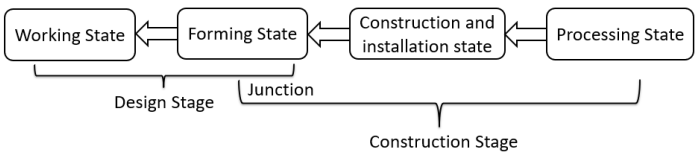

Figure 10. Design and Construction Stage.

In the process of manufacturing for complex steel structures, if the connection details are not fully considered in the design stage, it may cause processing difficulties, or even impracticability. At the same time, during the construction and installation process, the structure is the time-varying structure [10-11]. The composition, boundary conditions, internal force and deformation of the members are all changing, which affecting the structural forming. If the construction forming deviates too much from the original design, it will lead to problems, such as large geometric deviations, reduced mechanical properties, and even modification and adjustment of the structural plan. So, the design stage and the construction stage should be considered in the integrated manner.

In the steel structural design of Zhengzhou Olympic Sports Center Stadium, the design and construction were considered comprehensively. And the integrated technology of design and construction was formed, mainly including the following two points: 1) Tension numerical analysis based on time-varying structure; 2) Steel structure design based on BIM technology.

2.3.1. Tension numerical analysis based on time-varying structure

The large opening spoke-wheel-type cable-supported grid structure is set with inner ring truss. Due to the diagonal braces of inner ring, the tensioned cable-strut system is the statically indeterminate structure. And the time-varying installation will significantly affect the forming state of the structure. Analysis, calculation and consideration about the generation path of the members. The cumulative effect of stress and deformation. Tracking and analysis the whole process of tensioning and forming. And understanding the internal forces and displacement changes of the structure. With the objective of minimizing the difference between the forming state and the design target, the feasibility of the structure and the appropriate tensioning and forming method were evaluated during the design stage. The following 5 tensioning and forming methods were considered (Figure 11).

1) Tensioning of the complete structure with diagonal braces of inner ring; After diagonal braces of inner ring are installed, the radial cables are directly tensioned for forming.
2) Tensioning + in-situ installation of diagonal braces: Tension the radial cables, and then install the diagonal braces in-situ.
3) Tensioning + installation of the front-end diagonal bracing section: Tension the radial cables, and then install the diagonal braces of inner ring and the corresponding upper rigid grid.
4) Tensioning + installation of diagonal braces + jacking up of diagonal braces: Tension the radial cables, install the diagonal braces, and then install the jacks on the diagonal braces and push the diagonal braces in place.
5) Tensioning + end jacking + installation of diagonal braces: Tension the radial cables. After the tensioning is completed, jacking the cantilever section of the front-end of the roof by jacks, and then install the diagonal braces after the jacking is in place.

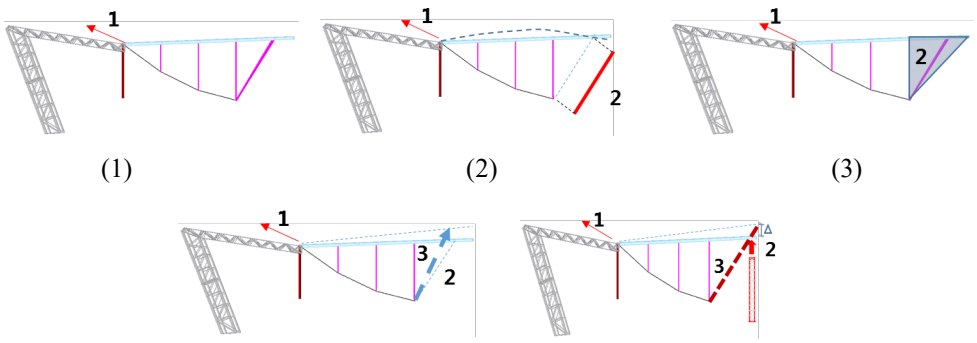

Figure 11. Five Tensioning Methods.

Table 7 is the comparison of each tensioning method. Method 1 has the largest deviation of cable force, and the maximum deviation of ring cable force is 11.5%; Method 3 has the largest displacement deviation which is 872mm; In method 2, the deviation of cable force is small, but the displacement and stress deviation of steel members are large; In method 4 and 5, the displacement, cable force and stress deviation of steel members are all very small, which meet the actual engineering requirements and can be used as the better implementation method. Method 5 was finally adopted for the construction.

Table 7. Comparison of Tensioning Methods.

Tensioning and forming method	Displacement Deviation/mm	Ring Cable		Radial Cable		Stress Difference of Rigid Member Value/MPa
		Cable Force Deviation/KN	Percentage of Cable Force Deviation/%	Cable Force Deviation/KN	Percentage of Cable Force Deviation /%	
Method 1	-270~86	-1924~-1241	-11.5~-7.5	-37~41	-1.36~1.4	-150~73
Method 2	-341~153	-1036~-856	-6.3~-5.1	-48~147	-1.5~6.3	-165~88
Method 3	-872~265	-1254~726	-7.5~-4.4	-202~-48	-6.3~-4.2	-104~96
Method 4	-2~16	176~226	1.1~1.4	-34~17	-2.6~0.6	-10~35
Method 5	-47~49	-65~-6	-0.4~-0.04	-51~70	-1.6~2.9	-33~36

2.3.2. Steel structure design based on BIM technology

Based on BIM technology, the digital 3D of structural model was built in the design stage (Figure 12). The BIM model can solve the problems, such as dimension matching and collision of members, and obtain joints that satisfy the calculation assumptions, are easy to process and beautiful. For the joints obtained by BIM technology, elastoplastic finite element analysis was carried out with application of Ansys software to ensured that the design of the joints met the force requirements (the ring cable clamp as an example, as shown in Figures 13 and 14). Through the application of BIM technology, the detailed design in the processing and production is advanced, which promotes the integration of design and construction, reduces the repeated work of adjustment, and greatly improves the quality of design.

2.4. Steel structure analysis of seismic performance

In order to accurately reflected the impact of the concrete structure on the upper steel structure under the seismic action, the concrete structure and upper steel structure were combined to the integration which was the collaborative finite element model in Midas Gen (Figure 15). The model considered the seismic action of three-dimensional dominated by horizontal and vertical earthquakes. And the seismic performance was analysed by elastic response spectrum method and time-history analysis method.

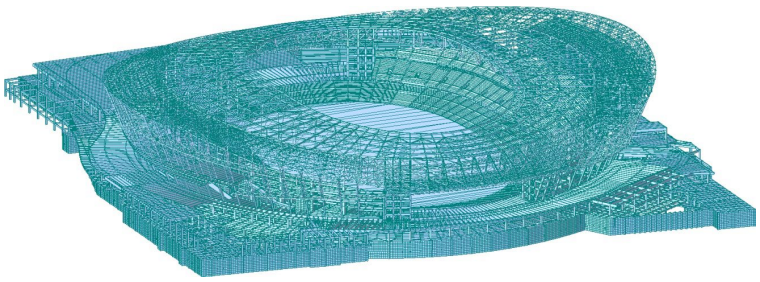

Figure 15. Collaborative analysis model of the Stadium.

The analysis results of elastic response spectrum are shown that: Under frequently occurred earthquake, the maximum stress ratio of the key members occurs at the struts of the cable-supported grid structure, which is 0.568 and less than the limit value of 0.75 (elasticity) in Table 2; The stress ratio of general members is less than the limit value of 0.9 (elasticity) in Table 2; The maximum stress ratio of the cable is 0.26, which is less than the limit value of 0.4 in Table 3. Under the precautionary earthquake, the maximum stress ratio of the key members occurs at the struts of the cable-supported grid structure, which is 0.854 and less than the limit value of 0.9 (elasticity) in Table 2; The stress ratio of general members is less than the limit value 1.0 (elasticity) in Table 2; The maximum stress ratio of the cable is 0.28, which is less than the limit value of 0.5 in Table 3. Under rarely occurred earthquake, the maximum stress ratio of the key members occurs at the struts of the cable-supported grid structure, which is 0.989 and less than the limit value of 1.0 (elasticity) in Table 2; The stress ratio of general members is less than the limit value 1.0 (non-yielding) in Table 2; The maximum stress ratio of the cable is 0.26, which is less than the limit value of 0.5 in Table 3. All kinds of members meet the objectives of performance under different seismic levels.

The results of time-history analysis method are shown that: Under rarely occurred earthquake, the maximum stress ratio of a small number of key members is 1.04, which is slightly greater the 1.0, but within 5%. The occurrence location is the web member connecting the grid and the façade truss. The stress ratios of the cables are all lest than the limit value of 0.5 in Table 3. And the members basically meet the objectives of performance. In general, the results of time-history analysis method are close to the elastic response spectrum.

The analysis shows that the roof structure can maintain the elasticity under frequently occurred earthquake or precautionary earthquake. Under the action of rarely occurred earthquake, roof structure can achieve the objective of performance about non-yielding, and has the good seismic performance.

3. Conclusion

1) The inner ring beam of the large opening spoke-wheel-type cable-supported grid has the large axial compression and weak out-of-plane stiffness, which is the sensitive area for stability and will lose the stability first. In general, the stability is good and controlled by strength.

2) Unfavourable snow accumulation condition in extreme climate should be considered in combination with the shape of roof. The safety can still be guaranteed of the structure by considering the snow accumulation at the depth of 1.36m in this project.

3) The large opening spoke-wheel-type cable-supported grid has the better performance against progressive collapse. The progressive collapse of the structure will not be occurred when two radial cables are broken.

4) For the complex steel structure, the design and construction stages should be considered in the integrated manner. Otherwise, the problems will be easily occurred, such as processing difficulties, large geometric deviations and reduced mechanical properties, and even modification and adjustment of the structural plan. The steel structure of Zhengzhou Olympic Sports Center Stadium takes into account the influence of time-varying during construction process, and combines BIM technology to achieve the integrated technology of design and construction.

5) The roof structure can maintain the elasticity under frequently occurred earthquake or precautionary earthquake. Under the action of rarely occurred earthquake, roof structure can achieve the objective of performance about non-yielding, and has the good seismic performance.

Abstract

This paper investigates the experimental response of digitally manufactured hollow timber columns incorporating dry mechanical connections (DMC). Timber plates were cut to complementary geometries and mechanically attached to interlock and form an integral joint. For this research, from existing DMC, rectangular tab and slot geometries were considered. Four sets of columns with different aspect ratios, were tested to assess the influence of member slenderness on the structural response, which has not been yet investigated. Complementary compression and tension samples, as well as single tab and slot joint shear and pull-out samples were also tested. After describing the design rationale and manufacturing methodology, the test results from more than forty material and structural tests are given. A full account of the deformational response, stiffness, strength and post-peak characteristics of each configuration is given. The material tests indicate both the compression and tension strengths of the plywood sheet are of similar magnitude in the range of 25 MPa. As expected, the tension failure was relatively brittle whilst crushing in compression was rather gradual due to the inherent properties of the engineered timber. The tab and slot joint shear strength was consistently above 6 MPa, whilst the friction strength around 0.5 MPa. Brittle failure was observed in all the column tests. The predominant failure modes were crushing close to the top or bottom of the columns, buckling of the tab-panels or slot-panels around mid-height, and separation of plies in the failed region. The load-shortening response indicated that the stiffness and strength of the DMC hollow timber columns reduces gradually with increasing slenderness. Relatively slender columns with an aspect ratio of 5.0, had about 22% less strength than stub columns with an aspect ratio of 1.0. These results provide a detailed insight into the structural performance of digitally manufactured hollow timber columns which can be employed in temporary lightweight structures that can be disassembled and reused.

Keywords: digital manufacturing, timber joints, dry mechanical connections, disassembly, compression members

1. Introduction

Engineered wood materials like glulam, laminated veneer lumber (LVL) or plywood (PW) overcome issues such as strength, durability, natural defects, and scalability occurring in sawn timber [1]. These were applied in a number of digital fabrication projects such as, The Vida Theatre in Switzerland, which adopts integral mechanical attachments or dry mechanical connections (DMC) inspired by traditional cabinetmaking, showcasing the potential of combining digital and timber technologies. Another example, the ICD/ITKE Research Pavilion (Figure 1a), was designed with birch PW strips utilising the elastic bending behaviour of the material. The strips were robotically manufactured as planar elements, and subsequently connected so that elastically bent and tensioned regions alternate along their length [2]. WikiHouse shown in Figure 1b is one of many prototypes designed worldwide using a unique digitally fabricated open-source building system that started development in 2014 and demonstrates the capabilities of typical off the shelf PW and OSB sheets in building compliant, affordable houses with minimal erection time and labour required. The concept of building blocks exploits the benefits of CAD

and CNC (3-axis) technologies to produce accurate and jigsaw-like components, to enable people with no foreknowledge of the construction industry to construct a WikiHouse [3]. The Hexbox shelter in Sydney depicted in Figure 1c, adopted tusk mortise and tenon/tab joints to construct a curved shell PW canopy with an assembly of 201 unique hexagon box-like segments with PW wedge connectors [4].

The DMC method is a conventional technique of joining timber without using additional connectors such as screws or bolts, as commonly used in building structures [5]. With time it became unfeasible due to high labour costs and the need for specialized workmanship. But with modern digital fabrication, this technique has been resurrected. It is also known as 'dry wood joints' or 'wood-wood connections,' and include different types of joints such as mortise and tenon/tab, notched, lap, and scarf joints [6] (Figure 2). DMC was used in computer-controlled fabricated folded CLT plate structures made to create a bidirectionally folded surface construction, joined using a customised single-degree-of-freedom (1DOF), multi tab and slot joint (MTSJ) DMC similar to those used in this paper and shown in Figure 3 [7]. Compared to the configuration in Figure 3, the geometry of the tabs and slots was trapezoidal [8].

On the fixity provided by DMCs, Ref. [9] explored the MTSJs with dovetail joints (DJ) for the joinery of LVL panel hollow beams. It was shown that DJ provide a highly feasible alternative to the traditional screwed connection, obtaining 96% of the rigidity comparing it to reasonable screw spacing, with a much shorter assembly time. Experiments comprised ten series of hollow beams, produced from 21mm thick LVL panels with spruce ply, and incorporating different connection types. Sensitivity analyses were conducted with respect to varying the tab length (41mm to 221mm) and the tab face angle (0, 15, and 25 degrees). The slot lengths were equal to the tab lengths for each configuration. It was concluded that increasing the tab face angle to 15 or 25 degrees increases rigidity by 26% and 38%, respectively. Larger angles, such as 25 degrees, increase transverse stresses and loads perpendicular to the panel grain.

(b)

(c)

Figure 1. Structures incorporating DMC, a) ICD/ITKE Research Pavilion 2010 [2]; b) Example of Wiki House construction [3]; c) Hexbox Shelter [4].

Two types of MTSJs were investigated, showing that the closed slot MTSJ was more efficient and structurally robust compared to the open slot MTSJ [10,11]. Closed slot (CS) MTSJ are like those from Figure 3, whilst open slots are joined at the edge of the two plates; i.e. the tabs and slots are in contact at three interfaces. The load-carrying capacity of the CS joint was studied in an experiment using five types of wood products, including OSB and LVL, and varying tab lengths [12]. Robeller et al. [10] tested the assembly of a folded timber plate structure with oversized DMCs of 0.05- 0.25mm.

They discovered that the force required for inserting tabs significantly increased for oversizing above 0.15mm. They also found that tilting the joint faces at a 1° angle across the edge greatly reduced the wedging effect. An investigation into the CS connection explored three different tab insertion angles (45, 60 and 90 degrees) with specimens loaded in the parallel and perpendicular fibre orientations, and the use of two LVL types. The in-plane strength was highest in specimens with a 60-degree tab insertion angle, as it activated both tension and shear capacities perpendicular to the grains in the tabs. The study also found that the tab insertion angle strongly influenced joint stiffness, while the fibre orientation had a significant impact on joint strength [6].

(a) (b) (c) (d)

Figure 2. Joint types a) mortise and tenon/tab; b) notch; c) lap; d) scarf.

Elsewhere, the structural response of an OSB roof (slab) components composed of large top and bottom panels (1.25 × 2.5m) separated and joined by web elements, and employing DMC CS joints. A fully robot-automated process was used for manufacturing and assembly. Shear tests showed that the CS joint behaviour is elastic and brittle, the panel thickness does not significantly influence the resistance and stiffness, but the machining of the panel does, and the joint spacing affects the shear stiffness up until an effective number of joints is reached [13].

DMCs called elastic interlocks or snap-fit joints were also developed [7]. These were used to join 21 mm thick Spruce Kerto-Q panels with a box beam that was CNC manufactured. The snap-fits only carried tensile forces, while prismatic tab-and-slot joints provided the share resistance, making the connection behave like a screwed joint. The snap-fit joints were only necessary during construction to keep the panels together, so they were not designed for high traction forces. Changing the hook geometry and the number of hooks could improve the shear capacity of the joint. Although DMCs have been studied in various applications, limited research has been conducted on its use for structural applications in typical framed buildings such as beams and columns. This study aims to investigate the structural performance of digitally manufactured hollow timber columns incorporating DMC, which has not been explored before. Such systems can be employed in temporary lightweight structures that can be disassembled and reused.

2. Methods and materials

To analyse the behaviour of DMC timber hollow columns in compression, four sets of columns were designed with different aspect ratios, to capture the effects of slenderness. Three specimens for each configuration were built. In addition to the column tests, material (tension and compression) and DMC (shear and pull-out) tests were also conducted to obtain the mechanical properties of the 18 mm hardwood plywood (PW) poplar core. These tests assess the compressive and tensile strengths of the material, and the shear strength of and adhesion (friction) of each tab and slot joint in the columns. A minimum of three material tests per configuration were carried out, in accordance with current procedures. The moisture content of the PW was obtained using the existing guidance [14]. This was 5.76 %. All samples were taken from PW sheets of 1220 × 2440 × 18 mm sheets. The methodology comprised the following stages: design, cutting of the material, preparation for testing, and testing, and post-processing. These are explained in more detail below.

2.1. Design and fabrication

Three-dimensional representations were developed using SketchUp, and AutoCAD 2022 was employed to produce the exploded columns in 2D drawings form, for CNC machining [15, 16, 17]. The specimen designs were constrained by the 3 axes of the CNC machine. Thus, the tab and slot DMC was chosen for these experiments. Column designs were also constrained by the CNC machine bed dimensions (600 mm × 900 mm), and a further reduction due to the spindle not reaching the full length of the bed. A schematic column design configuration (AR4), along with the other test specimens, are shown in Figure 3. Material/connection sample ID adopts the format xxx-y, in which xxx=Ten, Com, Shr, Pul for tension, compression, shear or pull-out, respectively, whilst y is for the sample repeat. Columns specimen ID

includes the definition Col-ARx-y, in which Col stands for columns, ARx is for aspect ratio with x=1,2,3,4,5, and y is for the specimen repeat. For example, Col-AR1-2, is the second column with aspect ratio of 1 (i.e. height to width ratio of 1).

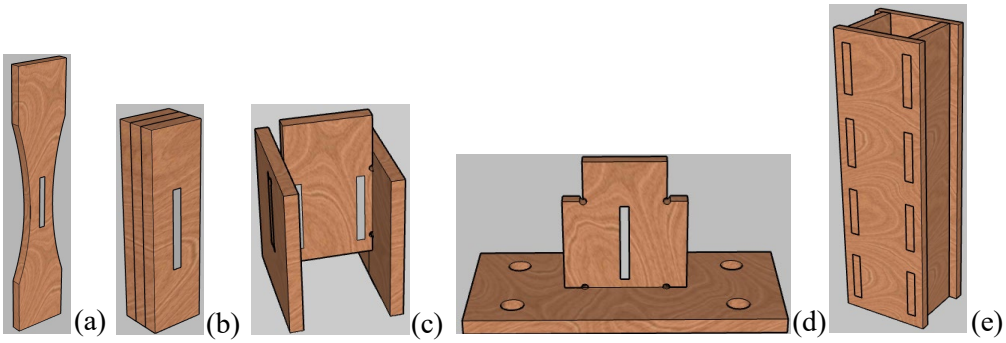

Figure 3. Material and column test specimens with location of transducers shown by grey shaded areas for: a) tension, b) compression, c) shear, d) pull-out, e) hollow column (AR4) (note: not to scale)

After the schedules were ready, they were opened on the CNC's VCarve Pro software ~~and~~ where the cut runs were configured [18]. Between 2 and 6 tabs of length 10 mm and thickness 4 mm were added to each element, to keep them secure while being cut. The router was configured to 7 passes at 3 mm depth for each element, corresponding to half the diameter of the router cutter. The first pass, however, was set to 0.5mm depth, to provide a clean finish. The entire cutting depth was set to 18.5 mm, 0.5 mm larger than the thickness to allow for cutter penetration. A sacrificial MDF board was used below the plywood boards to protect the CNC bed (Figure 4). A Spartan 6090, 3-axis CNC router, equipped with a straight, 2-flute cutter with a radius of 6mm, operated at a feed rate of around 3800 millimetres per minute (mm/min), corresponding to a chip load of 0.38mm, and a spindle speed of 10,000 revolutions per minute (RPM). The plunge rate was set to 254 mm/min. The cutting time for the scheduled board was around 35 to 50 mins, depending on the quantity and complexity of components per board. After each cut job was complete, the elements were marked with their identification code.

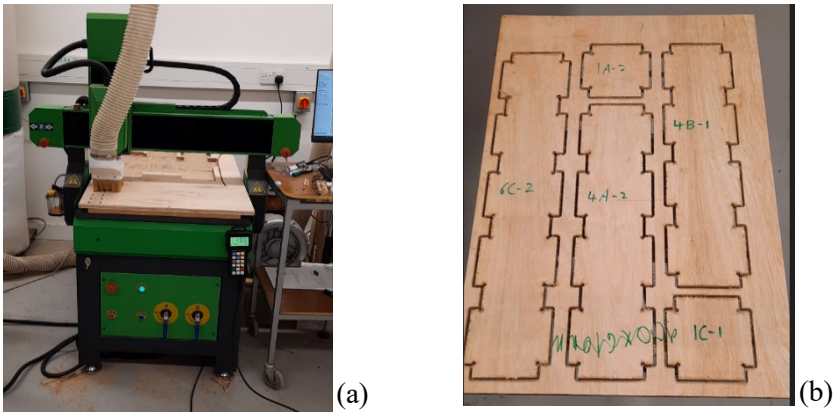

Figure 4. Digital fabrication of the specimens: a) CNC cutter operating on a cutting schedule; b) plywood board with column tab-panels post-cutting.

Once the schedules were finished on the CNC, the tabs were severed using a chisel and mallet, placing the plywood panels on a flat surface, and striking the chisel once for a clean cut. Sandpaper was used to lightly smooth down the rough surfaces where needed, particularly around tabs and slots. The perimeter of the components was also sanded to remove any sharp edges. A block plane was used to create a small (1 to 2 mm) taper on the edges of all the tabs on every panel to allow for easy assembly of the tab and slot joints. Specimens were prepared for digital image correlation (DIC) capture.

To assemble the hollow columns, the individual panels were grouped together according to their ID markings. A panel with the slots (slot-panel) was placed on a clean, flat surface, then one of the corresponding tab-panels was placed on top of the slot panel with the tabs and slots aligned. A rubber mallet was used to hit the tabs into the slots, beginning at one end of the panel, and incrementally hitting each tab downwards so that the panels join evenly, firmly applying pressure to the tab panel to limit any see-saw action. An inspection of all the joints was carried out, to ensure all the joints were fully connected. A block plane was used to smooth the top and bottom surfaces, where the column bases were slightly uneven. The same assembly process was undertaken for the shear and pull-out tests.

2.2. Testing arrangements and procedures

An Instron 600 kN testing machine was used for all the tests. The machine was fixed to the ground and applied load to/from the top of the specimens (Figure 5). For the compression-loaded specimens (compression shear, and columns tests), a base plate was mounted to the bottom jaw, with a round spring head attachment with a steel plate to distribute the load over the top. These enabled the uniform, concentric loading of the specimens with minimal eccentricities. For the tensile tests, the specimens were first mounted in the bottom grip at 50 mm from the bottom of the cavity, prior to the grips being closed. Once the top grips were lowered into position, they too were closed onto the top part of the dog-bones. The pull-out tests required the base (slot-panel) component to be attached to the base of the testing machine with four bolts; four holes were drilled to facilitate this. The upper machine grips were fixed onto the tab-component of the pull-out tests over round 25 mm depth. For the columns, a loading rate of 1 mm/min was used. For the material and DMC tests, a loading rate of 0.5 mm/min was used. These displacement rates are typical for monotonic testing of construction materials [19, 20].

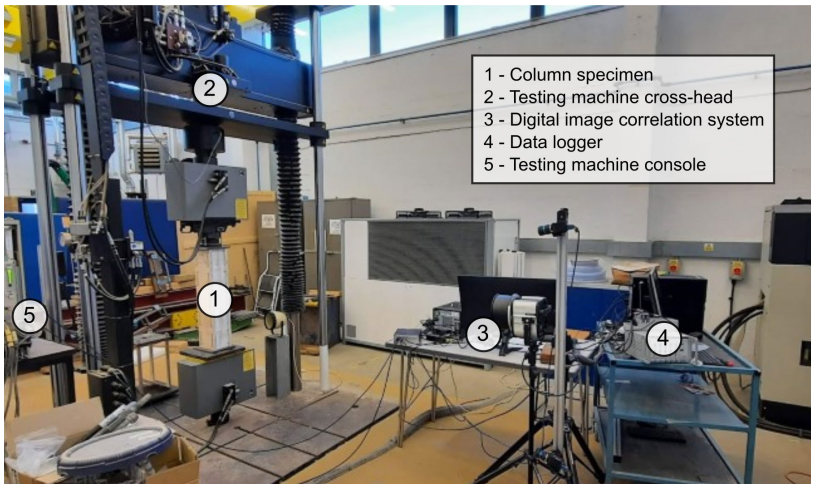

Figure 5. Test set-up for the columns.

3. Results and discussion

3.1. Material tests

Figure 6 shows the tensile stress-strain curves and typical representations of the dog-bone specimens after testing. The stress was evaluated by dividing the machine recorded force by the smallest cross-section of the sample, whilst the strain was evaluated from transducer data using a gauge length of 80 mm. From Figure 6, there appears to be a kink at a stress of 3.0-5.0 MPa in all the tension curves, exhibiting a bilinear response of the plywood. Subsequently, the stiffnesses of the lower and upper parts of the curves are calculated separately. Respectively, these are taken as E_1 (0 to 5 MPa), and E_2 (5.0 to 10.0 MPa). The average modulus of elasticity, E was 3.5 GPa. The average tensile strength exhibited by the plywood specimens was 22.4 MPa. The highest stress reached at 25.0 MPa at a strain of 0.0013, for Ten-1. The lowest stress was 19.9 MPa at a strain of 0.0096, for Ten-3.

The average tensile strength also agrees with the range of typical values for plywood, with variations due to differing plywood timber and moisture content [20]. Ten-2 shows a fracture line close to the centre of the specimen, which is expected (Figure 6b,c). From the second photo for Ten-2, the last few plies of the back face have separated from the specimen, with the crack propagating through a ply just above the transducer bracket. The fracture in Ten-3 was slightly lower than that of Ten-2, but a more visible fracture can be seen through the plies, with some separation between them. The failure of Ten-4 was similar to Ten-2, with the fracture occurring at 20-30 degrees at the centre.

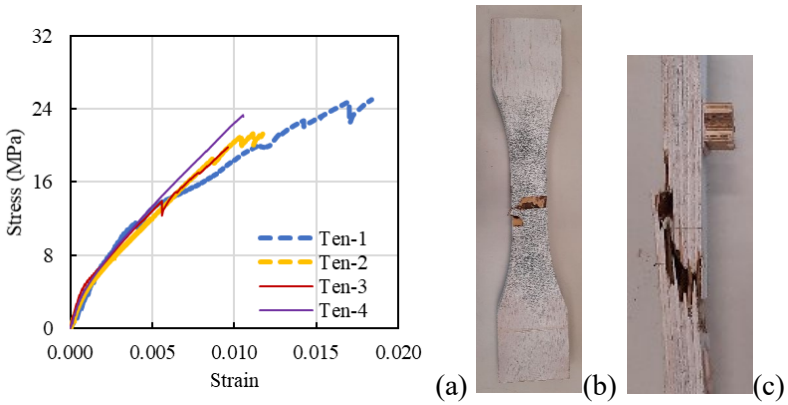

Figure 6. Tension tests: a) stress-strain curves; tension specimen Ten-4: b) after testing; c) side face fracture.

The results from the four compression tests showed the plywood to have an average compressive strength of 24.2 MPa. The compressive strength was evaluated by dividing the machine load by the cross-section of the sample, whist the strains were evaluated using the same approach as for the tension coupons. As a comparison, this value is close to the characteristic compression strength of other plywood materials [5, 20]. As shown in Figure 7, Com-2 achieved the highest peak stress at 25.7 MPa, with a strain of 0.0082. A shear failure occurred at the top of the specimen with an approximate angle of 45-degrees. Com-3 exhibited the lowest peak stress, 21.7 MPa at a strain of 0.0072. A modest crushing at the bottom of the specimen and some separations of the plies were observed.

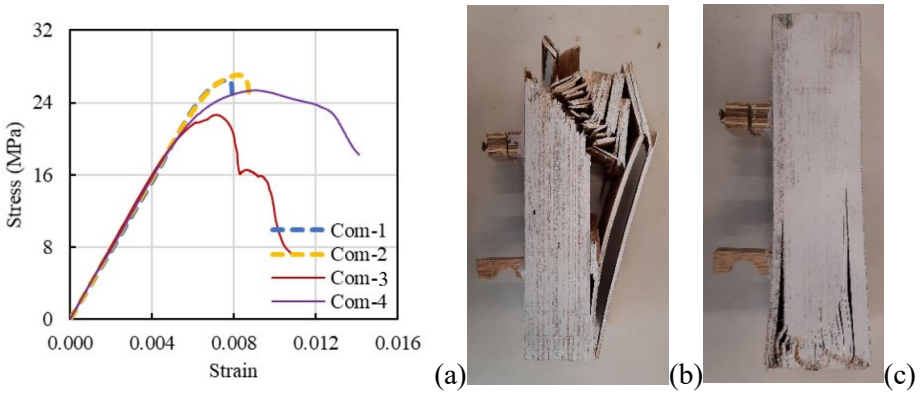

Figure 7. Compression tests: a) stress-strain curves, b) Com-1 after testing; c) Com-2 after testing.

Com-2 experienced severe separation of the plies during loading, which contributed to the inverted V-shaped crushing at the bottom of the specimen. Com-4 experienced a shear failure at the top of the specimen, along with partial separation of the plies at the back face of the specimen. This shear failure was similar to that of Com-1, but the shear angle propagated in the opposite direction. A large linear region is observed in the compression stress-strain curve, from 0 to 20 MPa. The average modulus of elasticity was 4.1 GPa, with a maximum of 4.7 GPa and a minimum of 3.9 GPa. These correspond to Com-3 and Com-2, respectively. The low standard deviation of 0.39 in the linear elastic range agrees with the stress-strain plot in Figure 7 as the curves of each specimen follow a similar path.

3.2. DMC tests

The results from the shear tests are shown in Figure 8. The highest peak load was 26.9 kN, corresponding to a shear stress of 3.8 MPa, and a displacement of 25.1 mm. This was exhibited by Shr-3, which also absorbed the most energy. The shear stress was evaluated based on the section of the tabs, and the energy refers to the area under the stress-displacement curve. The average peak load was 23.0 kN, but a standard deviation of 3.6 was calculated, reflecting some variance of these values. In terms of specimen kinematics, Shr-1 showed crushing and shearing of the right joint, but the left joint only showed crushing of the tab at the base of the slot. The same failure mode was demonstrated for Shr-2. Similarly, Shr-3 showed crushing of the tab on both the right and left side joints, but a more defined crack at the right joint propagated from the bottom right notch to the base of the panel, at a steep angle between 75 and 85 degrees. However, by observation of the curve in Figure 8, the linear region of the curve only reached 1 kN, although with a small displacement of less than 1 mm. This curve is somewhat different compared to curves from literature for LVL DMCs [6], which had a longer initial linear section beyond 5.0 MPa.

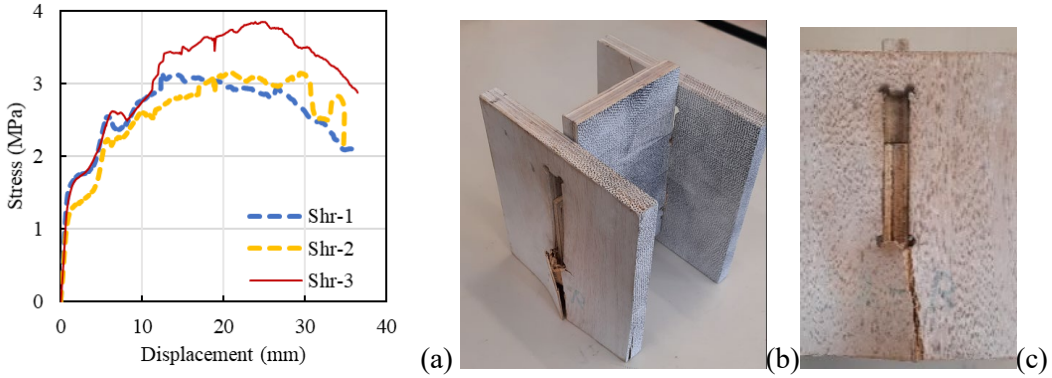

Figure 8. DMC shear tests: a) stress-displacement curves; Shr-3 specimen: b) after testing, c) left side fracture.

As shown in Figure 9, the maximum stress from pull-out tests was around 0.73 MPa, corresponding to 2.2 kN and a displacement of 2.04 mm, for Pul-2. The pull-out stress is the force divided by the contact area between the tab and the slot. On the other hand, Pul-1 sustained the smallest pull-out load, 0.27 kN. Although the displacement is only 0.43 mm, the capacity of the joint is significantly less than that exhibited by Pul-2. Despite the low magnitude, the tab does not have to sustain a large friction resistance, because its primary function is to secure the column panels together. Moreover, a very large friction resistance will induce difficulties in dismantling the columns.

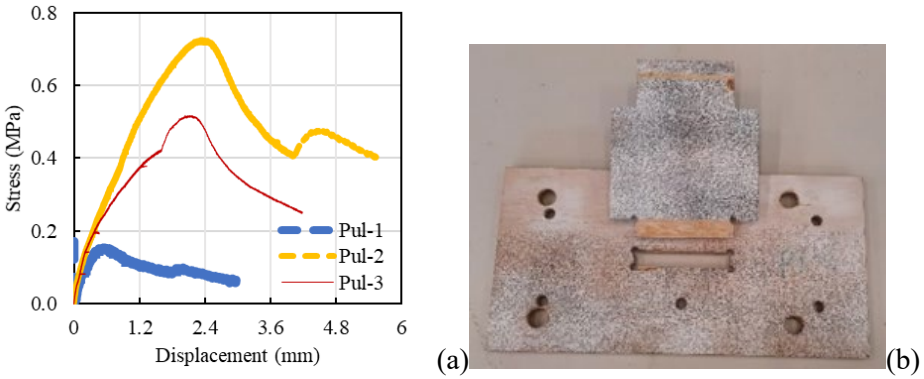

Figure 9. DMC pull-out tests: a) stress-displacement curves, b) specimen Pul-2 after testing.

The high standard deviation is likely to be due to the manual process of preparing and assembling the specimens. The total energy absorbed by each specimen varied substantially, with the lowest value, for Pul-1, and the highest value, for Pul-3. This is reflected in the curves; Pul-1 experienced a very short

curve which reached its maximum load very early compared to Pul-3, which gave a longer, but shallower curve, with a well-defined curved section at its peak. Overall, the results from the pull-out tests demonstrate that DMC tab and slot joints can vary substantially in load capacity by a factor of 5.1 and in displacement at the peak load of 4.1.

3.3. Column tests

Figure 10 shows the load-shortening curves and selected column specimens after failure. Table 1 depicts the main results as the average of the three tested specimens per configuration, as well as the standard deviation. Specimens Col-AR1 tests achieved a peak load between 195.9 kN and 216.4 kN, with an average capacity of 208.3 kN, equating to a stress of 19.3 MPa. The peak load, achieved by Col-AR1-2, was reached at a displacement of 2.3 mm. The failure mode had local crushing at the top of the specimen. Both findings could be expected, due to the stocky nature of the column, which, internally, has the form of a cube. The results from the Col-AR2 tests showed a decrease in the average peak load by 13.0%, compared with Col-AR1. Furthermore, a slightly larger displacement was observed in all the specimens, around 2.3 mm. The highest peak load, 185.5 kN, (17.2 MPa in stress), was achieved by Col-AR2-3; this is 10.4 kN less than the lowest capacity of the AR1 columns. Col-AR2-3 also experienced local crushing at the top of the specimen on one side.

Table 1. Main results for the column tests

Specimen ID	Length (mm)	Width (mm)	Height (mm)	Tabs/ slots (-)	Peak load P_{max} (kN)	Peak stress (MPa)	Displacement at P_{max} (mm)
Col-AR1	186	150	150	4	208.3±10.9	19.3±1.0	2.2±0.1
Col-AR2	186	150	300	8	181.3±3.7	16.8±0.4	2.3±0.2
Col-AR4	186	150	600	16	180.7±22.5	16.7±2.1	3.6±0.5
Col-AR5	186	150	750	20	166.4±13.9	15.4±1.3	3.9±0.6

From the Col-AR4 tests, a higher overall peak load was observed, in comparison to Col-AR2 tests, with the force reaching 201.5 kN, with a stress of 18.7 MPa, for Col-AR4-1. The deflection, 4.00 mm, was nearly double that of the Col-AR2 tests. A well-defined buckling on one of the panels was observed just above mid-height. The lowest peak load for Col-AR4, however, only reached 156.8 kN (14.5 MPa), by Col-AR4-3; a 12% reduction in capacity compared to the Col-AR2-2, which achieved the smallest peak load from the AR2 tests. This observation is reflected in the higher standard deviation of 22.50, compared to 3.73 for Col-AR2. Overall, a reduction of 13.3% in the average capacity, compared to ColAR1, was observed.

In parallel with the decreasing capacity trend from the previous column results, the results for the three AR5 columns showed a 7.9% reduction in the average capacity between Col-AR4 and Col-AR5, and an overall reduction of 20% between Col-AR1 and Col-AR5. The highest capacity, 176.5 kN (16.4 MPa) was achieved by Col-AR5-3, and the lowest, 150.6 kN (13.9 MPa), by Col-AR5-2. This was also the overall lowest peak load. Similar failure modes in plate buckling were observed in all three AR5 specimens; buckling occurred at the midpoint of Col-AR5-3.In relation to the material compression test, the strongest hollow column (Col-AR1-2, with a capacity of 20.0 MPa), is 17.0% lower than the average stress, 24.2 MPa. All other hollow columns achieved a lower compression capacity, particularly as the slenderness increases. This indicates a loss of capacity in the hollow columns, which would be increased through design changes, such as the addition of stiffeners or end plates.

With regard to the failure modes and specimen kinematics, Col-AR1-1 showed outward buckling of slot-panel at mid-height with some crushing near the bottom edges of tab-panel and slot-panel, Col-AR1-2 showed crushing at top of tab-panels and severe separation of slot-panel plies, whilst Col-AR1-

3 crushing at top of tab-panel and slot-panel, and fracture at top of slot-panel propagating from the notch. Specimens with an aspect ratio of 2 showed crushing at top of the tab-panel and slot-panel and some separation of plies in the failed region (Col-AR2-1), or buckling of tab-panel and vertical cracks at the mid-point of the slot-panel (Col-AR2-2), or 30° shear failure at the top edge of slot panel; some buckling at mid-height of tab panel (Col-AR2-3). All Col-AR2 specimens showed some separation of the plies.

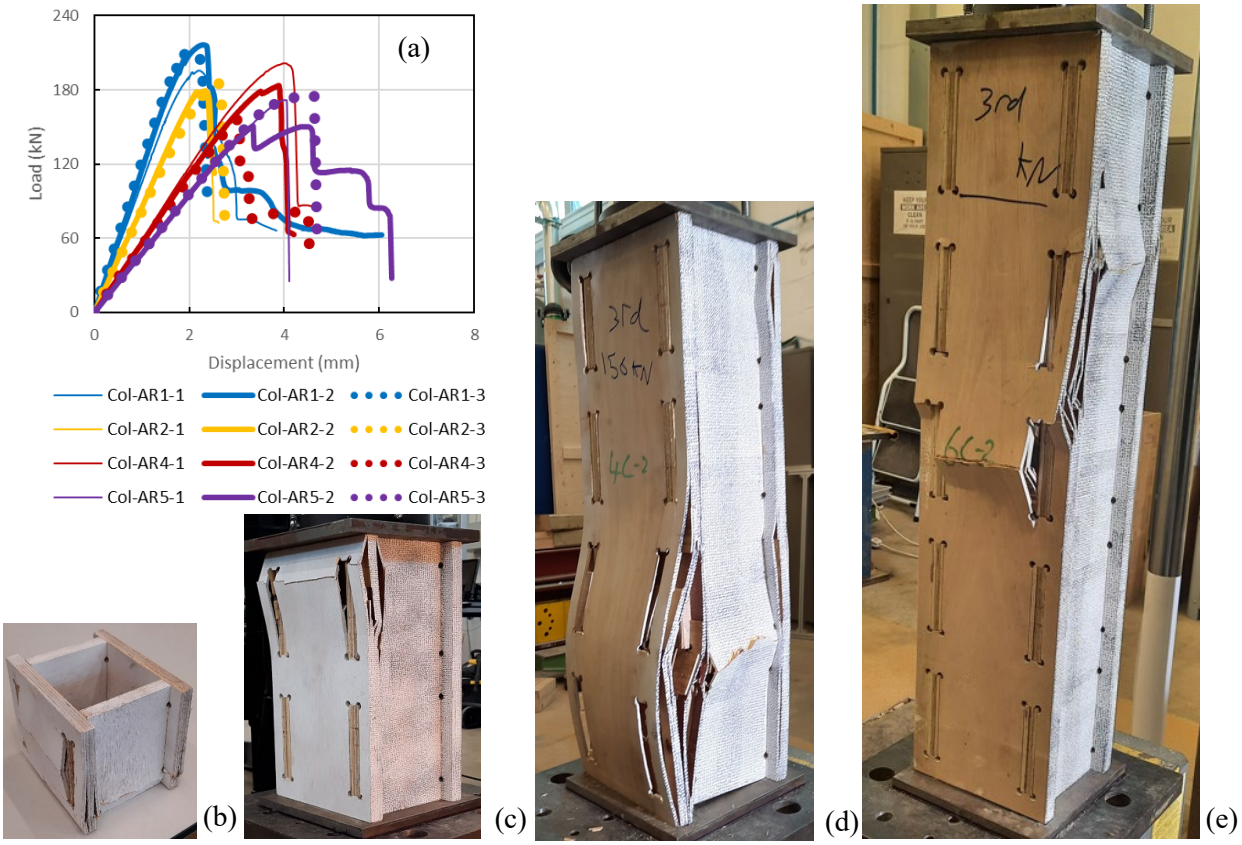

Figure 10. Results from column tests: a) Graph showing load-displacement curves for all the column tests; DMCges of failed specimens, b) Col-AR1-1; c) Col-AR2-1; d) Col-AR4-3; e) Col-AR5-3.

With an increase in height, a well-defined plate buckling just above mid-height of slot-panel or tab-panel with a fracture at the edge of slot-panel was observed (Col-AR4-1, Col-AR4-2). Col-AR4-3 failed with substantial separation of slot-panel plies, buckling of tab-panel at mid-height, and global flexural buckling of the column. Finally, the tallest columns (Col-AR5) had well-defined buckling modes at the tab-panel and slot-panel, with various levels of ply separation or splitting. Overall, the DMC hollow columns tend to experience brittle failure, with either crushing close to the top or bottom of the columns, buckling of the tab-panels or slot-panels close to mid-height, and separation of plies in the failed region.

4. Concluding remarks

This paper investigated the experimental response of digitally manufactured hollow timber columns incorporating dry mechanical connections (DMC). Timber plates were cut to complementary geometries and mechanically attached to interlock and form an integral joint. For this research, from existing DMC, rectangular tab and slot geometries were considered. Four sets of columns with different aspect ratios, were tested to assess the influence of member slenderness on the structural response, which has not been yet investigated. Complementary compression and tension samples, as well as single tab and slot DMC shear and pull-out samples were also tested. The main concluding remarks are below.

The material tests indicate both the compression and tension strengths of the plywood sheet are of similar magnitude in the range of 20-25 MPa. The tab and slot joint shear strength was consistently above 6 MPa, whilst the friction strength was around 0.5 MPa. Brittle failure was observed in all the column tests. As expected, the tension failure was relatively brittle whilst crushing in compression was rather gradual due to the inherent properties of the engineered timber.

The load-shortening response indicated that the stiffness and strength of the DMC hollow timber columns reduces gradually with increasing slenderness. Relatively slender columns with an aspect ratio of 5.0, had about 22% less strength than stub columns with an aspect ratio of 1.0. This corresponds to an axial peak stress at crushing of 63% and 80% of the compression strength of the material, respectively. The predominant failure modes were crushing close to the top or bottom of the columns, buckling of the tab-panels or slot-panels around mid-height, and separation of plies in the failed region.

These results provide a detailed insight into the structural performance of digitally manufactured hollow timber columns which can be employed in temporary lightweight structures that can be disassembled and reused. Additional benefits come from geometry optimisation and material minimisation for efficient transportation.

Abstract

The paper discusses the design, fabrication and assembly of a free-form roof structure constructed using a hybrid method of cross-laminating structural plywood. The research outlined the roof's design, fabrication and engineering workflow within an integrated fabrication environment led by the architect in collaboration with the engineer. Such workflow constructed resilience in the design and manufacturing process. The digital fabrication of the structure was developed in a single parametric model informed through 3 sets of physical prototypes. By incorporating as-built site information through digital scans, the assembly process was enhanced with feedback to ensure precision in manufacturing, thereby demonstrating care in construction through digital technology.

Keywords: timber structure, integrated design and fabrication, cross-laminated, designing for assembly, plywood, digital fabrication, prototyping

1. Introduction

Structural plywood and Laminated Veneer Lumber (LVL) are common building materials in construction, typically used as bracing and beam, respectively [1]. In recent years, Cross Laminated Timber (CLT) as a structural wood panel has increased usage globally and in Australia [2]. This paper expands on the research on timber laminated panel systems using digital fabrication and robotics [3] to explore a hybrid fabrication method called Cross Laminated Plywood (CLP). The CLP forms a structural wood panel and is an alternative to CLT.

The paper outlined CLP's integrated design, fabrication, and assembly workflow for a house project with a free-form roof structure, see figure 1. The roof design had multiple performative requirements. It provided a flat roof deck as a private open space, addressed overlooking issues from neighbours and diffused sunlight to the interior, see figure 2. Structurally, the roof was designed to support a biodiverse brown roof. It consisted of a set of CLP rafter beams and bracing plates as the primary structure, sheathed with plywood, insulated, and topped with a brown roof build-up. Through prototyping and structural testing, design information and construction parameters were integrated into the computation model to manage the complex geometry and the fabrication workflow. The paper concludes with the assembly methods, including in-situ templating and digital scans to accurately position each roof beam within a +/-2mm tolerance on site.

The research's significance lies in manufacturing the CLP within a small-to-medium enterprise (SME) context to reduce the design-to-production supply chain. The fabrication methods are relevant during and after the COVID-19 pandemic, where construction is often delayed due to an extended production chain and lack of human resources in Australia. CLP fabrication and construction methods provide an

alternative to CLT's large-scale production. The research highlights the need to integrate design, engineering and fabrication within a continuous construction ecology tested through a built project.

2. Background

LVL is similar to plywood except that there is no cross-banding in LVL. CLT is fundamentally a large format plywood with individual layers between 12-45mm thick in three, five or seven layers [4]. The larger dimension of CLT over a standardise structural plywood sheet (typically of 2.4 x 1.2m) allows for its application as full-size wall, floor and linear components with the ability to bear load in and out of plane. Both CLT and plywood have high dimensional plane stability due to cross-layering. In CLT, a single layer is typically finger-jointed. The cross layering of lumber is quasi-rigidly connected using annular ringed shank nails or hardwood dowels [5].

Since its development in the 1990s, CLT has shaped building design. It challenges structure and superstructure design replacing concrete as the primary material. While solid timber construction has significantly accelerated in the past two decades, the first CLT building was not completed in Australia till 2012 [6]. In 2015, Australia produced its first CLT panel, and manufacturing plants were established in 2017 [7], [8]. Before this, most CLT panels are imported from New Zealand or Europe (using Spruce and Pine species).

2.1. Project background and fabrication context

The Northcote House by LLDS architects was designed in 2015-18, with construction commencing on site in 2019-2023. The roof design and fabrication result from an integrated collaboration between LLDS architects and TGA engineers, a specialist timber engineering practice based in Melbourne. While it is common for engineers to develop design and fabrication within the same environment (such as specialist fabricators in steel and timber), architecture practices are often removed from the fabrication environment. While significant efforts to bridge the gap exist through direct file-to-manufacturing in the past two decades, the integration is often only through data management and rarely through physical manufacturing [9], [10].

The significant difference in this project is the fabrication context. The architect operates a 500-square-meter fabrication workshop located within 7km of Melbourne CBD called Power to Make, specialising in timber joinery and architectural components, see figure 1. The practice operates its own CNC machinery, including a large format Computer Numeric Controlled (CNC) router (suitable for standard 1.2 x 2.4m plywood panel), a Kuka KR120 robotic arm, traditional woodwork and metalwork machinery.

2.2. Roof design

Two 150mm thick concrete walls on the site's boundary support the timber roof. At its thickest point, the roof is 3 meters deep and tapered to the cantilever edge of 205mm. The roof was designed as a trafficable landscape (live load of 3kPa). It functioned as a brown roof that contributes to the site's biodiversity (500kg/m2), shedding water to the edge gutters, and the symmetrical apex is used to block views from the neighbouring buildings. Figure 2 illustrates the geometric parameters used to set up the roof design. The underside of the roof is an exposed waffled (or coffered) structure that gives the main living area of the house its dramatic volumetric form. It is defined by a centrally located parabolic curve which blends into the two (short) parameter straight edges, see figure 2A. The two straight edges interface with the opening of the façade identified as Beam 1 and 15; Beam 1 is conditioned by the concrete beam that ties the two concrete walls together; Beam 15 is required to interface with the entrance door.

The roof consisted of 19 rafter beams and 76 bracing plates. It was designed to be assembled in two phases. The first phase is from Beam 1 to Beam 15; see figure 2. The second phase forms the cantilever roof from Beam 16 to Beam 19; see Figure 2. Two waling plates designed with mortises were anchor-bolted to the concrete walls to receive the primary beams. The area covered by Beam 1 to 15 forms the main roof over the interior. Beam 15 marks the transition between inside and outside. After Beam 15, the primary beams changed orientation from north-south to east-west and cantilevered out to form the overhanging roof. These east-west beams rested on the first-floor slab for two reasons. First, it ties the

uplift forces of the cantilever roof to the first-floor slab. Second, the depth of these beams acts as vertical brise soleil and privacy screening from the street.

Thirteen cone-shaped roof lights in the coffered roof structure draw daylight to the interior, see figure 2b. The depth of the coffered soffit is driven by the need to (1) diffuse daylight during winter and (2) block direct sunlight during summer. The roof light's fabrication detail is outside the scope of this paper.

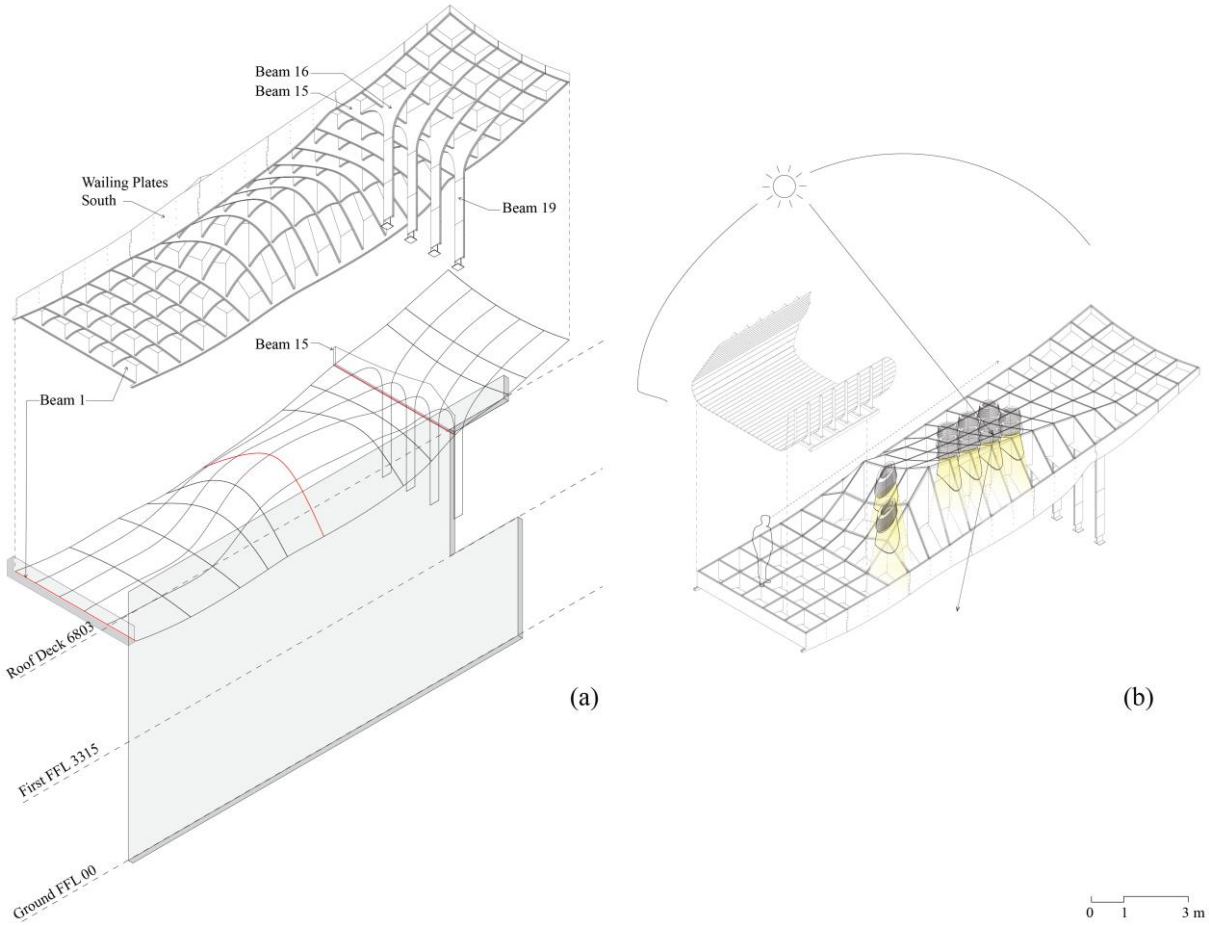

Figure 2. Left, (a) worm-eye isometric view of roof indicating the interior geometry parameters. Right, (b) isometric view of the roof illustrating the exterior requirements that shaped the roof design, including the 13 roof lights that bring diffuse lighting to the interior.

2.3. Motivations to reduce supply chain

During the schematic design phase in 2015, the nearest CLT supplier was based in New Zealand. The design team consciously shifted away from CLT, motivated by the need to reduce the roof's supply chain and the transportation cost (and carbon footprint). Two other design alternatives were considered, including (1) using LVL as a beam and rafter to construct a portal frame structure with plywood gussets or (2) constructing the roof using plywood-stressed skin panels [1]. The design team rejected these options as the width of the rafter will increase significantly from 54mm to 150mm. Further motivation to reduce the supply chain comes from the design team to integrate the design and fabrication of the roof structure within the manufacturing facilities of Power to Make. The workshop setup allows the design team to develop three sets of prototypes with the engineers. The testing and prototypes subsequently led to Power to Make fabricating and assembling the CLP onsite with the assistance of a licensed builder.

Reducing the supply chain has other implications. For example, the design team can monitor and control the cost of the CLP through its design. In-house production also allows the team to manage the quality of the finish, especially when the entire interior surfaces are visual. Structural plywood comes in five veneer grades (A, S, B, C and D), and the appearance can be further specified with ten different combinations of grading to the facing and back veneer (AA, AB, AC, AD, BB, BC, BD, CC, CD and DD). The structural plywood used in the project was specially pressed with the grain running along the panel's length and a BB/BB-facing veneer. The COVID-19 pandemic hit in January 2020 in Australia, halting all global supply chains. The roof was manufactured at Power to Make between March – August 2020, and installation on site commenced later that year.

3. Cross laminated plywood (CLP)

Standard plywood sheets come in 2400 x 1200mm. Each roof beam and bracing plate are glue laminated like a CLT - comprised of three layers of 18mm birch plywood laminated using structural polyurethane adhesive at 4MPA or a minimum of 500 PSI. Each layer was designed to be staggered vertically and horizontally, so there was no continuous joint line across the entire panel. Similar to CLT fabrication, each layer was edge-jointed with finger joint, $L \geq 45$mm, to reduce resistances and bend out of plane. The finger joints were CNC milled with 0.1mm tolerance.

The architects decided to use European Birch plywood as it was the most economical and dimensionally stable (compared to Hooped pine) in Australia. TGA engineers converted data for structural plywood performance certified to AS/NZS 2269.0:2012, in an equivalent of F17 grade timber to satisfy the Building Code Australia (Class 1) and simulated plate displacement and stress calculation analysis, see figure 3.

The main advantage of CLP is (1) it can be locally manufactured using a standard CNC router and (2) a single person can manually handle the standard-size plywood sheet. In this project, the authors fabricated the CLP under the guidance of TGA engineers. The largest panel fabricated was nominally 3.63m x 3m. In practice, the panel size is only limited by the constraints of the lifting equipment in the manufacturing facilities.

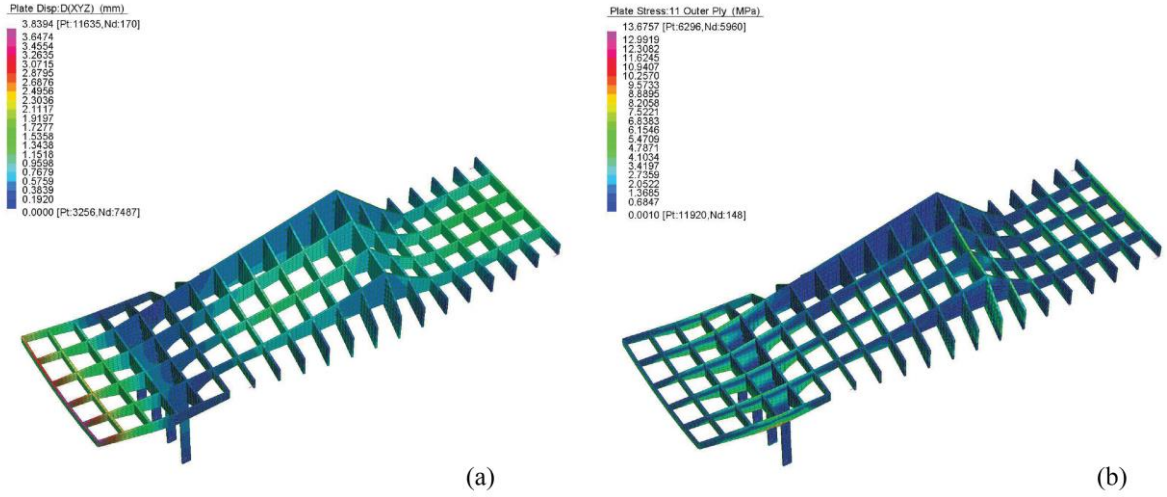

Figure 3. (a) Plate displacement analysis of 3-layer CLP. (b) Stress displacement analysis of 3-layer CLP. Image by TGA engineers.

3.1. Engineering and design feedback

The roof design evolved over two years, from initial sketch design to fabrication. To be resilient to the data updates and design changes, LLDS developed a single parametric model that processes the design constraints, detailing, engineering inputs, fabrication and assembly information into a continuous

workflow using Grasshopper 3D, see figure 4. The roof design was denoted by a set of base parameters, including a base grid, a collection of input curves and a surface (figure 4a). The input curves and surface respond to the criteria outlined in section 2.2. The model was evaluated through two sets of analysis: the minimal structural depth provided by the engineer (figure 4b) and the planarisation of the sheathing panels, refer to section 4.2. Rooflight detailing and its distributions were separately developed and integrated into the model (figure 4c). The structural members were separated into their assembly sequenced, and construction detail (figure 4c:11, 12 and 13) was added to the modelling, further expanded in section 4.1. The data was then checked against the as-build information (figure 4d:15); refer to section 5.1. The splitting of the CLP into its layers and joints was automated for CNC fabrication (figure 4d). The model enables LLDS to incrementally build design knowledge as the research team understands the roof's limitations and opportunities. In this instance, care in construction was created through the feedback system embedded in the parametric model, designed as an open system.

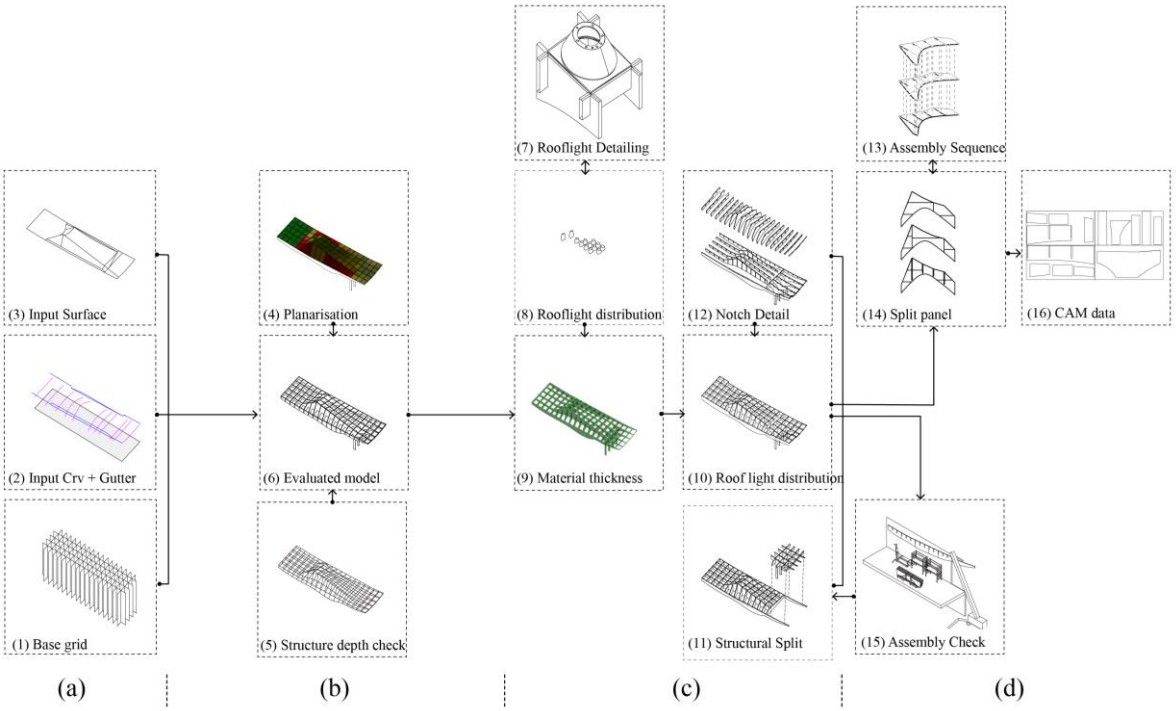

Figure 4. Integrated parametric design workflow. (a) Design input and criteria used to shape the roof geometry. (b) Evaluation of material and engineering requirements. (c) Inclusion of details developed through prototyping and construction sequencing. (d) Automation of fabrication information.

4. Learning from prototyping

Three prototypes are developed: (1) a 1m long junction with the 3-layer CLP composition, (2) a 1:1 prototype of a typical cell with a roof light and (3) a full-scale CLP Beam 1 for point load testing by TGA engineers. The purpose of these prototypes was to understand the fabrication sequence and technique of the CLP. Critically, the development led to Power to Make fabricating all the beams and plates in-house.

4.1. Prototype 1: fixing and lamination

Prototype 1 allowed LLDS to test the finger joints' tolerance, lamination techniques, and the junction between the beam and the bracing plate, see figure 5. The engineer specified 120mm long annular ringed shank nail to be screwed into the junction at a 45-degree angle, leaving little room for errors. Any deviation by +/- 3 degrees will cause the screws to penetrate the plywood on the other side. A jig was

designed to hold the screw at the correct angle. The screw hole positions were CNC piloted with an asymmetrical ellipse, used as a guide to orientate the screw fixing. It was pocketed so the fixing can be concealed with a plug. All the above are visual considerations.

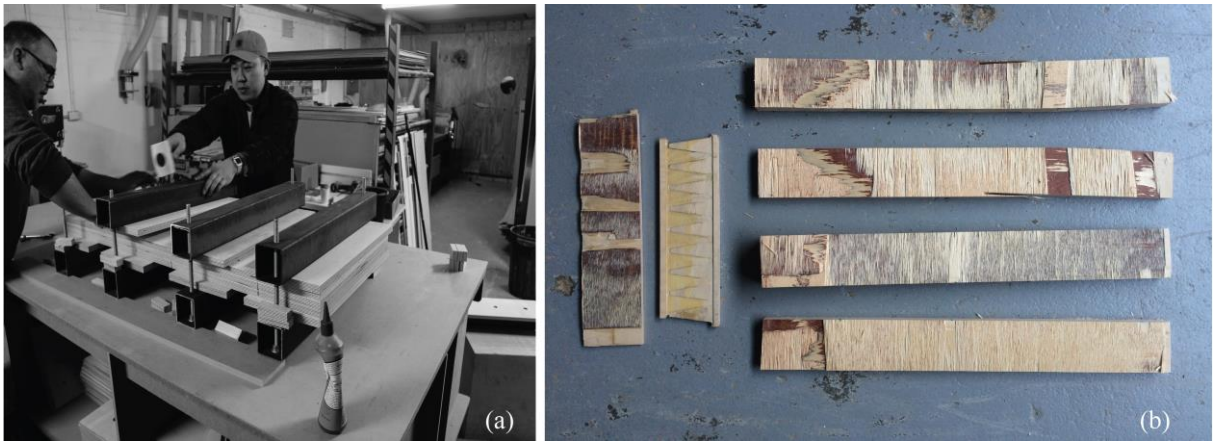

Figure 5. Left, lamination of prototype 1 illustrating the clamping device. Right, a splitted CLP demonstrates the glue bond quality between plywood layers.

A key aspect of CLP is the lamination techniques, particularly the consistent pressure required during the pressing process, as this needs to be proportional to the timber properties [11]. The engineer split the prototype with a chisel as a visual check. The glue is stronger than the timber, so the split did not yield a clean surface. Instead, it revealed the ply of each layer. Figure 5 illustrates the outcome, which indicates the lamination process was adequate.

4.2. Prototype 2: active bending

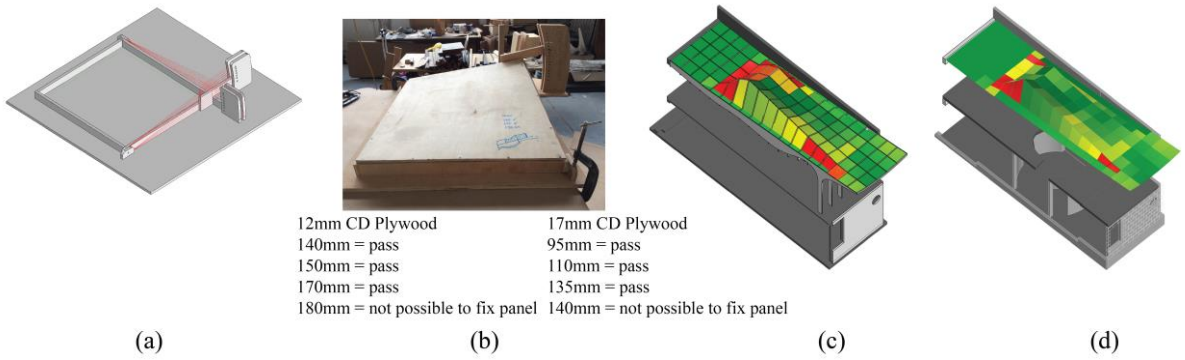

Figure 6. (a) Device used for testing the warp property of plywood. (b) Physical testing of plywood. (c) Roof model correlating sheathing geometry to plywood warp property. Red indicates the surface warp is out of range, and the dark green panel is flat. (d) The roof model was optimised to reduce the number of extremely warp panels to 8.

The second prototype is an entire roof cell with a roof light detail. This prototype illustrates the complexity of the sheathing to the roof. As the roof was subdivided into square cells (730 x 730mm), 75% of the 95 sheathing panels were doubly curved hyperbolic surfaces. Triangulating the sheathing panel into a planar surface was not an option without introducing another complicated structure to the cell and impacting the interior's visual quality.

LLDS developed a simple device to test the bending capacity of 12mm and 17mm plywood, see figure 6a & b. The physical tests provided data as input to the parametric model of the roof, see figure 6c. After several modifications to the surface geometry, the number of panels outside the active bending capacity of the plywood was reduced from 18 to 8 panels with the most extreme curvature, see figure 6d. These

panels are kerf and laminated separately. This results in all the sheathing panels being CNC milled and brought to the site, which speeds up the installation process.

4.3. Prototype 3: point load and deflection

The third prototype is a full-length beam, laminated with all the details captured in Prototype 1. LLDS designed a bespoke, flexible table clamp system to provide even compression pressure across the beam surface, see figure 8. The 3.63m long beam was point-load tested at the TGA workshop. It was designed to take up to 30kN. The result indicates the beam deflected by 21mm at 65.7kN (6.7 tonnes) with visible tear to the plywood core, see figure 7. The beam outperforms the design by over 200%.

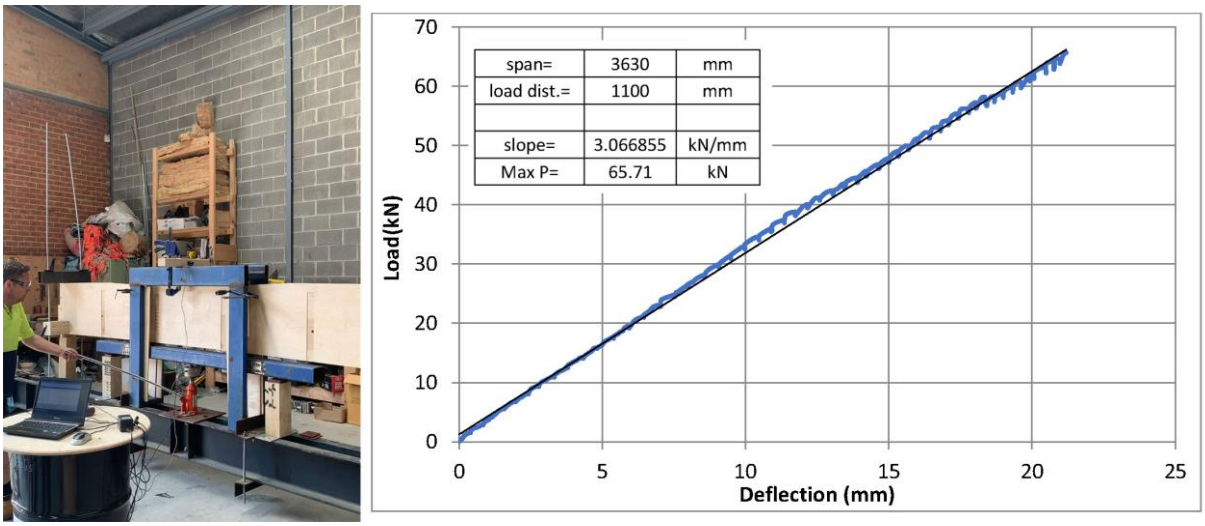

Figure 7. Left, point load deflection testing at TGA workshop. Right, load–deflection curve indicates the beam outperforms the design deflection by over 200%.

5. Assembly of the CLP roof

The authors installed the CLP roof structure with assistance from a registered builder. Before the final wailing plates were delivered to the site, LLDS architects produced a full-scale template of the waling plate in MDF. The templating process was critical as it allowed a final check on the wailing plates' alignment using laser levels and for the anchor bolt holes to be pre-drilled. Each wailing plate comprises five segments with a notch joint between each panel. Four segments were fully anchored to the concrete wall to receive Beam 1 to 15. The last segment was supported with 1/3 of its length fixed to the concrete wall (supported by a concealed steel bracket) and the rest cantilevering.

5.1. Site feedback

Once the final wailing plates were installed, the site was digitally scanned with a Z+F IMAGER 5016 terrestrial laser scanner with a maximum of 160m reach and a resolution of 0.8mm. A series of sections were extracted from the point clouds to check the as-built against the digital model, see figure 8. The scan data were used to (1) adjust the CNC fabrication information of the beams and (2) allowed Power to Make to trim the tenon ends of the beams to ensure the entire structure would fit before delivery to the site. With the scanning technique, LLDS comfortably work to a tolerance of +/- 2mm, just enough for the beam to wiggle into the mortise with a snug fit. The authors used this incremental construction technique in the concrete package previously published in another article [12].

Once all Beam 1 to 15 were installed, the bracing plates followed. The beam and bracing plates were mechanically screw-fixed at a diagonal per the prototype. The jig for the screw fixing and the pocketing to orientate the screw become useful onsite. The same operation applies to the second installation phase for the cantilever roof.

Figure 8. Top Left, clamping device developed by Power to Make. Top Center, Installation of the roof beam on site. Top Right, Installation of sheathing panels, showing both the pre-curved panels and active bending of the sheathing onsite. Bottom, point cloud of as-built concrete walls checked against the digital model of the roof.

6. Conclusion

The paper outlined the design and fabrication of a free-form roof using an integrated design and fabrication workflow, embedding architectural practice within a fabrication environment in collaboration with engineering. The research used CLT fabrication techniques to explore an alternative method using structural plywood as lumber layers, called CLP. CLP is designed to be manufactured within an SME context and to reduce the supply chain. Through 3 sets of prototypes, the design and engineering information was integrated within a single parametric model, allowing resilience in the design and manufacturing process. As-built site information was looped back into the fabrication data to ensure precision in site assembly, demonstrating care in construction.

Abstract

The construction and operation of buildings consumes a large proportion of the energy and raw materials available worldwide. In order to increase sustainability in construction, high-performance structural systems are required. Especially load-flow-adapted and form-optimized shell structures can bridge large spans with low material consumption. The asymmetric snow and wind loads are to be regarded as relevant for the design. Based on a comparison of international standards, it is shown that the lateral wind flow on shell structures is represented very differently or not at all. This leads to uncertainties among planners with regard to the loads to be applied. On the safe side, values are then set too high and the structure is overdimensioned. However, an individual and specific handling of the wind loads is essential against the background of ensuring structural safety, serviceability and sustainability. In this study, an approach to determine the wind load pressure coefficients for a timber shell support structure using computational fluid dynamics (CFD) is presented. Using a parametrically generated structure, different geometries can be generated and analyzed for wind load coefficients. Depending on the characteristic values, an algorithm is developed to derive a zoning coefficient according to wind load standards. In this way, an application without further CFD analysis is possible. Due to the variable approach, the developed algorithm can also be applied to free-form shell structures.

1. Introduction

1.1. Determination of wind loads for sharpe-edged buildings

The wind loads to be considered are essential input parameters for the dimensioning of the structure within the framework of a static as well as a dynamic analysis. Due to the wide range of influencing factors, such as wind speed, wind direction, turbulence intensities and roughness, these parameters must be determined individually for each structure to be investigated. Against the background of engineering practice, national and international wind load standards specify wind load parameters in the form of tables and diagrams for typical applications. These include, above all, geometric shapes of classical building components such as walls and common roof shapes (flat roof, gable roof, ...). The characteristic values given here are based on wind tunnel tests. The size of the investigated building and the wind tunnels makes it necessary to scale the model. For this reason, in addition to the geometric scaling, the other boundary conditions of turbulence, roughness and force ratios must also be considered.

$$Re = \frac{\rho v d}{\eta} \tag{1}$$

Where ρ = density, υ = flow velocity, d = characteristic length, η = dynamic viscosity.

In particular, the consideration of a correct mapping of the Reynolds number is essential for realistic and meaningful results. The Reynolds number describes as a dimensionless quantity whether a flow is laminar or turbulent, see eq. 1.

According to [1], the wind loads on sharp-edged profiles are usually independent of the flow-physical parameters, so that the wind loads can be determined on geometrically similar models in the wind tunnel. The preparation and execution of physical wind tunnel tests is time-consuming and costly, especially for complex geometries. This fact is of particular importance when several tests are carried out as part of parameter studies and thus wind tunnel series investigations. In [2], a comparative study of physical and numerical wind analyses is presented.

1.2. Determination of wind loads for curved buildings

In contrast to the previously described standard-based wind load characteristics for sharp-edged structural components, curved roof shapes, such as shell structures, are only represented in a few standards. Barrel-shaped roof structures, for example, are described in the Eurocode with respect to a lateral wind inflow, see fig. 1 (left), but not under longitudinal inflow. In contrast, this wind loading direction is considered in selected standards [AS/NZS: 1170.2: 2022 (2005), NBC: 1995 (2002), ASCE/SEI 7-05 (2006), IS: 875 (part 3): 1987 (1989)], see fig. 1 (right).

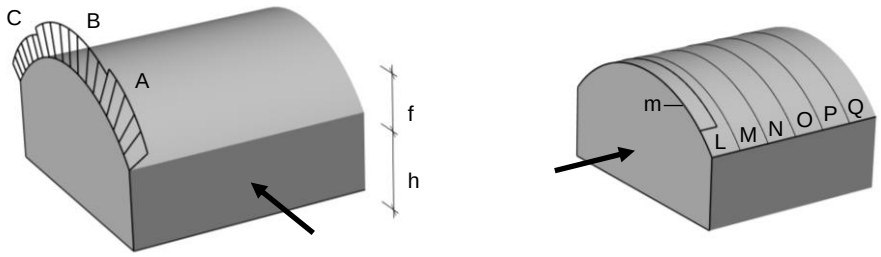

Figure 1. shell with lateral inflow (left) [DIN EN 1991-1-4]; longitudinal inflow (right) [NBC 1995 (2002)].

The wind load parameters can be determined on the basis of numerical flow simulations (CFD analyses). The modelling can follow all geometrically complex shapes. In [3] and [4], a procedure for curved roof structures is discussed. With regard to the calculation results, suitable turbulence models must be selected. In contrast to physical wind tunnel tests, no scaling problems are encountered. Special attention has to be paid to the detachment behaviour of the flow of curved surfaces [1, 5]. The resulting vortices or turbulences cause non-uniform pressure distributions.

In this study, the wind load characteristics of a shell structure, based on the Zollinger-System, are determined, see fig. 2. The basis for this study is laid in a master's thesis [6]. On these structures, previous investigations [7-10] have determined the basic properties and structural improvements. In this context, the relevance of half-sided loads, such as wind loads, for shell structures could be worked out. The workflow described in detail focuses on the underlying parametric modeling, the necessary input and calculation parameters as well as the derived conclusions. Thus, this study contributes to the further establishment of digitalization in the construction industry and the increase of sustainability capacities in timber construction.

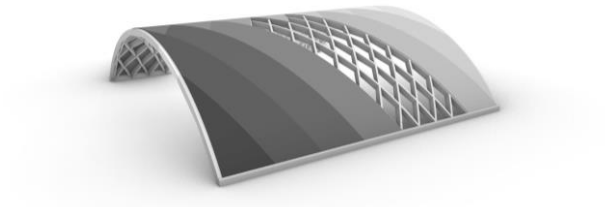

Figure 2. Timber grid shell structure, Project TimberPlan+.

2. Hypothesis and method

2.1. Hypothesis

The further development and resource-saving dimensioning of the Zollinger system and other curved shell structures is only possible on the basis of specific and exact wind load parameters. The relevant wind load standards do not fully describe these geometric shapes. If the user does not want to resort to the blanket use of "similar" classical geometry shapes, which are chosen on the safe side - and thus accompanied by higher material expenses - the application of wind tunnel tests or numerical computer fluid dynamic calculations becomes necessary.

Based on the research of standard-based wind load characteristics for curved shell structures and the computational preliminary investigations, the main hypothesis can be formulated as follows: The determination and definition of wind load characteristics for shell structures should be favoured using a CFD analysis in view of practical engineering use. In this way, load values can be generated that are more realistic and depend on the individual shape.

2.2. Method

The main hypothesis is investigated and evaluated on the basis of a specific timber grid construction, see Figure 3 (left). The methodological procedure described below is explained in detail and is suitable for transfer to other fields of application.

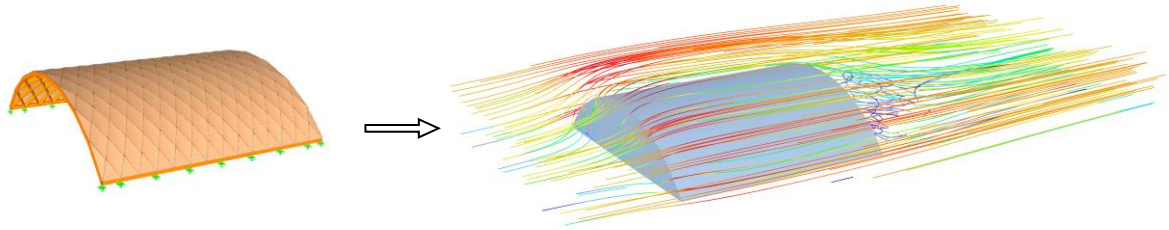

Figure 3. Parametric Finite Element Model (left) with lateral wind load (right), Project TimberPlan+.

The timber shell structure to be investigated is described with a parametric overall model, see fig. 4, with respect to the architectural dimensions (length, width, arch height and shape) and the statically relevant parameters (material grades, cross section dimensions, stiffnesses in the component connections, permanent loads and snow loads, etc.). For this purpose, the parametric programming platform Grasshopper3D is used. The further determination of the wind loads is carried out using the computer fluid dynamic calculation tool RWIND, which is based on OpenFOAM®. For this purpose, the developed parametric model can be directly transferred and analysed. The determined wind load parameters can be added to the overall model. Subsequently, the static finite element model can be merged for further analyses and transferred to the finite element calculation program RFEM, see fig. 3 (right). The parameter-based approach is highly flexible with regard to possible parameter variations due to architectural-planning and structural-constructional modifications. The automatic model data adjustment carried out in this context also enables variant investigations and parameter studies.

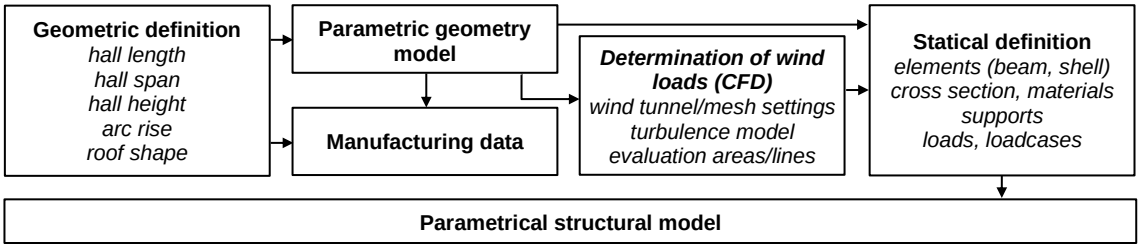

Figure 4. Basic structure of the holistic parametric model considering a CFD wind analysis.

3. Concept of investigation

The aim of the investigation is to determine wind load characteristics for shell surface structures with longitudinal inflow. On the basis of the parametric overall model, see section 2, the object of study can be developed considering parameters to be adjusted. In this way, the influence of the different component dimensions can be determined in relation to the generated wind load characteristics.

Against the background of non-uniform wind load characteristics distributed over the shell surface, suitable evaluation methods and ranges have to be analysed. Furthermore, the occurring turbulences have to be discussed.

3.1. Definition of the object of investigation

Different calculation models are generated for the wind load analysis. Here, a variation of span, length and height is applied, see Figure 5 and Table 1. The shell structure is modelled as supported on the floor, closed on the face side and without openings in the roof area. Dormers or discontinuities in the roof area are also excluded. The aim of the investigation is to determine the specific wind loads and, if necessary, to show conclusions about possible wind load characteristics to be standardized.

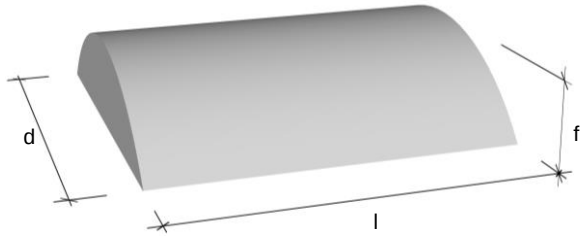

Figure 5. Visualization of the objects of study in principle.

According to Table 1, it can be noted that five different spans are investigated. In addition, a variation of the length to span ratio as well as the rise to span ratio is investigated. Due to the large number of models to be investigated, it is possible to identify the same or similar effects. Furthermore, the reproducibility and transferability of the approach chosen here can be investigated.

Table 1. Dimensions of the investigated structures.

Span d [m]	Length-span ration l/d [-]	Rise-span ration f/d [-]
5.0 / 10.0 / 15.0 / 20.0 / 30.0	1.0 / 2.0 / 3.0 / 4.0 / 5.0	0.125 / 0.25 / 0.375 / 0.5

3.2. Parameters of the CFD-analysis

For the computational fluid dynamics analysis, the generated models are supplemented by information on the wind tunnel dimensions and roughness parameters. Furthermore, the site parameters are defined, whereby the wind load zones and wind load profiles defined according to the standard are taken into account.

Since the accuracy of the results of a CFD analysis is very strongly dependent on the simulation accuracy in the area of detachment effects, see also section 1.2, a suitable turbulence model must be applied. The most widely used method for this purpose represents the application of the "Reynolds-averaged Navier-Stokes equations" (RANS) [11]. In contrast to direct numerical simulation (DNS), which place high demands on computational resources, turbulent flow is modelled here by averaged values and variance of velocity and pressure [12, 13]. Due to these generated equations, the computational time decreases. Here, the k-ε turbulence model is used in RWIND [14].

The size of the wind tunnel is determined depending on the object size to be investigated, always balancing between short calculation times and well-mapped flow conditions. In general, the distance on

the inlet side is shorter than on the back side, see Figure 6. Furthermore, the surface roughness can be defined for the floor surface, which also influences the flow properties around the object under investigation.

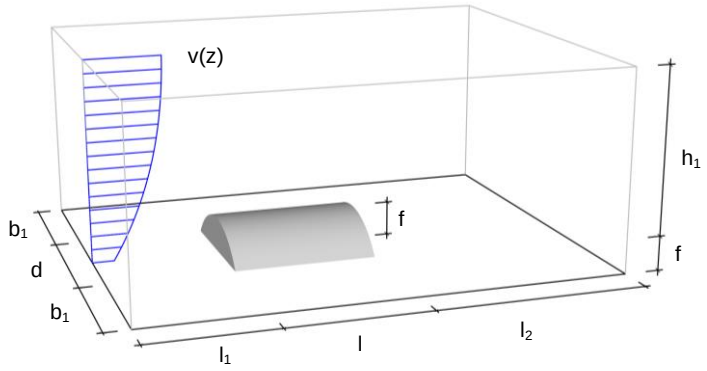

Figure 6. Wind tunnel dimensions and wind profile.

The wind profile to be used, taking into account the wind load velocity distribution over the height, corresponds to the specifications of the wind load standard applied. This is applied to the inlet zone of the wind tunnel within the framework of the computational fluid dynamics calculation, see Figure 6.

3.3. Determination for result evaluation

On the basis of the numerical wind load characteristic value determination, the evaluation and determination of the wind pressure coefficients (c_{pe}) on the shell structure can be carried out. Due to the symmetrical design of the structure and the longitudinal inflow, an evaluation can be carried out along defined lines, see Figure 7. For this purpose, the shell structure is divided into uniform sections along the arc. The number of these lines is freely definable. Against the background of a practical engineering application, a subdivision into two sections is sufficient. This takes into account the observation in the ridge and eave curvature areas. A further reduction in the scope of the evaluation can be achieved by considering only the left-hand and right-hand evaluation lines. On the basis of these lines, the pressure coefficients (c_{pe}) are displayed as a curve, which can be converted into c_{pe} zones by regions.

The c_{pe} curves and the evaluation of the flow lines illustrate any turbulence that may occur on the structure under investigation. In this case, adjustments with respect to the meshing or the specifications of the calculation parameters must be checked, if necessary.

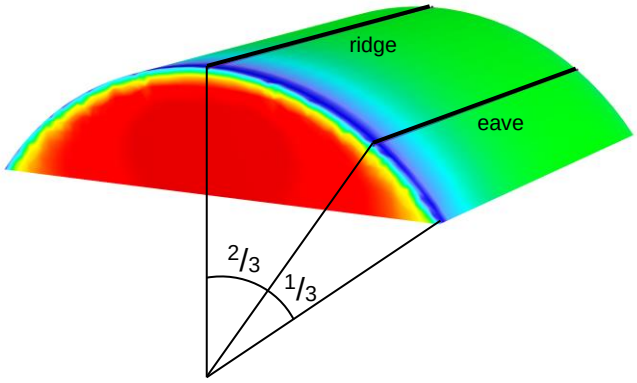

Figure 7. Shell structure with evaluation lines.

4. Results

The determination of wind loads of a shell structure considering different dimensions is performed on the basis of computer fluid dynamic calculation and evaluated in the form of diagrams.

4.1. Determination of the relevant evaluation line

Section 3.3 describes the defined evaluation lines. The possibility of half-sided observation (evaluation lines *ridge* and *eave*) is pointed out. In the following, the course of the c_{pe} characteristic values along the evaluation lines is examined for all variants according to Table 1. Figure 8 shows an example of the results for the variant d = 20 m, f/d = 0.5.

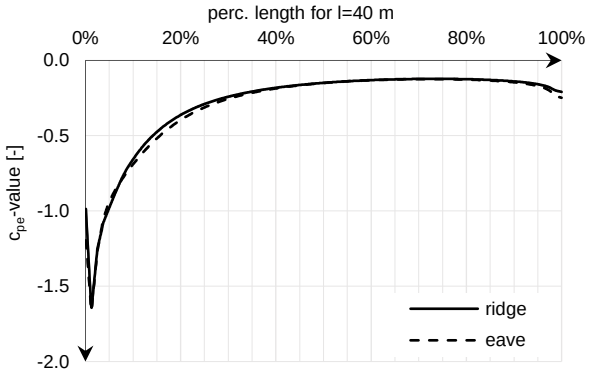

Figure 8. Course of the pressure coefficients (c_{pe}) of evaluation lines (*ridge* and *eave*).

It can be seen that both evaluation lines have similar courses. From this it can be concluded that the wind conditions are uniform in large areas and that the dimension of the selected wind tunnel is of sufficient size for the present investigation. The further investigation can be carried out only on the decisive evaluation line *ridge*.

4.2. Investigation of the pressure coefficients (c_{pe}) for variable length to span ratios

In the following, the further influence of different shell heights is considered. Figure 9 compares the c_{pe} characteristics for the 20 m span shell for a span-to-height ratio of 0.5 (left) and 0.125 (right). The following effects can be described: The shell with greater height has greater pressure coefficients (c_{pe}) (Fig. 9, left), with the maximum values occurring at the same distance from the side exposed to the wind. The greatest turbulence occurs in this region. Subsequently, the c_{pe} courses converge to a minimum value, with convergence occurring earlier at smaller f/d ratios (Fig. 9, right). The shell is affected in larger areas by the minimum wind loads. Increasing pressure coefficients (c_{pe}) are determined at the end of the shell. This is due to turbulence and detachment behaviour.

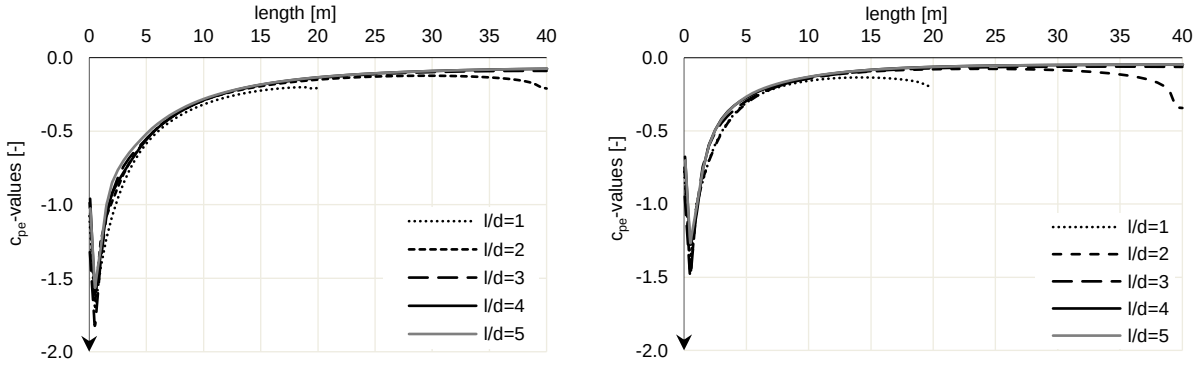

Figure 9. pres. coefficients (c_{pe}) for different l/d-ratios, fixed span (d=20 m); f/d=0.5 (left) and f/d=0.125 (right).

For further verification of the investigation approach, especially of the turbulence model and detachment behaviour, a comparative observation with a sharp-edged structure (cuboid) is conducted, see Fig. 10. The result curves show similar tendencies, which underline the possible applications of the chosen approach.

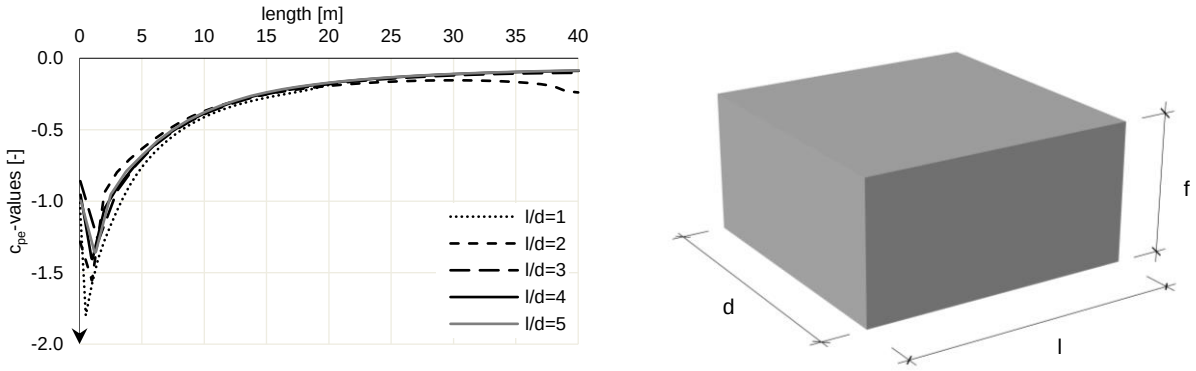

Figure 10. pressure coefficients (c_{pe}) for cuboid (d = 20.0 m and f = 10.0 m).

The c_{pe} characteristic values plotted in diagrams 9 and 10 can be used for a static analysis. Nevertheless, special attention must be paid to the turbulence and detachment behaviour at the beginning and end of the shell. The pressure coefficients (c_{pe}) given here represent absolute maximum values. The analysis of the turbulence behaviour in these areas can be performed with specially meshed numerical models.

With respect to a safe, engineering approach, further investigation is performed for the global regions of the shell structure. For this purpose, in the following considerations, the graphs are presented in the main continuity region, without considering the input region (5% of the total length) and the final region (10% of the total length).

4.3. Investigation of the pressure coefficients (c_{pe}) for variable height to span ratios

The further investigation of the c_{pe} characteristic values is carried out in dependence of the rise to span ratio exemplarily for the spans 20.0 m and 30.0 m considering geometric similarity on the basis of the length-span ratio l/d = 2.0, see Fig. 11 (left and right). The determined pressure coefficients (c_{pe}) are identical for the investigated variants. It becomes clear that the largest pressure coefficients occur at f/d=0.5. Thus, these characteristic values can also be assumed to be on the safe side for designs with f/d < 0.5.

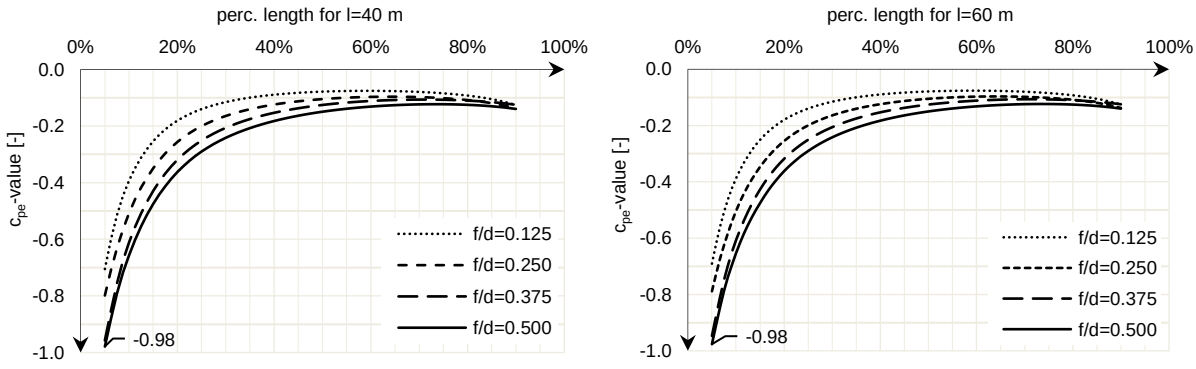

Figure 11. pressure coefficients (c_{pe}) for different f/d-ratios, fixed span; d=20.0 m (left) and d= 30.0 m (right).

4.4. Investigation of the pressure coefficients (c_{pe}) for different spans

The analysis of the wind pressure coefficients (c_{pe}) due to different span lengths is shown in the following Fig. 12 (left and right). Fig. 12 (left) shows a percentage length representation and Fig. 12 (right) a representation of the specific shell lengths in meters. For identical geometry ratios, a qualitatively and quantitatively uniform progression of the pressure coefficients (c_{pe}) over the longitudinal direction of the shell can be observed, irrespective of the span length, see Fig. 12 (left). The maximum wind load values due to initial turbulence decrease continuously with the shell length. For longer shell structures, this "harmonically" loaded region is more pronounced. Nevertheless, it can be seen that a convergence to the load minimum is reached for all shells considered.

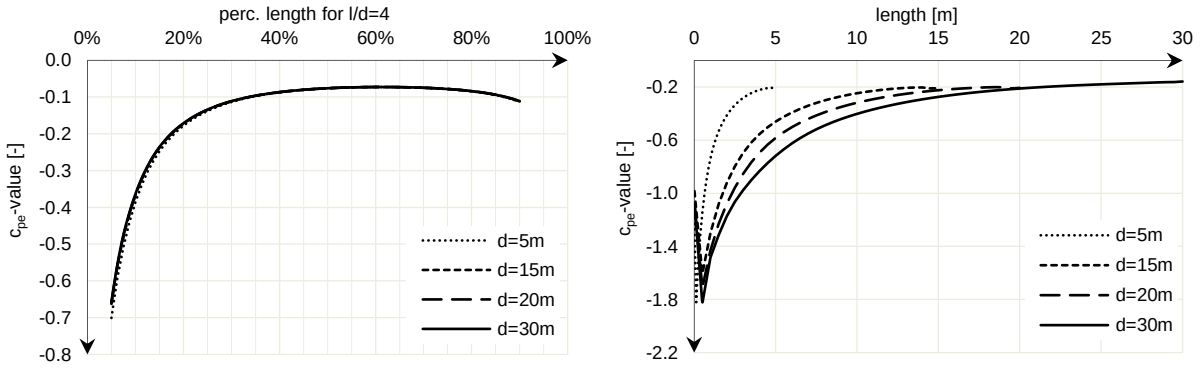

Figure 12. pressure coefficients (c_{pe}) for different spans, l/d=4 and f/d=0.5 (left) and l/d=1.0 and f/d=0.5 (right).

4.5. Derivation of applicable pressure coefficients (c_{pe}) and normative classification

From the previous analyses, the determined c_{pe} characteristics for the shell structure studied here can be classified and summarized.

Figure 9 clearly shows that an increase in the height-span ratio leads to an increase in the pressure coefficients (c_{pe}). In this study, this ratio was limited to f/d = 0.5. Figure 13 (left) illustrates an exemplary spatial representation of the wind load distribution on the shell structure. This wind load envelope is transformed into averaged zone areas in Fig. 13.

The pressure coefficients (c_{pe}) determined here are assumed to be on the safe side and are subsequently compared with the normative approaches according to DIN EN 1991-1-4. For this purpose, the characteristic values for flat roofs, see Fig. 14 (left), and gable roofs, see Fig. 14 (right), are used. The pressure coefficients (c_{pe}) specified in the standard are compared with the pressure coefficients determined in this study, see Table 2.

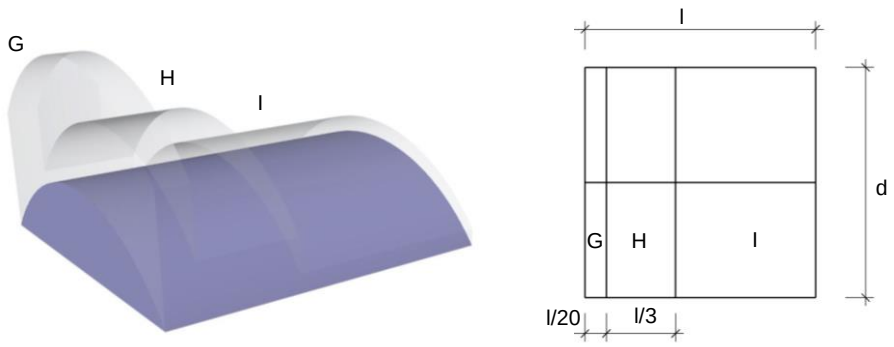

Figure 13. Exemplary wind load distribution on shell structure, determined values (left), averaged zones (right).

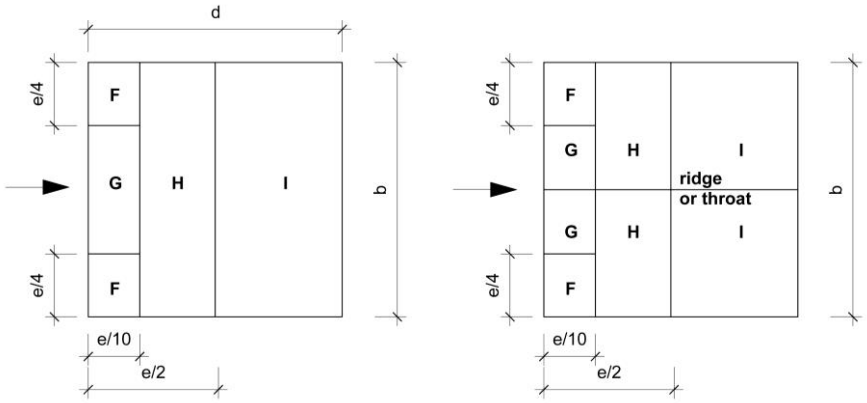

Figure 14. Division of the roof areas for flat roofs (left) and gable roofs (right) according to [EC1].

Table 2. Compilation of the pressure coefficients (c_{pe}).

Geometry or roof shape	Area			
	F ($c_{pe,10}$) [-]	G ($c_{pe,10}$) [-]	H ($c_{pe,10}$) [-]	I ($c_{pe,10}$) [-]
Shell		-1.8	-0.7	-0.2
Flat roof	-1.8	-1.2 ($c_{pe,10}$) -2.0 ($c_{pe,1}$)	-0.7	-0.2
Gable roof (inflow 90°, roof pitch 5°)	-1.8	-1.2	-0.7	-0.6

According to Table 2, it can be shown that the determined pressure coefficients (c_{pe}) correspond in the range of the normative characteristic values for flat and gable roofs.

On the basis of the previous investigations, see section 3, it should be noted that lower values can be determined in some cases if the exact geometric conditions are taken into account. Based on the geometry-dependent wind load values, a more sustainable design of shell structures can be carried out.

5. Summary and outlook

In this article, a contribution is made to the wind load determination of longitudinal shell roof structures. Based on extensive research, the current status of wind load standardization at European and international level is elaborated. It can be shown that the standardization approaches for these structural forms are very different. Furthermore, methods and fundamentals for individual wind load determination based on physical wind tunnel tests and numerical computer fluid dynamic analyses are researched.

Shell structures can cover large spans with low material expenses. On the other hand, these structures are highly sensitive to asymmetric loads. For this reason, exact, real expected wind loads are essential in the course of the design. The procedure for determining wind loads is presented using a Zollinger roof structure based on a computational fluid dynamics calculation. With the aid of a parameter study, the calculation accuracy, result reproducibility and transferability can be clarified. By considering specific evaluation lines and areas, a direct comparison to standard approaches can be drawn. The determined wind load coefficients of shell structures are compared with those of available roof shapes. Here, a reference is drawn to flat roofs or gable roofs. It can be shown that the results determined here follow the courses of the standards, but that lower wind load values can be achieved.

The results obtained are to be verified in further investigations. In addition to physical wind tunnel tests, comparative calculations with other CFD systems can also be carried out. Especially the consideration of the further influence of the CFD wind tunnel dimension, discretization of the finite volume mesh and the detachment and turbulence properties especially at the curved roof edges are to be focused. In

conclusion, specific wind load assumptions are essential with regard to material-saving and resource-efficient roof structures. For this purpose, approaches of further topology optimization and sustainability investigation of supporting structures should be mentioned, for example.

Digital twins of wooden shingle envelopes

Farzaneh ESKANDARI[*], Yves WEINAND[a]

[a,*] École Polytechnique Fédérale de Lausanne
GC H2 711, Station 18, 1015, Lausanne, Switzerland

Abstract

Wooden shingles have long been used as a vernacular roofing technique in many well-wooded areas. Despite the fact that shingles, as local raw materials, are low in embodied energy, nowadays they are not much used in construction, as the specific craft knowledge for building shingle roofs and facades has not been well-documented. Consequently, it is now becoming more difficult to find a new generation of skilled workers who can perform this task. As a result, this type of architecture is gradually disappearing. This research aims to provide a technical approach for digitization and generation of an as-built three-dimensional (3D) reconstruction of wooden shingle envelopes. Towards this aim, digital twins of wooden shingle envelopes are generated based on step-by-step real-time 3D scanning of shingles and point-cloud processing of the obtained scans, while they are placed by craftspeople. Two experiments on two different types of wooden shingles are conducted to validate the proposed method, and a precise digital model of this valuable type of vernacular architecture is produced. Furthermore, the exact geometrical configuration, assembly rules, installation patterns, and technical details of the construction process are documented and explained in detail. This work concludes with potential future research directions including design automation and optimization of wooden shingle envelopes which could help the industry re-introduce the use of local raw wood in contemporary architectural constructions, and revive this cultural and artisanal heritage.

1. Introduction

Emissions of carbon dioxide and other greenhouse gases continue to rise rapidly [1], with a considerable amount coming primarily from the building and construction sector due to the manufacture of building materials and products such as steel, cement, and glass [2]. Additionally, the dramatic growth of the world population will require significant construction efforts which compel the building industry to implement more sustainable materials. Among all construction materials, wood as a natural material for construction purposes is in a highly advantageous position and has recently been promoted to the center of interest [3]. However, engineering wood for the production of timber panels and beams consumes a large amount of energy and requires unsustainable processing and modification techniques. Additionally, if treated with chemical substances, it will eventually increase the carbon footprint, and consequently, reduce the inherent sustainability of raw wood [4]. Indeed, raw wood as a local material is low in embodied energy and has been widely used in traditional and vernacular constructions, and has become part of the cultural heritage of many well-wooded areas. Vernacular architecture with local raw wood has always relied on the technique [5], and expertise of craftspeople. Regrettably, this knowledge of craftspeople for these kinds of vernacular constructions has been passed down from generation to generation only practically, yet has not been well-documented and archived scientifically in terms of technical details, geometrical configurations, and construction rules. As a result, many of these

Copyright © 2023 by Farzaneh ESKANDARI and Yves WEINAND. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

worthwhile traditional building systems are disappearing, and industries mainly tend not to use local raw wood due to labour shortages and construction difficulties with such irregular unprocessed material. Even in rare cases where these traditional building systems are implemented in contemporary constructions, they are of lower caliber with a lack of attention to the culture, context, and building performances in response to the environment.

Wooden shingles are one of these sustainable vernacular building materials and were widely used by expert craftspeople to cover building roofs and facades. This roofing technique greatly depends on craft knowledge and nowadays only a limited number of artisans know this technique. Subsequently, wooden shingle envelopes have remained unknown to many contemporary architects and have been being replaced with unsustainable materials such as metal or cement, even in areas where local wood resources are abundant (Figure1). This is mainly due to a lack of proper documentation and reliable 2D and 3D drawings to guide non-specialized builders to use this type of material.

The emergence of the "digital twin" concept in the fields of manufacturing, and production [6], along with advances in the field of computational design and computer vision has assisted the progress of digitization of local building systems and cultural heritages [7] to make thorough documentation of them. Digital twins are defined as three-dimensional virtual models of a system [8], which indicate the physical characteristics and functional attributes of that system. This type of information from the buildings can be obtained by real-time monitoring of the construction process using advanced sensing technologies such as laser scanning (LIDAR) and photogrammetry [9], which can provide useful data for architects, engineers, and builders. The obtained data from the sensors are processed using computer vision algorithms and libraries such as PCL [10], Open3D [11], CGAL [12], and Cilantro [13], as cutting-edge libraries that provide comprehensive functions to post-process the aforementioned data for digitization of the systems. Digital twins for construction are highly beneficial not only for the automated data acquisition from construction sites and supply chains, but also for surveying and virtual reconstruction of archaeological sites [14, 15], and acquisition of as-built geometry and documentation of traditional building systems [7]. However, the current state of the art in digital surveying of traditional buildings mostly centers on the protection, maintenance, and preservation of cultural heritages, without providing much information on technical details of the step-by-step construction procedure, assembly sequences, and material properties, with no guiding principles or plans.

In this paper, we present an approach for the digitization of traditional wooden shingle envelopes for two types of shingles, known as Bardeaux and Tavillons, which are used as roof and facade tiles in well-wooded areas. Our methodology contains a step-by-step as-built three-dimensional reconstruction of shingles, based on obtained point clouds from a 3D scanner. One scan is taken for each element during the assembly process, following that, the point cloud is post-processed by our algorithm, and the three-dimensional model of the element is retrieved. Two prototypes are built by expert craftspeople to validate the proposed methodology. Subsequently, the proposed approach enables us to make the digital twin of shingle envelopes, document and archive all the details for the assembly sequence, installation patterns, material properties, horizontal and vertical overlaps, size of elements for each row of shingles, and the quantity and position of nails for fastening the shingles. The outcomes could guide builders to use this type of natural raw material in contemporary architectural constructions, respecting traditional rules.

To the best of our knowledge, this is the first time a digital twin of wooden shingle envelopes has been developed in accordance with craft knowledge and traditional standards.

2. Related works

In the past few years, a number of projects in the field of architecture and engineering have attempted to make digital twins of various historical buildings such as bridges, churches, theaters, etc., with the help of 3D scanning and photogrammetry techniques. Projects and research of this type have assisted the progress of prediction of damages, preservation, and restoration of monuments and archaeological

sites. Bilis et al. [16] made thorough documentation and conducted a graphic restoration study of the ancient theatre of Nikopolis, with the aid of 3D scanning and image-based 3D reconstruction. The study on the object dimensional imprinting of the Byzantine church of the holy apostles in Thessaloniki by Katsoulis et al. [17] provides the data collection of the geometric information, such as the shape, the size and the location of the monument. "Cyclopean Cannibalism", a traditional masonry technique, was translated into a contemporary digital procedure by Clifford et al. [18], through scanning and virtual algorithms. Betrocci et al. [15] also presented a digital survey for the archaeological analysis and enhancement of Gropina site, by integrating data from laser scanning and photogrammetric instruments. In addition to the aforementioned projects for the digitization of cultural properties, the digital twin technique has also gained increased popularity in the domain of on-site construction, for automating building processes [19], autonomous navigation, object detection, real-time robotic assembly [20, 21, 22], and also the autonomous robotic fabrication of raw wood [23]. However, there is no proof of concept on the digitization of traditional wooden shingles, and this type of architecture is investigated in this article.

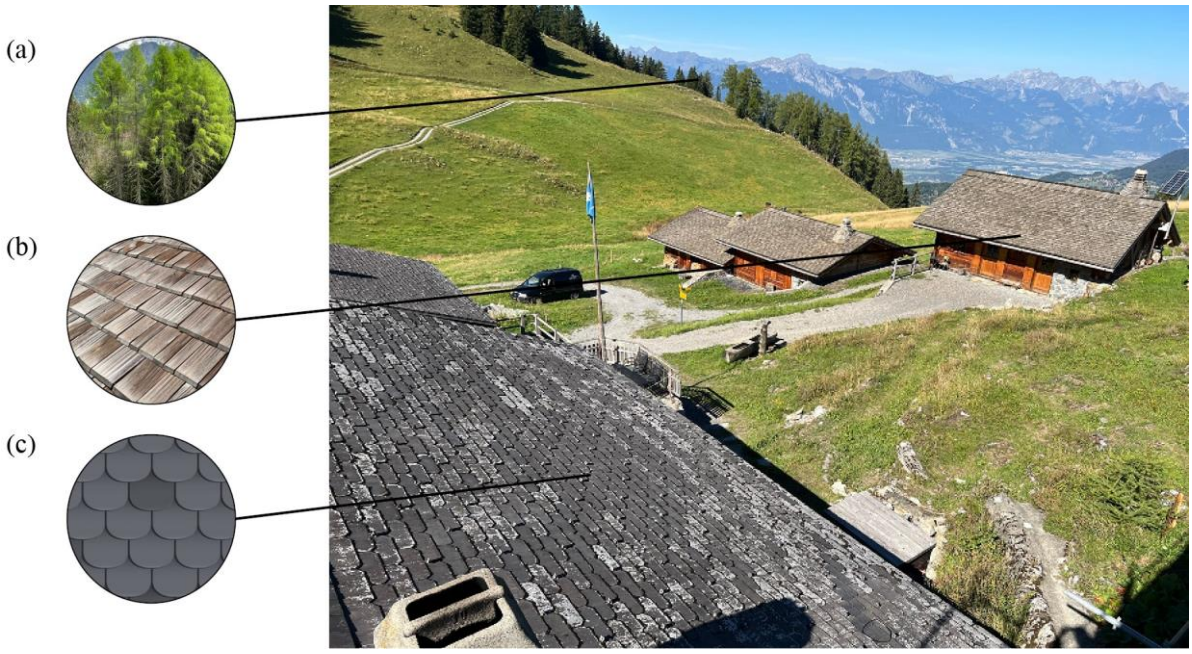

Figure 1. Implementation of unsustainable materials such as metal shingles in the construction of contemporary buildings, in areas where there are abundant wood resources that were traditionally used by local people in the past to construct age-old wooden shingle roofs: (a) Available material resources, such as larch trees, for wooden shingles, (b) Age-old wooden shingle roofs from 25 years ago constructed by local craftspeople and (c) a contemporary metal shingle roof built by present-day industries [Gryon, Switzerland].

3. Age-old wooden shingle envelopes

In this section, some general information is provided on the material characteristics and assembly rules of the historical wooden shingle envelopes according to some ancient references.

Shingles have long been used as a vernacular roofing technique in well-wooded areas. Attentively and dexterously done, shingles are superior to many other roofing methods in terms of durability, sustainability, exquisiteness, and monumentality [24]. The specific fabrication process of the material, makes the roofs and facades watertight and highly resistant against weather-induced decay, without using any chemical coatings [25]. Historically, shingled roofs were of immensely high caliber and were built by eminently expert craftspeople. There are two types of wooden shingles, known as tavillons and

bardeaux in French. The key differences that distinguish these two types of wood are mainly the overlapping method and material resources, which will be explained in the following.

The thin nature of the shingle, its fabrication process, and its exposure to rain, snow, and sun necessitate high-quality wood. An ideal tree for this application should be straight, and must not be twisted. Additionally, it has to be mature and fine textured, without too many knots, and free from rot and blue stain fungi, with a large proportion of heartwood in relation to sapwood. Trees for this application should not be cut during spring or summer but in winter as it ensures high-quality wood. Tree felling is also bound to the phase of the moon. Thus, felling has to occur when there is a new moon, as it would make the timber more resistant to rot and to the depredations of insects. Trees should be barked immediately after felling, and definitely before spring to avoid the risk of rot and damage by insects. After bark removal, the trunks are sawn into log sections with the desired length, known as bolts [24, 26]. Afterward, each bolt is split in quarters from which sapwood is removed, all of which then is chamfered at one corner to avoid over-thickness during installation [24]. Following that, they would be split into rough shingles with a wedge and mallet [24, 27]. Tavillons are left submerged in the water to make them flexible for assembly, as they are naturally quite brittle when dried. Shingles are quite thin (0.7-1.9 cm), relatively narrow (7.6-20 cm), and with varying lengths (35-90 cm). The final products are always irregular with disparate geometry and size, and bumpy surfaces. The laying process is conducted by a series of rules conveyed by oral transmission and collaborative practice, without any execution drawings or technical documentation. A specific frame has to be built as the structure underneath, on which shingles are laid and nailed. The main constraint for the sub-structure is the slope which should not be less than 27◦, due to water tightness issues. What should be taken into consideration, first and foremost, is the consistency of the rows of shingles. Tavillons are placed over the previous one laterally with a side overlap corresponding to 1/3 of their width, this leads to three thicknesses per row. Each row vertically overlaps the previous one so that only 1/4 of the tavillon length would remain exposed, this ensures 12 thicknesses of the shingles. Mechanical fasteners are used for connecting tavillons, at least one nail is used per two tavillons. Some craftspeople use a different method, in such a way that instead of placing tavillons one by one, they place the tavillons in pairs and fasten them with one nail. On the other hand, bardeaux are placed beside each other with no horizontal overlapping. However, it is important to stagger each bardeaux by a minimum of 30 mm to avoid a seam alignment and a direct path for water leakage and thus ensure water tightness. Additionally, leaving a small space (3-12 mm) between two neighboring bardeaux is necessary for free swelling, due to the extreme variations of temperature and humidity they undergo. The same vertical overlapping as explained for tavillons is considered for bardeaux as well [26].

4. Digitization of wooden shingle envelopes

4.1 Methodology

In this section, a technical approach is presented for automating the as-built three-dimensional (3D) reconstruction of the wooden shingle envelopes in real-time based on point cloud processing. In this work, the already developed functions for point cloud processing from three main libraries including Open3D [11], CGAL [12], and Cilantro [13] were used to develop the digital twin. Furthermore, other functions were also developed by the authors. The main objective of the proposed approach is to achieve a reliable CAD model of the vernacular shingle envelopes by which we can detail all the specifications of shingled roofs and facades. As mentioned in the previous section, the shingle's geometry is uncertain, and each of them is of a different size and curvature, so the generation of CAD models cannot be carried out manually in CAD software such as Rhinoceros, or AutoCAD. Moreover, as shingles are laid over each other with horizontal and vertical overlaps and cover one another, it is not feasible to obtain an accurate 3D model of the roofs by 3D scanning of existing buildings with the conventional digital twin generation methods (see Section 2). Figure 2 shows a 3D model of an existing shingled roof covered with tavillons, generated by 3D scanning of the building using a Faro Focus 3D scanner, which was

conducted as the first step for this research [28]. This 3D model could only provide some general information about the roof such as the size, the minimum required slope for the roof, and also a general

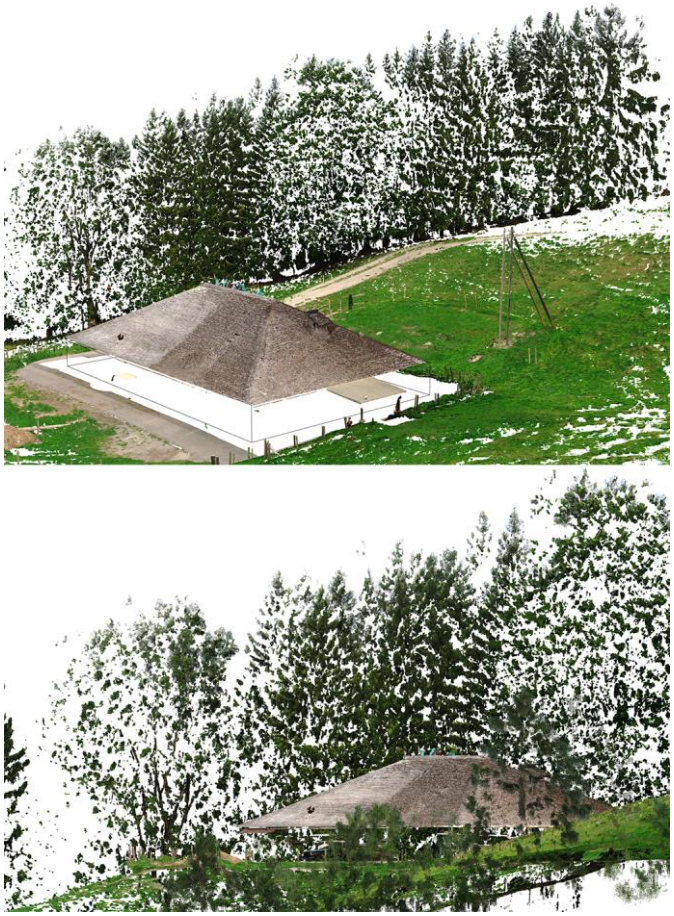

Figure 2. Three-dimensional model of an existing age-old wooden shingle roof in Rossiniére, Switzerland, 2022.

overview of shingles, without any specific details on the laying sequence and installation patterns. Therefore, in order to generate an accurate and complete 3D reconstruction of these envelopes, an approach is presented to scan and digitize the shingles during the assembly one by one in order to extract the individual 3D models of each of them. Subsequently, an experiment is set up as shown in Figure 3-a. To detect the in-progress shingles and the sub-structure, a Faro Focus 3D scanner is mounted statically on top of the workspace to provide the 3D scans. The scanner is connected online via computer, in order to transfer the captured point clouds in real-time [29]. A sub-structure, composed of rafters (known as contre-lattage in French) with an 800*600 mm section and battens (known as Lattage in French) with a 27*100 mm section (the first row of battens has to be of a 27*160 mm section) and 100 mm spacing, which are installed on rafters, is fixed on the worktable with four targets at the corners. One scan is taken per shingle right after it is positioned by a craftsperson (Figure 3-b), and then it is imported into our C++ project to be post-processed in order to extract only the detached 3d point cloud of the last assembled shingle (Figure 4). The surrounding environment is filtered out (Figure 4-a) and the points belonging to the last assembled shingle are clustered (Figure 4-b). This process is repeated for all the shingles until the full 3D model of the prototype is obtained. The result could elucidate all assembly techniques which are performed by craftspeople.

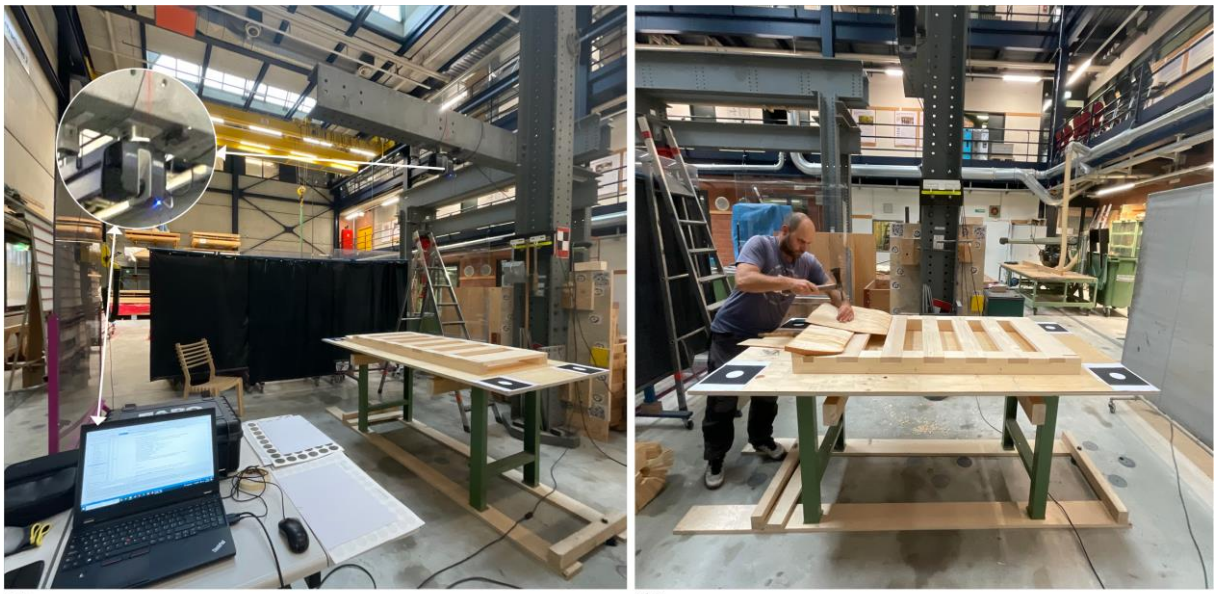

Figure 3. Experiment set-up for the real-time 3D scanning of shingles assembly: (a) A 3D scanner that is connected online via a computer and mounted statically on top of the workspace to provide the 3D scans and transfer the captured point clouds in real-time, (b) A craftsperson assembles the shingles one by one as the process is recorded.

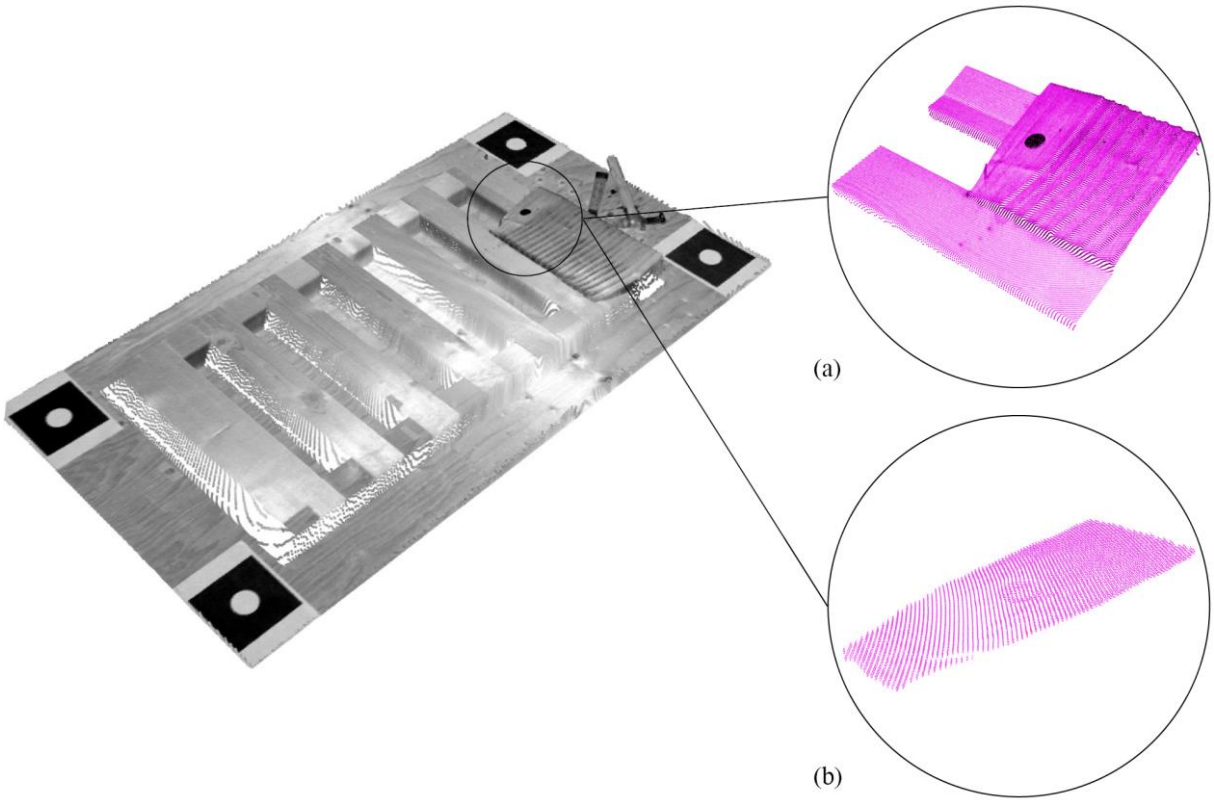

Figure 4. Scanning each shingle after it is placed by the craftsperson: (a) Filtering out the surrounding environment, (b) Clustering the last assembled shingle.

4.2 Experiments and results

Two prototypes are designed and built with two skilled craftspeople, on two types of wooden shingles including tavillons and bardeaux, in order to both validate the proposed methodology and document the details of the two types of shingles. Both prototypes are of a width of 80 cm and a length of 140 cm. A craftsperson builds the prototype in accordance with traditional techniques, and the shingles are scanned one by one. The obtained scans are then post-processed with the above-mentioned methodology, the accurate digital twins of two prototypes were made [30] and the details of the prototypes are documented and will be explained below.

4.2.1 Tavillon

For the first experiment, a prototype was built with tavillons and the following assembly rules were extracted. The first row of tavillons is laid at the lowest point of the substructure, and elements are placed one by one from left to right. The first batten has an inclined surface with a gentle slope, which provides the proper inclination angle for the envelope, thus ensuring the rain drips off the roof. The first row of tavillons consists of elements with a length of 25cm and a width of 10 cm. Each tavillons is placed over the previous one laterally with a side overlap corresponding to 1/5 of their width, such that only 2cm of the tavillon width is exposed. Each tavillon always covers 3/5 of the second last one. The second layer is made up of longer tavillons with a length of 45 cm, and a width of 12cm. The horizontal offset is 2.5-3.0 cm (1/4 of the tavillons width). Additionally, the second row should begin 2.5 cm further back from the first row. From the third row on, each layer is composed of tavillons of the same size as the second row. However, the horizontal overlaps correspond to 1/3 of the tavillons width, meaning that only 4cm of each tavillon is exposed and each tavillon covers 1/3 of the second last one. Furthermore, each row is placed over the previous one, with a vertical overlap corresponding to 1/4 of the tavillon length.

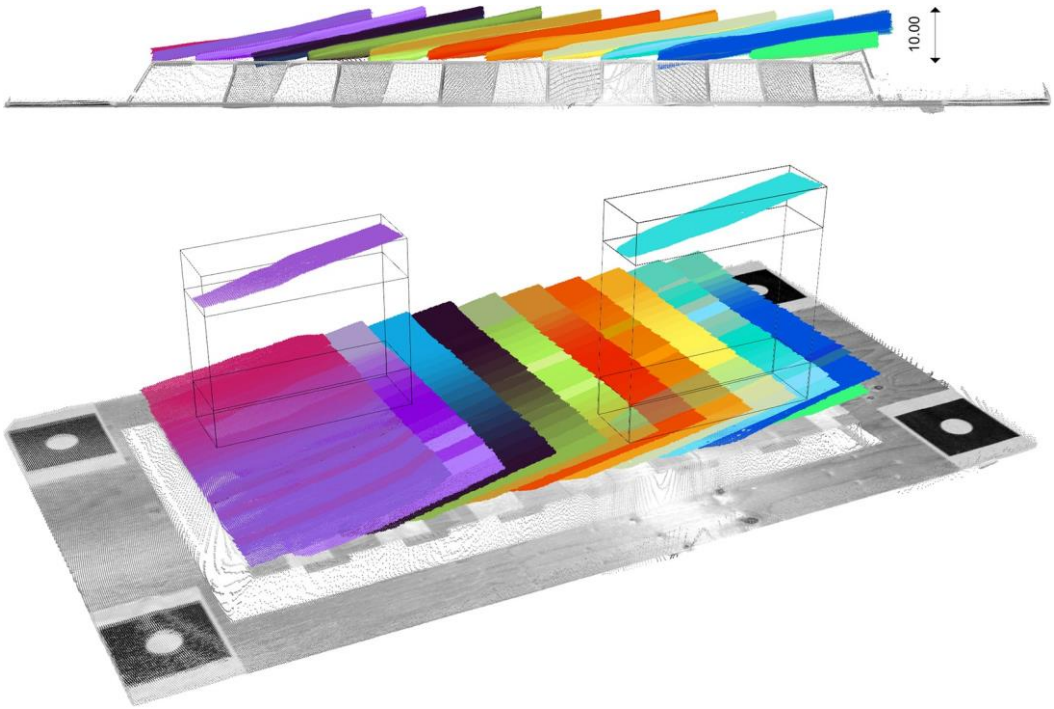

Figure 5. Digital twin of tavillons envelopes

Finally, for the last row, tavillons are placed with the same horizontal and vertical overlaps, but in the opposite direction, such that the thicker side of the material would be placed at the end. In the end, we

always have 12 layers of wood (10 cm thickness) at each point of the prototype, which is essential to ensure the water-tightness of the envelopes (Figure 5). Each tavillon is fastened to the substructure with galvanized nails with a minimum length of 5 cm. the nails must be intersected with battens underneath in order to fix the tavillons properly. Additionally, nails can only be applied in the regions that are covered with the next layer, which indicates that we cannot have any nails in the first quarter of the tavillons length (below the exposure line), otherwise, the nails are exposed to rain and would rot, which results in wood decay. Moreover, the position of nails is different for each layer, as the position of the tavillons changes in each layer in relation to the position of the battens underneath.

4.2.2 Bardeaux

For the second experiment, a same-size prototype was built with Bordeaux. Each bardeau was scanned and post-processed using the same methodology as the one used for tavillons. However, the assembly rules are quite different. Just like tavillons, the first row of Bardeaux is built with shorter elements, with a length of 25cm. The elements are placed next to each other with a minimum spacing of 3mm, but unlike tavillons, with no horizontal overlapping (Figure 6). The second row consists of elements with a length of 35cm which are aligned with the bottom of the first row. The elements are selected based on their width, such that they stagger by a minimum of 30 mm, so no seam alignment occurs. The third and fourth rows begin 2.5 cm further back from the two previous rows, with a length of 45cm, and the same staggered pattern. From the fifth row to the third last row, the elements with the same length as the previous row, with a 12cm vertical offset and with the same staggered order are used. For the two last rows, elements with a length of 30-35 cm are used and are placed over each other with no vertical offset, and with a 12cm vertical offset in relation to the previous row. In the end, we have 8-10 cm thickness at each point of the envelope, which is necessary for water tightness concerns. Nails are also positioned with the same rules as for the tavillons.

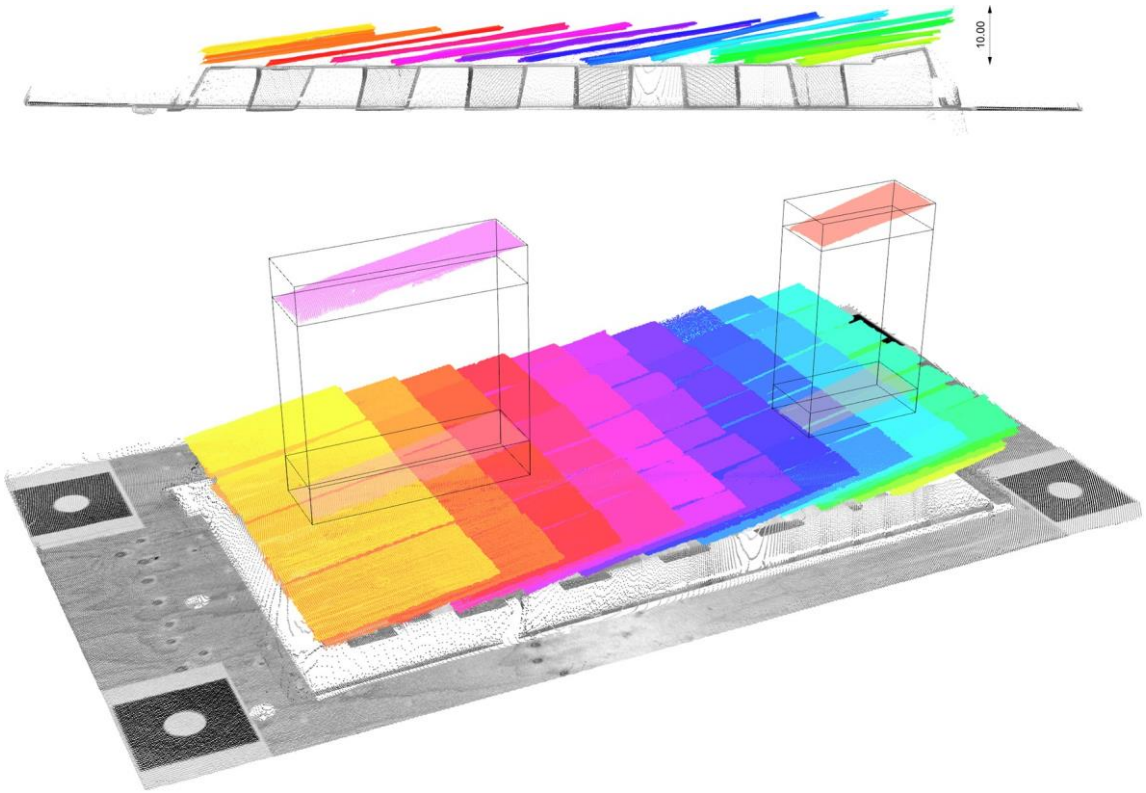

Figure 6. Digital twin of bardeaux envelopes

5. Conclusion

This research demonstrates the first digital three-dimensional reconstruction of vernacular wooden shingle envelopes, along with the details of installation patterns, assembly sequences, and material properties for two types of wooden shingles, known as tavillons and bardeaux, in conformity with craft knowledge. We present a real-time mapping algorithm combined with a vision system that enables the detection of in-progress shingles while a craftsperson assembles them, based on point cloud processing techniques. Unlike most common digital twins of historical buildings, which only provide the exterior surface of the existing buildings' envelopes, in this research, the step-by-step approach for the 3D scanning of the assembly process of shingles produces a fully 3D model of all individual objects, even the elements in the lower layers of the envelope which are covered with topmost layers. The described mapping tools and algorithms could be used for the design automation of wooden shingle envelopes by present-day industries to re-introduce this local raw material in contemporary constructions, which not only would help revive this traditional building system and cultural properties but would also help achieve more sustainable buildings and reduce the carbon footprint of the building and construction sector.

Abstract

Current construction practices follow linear economic models of "take-make-dispose" that result in substantial material landfilling after the end-of-life of buildings. This issue takes relevance given the construction industry's significant stake in the high levels of resource depletion and waste production observed today. As an attempt to address the problem, this paper presents an experimental investigation on the bending behavior of glue-laminated timber (GLT) slabs -Pixel Slab System- designed for open-ended reuse following Circular Economy principles. The system employs an arrangement of orthogonally intersecting GLT beams to form a reuse-ready grid slab, relying on adjustable static heights, reversible connections, and modular elements to guarantee easy disassembly and reassembly in unknown configurations. To evaluate the system performance, twelve full-scale GLT beams were tested under bending load, employing different spans, depths, and connection placements. Results showed that the system has adequate performance under 3- and 4-point loads; however, the use of notches at the intersections reduced its stiffness and moment capacity by 23% and 29%, respectively. Using reversible steel connections to join consecutive slab modules proved to deliver a proper mechanism to transfer axial, shear, and bending loads, while not affecting the elastic response or failure mode of the beams. Finally, a constructability analysis showed that the concept poses no constraints to on-site construction/deconstruction, since low-tech procedures are used for assembly/disassembly.

Keywords: component reuse, design for deconstruction, circular economy, sustainable buildings, wooden beams

1. Introduction

The Pixel Slab is a new slab-column system designed for deconstruction and open-ended reuse over several lifespans. By employing modular elements and reversible connections, the proposed concept allows effortless assembly/disassembly procedures and subsequent reuse in diverse architectural layouts, including ones requiring greater static height [1]. As Figure 1 shows, the system is comprised of modular timber slab elements (2.4×2.4 m) made up of orthogonally intersecting beams that transfer loads to adjacent slabs or columns. Slabs are arranged horizontally by means of in-plane “IP” connections to create a lateral surface. If required by design, the slab’s thickness can be increased by vertically attaching additional slab elements with out-of-plane “OoP” connections to reach longer spans or greater loads. Columns can be placed at any position within the slabs to allow flexible layouts, and their length can vary to satisfy different story heights. This way, the structural elements pose no restrains to flexible architectural requirements, making room for future open-ended reuse. Finally, non-structural elements, such as tiles or insulation, can be assembled on top of the slab elements to provide a flat surface and disassembled for replacement or reuse.

Slab elements are manufactured using glue-laminated timber (GLT) beams with half-lap joints (beam-to-beam "B2B" connectors) at the orthogonal beam intersections, forming a uniform grid across the slab. This allows standardizing the manufacturing by using a single beam geometry for all elements in the modules while being compatible with the current GLT manufacturing process.

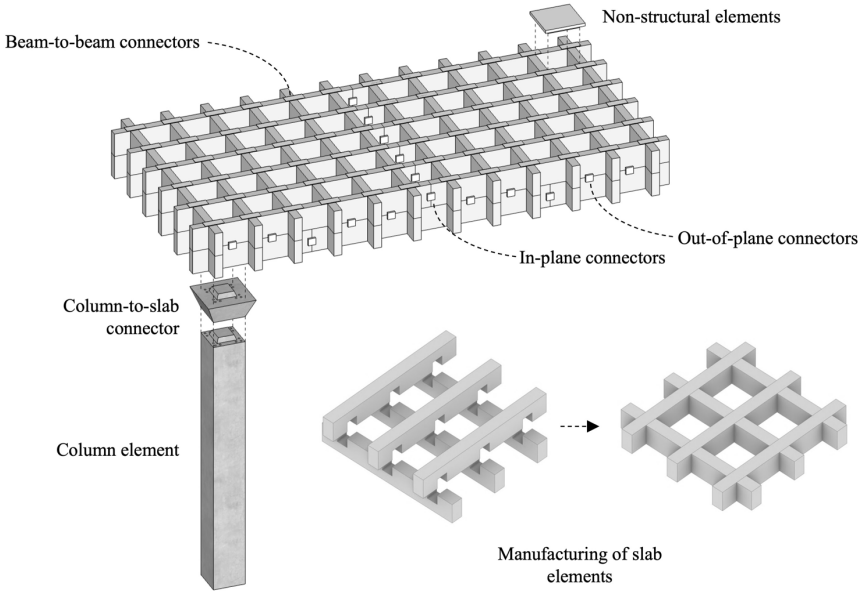

Figure 1. Elements of the Pixel Slab system and manufacturing of slabs.

To better understand the structural performance of the Pixel Slab under vertical loads, this paper presents an experimental investigation on the bending behavior of two main system components: (1) superimposed GLT beams with OoP connectors, and (2) GLT beams with notched B2B connectors. Test results provided insightful information on the load-carrying capacity of the system, geometry/capacity connections compatibility, and suitable design strategies for component design. A full understanding of these phenomena is key for proper implementation of the Pixel Slab, since the slab's behavior, strength, stiffness, and deflection are governed by the mechanical properties of the beams and their connections.

2. Connection design

2.1. Out-of-plane OoP connections

The Knapp MEGANT connector [2] is proposed for the OoP connection. To achieve the composite action between two beams, the connectors need to be placed horizontally at the interface between the top and bottom beams as Figure 2(a) shows. To minimize the impact on the B2B connections, only the smaller Knapp connector length of 310 mm was selected. Three width variants exist for this length, with capacities ranging from 97 to 156 kN and slip modules from 40 to 88 kN/mm. To determine the connection capacities, the MEGANT connector variant was maximized for each cross-section width.

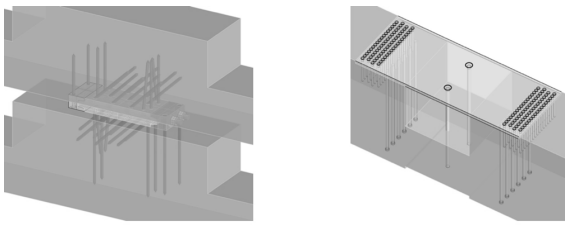

Figure 2. (a) Out-of-plane OoP connection, and (b) beam-to-beam B2B connection.

One drawback of this connection as it is available, is that while it is reversible, it does require to be oriented in the right direction to achieve its highest capacity and slip modulus as provided by the manufacturer. Indeed, in order to benefit from the 45° screws working in withdrawal (tension), they need to be oriented in the direction of the shear force. Alternatively, the screws would work mainly in shear and compression, which are significantly weaker. The load-carrying capacity in this "weak"

orientation is 30-40% that obtained in the "strong" orientation [3]. The slip modulus for the connection in the "weak" orientation is not given in the manufacturer specifications.

To calculate the composite action between elements the gamma-method was used as presented in EN1995.1.1 - Annex B [4]. This method requires the definition of the connection's slip modulus, spacing and element length. For serviceability limit state calculation, the above slip modulus K_{ser} can be used, while for ultimate limit state calculations, a reduced slip modulus $K_u = 0.66\ K_{ser}$ needs to be used as per EN1995.1.1 – 2.2.2 (2) [4]. These are then used to determine gamma coefficients relating to the degree of shear transfer at the interface between two elements. Using these coefficients, the effective bending stiffness $(EI)_{eff}$ can be obtained for direct use in standard calculations. Besides, since all elements have the same rectangular cross-section and modulus of elasticity, the effective height can be calculated as:

$$(EI)_{eff} = E\frac{bh_{eff}^3}{12} \Longrightarrow h_{eff} = \left(\frac{12\cdot(EI)_{eff}}{Eb}\right)^{(1/3)} \quad (1)$$

The results for the obtained effective bending stiffnesses and heights for the considered cross-sections and MEGANT connectors are summarized in Figure 3. Figure 3(a) shows that for two-layer elements, i.e., when two slabs are superimposed, the effective bending stiffness obtained from the gamma-method for the 800 mm connector spacing was 33% of the maximum theoretical stiffness compared to 17% for three-layer elements. This corresponded to effective heights of two-layer elements being on average 69% of the maximum theoretical value compared to 55% for the three-layer elements.

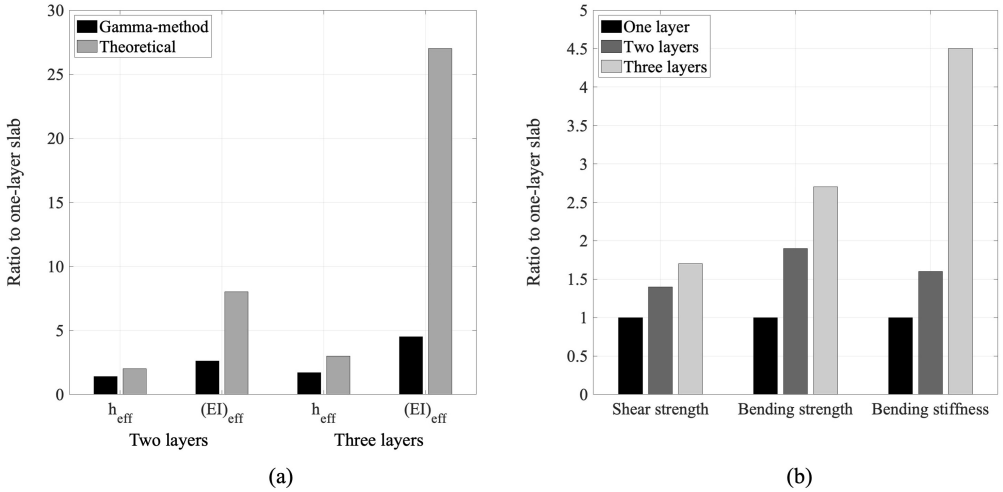

Figure 3. (a) Comparison between theoretical and calculated values for a MEGANT connector spacing of 800 mm, and (b) comparison between strength and stiffness for different element layers.

Compared to single layer elements in Figure 3(b), these gains represent a 38% increase in height for two-layer elements and 65% for three-layer elements. In terms of strength, this would translate to a 38% increase in shear strength and 91% increase in bending strength for two-layer elements. For three-layer elements, those gains would equate to a 65% increase in shear strength and 173% increase in moment resistance. These gains are much lower than the maximum theoretical 2 and 4 times increase in shear and bending strength respectively for the two-layer elements, and 3 to 9 times increase in shear and bending strength respectively for the three layers. In terms of stiffness, the OoP connection results in a 160% and 350% improvement for two- and three-layer elements over the single element layer.

2.2. Beam-to-beam B2B intersection connections

The proposed solution consists in using 90º nails working in shear through a steel plate to transfer the normal forces from the bending moments across the discontinuity. This connection benefits from nails having a smaller diameter and minimum spacings requirements to obtain a significantly higher the

number of fasteners within the limited space available. Here for both tensile and compressive forces, the nails work in shear between the timber beam and the steel plate. The latter then transfers these normal forces across the beam intersection. The steel plate's capacity in tension is defined by the net area, or block shear capacity while its compressive capacity is controlled by the flexural buckling capacity. To this end, fully threaded countersunk head "stability" screws are positioned at the plate centerline to halve the effective length and keep the steel plate as thin as possible. These "stability" screws also serve a fabrication purpose in tying the intersection beam together. Here, again, the connection configuration has the normal force transmitted at the top fiber of the cross-section resulting in an equivalent moment resistance of $M_{Rd} = 5Nh / 6$.

Regarding the shear strength, it is defined by the minimum of the shear capacity of half of the beam cross-section, or the augmented capacity obtained using the reinforcement screws on both sides of the joint. The B2B connection is illustrated in Figure 2(b).

3. Experimental testing

3.1. Out-of-Plane OoP connections

Three-point bending tests were carried out to investigate the capacity of the double beams assembled using the OoP connectors. In total, five tests were conducted: for the first three tests (OoP1, OoP2 and OoP3) the double beams were linked using two MEGANT connectors spaced at 2300 mm, while for the last two tests (OoP4 and OoP5) the beams used six MEGANT connectors spaced at 767 mm along the beams. The specimens were two 4800 mm long GLT elements with a cross-section of 180×280 mm and a GL24h strength class. For the connections, two or six Knapp MEGANT 310×100×40 mm were used. Each connection consists of two connector plates, two clamping jaws, 4–8×240 mm fully threaded screws, 26–8×160 mm fully threaded screws and 2–16×340 mm threaded rods with washers and nuts.

The testing setup is shown in Figure 4. To prevent crushing perpendicular to the grain at the supports, 180×300×5 mm steel plates were screwed on the underside of the bottom GLT beam. At the load application point, located at midspan, the jack head area of 180×300 mm was sufficiently large to avoid crushing perpendicular to grain for the given load and no bearing plate was added. Deformations were recorded at several locations in the beams employing linear variable differential transformers LVDTs.

The testing procedure was divided in two parts. The first part consisted of three loading cycles up to 10 kN and down to 1 kN with a two-minute interval between each cycle. The results from the last two loading cycles were used to determine the effective elastic bending stiffness $(EI)_{eff}$ of the specimens. The obtained elastic bending stiffness can then be used to calculate the effective height of the composite cross-section, as shown previously. The second part consisted in loading the specimen until failure. The loading rate was set to 0.02 mm/s (1.2 mm/min) for both parts of the test.

Figure 4. Three-point testing setup for OoP specimens and failure modes.

The elastic bending stiffness was computed for all specimens from the results of the first part of the test. For the specimens OoP1-2-3, the average effective bending stiffness was of $(EI)_{eff,avg}$ = 6.93e12 N/mm^2 with a coefficient of variation (CoV) of 19.1%. This high CoV value is explained by the higher performance observed for specimen OoP3. The obtained effective bending stiffness translates an average effective height of $h_{eff,avg}$ = 432 mm, assuming the mean elastic modulus E = 11 500 N/mm^2. This is below the theoretical values obtained using the gamma-method, for both serviceability and ultimate limit states. In addition, this average effective height is lower than the theoretical value for two vertically stacked beams having no shear transfer between them. Superimposing two beams would result in doubling the stiffness which result in an effective height equal to $h_{2,eff} = 2^{1/3} \cdot h$ = 353 mm Therefore, the large 2300 mm connector spacing shows an effective reduction in overall bending stiffness of the system. This could, however, not entirely be caused by the presence of the connectors and may be also explained by the elastic modulus of specimens OoP1 and OoP2 being lower than the mean value due to the high natural variability of timber elements. Another possible explanation for such observation could relate to the fact that the ends of the top beam, past the connection point, do not contribute to the overall stiffness of the system. Indeed, since all the internal forces are transferred at the connector point, only the central half of the top beam is being solicited.

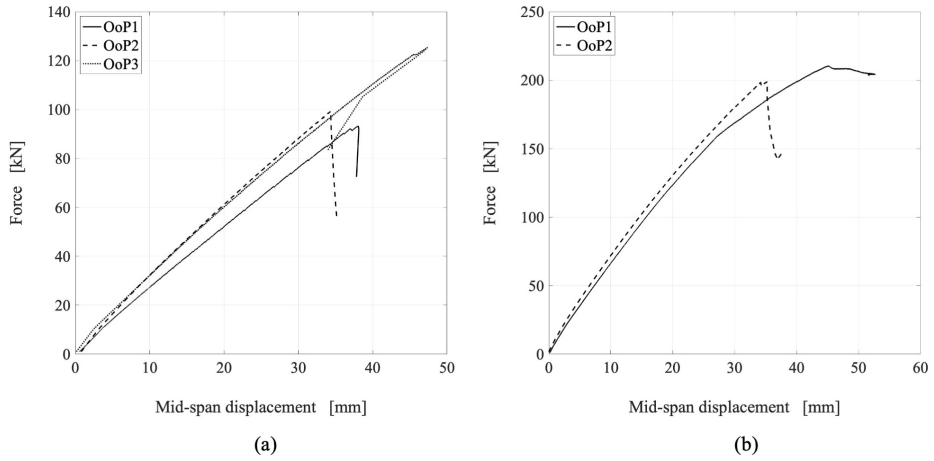

Figure 5. Force-displacement results for OoP specimens.

For the second part of the test, the specimens were loaded up to failure. From the force-displacement results in Figure 5, it can be observed that for specimens OoP1-2-3 there was a higher initial stiffness which reduced slightly around a midpoint deflection of 4-5 mm and remained constant throughout the test. All three specimen exhibited a linear elastic behaviour up to failure. Specimen OoP1 showed the lowest stiffness and ultimate load of 93.3 kN. Specimens OoP2 and OoP3 showed a very similar stiffness throughout the test, however the specimen OoP2 failed at a load of 99.3 kN compared to 125.3 kN for specimen OoP3. The failure mechanism was the same for the three specimens with the bottom beam failing on the underside due to tension from the bending stresses (Figure 4). In all three cases the tension crack originated at a knot on the bottom lamella which then propagated across the cross-section. This failure mode was extremely brittle as can be observed in the graphs by the instantaneous drop in force following the ultimate load.

For specimens OoP4 and OoP5, the latter can be seen to have a higher stiffness overall. For both specimens however, the force-displacement relationship is not as linear as for the specimens OoP1-2-3. After reaching 165 kN, a decrease in stiffness can be observed, which is more apparent in OoP4. This can be due to cracks forming in the beams as the loading increases. However, the post-peak behaviour of specimen OoP4 was not representative since towards the end of the test, the steel bearing plates at the supports yielded, resulting in crushing of the bottom beam at the supports. This therefore limited the beam develop additional bending stress and the specimen simply exhibited larger support settlement before the test was stopped. Nonetheless, both specimens reached a peak load around 200 kN which is

roughly twice that of specimens OoP1-2-3, while exhibiting similar midpoint deflections. For both specimens OoP4 and OoP5, the failure mechanism was the same with the bottom beam reaching its tension capacity on the bottom lamella due to bending.

A similar strength performance was observed for specimens OoP1 and OoP2 with peak bending moments around 110 kN-m. Specimen OoP3 on the other hand, again exhibited a higher performance reaching a maximum bending moment of 144.1 kN-m. This leads to an average bending resistance of 121.9 kN-m and translates to a CoV of 16.1% for these three specimens. With regards to mid-span deflection, the average for specimens OoP1-2-3 was 39.9 mm, with a CoV of 16.8%. The high CoV values here are due to the relatively high performance of specimen OoP3. In the second series of tests, specimens OoP4 and OoP5 performed very similarly with an average ultimate bending moment of 235.1 kN-m and a CoV of 4.0%. With regards to maximum mid-span deflection, the resulting average deflection was found to be 40.2 mm for a CoV of 17.5%. This high CoV value can be attributed to the bearing plate failure for specimen OoP4, as discussed previously.

3.2. Beam-to-beam B2B intersection connections

Four-point bending tests were carried out to investigate the capacity of the B2B connection. In total, seven tests were conducted: the first test was done on a reference beam with no notches or connection (Ref), then three tests had the connection on the tension side of the beams (T1, T2, T3) while the last three tests had the connection on the compression side of the beams (C1, C2, C3). The specimens were made using 2400 mm long GLT elements of cross-section 180×280 mm and strength class GL24h. The specimens T1-2-3 and C1-2-3 had two notches of dimension 180×180×140 mm located at 300 mm on each side of the beam centerline. Those notches were filled using GLT blocks of the same dimension as the notches and were oriented with the grain perpendicular to the beam direction to replicate the intersecting beam. The connections consisted of 180×480×6 mm steel plates of grade S355, fastened using 66–6 mm diameter × 100 mm long LBA nails, and 2–9 mm diameter – 260 mm long fully threaded countersunk-head VGS screws. The shear reinforcement screws used 6–7 mm diameter – 260 mm long fully threaded cylindrical head screws per side of the notches, for a total of 24 screws per specimen.

Figures 6 and 7 show the testing setups for specimens C and T, respectively. As for OoP specimens, steel plates were installed at the edges to prevent crushing of the wood. Similarly, the testing procedure was divided in two parts. The first part consisted of three loading cycles up to 10 kN and down to 1 kN at each jack. A two-minute pause was made between each cycle. The results from the last two loading cycles were used to determine the effective elastic ending stiffness. The second part consisted of loading the specimen until failure. The loading rate was set to 0.02 mm/s (1.2 mm/min) for both parts of the test.

Figure 6. Three-point testing setup for C specimens and failure modes.

The elastic bending stiffness was computed for all B2B specimens. For the reference specimen this value is a characteristic property since the geometric properties of the element are uniform over its length. On the other hand, for the specimens with the half-lap notches, these obtained values represent effective properties. The effective nature of the obtained bending stiffness can be attributed to the elastic modulus E_{eef} or to the moment of inertia I_{eff}. Therefore, two alternatives were evaluated.

First, the effective elastic modulus E_{eef} was determined considering the full height of the beam h = 280 mm in the calculation of the moment of inertia $I = b \cdot h^3/12$. It was found that for the specimens with the B2B connection in tension and in compression, the obtained values are between 33% and 45% the theoretical mean value of $E_{0,mean}$ = 11 500 N/mm^2 from the GL24h material properties. Comparatively, the reference beam had a 44% higher stiffness compared to the expected mean value. However, it is important to note that since only one reference beam was used in the testing, no statistical relevance can be derived from the obtained results. Alternatively, for the notched specimens, the effective height h_{eff} can be calculated from the effective moment of inertia assuming the theoretical mean modulus of elasticity. These results show, the effective height was lower than the actual beam height by 23% to 31%. Therefore, the notches in the beams have a negative impact the bending stiffness.

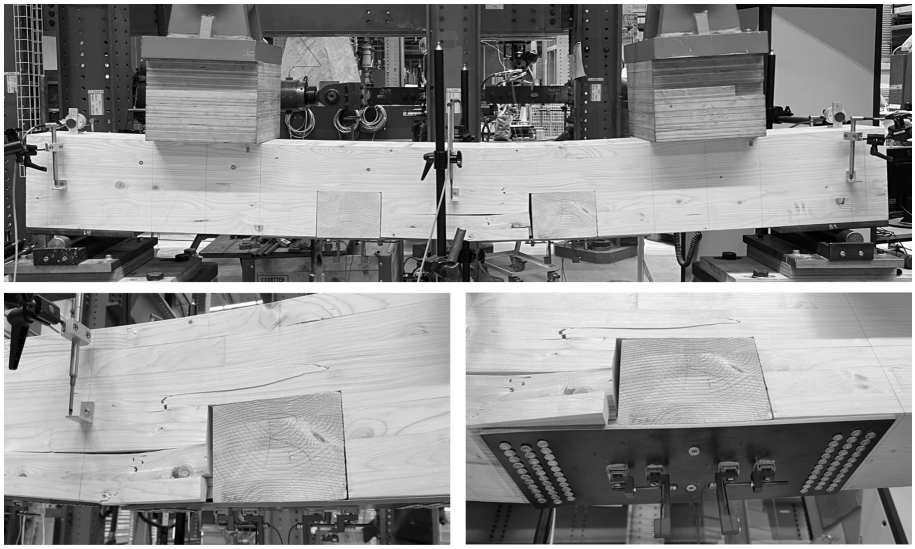

Figure 7. Three-point testing setup for T specimens and failure modes.

As Figure 8(a) shows, the three specimens C1, C2 and C3 exhibited different force-displacement relationships. First, the ultimate load for the specimens C2 and C3 was just above 80 kN while specimen C1 reached 50% higher load at 126.6 kN. This can be attributed to the fact that the failure occurred in the tension fibers between the lines of reinforcement screws in specimen C1. Comparatively, the failure line in specimens C2 and C3 occurred at the shear reinforcement screw location (Figure 6). This discontinuity in the bottom fibers due to the presence of the screws could have resulted in the creation of weaker lines across the width of the beam having a reduced net section to resist the tension force. Therefore, the different failure line could be partly responsible for the observed difference in strength between the specimens. Furthermore, the failure mode of specimens C1 and C3 can be observed to be more ductile.

These specimens show a marked stiffness reduction after reaching around a load 90 kN and 70 kN respectively. From the force-displacement graph, it can be observed that these specimens exhibited sudden strength drops due to crack formation inside the cross-section as the loading increased which reduced the element stiffness. On the other hand, specimen C2 failed in a more brittle manner immediately after reaching its ultimate load. Nonetheless, all three specimens showed a very similar stiffness throughout the testing up to failure and a linear elastic behaviour until cracking occurred.

For specimens T1-2-3, as shown in Figure 8(b), it can be observed that there was a relatively large difference in stiffness between the three specimens up to the onset of the first crack. Following cracking of the beams, failure did not occur immediately. Rather, the specimens exhibited relatively high levels of ductility, especially compared to specimens C1-2-3 as can be observed in Figure 8. The specimens were able to maintain some load-carrying capacity, albeit a very low, or null stiffness, by continuing to deform under constant or slightly increasing load by up to 47 mm for specimen T1 before reaching ruin. This ductility can be attributed to the B2B connections which, due to the shearing of nails-timber interface, resulted in an initial local splitting without the fibers reaching their capacity (Figure 7).

The nailed connection still had load carrying capacity due to the high number of nails in the connection, providing a high degree of redundancy thus translating to the observed ductility. Then, once the deformation reaches a critical point the ruin occurs by the crack propagating perpendicular to the grain. Furthermore, the ultimate load reached by the three specimens was between 70 kN and 80 kN, showing less variability compared to the specimens C1-2-3.

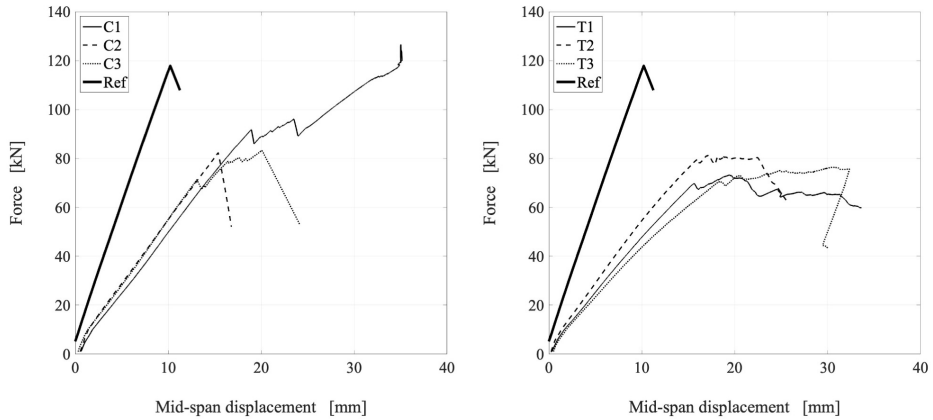

Figure 8. Force-displacement results for B2B specimens.

The reference beam exhibited a linear elastic behaviour throughout the test. The higher stiffness of the beam is apparent in the steeper slope of the force-displacement relationship presented in Figure 8. The failure occurred at the bottom fiber due to the tension stress from the bending moment. While the specimen reached a high ultimate of load, at 117.9 kN, its displacement capacity was limited by the brittle nature of the failure mechanism.

The results for the maximum bending moment and associated jack load and mid-span deflection were computed for all beams from the test data. With regards to the maximum bending moment, all the specimens fitted with the B2B connection reached a similar value around 30 kN-m with the exception of specimen C1 which exhibited a significantly higher performance attaining a bending moment of 50.6 kN-m. This discrepancy leads to a high CoV of 26.0% for the maximum bending moment for specimens C1-2-3. In comparison, specimens T1-2-3 all performed similarly in this regard and displayed a CoV of 5.3%. The reference specimen reached a peak bending moment of 47.2 k-Nm.

For the peak mid-span deflection, the average for specimens C1-2-3 was of 25.4 mm while for T1-2-3 was 33.2 mm, which represents a 31.0% increase compared to specimens C1-2-3. Both series of tests exhibited high variability and dispersion around the mean with a CoV of 36.4% and 24.3% for specimens C1-2-3 and T1-2-3, respectively. For the former, this value can be explained in part by the high performance of specimen C1. For the latter, since in all three tests the maximum bending moment was reached during the plateau region of the force-displacement, the corresponding mid-span deflection values varied according to the propagation of cracks cause by the nail-timber shear failure. This ductile behaviour also explains the higher average for those specimens, which deformed more significantly before reaching their peak capacity.

4. Performance review and design implications

4.1. Out-of-Plane OoP connections

The initial stiffness results show that the gamma-method can be suitable to estimate the effective composite cross-section properties but only at smaller spacings. Indeed, in the first tested configuration with two connectors spaced at 2300 mm, the internal force transfer between the two beams relies solely on those two discrete points. This, in turn, limits the contribution of the top beam since only the central portion of the beam between the two connectors is utilized. In comparison, the second configuration has six connectors evenly distributed along the lengths at one third the spacing of the first configuration. This allows the two beams to be utilized over a longer length and benefits from three times the number of points of force transfer thus distributing the internal forces more gradually along the element length.

Overall, these tests demonstrate that for the OoP connection system to work well for a connector spacing equal to the beam grid spacing, 800 mm or less, corresponding to the second tested configuration. Comparatively, the first configuration with the connector spacing of 2300 mm, would be equivalent to having one connector per beam grid module. This would therefore not be sufficient as the resulting stiffness gains are insufficient to justify the addition of an out-of-plane module.

Therefore, while not achieving a completely rigid connection between the elements, the system can be calculated and analysed easily using the gamma-method. Combined with the reversible nature of the connection, this improved performance compared to the current design of this connection, as presented in Section 2.1, and validated by the testing, and easily implementable calculation methodology makes the Knapp MEGANT connector a viable option for the OoP connection.

4.2. Beam-to-beam B2B intersection connections

A comparison can be made to the expected theoretical failure mechanisms and maximum loads. The unfactored bending capacity of a full 180×280 mm GLT beam is $M_{y,Rd}$ = 60.9 kN-m, which under a 4-point bending setup, should have been reached for a jack load of P = 152.2 kN. For specimens C1, C2 and C3, the expected failure mechanism was the plate buckling under the compression due to bending. The calculated buckling capacity of the 6 mm steel plate was $N_{b,Rd}$ = 120,1 kN, which would have been reached for a bending moment equal to $M_{y,C,Ed}$ = 28.0 kN-m corresponding to a jack load of PC = 70.0 kN. However, those specimens all failed in tension on the underside due to the bending moment (Figure 6). A few reasons can explain this discrepancy.

The first being the potential weakening of the cross-section on the bottom fiber due to the reinforcement screws as discussed previously. The second reason could be the reduced bending stiffness (or corresponding effective cross-section height), which reduced the bending strength of the beams. Indeed, the unfactored bending capacity of a beam of dimensions 180×206 mm – corresponding to the average of the effective heights from specimens C-1-2-3 – can be calculated to be $M_{y,Rd,C,eff}$ = 33.6 kN-m, corresponding to a jack load of $P_{C,eff}$ = 84.0 kN. This effective capacity is, however, still higher than the expected failure load for buckling of the steel plate. Therefore, in addition to the B2B connection, another compression force transfer mechanism must be involved around the notch, since the B2B connection did not reach its expected buckling capacity.

Indeed, upon reaching higher curvature and slip in the connection due to the increased beam deformation and bending force respectively, the notch and transverse beam "block" were seen to be in contact. The compressive stresses could therefore be transferred by compression perpendicular to grain between those elements. This would explain the observed failure mechanism in bending and the ultimate loads around 80 kN for specimens C2 and C3 corresponding to the effective strength of the element. For specimen C1, the failure load corresponds to that of the reference beam which failed at about 80% of the expected jack load. This could be explained by variability in the timber beams with the presence of knots on the bottom fiber where the failure occurred in specimen C1, or by the high stiffness of the tested reference beam.

For specimens T1, T2 and T3, the failure mechanism was expected to be the shear failure of the nail-timber connection, with a capacity of V_{Rd} = 174.2 kN, which would be reached for a bending moment equal to $M_{y,T,Ed}$ = 40.7 kN-m at a jack load of P_T = 101.7 kN. This failure mode corresponds to the observations from the testing as Figure 7 shows. In all three cases, the failure initiated from a lengthwise splitting of the cross-section at the edge nail locations closest to the notch, which then propagated across the cross-section. This can be due to the shear capacity of the beam being reached at this point. However, the failure load only reached 70 to 80% of the expected value. This could again be due to the reduced stiffness of the beams, as discussed above. Using the average h_{eff} = 203 mm for the three specimens, the equivalent bending moment required to develop the connection's shear capacity V_{Rd} = 174.2 kN can be calculated as $M_{y,Rd,T,eff}$ = 29.5 kN-m. This bending moment is reached at a jack load $P_{T,eff}$ = 73.8 kN. For these specimens, calculating the unfactored effective bending capacity using the average h_{eff} results in $M_{y,Rd,eff}$ = 32.6 kN-m. Thus, the beam's effective moment capacity is higher than the equivalent effective connector's moment resistance and relates to the observed failure mode of the nail-timber connection.

4. Conclusions

This paper presents the results of an experimental investigation on the bending behavior of reusable timber slabs – The Pixel Slab System. Twelve beam specimens with different spans, depths, and connections were tested with 3- and 4-point bending setups. Two connection methods were studied: (1) superimposed GLT beams with OoP connectors, and (2) GLT beams with notched B2B connectors.

The proposed OoP connection employed a Knapp MEGANT connector at the interface between the vertically arranged beams. Test results of this connection show that the wider connector spacing did not successfully achieve full composite action between two beams. The smaller spacing however, exceeded the theoretical expectations with regard to the effective heights obtained with the gamma-method. While not achieving full shear transfer between two beams due to the connection slippage, the performance still was found suitable for the application thanks to the reversibility potential of the Knapp MEGANT connector. Yet, the connector's directionality and constructability constraints could be further refined.

The proposed B2B connection uses half-lap geometry to join the intersecting beams together. To achieve the element continuity, a nailed plate is installed on one side of the beams to tie the discontinuous beam ends around the half-lap notch. The results from the experimental testing for this connection shows a significant reduction in stiffness up to 66% of the expected mean value, due to the half-lap notches and the connection slip. In tension, the B2B connection performed as expected. However, in compression, the connection slip induced bearing perpendicular to the grain between the notched ends and the perpendicular block. Hence, care should be taken to dimension the notch to account for this issue.

Abstract

This paper describes the integrative approach of timber experts to achieve an innovative bent on-site timber gridshell in a combined effort and focusses on the different challenges and how each discipline responded to them, including workflow, exchange, and an interdisciplinary digital master model. The timber gridshell 'Wisdome Stockholm' is an extension of the Tekniska Museet in Stockholm, Sweden. The gridshell is constructed out of five crossing layers supported by pre-tensioned timber columns. The lower layer acts as falsework and is assembled from pre-curved, CNC-machined beams, while the upper four beam layers are bent on-site from laminated-veneer-lumber (LVL), a planar sheet material, held in place by wooden dowels and screws enabling loads to be transferred via contact. This innovative construction method was developed due to a central prerequisite: the mandatory usage of LVL as main material due to sponsorship. Finding this solution could only be achieved by early on integration of knowledge along the whole process chain. The collaborative team consisted of timber experts in digital planning and timber construction, engineering, and fabrication and assembly.

1. Introduction

The 'Wisdome Stockholm' is an extension of the National Museum of Science and Technology (Tekniska Museet) in Sweden, designed by the local architects Elding Oscarson. The building consists of an interior wooden dome, housing a 3D-cinema, covered by a conditioned free-form timber roof. This innovative gridshell covers 1,128 m^2 and is constructed out of five crossing layers with a maximum span in the longitudinal direction of 47 metres, supported by pre-tensioned timber columns (see figure 1).

Figure 1. Wisdome Stockholm project, bent on-site timber gridshell currently under construction

The five crossing layers (layers ‘A’ to ‘E’, see figure 2) span alternating along the short and long section of the building, which leaves three layers along the short distance of the building and two layers along the long distance. In contrast to other timber gridshells, like the Centre Pompidou-Metz or the recent Swatch Headquarters in Biel [1], only the lowest layer (layer ‘A’) is assembled from pre-curved, CNC-fabricated beams, and works as falsework. The upper four beam layers (layer ‘B’ to ‘E’) are bent on-site from five LVL sheets (sublayer ‘a’ to ‘e’) each, with bending and torsion held in place by 3,500 wooden dowels and screws enabling loads to be transferred via contact. Stora Enso sponsored the project and mandated the use of LVL, which was also the key to enable this innovative construction method.

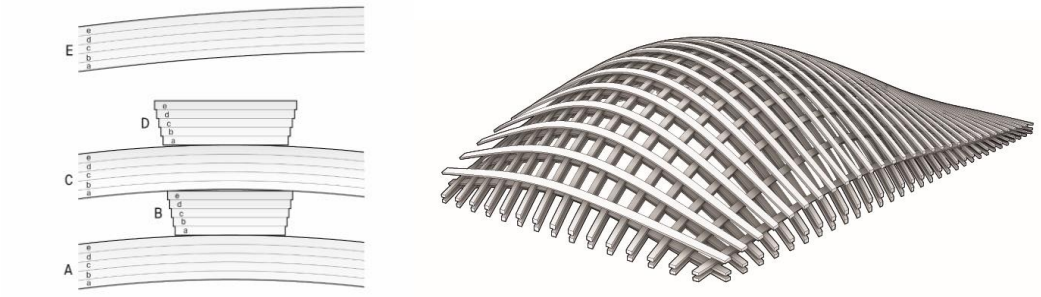

Figure 2. Gridshell layer and sublayer overview

1.1. Background and context

Gridshell structures have the advantage of covering large spans without intermediate supports, enabled by their geometry. In the past decade, there has been an increased development in the design and construction of innovative and advanced timber gridshells [1][2]. Timber is the ideal material for shell structures and has several advantages over other materials: excellent strength to weight ratio; machinability; elasticity; environmentally friendly and sustainable; structural flexibility by customisation possibilities of the material; adaptability to geometric demands; and it is a light and dry construction material making it ideal for prefabrication. Timber gridshells, and in particular timber elastic gridshells, e.g. Mannheim Multihalle, Weald and Downland Museum and PEMADE gridshell [3], use thin, slender members and by doing so, the geometrical torsion in the members is reduced [4]. To be able to control the horizontal thrust of bending the members, these gridshells are often continuous facades of a building starting at ground level and covering wall and roof geometry. Apart from the following examples, Savill Garden Gridshell and Flimwell Woodland Enterprise Centre are solely a roof on columns with either a ring beam transferring the forces to the ground via inclined columns, or by having columns tangentially oriented to the roof surface [1].

In ‘Construction 4.0’, the use of advanced building materials and prefabrication is key, by combining digital planning and fabrication, time and resources can be managed more efficiently [5][6]. Due to the advances in digital fabrication, timber gridshell design has shifted away from bending elements on-site to prefabricating glued laminated (glulam) beams. This is largely due to new CAD, CAE, CAM and CNC technologies. Furthermore, these technologies enable curved glulam beams to expand the design space, and avoid difficulties encountered during the design and construction of elastic gridshell structures [7]. A range of alternative timber gridshell types and connection systems were developed using glulam beams, among others: Zollinger system (Toskana Thermal Springs), use of lap joints (Swatch Headquarters), hierarchical beam directions (the French Pavilion Expo 2015) and the use of timber dowels (Centre Pompidou Metz) [1].
In order to overcome the limited design freedom, construction constraints and complexity of the design, research evolved by bending continuous elements in timber gridshells in an innovative way. Bend-plate gridshells, such as the 2010 ICD/ITKE research pavilion, enabled the use of single curvature locally [8]. Ribbed and cross-ribbed shells are constructed by means of falsework and the members are doweled or nailed together [9]. Alternatively, wood's hygroscopic properties can be used to form surface-active plates [10].

The use of a single material that speaks the same language for connection and structural member is crucial in timber construction. In recent decades, extensive research has been conducted on the use of dowels to mechanically laminate timber. As early as the 18th century Hans Ulrich Grubenmann built bridge arches with dowelled solid beams. Later in the 19th century Amand-Rose Emy illustrated mechanical lamination of timber by bending timber elements in a jig and fixing them with bolts and clamps [11][12]. Research conducted more recently has shown how dowel laminated timber (DLT), ribbed shells with doweled planks, and shear keyed beams, improve the overall stiffness and efficiency of beams [13][9][14][15].

Wisdome Stockholm is part of Construction 4.0 and extends the state-of-the-art structural design method of elastically curved, bent-on-site gridshells and addresses the design freedom and construction constraints.

1.2. Challenges requiring cross-disciplinary collaboration

The winning design of the Wisdome Stockholm competition was a rectangular floor plan housing a dome-shaped, wooden lattice structure as roof. Due to the free-form geometry of the roof outlining the interior dome, the loadbearing behaviour deviates from an ideal dome where the structural components are mainly subjected to pressure. The shape of the roof is very flat on one side and very steep in the other direction. This has the consequence that on-site assembly is more complex in the steep areas, and that the complexity of components is increased due to the requirement of more flexibility in the connection details in order to ensure engagement of all elements. The Wisdome roof is elevated from the ground by vertically oriented timber columns, which can only take limited horizontal thrusts from the roof. This results in a gridshell structure that is mainly subject to bending stress in the flatter area. In gridshell design, this is mostly managed with glulam elements with a large cross-section height. Due to the material supply of Stora Enso, a solution based on planar LVL panels of limited thickness needed to be found. The challenges and facilitations that this new prerequisite entails had to be balanced to ensure time, cost, risk, and quality.

This project pushed boundaries. The 5 layers of the gridshell in LVL in itself was an experiment, this was exacerbated by the grid organisation to be able to transfer the loads to the columns, such that they were rigid in the key areas and the pre-tensioning of the columns themselves. The experiment was embedded in the framework of an executed, real large-scale project. The entrepreneurial aspects of the client and the executing companies limited the scope and brought the constructive pressure for healthy pragmatism for the development, planning and implementation of the project.

The first challenge in the development of complex experimental projects was the alignment of the team of specialists. The goal was to get a holistic view of the project and the process behind it. The project should be a success for both client and users. In addition to the architectural and constructive ideas, the time and financial framework in which the project must be implemented are fundamental to the success of the project. Topics such as local value chains and the cross-generational reuse of components are increasingly used by decision-makers and are more and more influencing the solution space.

1.3. Cross-disciplinary collaboration

The success and completion of this challenging experimental project could only be achieved through early integration of knowledge throughout the whole process chain and required a close-knit cross-disciplinary team.

The collaborative team consisted of timber experts in digital planning, timber construction, engineering, fabrication, and assembly. Timber contractor Blumer-Lehmann AG, responsible for planning and execution of the timber construction, contracted long-term partners Création Holz, SJB Kempter Fitze

and Design-to-Production early on in the project. Création Holz and SJB Kempter Fitze are the timber construction engineers, involved in structural concept design and development. Design-to-Production delivered timber consulting, project management support and digital planning. The team has extensive experience with collaborating on free-form projects, for example Swatch Headquarters in Biel in 2019, Cambridge Mosque in Cambridge in 2017, and Nine Bridges Golf Club in Yeoju in 2008.

Requirements for cross-disciplinary collaboration are understanding the needs and interests of all parties and incorporating them into solutions and suggestion, a high degree of openness and transparentness in discussions, trust between all parties, knowing what the others are capable of, and taking responsibility. As the solution space is unclear and undefined in the concept phase of a project, all ideas and solution approaches from different specialist shall be considered and analysed to create an in-depth synergistic and iterative solution process. In addition to improving quality and achieving project completion on time, cross-disciplinary collaborations encourage teamwork, stimulate information sharing, and enhance communication among project members [16].

2. Integrative design concept

A design concept always starts from the architectural intent. The whole team was focused on the vision of the architect to realise a prefabricated supporting and enveloping structure made of wood. The development and documentation process lasted one and a half years and involved a series of physical mock-ups at a 1:1 scale alongside a thorough analytical approach to validate progress.

2.1. Trade-offs

Processing in the constructional development started with solution approaches in assembly and worked its way "backward" via transport and logistics, pre-assembly, CNC production, material procurement, execution planning, digital planning, structural engineering all the ways to architecture. For the sake of the story of this paper, the approach is reversed.

2.1.1. Structural concept

Modern timber constructors have the opportunity to be inspired by engineers of the last centuries. Hans Ulrich Grubenmann and Amand-Rose Emy created arches by doweling beam elements [11][12], while Arthur Vierendeel designed and implemented bridges without diagonals according the well-known Vierendeel girders [17]. These two solutions were the initial step to the concept of the Wisdome.

On the one hand the first mock-up (see chapter 2.2) has shown that is not useful to dowel the lamellae into ready-made structural elements. This is due to a large recoil after release from the fabrication jig and the effort that goes into the assembly for the subsequent lack of accuracy. Ensuring that the five-by-five (in total 25) lamella layers all meet exact points in space for idealised load transfer is an unwieldy challenge. On the other hand, production of the LVL lamellae according to the glulam technology, does not bring the required accuracy we expect from the elements. All-round milling, like with glulam blanks, would be very costly and not an efficient option. With their various advantages and disadvantages, both approaches have found their way into the project. The glued LVL beams for the bottom layer (layer A), as part of the falsework and, so to speak, the template for all subsequent layers (layers B to E). With the four additional beam layers, the advantages of the individual lamellae bending on-site outweighed the disadvantages, even though the bending on-site of individual lamellae into the required shape quintuples the number of components and is a new construction method in type and size. This means that two different construction principles had to be implemented in this roof construction. In this scope of the project, this affects the processing intensity for development and production, from assembly to planning. The width of the lamellae is stepped to visually circumvent any visual tolerances during bending of the elements. The minimum width of 380 millimetres, and the maximum width of 500 millimetres, with a step of 7.5 millimetres on each side were defined by the architectural intent. To be able to bend the

lamellae, the LVL thickness of 31 millimetres was chosen. The large width of the lamellae allowed for enough structural cross-section to be left after cut-outs were made for the dowels.

Besides the beams, the structural concept consists of five different elements. Firstly, for the dowels there are two main types in the roof, namely the cross-dowel and the shear-dowel. The cross-dowels ensure that the different layers of beams are held in position, are connected, and transfer loads at the crossing points, while every other layer is connected with a shear-dowel to transfer shear loads between the layers to achieve the same principle as shear keyed beam [13]. The tenons of the shear-dowels are tapered to make the assembly easier and to ensure a tolerance-free connection and therefore transfer loads at the contact face between dowel and lamella. The fibre direction of these dowels is in the longitudinal direction (see figure 3). The cross-dowels are cone shaped to simplify the assembly and create a tolerance-free connection. No fibre direction was specified as forces were coming from two different directions, and calculations were performed with cross-grain values.

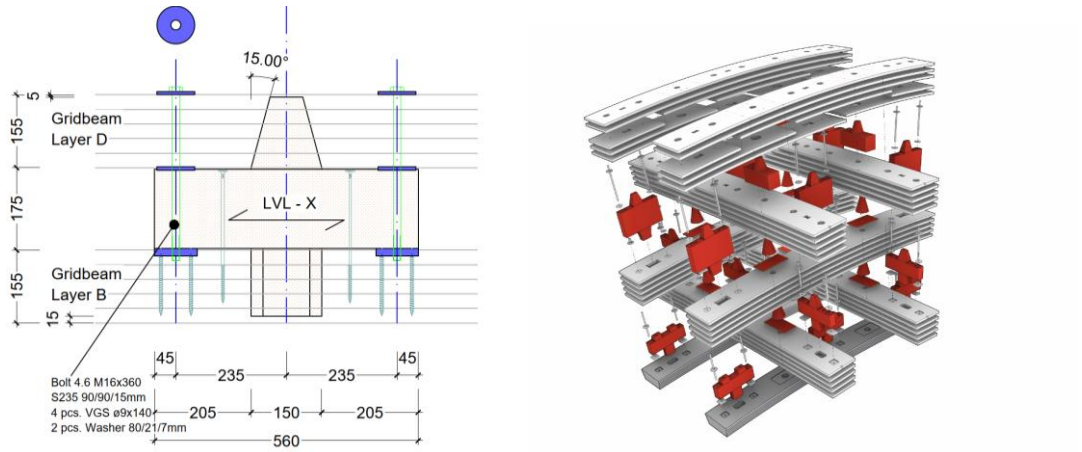

Figure 3. Overview shear-dowel and detailed roof build-up

Secondly, along the edge of the building, three-metre-high up to seven-metre-high hybrid timber columns are supporting the roof. Due to the asymmetrical arch-shape of the roof, the horizontal thrusts deform the columns individually (see figure 4). By pre-tensioning the timber columns the horizontal deformation is absorbed. As a fixed connection at the column foot was not sufficient, the vertical deflection of the roof is reduced and custom pretension of the columns allowed for a uniform deflection along the whole facade. Pre-tensioning of the columns is done by embedding steel rods without bond and connecting them to the concrete at the bottom of the base plate. Non-linear behaviour is introduced by the individual behaviour of each column, either the steel rod absorbs the forces for the deformation, or the E-modulus of the wood does.

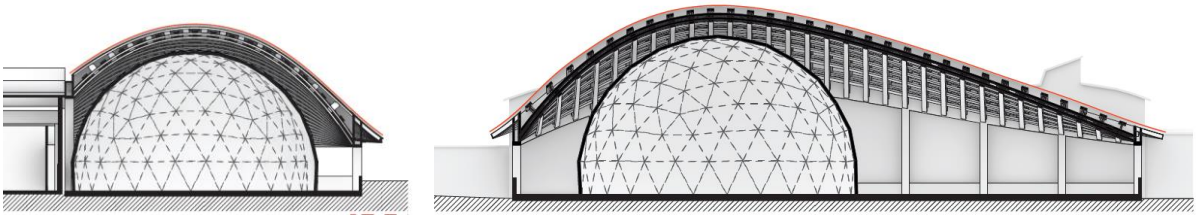

Figure 4. Cross-section through the roof in the short and longitudinal direction

Thirdly, running along the edge, the edge beam and edge panels transfer the vertical and horizontal forces from the received roof layers to the columns. A shear panel is located between the grid beams that directly arrive at the column. These panels, connecting layer C and E, create a frame connection with the column to further stiffen the elements for the roof structure and building. Lastly, to the edge beam and edge panels, rafters are connected to build a cantilevering canopy for the roof.

2.1.2. Engineering

In the early design phase, the balance between simplified calculation models and adequate detail needed to be balanced. One wants to draw quick decisions but still have all elements in the model that impact the structural behaviour. Possible solutions to the different challenges for early structural design decisions were strengthened by the experience of the different parties.

The engineering of the gridshell was done in a two-step calculation process. First, internal stresses, due to bending and torsioning of the beams from layer B to E needed to be calculated. Because each member of the roof has a slightly differing geometry, the internal stresses differentiate along the whole roof. The internal stresses were taken into account by applying (in a parametric matter) a torsional and bending force on the lamellae to approximate the final geometry. These loads were transferred to the second step in the calculation process, namely, the final geometry of the lamellae, to simulate the recoil. It is important to consider these recoil forces for the connections that keep the lamellae in the desired shape. Relaxation of the lamellae is advantageous for the structure as internal stresses will be reduced over time; no relaxation reduction was taken into consideration. While creeping effects of the structure were considered within the analysis.

Due to the structural concept of individual lamellae, lots of single individual members had to be modelled, which increased the importance of tolerances. Even though larger tolerances were helpful for assembly, in the case of structural design it complicated the process due to different connection properties between each connecting element. This emphasized the collaboration between engineer and manufacturer to define a manageable tolerance for both fields.

The shear- and cross-dowels are main connection details within the roof. Depending on their location, a different size of forces is received by the dowels. To maximise standardisation, but avoid waste of material, a certain number of dowel types are defined. This involves an iterative process, as choosing a dowel type in a certain location, influences the stiffness and the size of the forces attracting the dowel compared to the rest of the roof. Even though layers B to D are offsets from layer A, the dowel height needed to be adaptable to accommodate a small height difference at each dowel due to local curvature and torsion. Each dowel type uses the smallest required height in the roof, and the variable height is achieved by steel washers partially sunken into the lamella. Slack and slip between the different elements and connections were applied in the structural model through member hinges.

The most complex connection in the building was the connection from the roof to the column (see figure 5). This connection was structurally used to get more stiffness into the roof structure by creating a frame through transferring bending moments from the roof to the column. Layers A, C and E are connected to the column head, while layer A would mainly deliver a compression force, layer E delivers a tension force. Due to the fact that each column received a different size of forces, and a different geometry arrived at each column, and these are not aligned thus there is no worst case to calculate. This resulted in a calculation of every individual column, which was made possible by using a parametric process. The compilation of all connections of the roof beams, edge beams, edge plates and shear panel, made the overview of the stresses within the column head complicated and obscure. On top of that, all these connections needed to be designed in a way that assembly on-site can happen in the most efficient way possible, see chapter 2.1.6.

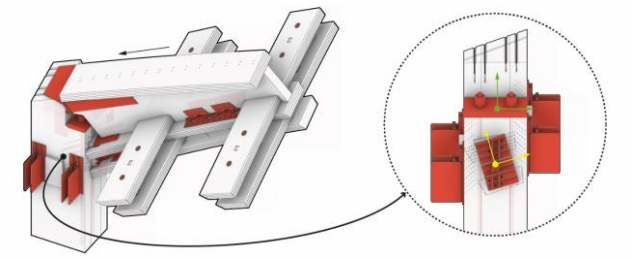

Figure 5. Column head and all its connections to take the forces from the roof

2.1.3. Constructional development

Wisdom is an extension of the museum and is to be built alongside an existing building (Wallenberghallen). This had to be taken into the consideration for the construction process and limits the accessibility to the components and connections. Another restriction is the 3D-cinema dome. With a diameter of approximately 20 metres, the dome extends up to 1 metre below the roof structure and therefore had to be integrated into the falsework construction.

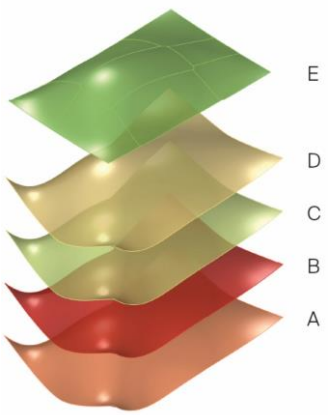
The interface between the foundation and the timber column is a concrete support base where the pre-tensioned rods of the columns are connected to. A zero tolerance between concrete and wood is required to avoid slack, and for architectural aesthetic reasons.

2.1.4. Digital planning

Geometric description of a free-form gridshell requires advanced geometry and modelling knowledge. It was clear from the start that pre-fabricating all parts of such a complex structure could only be achieved by means of digital CNC-production. Thus, the objective for digital planning always was to eventually create production-ready data. Based on the multi-scalar modelling-process developed by Design-to-Production [18], not just one but a stack of four digital 3D-models was developed over the different stages of the project (see figure 6):

1. A **context-model**, defining the relevant surroundings (outside the project scope) and the building-grid-and-levels defined by the architects. This served as a common reference for all subsequent digital modelling within the project.
2. A **reference-model**, defining the geometry of the roof surface and its different layers (as precise NURBS-surfaces), the beam axis grid, and placeholders for all connection nodes. This was used to identify geometrical worst cases and provide initial input for other digital modelling efforts (e.g. by the engineering team).
3. A **coordination-model**, fixing all component dimensions and breaking the continuous beams of the reference-model down into segments and lamellae, so that the necessary raw-material for all components could be evaluated and ordered. Also, collision testing for the numerous connection details was done at this level, to find collisions between neighbouring joints and to ensure that assembly was possible despite the complex geometry.

All but the first of these models were parametrically generated from their respective predecessor (after this was carefully checked and approved) with only very little manual modelling involved. Thus, very low error rates could be achieved in the overall process. Likewise, changes (e.g. in the detailing) could easily be accommodated by altering parameters and re-executing the respective step of the parametric modelling process – based on the stable model of the previous detailing level.



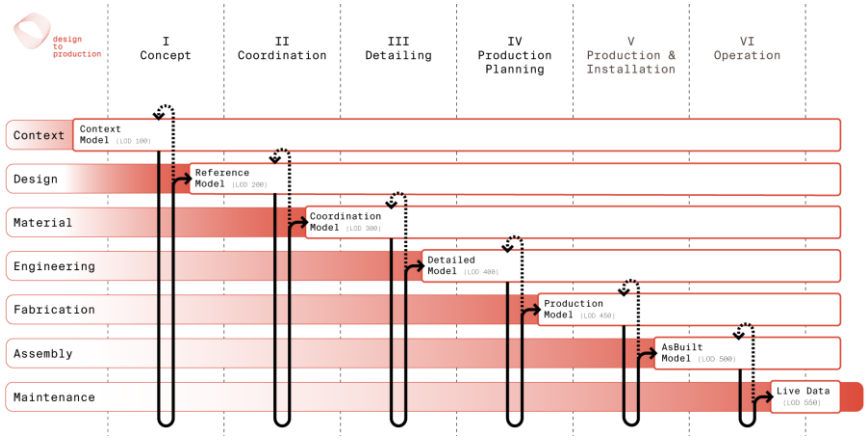


Figure 6. Left: Agile Design-to-Production process. Right: Reference-surfaces of all 5 beam layers

From the last model, production data in various formats could then be extracted and delivered to various fabricators. A special challenge in this final step was the two-fold unrolling of the curved LVL-lamellae: first from the undetailed coordination model, in order to nest the lamellae on flat LVL-panels and order raw-material, which had a lead-time of several weeks. During this time, detailing was finalised, and the lamellae were subsequently unrolled a second time, now including all their complex detailing, production-ready for 5-axis CNC-fabrication.

2.1.5. Machining and fabrication

The decision to only glue beam-layer A, led to a significant streamlining of the production process for layers B to E. The fabrication process of all layers started the same with the 3-axis contour milling of the lamellae out of standard flat LVL panels. The aim of layer A was to avoid contour 5-axis machining along the longitudinal edges, like with glulam blanks, which made precise positioning of the CNC milling a challenge. An individual gluing formwork for each beam segment was created. As there were only end cuts and machining where connection points need to be created, the positioning and gluing of the lamellae needed to be accurate. As a last step, 5-axis milling of the beam segment was performed: the end sections, connections to the edge beams, longitudinal joints, screw holes and spacers for plates and washers were milled. Positioning of the beam to the CNC system was done by re-using the gluing formwork which were placed in a rigid frame and thus the exact planned geometry could be imposed on the bendable beams on the machine table. For layer B to E an additional 5-axis CNC milling was added to mill the connections to the edge beam, cut-outs for dowels, drills for screws and pocket milling for spacer plates and washers. A challenge here was how the visible lamella (sublayer a) was processed from the bottom, while other lamellae were processed from the top. To help sorting the five lamellae that belong together in the correct order, orientation and correct displacement in relation to the longitudinal direction (overlapping longitudinal joint), a milling mark was introduced in the process.

2.1.6 Assembly

It was already clear in the early phases of the project that the assembly of the entire wooden structure would take place in a closed tent. This tent covered about one and a half times the floorplan of the building and included a powerful gantry crane which operates the entire tent area. This was taken into account from the beginning when developing the production and assembly concept. Usually, the quickest possible assembly of the supporting structure is encouraged so the building envelope can be closed within a short amount of time, and side-to-side (e.g. left to right) assembly process is recommended. The tent ensures a weather-independent installation, even during winter, so that the gridshell beams could be installed layer by layer, namely bottom to top.

Important for a smooth assembly of the gridshell was a very precise assembly of the columns and edge beams, which had to be held in position by temporary struts to prevent displacement during the assembly of the roof structure. Also important was a temporary substructure (precise, 5-axis milled templates

placed on surface scaffolding) which enabled precise positioning of the layer A beams. The timber columns were placed over the rebars of the concrete base, formwork was built, and concrete was poured. With the assembly of the layer A, in which all connection dowels were pre-assembled as an interface to layer B and C, a perfect template was created for the other layers of the gridshell. All beams of layers B to E were delivered as flat lamella packs in the correct order, and automatically found their final position when attached through the conical plug-in connections, namely cross dowel. In case of more curved areas in the roof, the segment length was limited by the entry vectors of the dowels. In flatter areas, a maximum segment length of 13.30 metres was chosen. On the one hand, this enables standard transport (including the raw panels) with closed trailers, but on the other hand, the handling of 31-millimetre-thick panel strips with greater lengths is very difficult. The load required to force the plate packs into the desired curvature could be applied using screw clamps (see figure 7). Once in the final position, the parts were screwed together to secure the position.

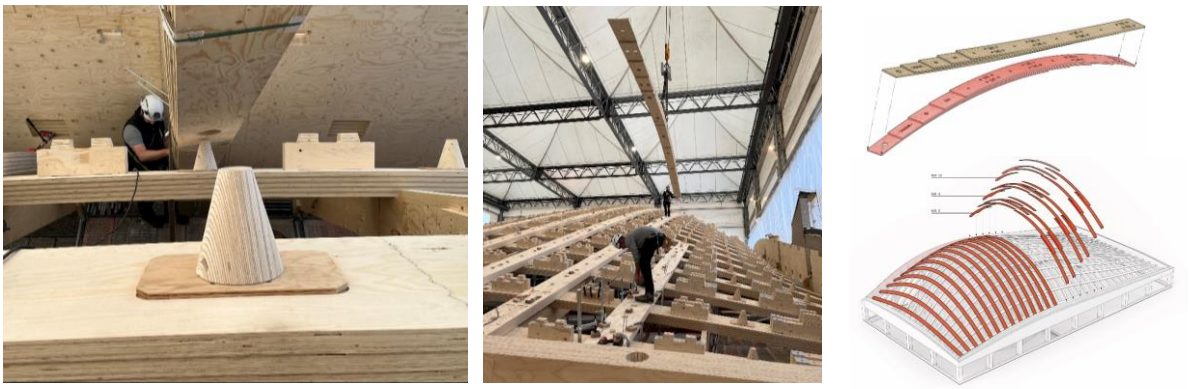

Figure 7. Assembly of the roof structure

2.1.7. Logistics and transport

The goal of every timber project is to reduce transport to a minimum, and optimise truckloads to the fullest, and make logistics as straight forward as possible.

Similar to transporting curved glulam beams, the 93 beam segments of layer A could not be stacked due to their double curvature. The formwork was reused from previous projects for transportation in a bespoke designed frame, but even then, the loading capacity of the truck was still limited in size. The load sequence of the truck was coordinated with the assembly process to guarantee an efficient assembly on site. In contrast, the lamellae for layer B to E could be stacked in a flat packed configuration, transporting significantly more material per truckload (see figure 8). In total 22 closed truck trailers were loaded for transportation to the building site, including columns, dowels, edge beams and panels, and rafters. In order to keep track of the 2,186 lamellae and the resulting 444 beam segments, a numbering system was developed already in the concept phase, which allowed a logical assignment of each individual component without having to consult a list or plan. Each of the individual lamellae were labelled accordingly.

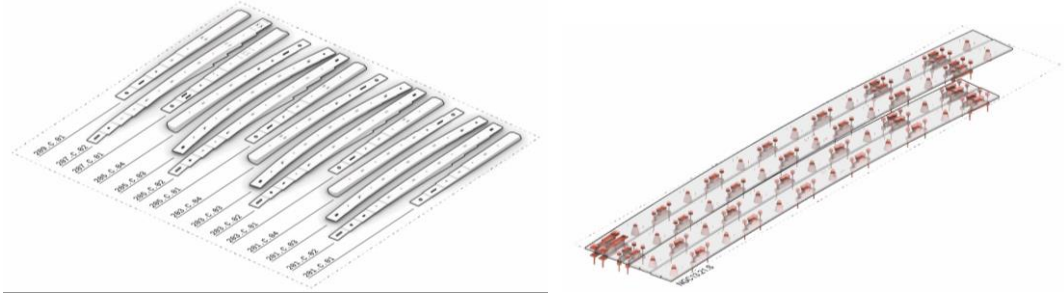

Figure 8. Flat packed beam segments and production export per sheet

2.2. Process and methodology

In the early stages of the project a feasibility study was conducted by the whole team as the project reached beyond the experience of the experts. This included a digital 3D model of the shell structure, analyses of the 3D model, and structural concepts which were tested and quantified by three 1:1 mock-ups, all within a period of 4 months. First, the *design mock-up* is a cut-out of the roof and was made out of eight beams which consist of four crossed layers of two beams each (see figure 9). With this mock-up, the client and architects were able to validate the aesthetic, as well as the connection between the different beam layers. Second, two *technical mock-ups* of each one beam segment were fabricated. These two beams had respectively the highest amount of torsion (8,4 degrees per meter) and bending (radius of 10 metres) in the entire roof. With these mock-ups, the recoil of the elements, the fabrication and assembly process of the beams, drilling holes in the high-tension zone of the beam, dowel connection holding the shape, and feasibility of the input force to bend and twist the beam were tested.

Figure 9. (From left to right) Technical mock-up, design mock-up and constructional mock-up

A fourth mock-up was made 10 months after the start of the project to test the construction development. The mock-up was a cut-out of the roof in an area where the torsion value was high. A variation of tolerances of all dowels, connection and tolerance of the shear panel, fabrication of all dowels, digital planning process, resolving all details and collision detection was tested and quantified. This mock-up served as a dry-run for the final construction and involved the whole team including the subcontractors. The mock-up was a success and allowed for further optimisation of the constructional development and collaborative teamwork.

3. Collaboration between disciplines according to an integrative approach

Success of the concept and the feasibility to complete this experimental project with a high quality and within budget and short time frame was only possible with the close collaboration and commitment of the cross-disciplinary team of experts [16].

During the development process of the project, questions, objectives, and basic rules of the individual project stages resulted in concepts and possible solution spaces in which the different experts contributed with arguments, and these arguments are the basis for the realisation of the project. These were evaluated qualitatively and quantitatively and compared with the objectives and basic rules of every discipline. To verify the solution approaches, built mock-ups were verified. In addition to the physical result of the mock-up, feedback was received from the whole team and an overall assessment could be made to achieve a compromise. With the help of this evaluation, decisions could be made on a broad basis, or the solution approach could be corrected at an early stage. From the start, everyone understood that the level of uncertainty would remain high throughout a large part of the process. However, despite the lack of total confirmation, everyone continued to work on the project. Otherwise, the specified tight timeline would not have been feasible.

When the solution area became narrow enough, all project participants had the basis for their technical elaboration, the project framework conditions (e.g.: budget, deadlines, and local use of resources) were aligned, the project guidelines were formulated and set. During the further planning of the project, it

was necessary to coordinate the ensuing questions and adjust proposals based on in-depth knowledge with the project guidelines and thus to ensure the quality assurance of the timber construction planning and execution.

To be able to speed up the overall workflow, the process was divided into multiple branches during the coordination stage to allow parallel coordination, detailing, and production of component types defined by the order of production and assembly (pull planning) [19].

The narrow collaboration, the iterative process and the back and forward exchange was made possible by balancing business, technology and people, where trust and engagement played a crucial role [20]. Communication was mainly done digitally by means of email, project management software and video calls. On a few occasions, the different parties had in-person discussions during visits to the production facilities. The form of information exchange between the parties were set at the beginning of the collaboration, and included excel sheets, 3D models, 2D drawings, and a component and detail catalogue.

4. Conclusion and discussion

The complexity of the experimental Wisdome Stockholm project is evident. Thanks to the excellence (both professionally and personally) of everyone involved in the project, from the carpenter on the construction site to the architect, the project was successfully completed. Its success can be seen from different perspectives. Firstly, the structure is built, and learning is done successfully. Secondly, the network was strengthened by the great performance and collaboration. Thirdly, the project was completed within time and with high quality. And finally, the vision of the client and architect was realised.

The project requested a higher investment of working hours compared to traditional glulam gridshells, mainly due to the many challenges and unknowns, discussed throughout this paper. The challenges and facilitations that this new approach of bending LVL on-site entails had to be balanced to ensure time, cost, and quality. Logistics, structural concept, engineering calculations and details, digital planning, and assembly were found to be more difficult, while transport, machining, and material efficiency proved to be advantageous. In addition, the standard challenges such as geometric boundary conditions, architectural intent, extremely tight timeline, etc. were contemplated.

Acknowledgements

The Wisdome Stockholm, designed by Elding Oscarson and commissioned by Tekniska Museet, is a collaboration between different companies: Florian Kosche, Stora Enso, SJB Kempter Fitze, Création Holz, Design-to-Production, Blumer-Lehmann, Roth, Balteschwiler, Mueller, Olijbe and Oberholzer.

Special thanks to the core team of the Wisdome Stockholm: *Stora Enso* (Carl Humble and Jessika Szyber) for the material sponsorship; *Elding Oscarson* (Johan Oscarson and Arin Alia) for believing in the timber team, always being enthusiastic and being the initiative of this building; *Tekniska Museet* (Astrid Stenberg and Frederik Eriksson as representative of the client) for aiming high and investing in innovation and the future, *Blumer-Lehmann AG* (David Riggenbach, Valentin Künzle, Martin Looser-Frey, and Kai Strehlke) for all the valuable input, for coordinating and trusting the team and execution of the project; *Création Holz* (Hermann Blumer) for the great initial concept development of the building, as always, and thinking about timber construction in a novel way; *SJB Kempter Fitze* (Christoph Meier, Stefan Rick and Dominik Fischinger) for being able to analyse and calculate this complex building, for realising Hermann's ideas and being open to innovation and pushing the boundaries; *Design-to-Production* (Fabian Scheurer, Martin Antemann, Sylvain Usai, Moritz Niebler, Matthias Hornung, Valeriia Vlasenko and Evy Slabbinck) for timber consulting, parametric and digital planning and supporting the project management.

We would also like to thank Claes Nyberg of Olijbe, Herbert Schmid and Sven Bill of Balteschwiler, Thomas Brühlmann of Gebhard Müller for collaborating on the project. And Valentin Kubatta and Daniel Christev for their contribution to this paper.

Abstract

To improve the overall supply of renewable building materials, forestry industries around the world are seeking better ways to yield structural timber products from low diameter logs. Such logs are produced in large volumes, from both plantation thinnings and as the crowns of harvested saw log. However, they are marginally valued for use in conventional structures due to their small diameter, high dimensional tapering, and relatively low recovery volume and structural capacity when milled into sawn boards. This paper investigates the design of an optimised branched timber structure that utilises minimally processed round logs in their near-to natural dimensions, using a digital form-finding tool that combines the dual processes of *Inventory-Constrained Design* and *Combinatorial Equilibrium modelling (CEM)*. A material inventory was generated directly from small diameter logs harvested from a plantation, giving a unique series of member lengths with associated diminishing diameters. The CEM model was used to optimise the geometric assignment of the inventory in a branched column structure, that also inherently benefits from members with diminishing diameter. This geometry was then developed into a proposition for a full scale branched column structure, with proof-of-concept design and prototyping of the intersecting geometry at the connection nodes undertaken. The development of this optimisation tool and the prototyping of the nodes, demonstrates feasibility for a novel application of this marginally valued forest resource that reduces material waste within the forestry and wood product value chains.

Keywords: inventory-constrained design, form-finding, round timber structures, combinatorial equilibrium modelling, timber connection design

1. Introduction

Structural form finding models such as Combinatorial Equilibrium Modelling (CEM) are designed to reduce material in structures through the optimisation of force path geometry. CEM is a sophisticated and powerful design tool for form finding of reticulated structures such as branched tree and truss structures [1]. It allows the designer to iterate through alternative equilibrated options for structural geometry based on input and constraint criteria such as member length, node position, force quantum and direction. Adjustments of one or more of the inputs will trigger a responsive and precise adjustment of the overall geometry and force paths to approach or reach equilibrium.

Inventory Constrained Design is a process whereby a given inventory of available material is consumed in an optimised configuration, based on a set of prescribed selection criteria, or heuristics, typically targeting minimisation of material waste [2]. With the global urgency to reduce carbon emissions,

building designers also have the opportunity to directly influence the carbon footprint of a given structure. Being involved in the early stages of the design process, they are in a decisive position to measure and control the embodied carbon, and to design structures that maximise the quantity of carbon that can be locked-up in a structure, instead of releasing it back into the atmosphere. Toward this goal, recent studies have suggested the use of *inventory constrained* or *stock constrained* [1] design processes to enable the use of timber and forestry by-products as value-added structural components. This optimisation process customises the geometry of the structure through assignment of unique member lengths as in [3], or adaptations of unique connection intersection angles as in [4] in order to utilise the maximum amount of available resource, and minimise waste through the manufacturing process.

The research therefore develops a tool that employs three parallel material optimisation processes. It optimises the structural distribution of material, minimises waste from the material source, and maximises the carbon locked up in a structure for its given structural capacity. The first part of this paper discusses the design of the digital form finding tool and the second demonstrates the feasibility of the construction of a novel connection node.

2. Small diameter round timber members as an inventory

In any natural forest ecosystem, variation of tree size and form occurs between individual specimens. The degree of variation is reduced in plantation forests grown for timber harvesting, through close and regular planting of controlled genetic tube stock. There is however, a percentage of dimensional variation between specimens due to variable tree health, local soil and water availability, location within the stand, and damage due to animals or adverse weather conditions [5]. As such, even within regularly planted stands of trees of the same age, substantial variation occurs in the length and tapering diameters of harvested logs.

The forest selected for this project is a plantation of native Australian hardwoods in Queensland, Australia. The plantation is young, ranging 12 to 15 years old, and as a result, logs are relatively small in diameter (90-150mm) as shown in Figure 1. This is due to initial planting at high densities forcing trees to grow straight and thin as they compete for available light. When the stand reaches the age of 12 to 15 years, a percentage of trees (40-60%) are removed or ‘thinned out’ in order to allow the remaining straight trees to slow their growth in height, and increase their girth [5]. As a output of this thinning process, a significant volume of timber is harvested, however due to the relatively small diameter of the logs, there is only marginal market value realised by current processing practises. Given the abundance of small diameter logs within the plantation industry, increasing their utilisation is a particularly relevant opportunity for designers of timber structures [6].

(a) (b)

Figure 1. Juvenile hardwood trees prior to thinning (a) Typical stand (b) individual specimen.

Current timber processing practises are largely driven by market demand for sawn timber sections. When logs are sawn into dimensional rectangular sections, the process is a calculated compromise between the maximum structural timber yielded from the log and the economies of dimensional standardisation of cross sections profiles. When round (or near round) logs are sawn into rectangular or square sawn profiles, there is resultant waste in the outer flitches or 'cheeks' of the logs, and in the accounting for the natural taper of the log along its sawn length (the smallest end diameter will determine the maximum resultant cross-section) [7]. Modern harvesting and transportation logistics also mean that trees are cut into logs of regular length (typically six or eight metres) and the remaining top of the stem, along with the branches, are typically left on the ground in the forest to return to the ecosystem as mulch, or otherwise chipped to be used as fibre for chipboard or pulp. Whilst this paper does not deny the practice of mulching after harvest is valuable in terms of ecology and biodiversity [8], the process does release carbon into the atmosphere. Many fibre-based products also have short carbon lifecycles. By utilising as much of the usable timber from the tree in permanent timber structures, carbon can be stored for a longer period of time.

This paper investigates the opportunities for maximising the utilisation of a plantation's available timber in building structures, by addressing this material compromise in two ways. Firstly, the structures investigated are proposed to utilise logs in their near to natural round geometry, where only minimal processing is employed to turn the 'natural round' log into a 'true round' cross section, principally for reasons of manufacturing standardisation, but also for reasons of aesthetic preference[1]. Secondly, the structures will be parametrically optimised to utilise the complete length of each harvested log. In this way, the resultant waste from the processed stand of trees is minimised, whilst the quantity of CO2 locked up in the structure is maximised.

3. Tree geometry and part assignment

A generic branched tree structure was investigated as the test case for combining an Inventory Constrained design process with CEM form finding. The goal for this structure was to utilise the entirety of a given log in the inventory and apply CEM to maintain structural equilibrium. The initial base geometry of the tree structure was explicitly modelled with 3 levels of branches. Part lengths per level were arrayed at the ratio of 2:2:1, with bifurcation angles of 90 and 60 degrees between levels 1 and 2, and levels 2 and 3, respectively.

Provisional tension members were applied horizontally between the nodes at the intersection of level 2 and level 3 branches and between the tops of branches in level 3. As described later, these represent a transverse load carrying capacity, which was later replaced by a semi-rigid flexural capacity designed into the physical node prototype as part of this test case.

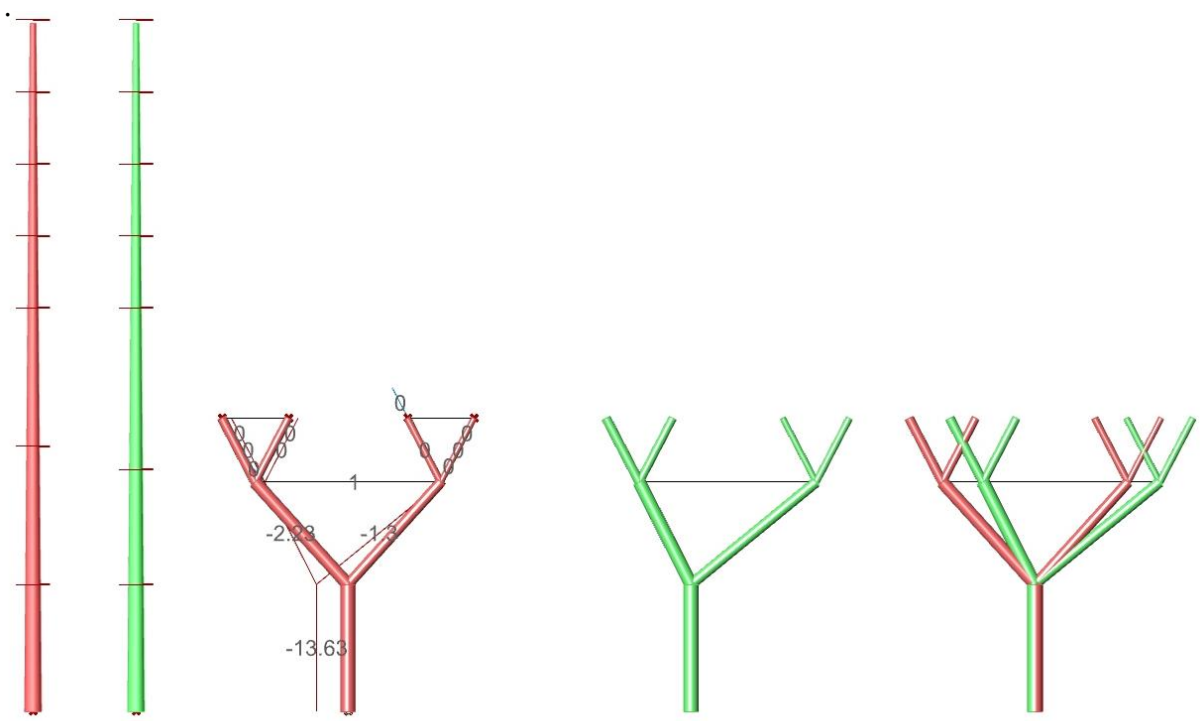
The part assignment heuristic based on this ratio could be applied to any of the unique logs in the inventory and the resultant tree's branch length (and associated large and small end diameters), assigned accordingly. When tested on the range of logs in the inventory, the overall tree structure's aggregate part length established a range of potential heights from 3.6m to 4.5m. Applying a constraint to the

[1] Logs could be used in their natural, unprocessed form. Whilst this paper does not evaluate the economic value of a 'natural round' timber member with natural features (such as branch stumps and remnants of bark, along with natural geometrical variations) compared with a 'true round' (that has been peeled to remove bark and some sapwood to create a true cylindrical member) it does take the position that the 'true round', in addition to being more readily deployable in structures with array of joined members, is likely more aesthetically desirable and result in a higher uptake in industry.

overall tree structure height (in this case 4.0m was chosen as a median height) resulted in a relative increase or decrease to the bifurcation angles when longer or shorter logs from the inventory were used.

When applying the part assignment heuristic to a unique log in the inventory, each part within the tree was assigned a unique section from the log, with a unique large and small end diameter and a corresponding unique mass, even when lengths with each level remained identical. Thus, when distributed throughout the tree structure symmetrically, the imbalance of masses between the elements would result in disequilibrium.

CEM was then applied to the part assigned geometry to re-equilibrate the overall tree structure, whilst maintaining the original total aggregate log length. As can be seen in Figure 2, this was achieved by allowing the branch in level 1 and its node between levels 1 and 2 to move location in the x, y plane. The lengths of all members in level 3 were constrained to their original length, but the nodes between levels 2 and 3, and the location of the top node of level 3, were allowed freedom in the x, y plane only. This allowed adjustment of the individual branch lengths in levels 1 and 2, whilst maintaining the original aggregate length of members in levels 1 and 2, and arriving at a state of equilibrium. With re-assigned inventory lengths for branch level 2 (and corresponding masses) applied, the CEM model was then run again for a final re-calibration of the geometry.



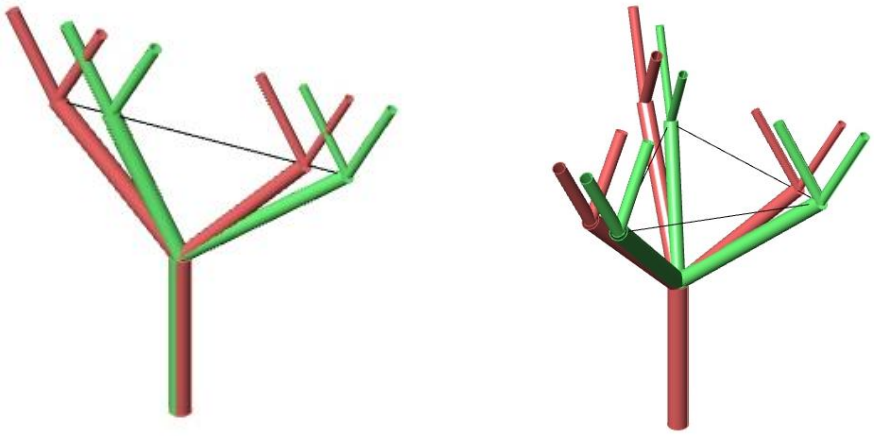


Figure 2. (a) and (c): Log inventory part assignment and correlating tree structure based on initial explicit definition of geometry, (b) and (d): log inventory part assignment and correlating tree structure after CEM adjustment to reach equilibrium (e): superimposition of (c) and (d).

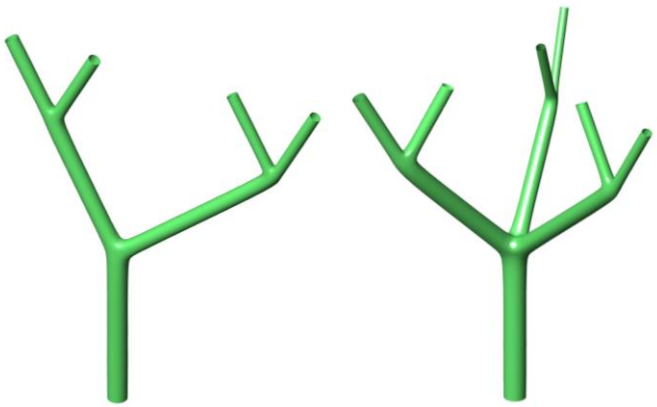
After testing this form finding model in a co-planar branched tree structure with 2-way branches, a second structure was modelled using a non co-planar branch connection using 3-way branches between levels 1 and 2, utilising 3 more branch lengths on the overall structure. In this case, when the same part assignment heuristic was applied, iterations resulted in either: *i.* when applying the same initial log from

the inventory, the overall tree structure was shorter; or *ii.* an alternate, taller log was selected from the inventory for the assignment, such that the overall tree structure could reach an equivalent height.

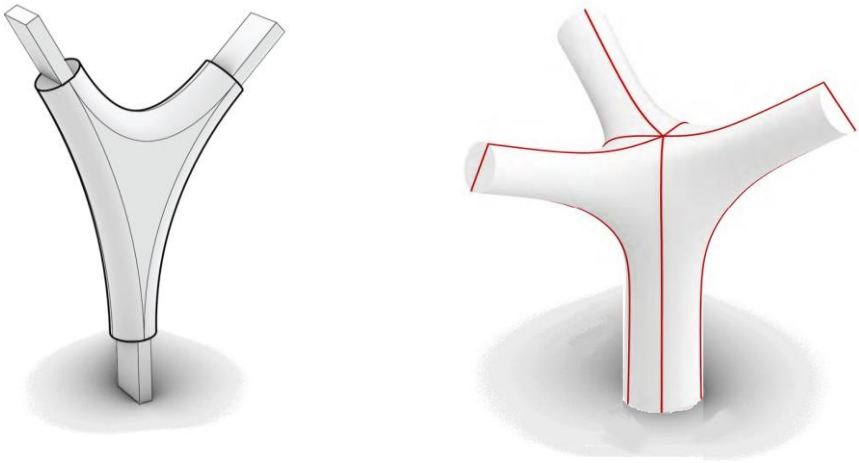


(a) (b)

Figure 3. (a) co-planar tree structure with three levels of 2-way co-planar branches, (b) non co-planar tree structure with 3-way non co-planar branch between levels 1 and 2, and 2-way co-planar branches between levels 2 and 3

4. Node design and prototyping

4.1 Node modelling

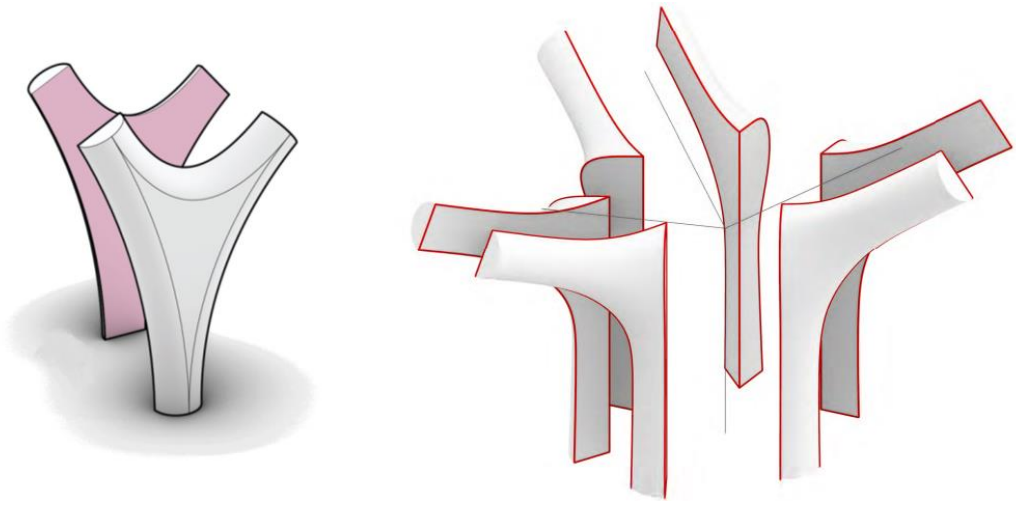


Once the tree structure geometry had been optimised through part assignment and CEM, the intersecting geometry of the co-planar and non-coplanar node types was resolved through the design of node that performs as a semi-rigid connection, alleviating the need for a tension member at the intersection of level 2 and level 3 branches and between the tops of branches in level 3. A custom laminated timber node utilising short length timber offcuts with a similar design approach as used in [9] was developed to create a smoothly blended node form that could parametrically resolve the intersecting branch geometries.

(a) (b)

Figure 4. (a) co-planar tree structure with 2-way co-planar branch nodes modelled, (b) non co-planar tree structure with 3-way non co-planar branch nodes modelled

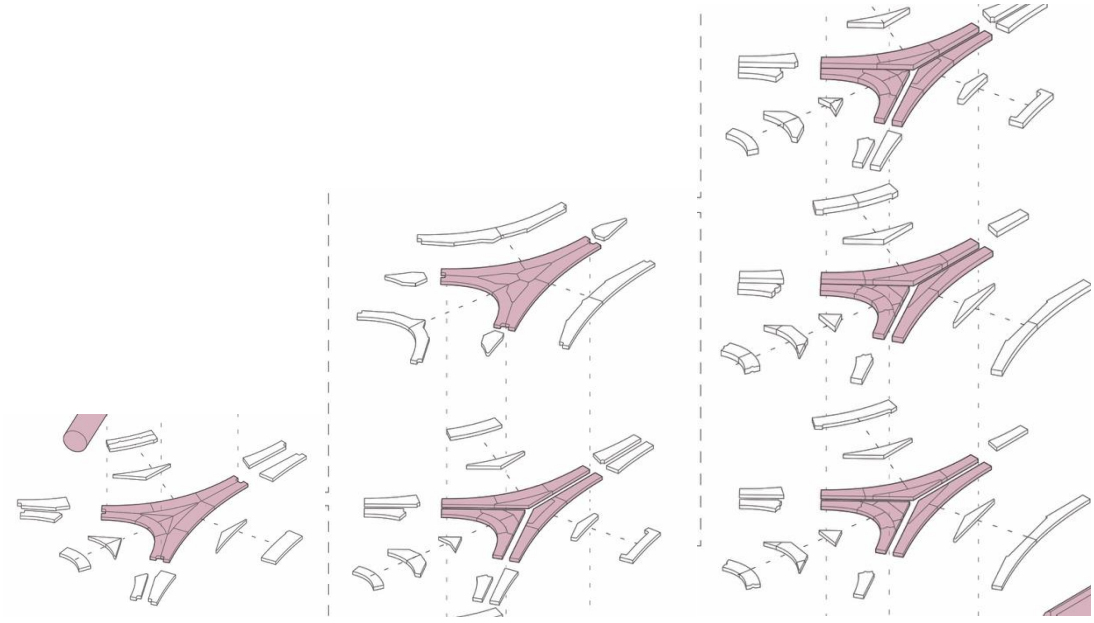
In this demonstration, both 2-way co-planar and 3-way non co-planar nodes were designed using the process of mediating convergent centreline vectors. Geometries of both co-planar and non co-planar nodes were designed through parametric NURBS modelling within Rhino and Grasshopper. In both strategies, a solid geometry was generated to correspond to resolve the varying cross section diameters of the part-assigned branches. Planes perpendicular to the centreline geometries then bisected the branched node arms with defined length offsets, allowing enough material for future connection featuring, as shown in Figure 5.



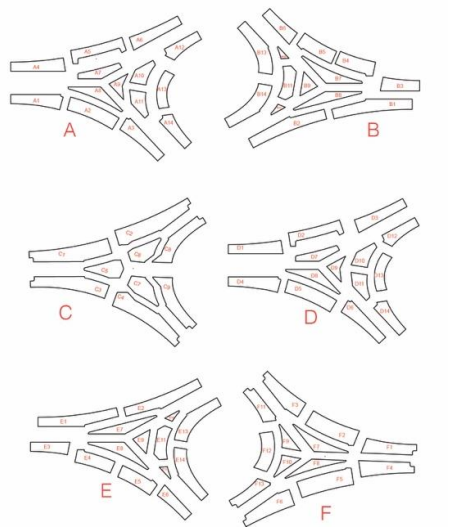
(a) (b)

Figure 5. NURB modelling based on mediating convergent centreline vectors in (a) co-planar node and (b) non co-planar node

4.2 Rationalisation for fabrication



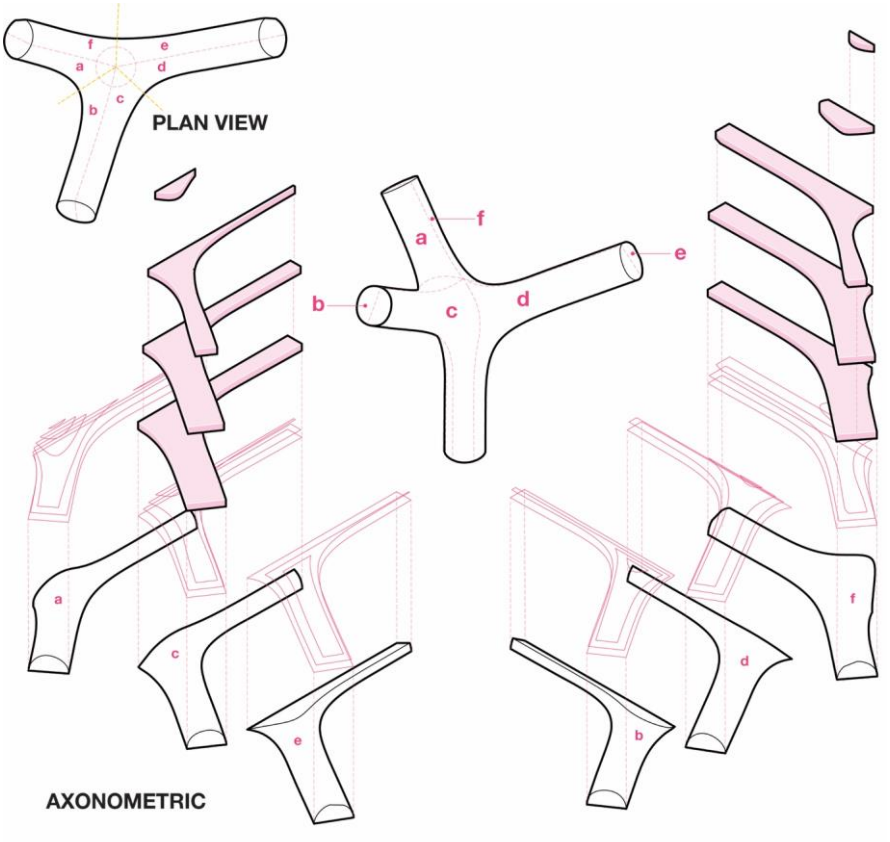
For the purposes of custom lamination and machining, nodes were bisected about identified common planes. This enabled the timber parts to be laminated with grain running parallel to the force direction, and also for the parts to be simply machined on a 3-axis router, with the bisected plane laid on the flatbed of the router. The co-planar node was bisected into two mirrored parts about the plane formed by the 3 centrelines of the co-planar branches, whilst the non co-planar node was bisected into six parts based on the 3 planes formed between the common centreline axis of the lower level branch, and each of the 3 intersecting branches respectively, as shown in Figure 6.



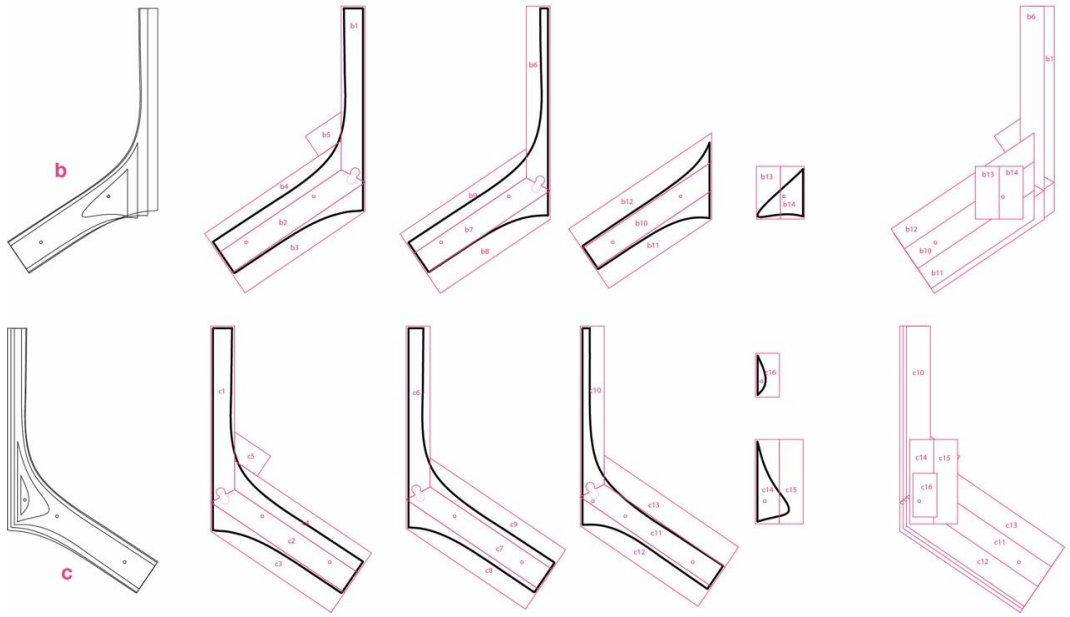
(a) (b)

Figure 6. Bisecting the nodes about common symmetrical planes (a) co-planar node, (b) non co-planar node.

From here, the process for fabricating both the co-planar and non co-planar node parts was similar, the flat face of each part corresponding to the plane of bisection, is rotated in 3D to orient to the x, y plane corresponding to the machine bed of CNC router. Each part was then further subdivided through contouring parallel to x, y axis (laying flat) to generate a series of laminations, or lamellas, to be constructed from edge glued timber members. The lamellas were in-turn further subdivided for edge gluing through the introduction of custom alternating layups of short-length dressed timber boards. These were arranged to ensure sufficient overlap of individual boards between the lamellas, ensuring grain direction is aligned to the compressive load path through each part as shown in Figures 7 and 8. Where timber boards changed direction to follow the geometry of the overall part, an internal lapped dovetail connection was pre-featured, primarily to aid in accurate assembly of the lamellas, but also to contribute some stiffening to the overall assembly. Locating holes for dowels were also machined to aid in positioning assembly in the following stages. Boards were then pre-glued into lamellas and then laminated and press glued to complete the rough billet for CNC machining.



(a)



(b)

Figure 8. (a) Contouring of the non co-planar node into lamellas, shown in axonometric and plan views. (b) Custom arrangement of short length timber boards for fabrication.

4.2 Machining sequence and assembly

Machining of the parts from the laminated billet was tool pathed through RhinoCAM, which directly integrated into the Rhino interface for a continuous workflow. The previously machined pockets for locating dowels in the billet were then matched to their corresponding positions cut into a sacrificial sheet on the CNC bed for coordination. The machine sequence was then executed in two processes, first a rough-mill was programmed to remove excess stock, followed by a final contoured parallel finishing pass with a ball nose to complete the process to higher level of finish. Utilising the locating dowels, the completed segments were then assembled, with hand finishing on a linisher where required. Finally, all parts were glued together at their bisecting planes. Prototypes of both co-planar and non co-planar nodes are shown in Figures 9-11.

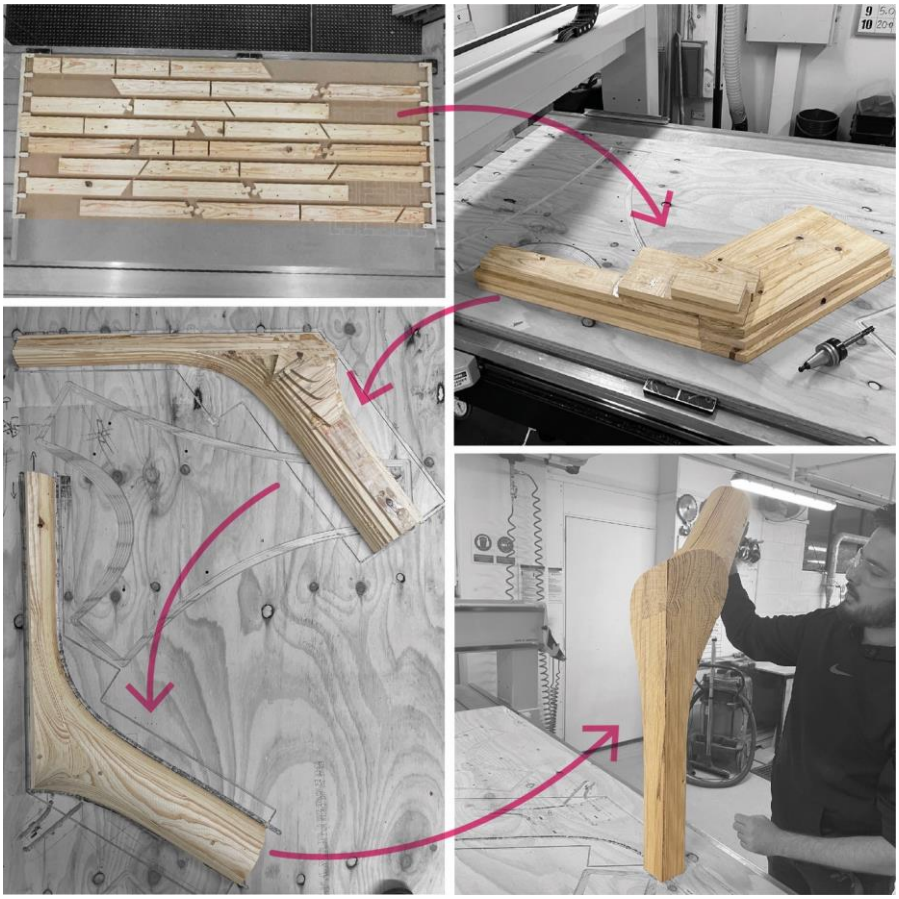

Figure 11. Prototyping of an individual non co-planar node element at 1:1. Sequence showing individual lamella boards machined, laminated into the billet, first pass and second pass CNC machining, and completion of one of the 6 node elements.

5. Discussion

The CEM modelling developed was shown to be an effective and agile tool for ensuring an equilibrated solution is reached for a range of tree structures, based on variable log length with corresponding variable branch diameters and masses. The applied part assignment heuristic was able to ensure the structures could utilise the entirety of the material in the log inventory. The effective combination of both of these tools, however, is of most significance, as it demonstrates the capability to simultaneously optimise for material usage based on structural efficiency, waste minimisation due to an inventory constraint, and minimisation of the structure's carbon emissions. Finally, the modelling and prototyping of the semi-rigid nodes demonstrates feasibility for complex three dimensional intersections to be resolved in timber, providing an elegant connection solution for round timber members of variable diameters.

Abstract

The rising demand for low-embodied carbon materials and supply chain disruptions, such as climate change impacts and global crises, necessitate a sustainable wood supply for building products. Supporting local capacity to grow, manufacture, and supply timber-building products can surmount international trade barriers. In the UK, the market is import-oriented, with forests in England primarily utilised for short-term purposes. This study explores material-efficient, optimisation-driven structural timber systems using local underutilised English timber for low to mid-rise buildings and retrofitting. Adding value to this timber offers long-term carbon sequestration, addresses the demand for low-embodied carbon materials, and provides socio-economic benefits through local education and employment. We present designs and simulations of structural prototypes using underutilised English timber and analyse timber-based truss system performance. Preliminary results show effective and scalable approaches for optimised truss, beam, and joist systems relevant to those interested in material-efficient timber structures with underutilised timber resources.

Keywords: nature-based solutions; harvested wood products; wood utilisation; topology-optimised structures; material-efficiency; underutilised timber; timber design; robotic construction

1. Introduction

The global built environment is projected to expand by 230 billion square meters by 2060, approximately double its current size [1]. By 2030, this increase is expected to reach 20%, with the majority of growth occurring in emerging and developing regions [2]. The materials used for constructing these buildings will profoundly impact the environment and how we live. Raw material consumption nearly doubled by 2016, and based on current trends, the global demand for natural, replenishable materials is anticipated to more than double to 190 billion tons [1], [3].

Traditional construction practices often rely on carbon-intensive resources such as steel and concrete. Nature-based solutions (NBS) offer alternatives such as timber, bamboo, hemp, or earth, which are both renewable and carbon-sequestering. By adopting NBS in construction and substituting high embodied carbon materials like steel and concrete with natural alternatives like wood, it is possible to reduce carbon emissions by 0.9 kilograms for each kilogram of carbon sequestered in the wood [4]. Thus, due to the urgent need to reduce greenhouse gas emissions and promote carbon sequestration strategies, there is a need for a rapid shift in practices across the construction industry.

Timber, the most advanced natural material in use, is processed for various purposes, from packaging and building products to fuel, food, and textiles. The demand for structural timber is significant, and the desire for an increase in engineered wood construction, such as mass timber, is substantial. The United Kingdom (UK), is the second-largest net importer of timber globally, with 82% of its timber imported [5]. However, the timber global trade is vulnerable to supply chain disruptions resulting from climate

events, forest disease and impacts, pandemics, invasions, and wars; therefore, ensuring the continuous and affordable supply of sustainably harvested wood for building products is a pressing issue. One way to meet demand and overcome international trade barriers is to support local and sovereign capacity to grow, manufacture, and supply timber-building products.

The UK, comprising roughly 3.24 million hectares of woodland, representing 13% of its total land area, boasts a vast array of forest types and management practices [6], [7]. These span from small private landowners and extensive monoculture plantations to progressively mixed, biodiversity conservation-focused forests. Conifer plantations, primarily situated in the North and West of England, Scotland, and Wales, supply the majority of domestically-produced structural softwood sawn boards utilised in building and construction.

In England specifically, forests account for 10% of land cover and exhibit a diverse assortment of species. Conifer plantations typically include Scots or Corsican Pine, Sitka or Norway Spruce, Larch, and Douglas Fir. Conversely, broadleaf stands may encompass Oak, Elm, Sycamore, Chestnut, Beech, and Ash species, which are particularly favoured by private small-lot landowners in the South. Conifer resources, particularly pines, are predominantly used for bio-energy, pallet and packaging production, and agricultural fencing [8]. Broadleaf species are preferred for specialised construction, boat building, and furniture markets; however, their value can be challenging to optimise for larger sawmills due to factors such as location, proximity, volume, and species diversity within each forest stand. Characteristics like log size, quality variance, and the extended processing time required for drying broadleaf species contribute to the limited adoption of structural broadleaf-sawn boards in building products. As a result, the majority of structural sawn board supplies for building products are imported, whilst locally-grown English timber remains underutilised and reserved for short-term applications.

In addition to supply chain challenges and lack of sovereign capacity to produce timber building products, like many regions worldwide, England and the UK are facing an increasing population, rising inflation and expenses, infrastructure and a building crisis, characterised by outdated and energy-intensive building stock, poor-performing public infrastructure, and an under-supply of housing [9]–[15]. There is an urgent need for new construction, retrofitting and renovation of existing buildings that incorporate NBS that are structurally capable and carbon-sequestering. Although the substitution of timber in structural building design is increasing and is heralded as the material of the future [16], [17], an increased demand requires greater material efficiency and lower-consuming timber products [18]. Focusing on residential buildings, material efficiency strategies can reduce emissions in the material cycle by over 80% by 2050 [4], [19].

This research adopts a material-efficient approach to investigate optimisation-driven structural systems using local underutilised English timber for low to mid-rise buildings to meet housing supply and retrofit existing poor-performing buildings. Adding value to local underutilised English timber through building products offers long-term carbon sequestration, supports the growing demand for low-embodied carbon construction material and brings a raft of socio-economic benefits to communities through local and regionalised education and employment. In the following sections, we present the structural performance of a timber-based truss system, looking at member utilisation, material volume and embodied carbon. The paper contains preliminary findings that inform a larger project looking to add value to English underutilised timber for use in construction.

2. Methods

This study aims to promote more efficient uses of homegrown local underutilised English timber, to provide opportunities to generate the local supply chains and industry and thus enable low-embodied carbon options for locally manufactured construction products through efficient structural design. The study was based on the properties of available materials, which are discussed in the following sections.

2.1 Material-efficient design development

A computational workflow has been developed using a parametric 3D modelling environment to design and analyse truss-like structures. Timber trusses are considered efficient structural typologies because they are primarily subject to axial stresses (tension and compression) rather than bending moments. The optimisation of these structural typologies to improve material efficiency has been extensively investigated, originating in the studies of A. G. M. Michell (1904) [20]. Recently, thanks to advances in computational power and software development that allow faster calculations [21], its potential is being explored further. For instance, Fairclough, Gilbert and Thirion [22] have demonstrated through a case study of a large transfer truss, industry-ready design solutions that enable reducing embodied carbon (EC) by customising the truss layout based on project-specific variables

Ching and Carstensen recently explored the optimisation of member layout in truss systems to reduce EC using the Ground Structure (GS) approach [21]. This approach consists of a dense structure populated with multiple potential elements, undergoing a sizing optimisation that allows the minimum bar area to approach zero. The GS method's first step is to define the design domain, load application, and boundary conditions. The domain is then populated with a grid of points, all connected to form potential truss elements. The optimisation criteria focus on minimising the weight and, in mono-material trusses, the volume of the employed resource. A material-agnostic method has recently been developed and made accessible to designers and engineers through a user-intuitive interactive design tool [23].

Using parametric modelling platforms, such as the Peregrine plugin [24] in the Rhino-Grasshopper environment, users can run a structural simulation that indicates the best truss layout given design boundary conditions and load cases. The contribution of a layout optimisation method in trusses for weight and volume savings can vary based on several variables, such as domain configuration, buckling of compressed members, load cases, allowed deflections, and manufacturing constraints. In some practical cases, this optimisation method can achieve up to a 40% volume reduction compared to a traditional Warren-truss layout with optimised cross-sections [22]. The primary trade-off for volume reduction lies in the layout complexity and related manufacturing constraints. The employed plugin (Peregrine in Rhino-Grasshopper) allows for post-processing rationalisation to simplify the design by reducing the number of joints and members.

Figure 1. Typical floor joists with open steel webs. The top and bottom chords are made of softwood-graded TR26.

This study leverages the Peregrine plugin in the Rhino-Grasshopper environment to design and analyse truss-based floor joists suitable for low- to mid-rise applications in multistorey residential, office, or school buildings, addressing the high demand for such structures in England and the UK [23]. Secondary structural elements, such as floor joists, are the primary focus and explore the potential of implementing English timber by replacing steel web joists with wooden alternatives. The industry benchmark for comparison is the conventional steel web joist with wooden top and bottom chords, a design widely employed in the UK construction market for timber-framed buildings (Fig. 1).

The workflow, developed within the Rhino-Grasshopper environment, integrates layout optimisation with Peregrine and structural analysis in Karamba 3D[25]. The process can be summarised in four main steps: i) defining the domain and boundary conditions (joist dimensions, material properties, load cases) and performing layout optimisation using Peregrine; ii) selecting the minimum cross-section according to maximum utilisation values for members and manufacturing constraints (e.g., joint typology); iii) optimising the cross-section and conducting structural analysis with Karamba 3D; and iv) comparing the results with the industry benchmark in terms of embodied carbon and timber volume through an A1-A4 life-cycle assessment.

2.2.1 Material properties

The primary factor influencing the design of structural timber is the grading system. The top and bottom chords in steel web joists typically comprise TR26-graded softwood, often imported from Scandinavia. Compared to the C-grading system, TR26 characteristic values closely resemble C27[26]. Utilising high-grade timber versus low-grade timber can significantly impact structural performance.

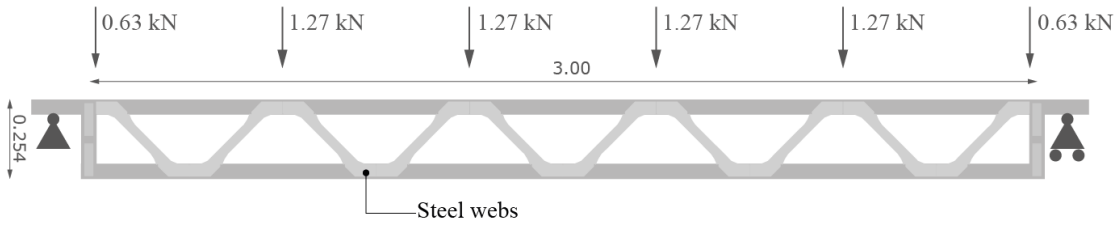

Figure 2. Typical floor joists are used as an industry benchmark for prototype design analysis. Chords cross-section 47x72mm softwood graded TR26, with open steel webs.

Earlier research on English timber has found potential for structural yield of strength classes around C16 [27], [28]. Thus, the study constrains availability to C16-graded softwood timber as the primary resource and considers underutilised and out-of-grade softwood sawn boards [29], [30], looking to existing agriculture and pallet and packaging markets to evaluate their potential structural performance. In England, more than 70% of sawn softwood processed goes to pallets, packaging, and fencing [7]. Additionally, broadleaf stands account for approximately 70% of English woodland, and therein lies potential for how more significant volumes can be value-added to long-lasting timber-building products.

By examining alternative timber sources and grading systems, this research aims to promote sustainable and locally sourced materials in the construction industry, fostering a more material-efficient approach to designing timber building products.

2.2.2 Prototype design

The prototypes are 3-metre-long joists with 20 cm supports at both ends of the top chord and a 25 cm distance between the chord axes. These dimensions were established based on examples of timber-framed three and four-bedroom houses featuring open-web floor joists, where 3 metres is a typical small span, while also considering the ease of manufacturing and manoeuvrability within a testing laboratory. The design optimisation objective is to reduce volume, with the minimum cross-sections of each member determined primarily by two parameters: a numerical factor, the utilisation of members in tension and compression (capped at 85%), and an empirical factor, manufacturing constraints such as joints.

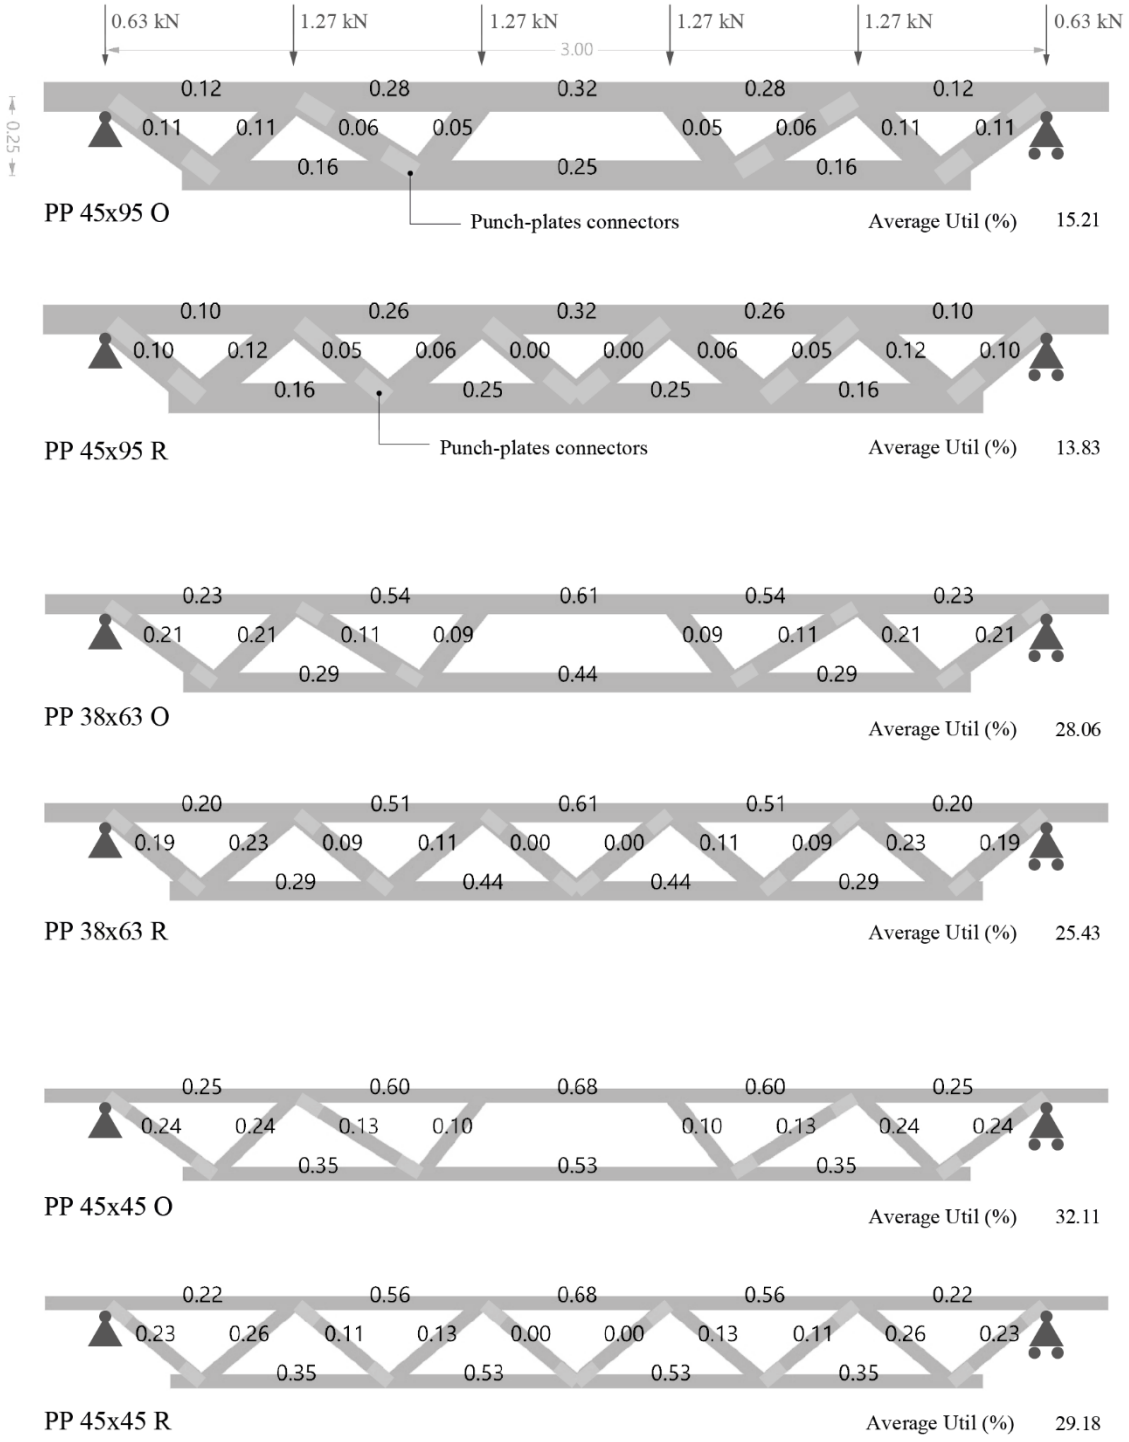

Figure 3. Prototype design proposals joined with steel punch-plates to assess the effects of cross-section variations according to commercially available industry standards (45x95mm treated wood, 38x63mm untreated wood).

Due to the limited truss domain height (25 cm), the grid division for layout optimisation has points only at the top and bottom chords to prevent the generation of complex nodes in between. The applied loads include 1.5 kN/m2 for live loads, 0.6 kN/m2 for top chord dead loads (timber floor and framed walls),

and 0.25 kN/m2 for bottom chord dead loads (ceiling), each multiplied by a safety factor of 1.5. A single 3-metre joist with 60 cm centre spacing is designed to support 6.34 kN or 3.52 kN/m^2. The loads are applied at nodes of the top chord spaced every 60 cm along the chord for consistency with the industry benchmark (steel web joist) and to maintain the same setup for mechanical testing to be conducted in subsequent research phases.

Regarding potential applications in the construction industry, the cross-section specification for C16 carcassing timber is typical for industrial softwood producers in the UK. A series of design tests have been developed for both currently available commercial cross-section sizes and speculative future sizes, which could be more diverse and vary in scale. For the 3-metre prototype, the minimum cross-sections tested in the simulation are 45x95 mm and 38x63 mm for the graded ones and 45x45 mm for the ungraded ones. In the examples presented in Figure 3, the chords and webs are designed with the same width for each case (45 or 38 mm). The connections of tension webs to the chords are intended as steel punch plates. This impacts the EC calculation, with 63x152 mm plates for the 45x95 mm case and 38x76 mm plates for the other two cases (38x63 and 45x45 mm). Connection details can significantly influence structural performance, embodied carbon, or volume data, leading to the proposal and implementation of two alternative joining systems in distinct prototypes.

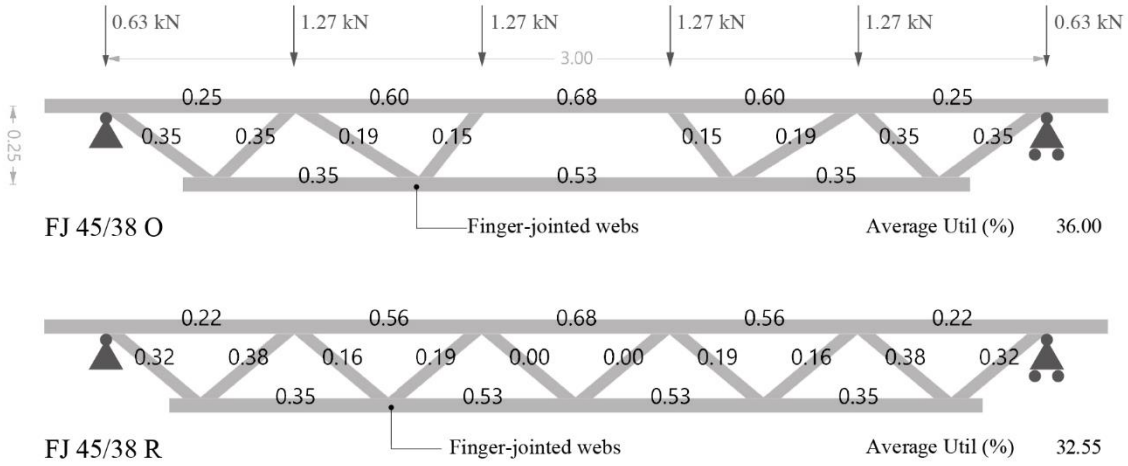

Figure 4. Prototype design proposal for finger-joint floor joist to assess steel-free connections' contribution to embodied carbon. In this case, an adaptation of the commercially available cross-sections is considered for the webs (38x38mm).

Prototype 1 – Steel punch-plates

The first prototype, depicted in Figure 3, features chords and webs connected through steel punch plates, a method currently prevalent in the construction industry. To minimise EC, the punch plates are strategically employed only for joining the tension chords. This selective application of punch plates serves to contain both the EC and volume when compared to industry benchmarks, showcasing an innovative approach to balance material use and environmental impact in the construction process. By refining traditional methods in this manner, the first prototype demonstrates the potential for improving the efficiency of widely used construction techniques.

Prototype 2 – Finger-joint

The second prototype features a truss system with finger-jointed webs and chords, a method commonly employed in the North American construction industry [31]. This design permits using more minor webs

than chords, potentially leading to additional material savings. Although the absence of steel connectors significantly reduces EC values (as shown in Table 1), industry-based examples often utilise resorcinol resin containing formaldehyde for gluing, raising health concerns. As an alternative, polyurethane-based glue will be used for assembling this prototype in future investigations.

For both prototypes, two alternative member layouts have been considered: an optimised layout, in which member distribution is derived from the Peregrine method and each diagonal has a different angle, and a regular layout, in which all diagonal webs maintain the same angle, similar to a Warren truss.

Since the prototypes are relatively small and subject to minor loads as secondary structural elements, the primary distinction between the two layouts is the absence of two central tension webs in the optimised version, which are omitted due to their near 0% utilisation factor. However, for ease of manufacturing and considering the potential improvement in overall stability during truss handling, the initial prototypes to be tested will be based on a regular layout.

Table 1. Overview of the design proposals compared with the industry benchmark. PP stands for Punch-plates connected, FJ stands for Finger-joint, R is the Regular layout of webs, and O is the Optimised layout of webs.

	Standard joist	PP 45x95 O	PP 45x95 R	PP 38x63 O	PP 38x63 R	PP 45x45 O	PP 45x45 R	FJ 45/38 O	FJ 45/38 R

2.2.3 Life-cycle assessment

To evaluate the carbon impact of the design, a Life-Cycle Assessment (LCA) calculation has been performed considering the stages A1-A4, which are from cradle (A1: raw material supply) to gate (A3), and then adding the transportation to the construction site (A4). In this context, there is no information on the emissions during the construction phase (A5). The comparison between a typical floor joist with metal webs and the proposed prototypes would not affect the comparison since the installation procedure should be the same.

For timber, the LCA is performed using the Inventory of Carbon & Energy (ICE) database [32]. The calculations are based on the weight of the timber, and the EC values refer to "Timber, Softwood, No Carbon Storage", where the EC for the modules A1-A3 is 0.263 (kgCO2e/kg); this value has been used for both the prototype and the industry benchmark. The A4 module is calculated using the table of transport emission factors for the UK [33], which identifies "European manufactured" 1500km by road, 0.160 (kgCO2e/kg), and "nationally manufactured" 300km by road, 0.032 (kgCO2e/kg). The biogenic carbon as the contribution of timber to sequester atmospheric carbon is -1.64 (kgCO2e/kg). Two EC values are analysed, with and without biogenic carbon, EC+Seq (kgCO2eq) and EC (kgCO2eq).

A ratio (V/Av Util.) was developed, as shown in Table 1, normalising the volume against material utilisation, showing the importance of considering both aspects of biogenic carbon and material utilisation to maximise material efficiency.

For the steel components, the webs and punch plates, the EPD data are derived from one of the available manufacturers on the market. For the selected manufacturer, the embodied carbon (A1-A4) for both is 2.297 (kgCO2e/kg). The carbon impact of the polyurethane glue for the considered LCA modules is 0.876 (kgCO2e/kg), and the average amount considered is 0.3 kg of glue per finger-jointed joist. To give a reference value, the glue accounts for an increase of about 2% in the EC calculation.

3. Results

This research adopts a material-efficient approach to investigate optimisation-driven structural systems using local underutilised English timber for low to mid-rise buildings, to address housing supply challenges and retrofit existing poor-performing buildings. The study focuses on the structural performance of optimised truss systems, analysing various parameters for comparison, including member utilisation, timber volume, and embodied carbon, both with and without sequestration. All data are expressed as increased or decreased percentages relative to an industry benchmark for the same span load case (Table 1). The developed algorithm will serve as a fundamental basis for studying and designing larger building products, such as truss beams employed as primary structural elements. The simulation results show promising outcomes, with expected structural performance according to initial inputs such as geometry, loads, and material properties.

For the design of floor joists, the research analyses several combinations of member cross-sections and joining techniques. All proposed solutions demonstrate a lower EC compared to standard systems. The reductions in EC range from approximately -17% to -74% without accounting for carbon sequestration. This reduction can be attributed to substituting steel webs with timber and the lower impact of the LCA A4 module for local timber transportation. Concurrently, the use of steel in the designed prototypes is minimised and restricted to tension webs.

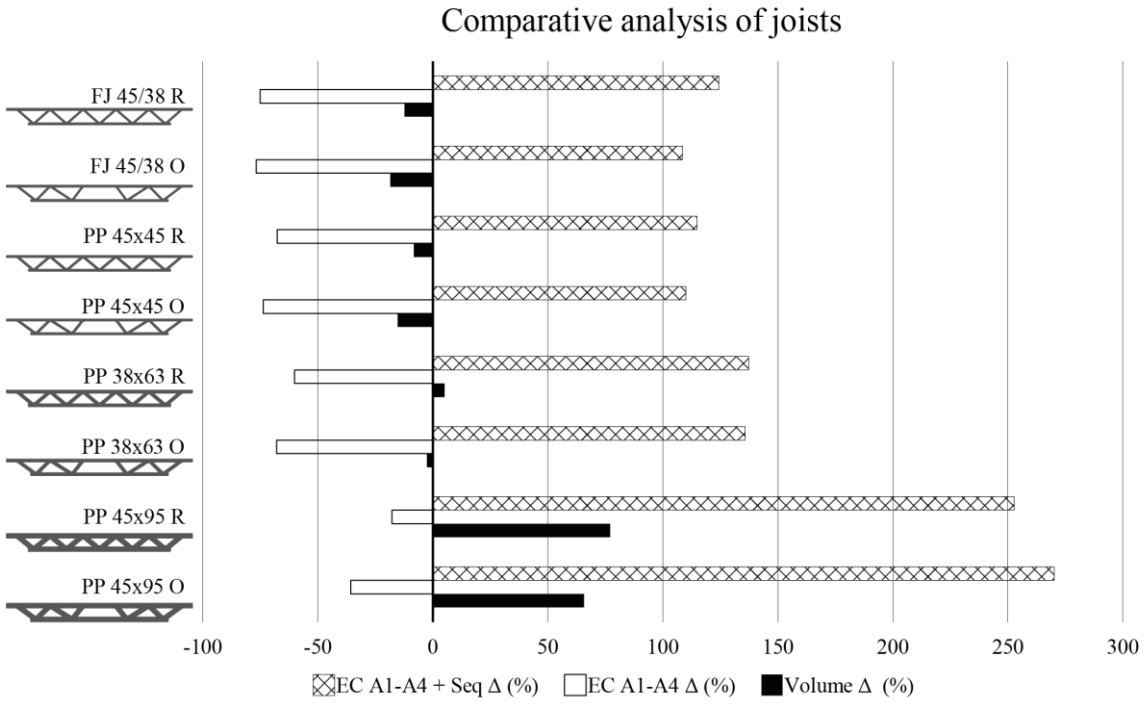

Figure 4. Overview of the design proposals compared with the industry benchmark. PP stands for Punch-plates connected, FJ stands for Finger-joint, R is the Regular layout of webs, and O is the Optimised layout of webs.

In contrast, the volume of timber employed in the prototypes varies between approximately +77%, with an average member utilisation of 14% and a maximum of 32%, to -18.5%, with an average member utilisation of 36% and a maximum of 68%.

In the comparative analysis of joists (Figure 4), the EC+Seq (kgCO2eq) reveals a significant rise in the sequestered carbon within each joist. Compared to the industry benchmark joist (-3.56 kgCO2eq), PP 45x95 O showed the highest level of carbon sequestration (-13.21 kgCO2eq) due to larger dimensions in the chords, and the use of timber rather than steel in the webbing.

4. Discussion and conclusion

This study employed an optimisation-driven approach to develop material-efficient structural systems that utilise locally underutilised English timber for low to mid-rise buildings. The aim was to address housing supply issues and retrofit existing poorly-performing structures employing local resources. The research analysed optimised truss systems, considering parameters such as member utilisation, timber volume, and embodied carbon. The developed workflow can potentially design more significant building components, such as truss beams used as primary structural elements.

The findings revealed that the proposed solutions exhibited lower embodied carbon than standard systems, which can be attributed to substituting steel webs with timber and reducing the impact of local timber transportation. However, timber volume and member utilisation demonstrated broader values among the prototypes. The prototypes represent viable alternatives to current practices. Future structural testing is required to evaluate their potential for application in real-life scenarios. As the larger project, which this study is a part of, evolves, these promising alternatives will be assessed through manufacturing and structural testing, examining real-world applicability. Following the testing results, subsequent phases of the research will focus on larger primary structural elements such as beams, walls, and columns, as well as the supply of local resources.

In summary, this study establishes the foundation for the development of material-efficient timber structural systems for low to mid-rise buildings, employing locally grown and manufactured English timber. These systems have the potential to contribute to addressing housing demand and the retrofit of poorly performing and outdated existing buildings. The material-efficient design workflow is transferable and relevant to audiences interested in material-efficient topology-optimised timber structures, which can apply the insights to regions where stocks of underutilised timber resources exist. The research findings present a promising avenue for promoting sustainable and regionally-sourced solutions within the construction industry.

Acknowledgments

This research forms work from the Timber in Construction (TIC) project funded by the Forestry Commission, and the Growing the Future Project funded by the Laudes Foundation. The authors would also like to thank and acknowledge TIC partners Timber Frame Management, Smith and Wallwork Engineers, Rothoblaas, and Ecosystems Technologies for their insights and constructive feedback on this work.

Abstract

For a sustainable built environment, there is an increasing need for optimised (new or renovated) designs, including the customisable fabrication of their components. This paper (i) presents a general approach to translate design problems into a Topology Optimisation (TO) strategy; (ii) shows multi-disciplinary TO for multi-material components, including concrete, which behaves differently for compression or tension; and (iii) addresses issues in the process from design to fabrication. Applying the general approach and TO, two cases are studied: a part of a façade panel and a sandwich panel. A TO design for the sandwich panel was tested for fabrication by black-and-white printing and functional grading. These tests revealed that design by TO requires specific print path plans and tweaking of system dynamics for the fabrication by 3D printing. Vice versa, fabrication requires modifications to the design by TO, e.g., geometrical adjustments. In the future, TO density filtering using a print path shaped inclusion zone can be studied, and mass minimisation with a stiffness constraint.

Keywords: topology optimisation, 3D printing, multi-material components, multi-disciplinary optimisation, sustainability, built environment

1. Introduction

For the built environment, quite some challenges are ahead. With a world population growing fast, many new buildings should be constructed for living, work, and care. At the same time, energy resources are getting depleted, and for sustainability reasons, existing buildings should be renovated. Consequently, the built environment should be optimized, either by design if new, or by (design of) renovation of the existing building stock.

Within the above framework, this paper presents an approach to design and fabricate multi-material components, specifically for renovation. The approach ensures that structural and thermal performances are optimised. The multi-material setup delivers an optimal amount of each material to be used. Also, the approach is flexible and adaptable, since for each specific building, dedicated components can be designed, fabricated, dismounted, and reused. This all contributes to a sustainable built environment. The research presented is part of the Dutch governmental RVO financed MMIP program, with seeks to enable the energy transition of the existing residential building stock in The Netherlands.

In section 2, the translation will be discussed of a design problem into a so-called Topology Optimisation (TO) strategy, which finds designs for (conflicting) objectives and boundary conditions. TO implementation and multi-material aspects will be covered in section 3. Section 4 presents two cases studies: The first study shows the functionality of the TO developed, whereas the second tackles a realistic sandwich panel. Finally, Section 5 and Section 6 discuss fabrication and conclusions and future work respectively.

2. The translation of a design problem into a TO strategy

A design problem for a building component can often be regarded as finding a geometry with a material distribution. This fits TO well, as it basically generates the optimal (given objectives and boundary conditions) distribution of a certain amount of material within a spatial domain. For structural applications, in civil engineering, the method was pioneered by Bendsøe and Kikuchi [1], and several approaches can be used, as reviewed by Sigmund and Maute [2]. In the beginning, often a maximum structural stiffness, i.e. a minimum compliance, was used as the objective, together with a certain amount of material as the constraint. Later, also constraints related to allowable stresses were studied, in combination with the objective to minimise the amount of material, the practical implication being a design in which all material is fully utilised. In this latter case, as long as e.g. Von Mises stress constraints were used, it showed to be relatively easy to steer solutions into the right direction. However, for concrete, which has quite different strengths for compression or tension, for which e.g. the Drucker-Prager yield criterion can be used, solutions need further attention: Van de Werfhorst-Bouw *et al.* [3] demonstrated that for volume minimisation, some TO approaches result in designs with most parts in tension, whereas better minimisation would be achieved with so-called Traditional TO (TTO), yielding a design with most parts under compression, More recently, TO has been studied and applied in several other domains like heat transfer (Cho and Choi [4]), fluid flow, and acoustics, and increasingly for multi-material design variables, multi-physics objectives, and complex constraints. Examples are the work by Das and Sutradhar [5], which involved TO for optimally designing structurally stiff and heat-dissipating (porous) structures, and research by Tavakoli and Mohseni [6] that involved multi-material problems in the structural and thermal domains. Even more close to this paper, Bruggi and Taliercio [7] studied the optimisation of the insulation performance of masonry blocks, at the same time maximizing their structural rigidity, resulting in a new internal block layout.

In this section, first a case representing a design problem will be introduced (discussed in detail in Section 4.2), whereafter it will be translated into a TO strategy. The design problem involves a sandwich panel, meant for the renovation of terraced houses, planned to be 3D printed with two materials: concrete and insulation. Except for architectural voids, e.g. a window opening, the panel is solid, which means in TO terms that the sum of the relative densities of concrete and insulation always equals 1.0. The involved structural engineering firm defines the requirements: (a) a stiffness requirement, the maximum panel's horizontal deflection being smaller than 1/150 of the height; (b) a strength requirement, the concrete maximum stress being 3 MPa in tension and 30 MPa in compression; and (c) a minimal thermal resistance of 4.7 m^2K/W. No explicit objectives are given, however, TO needs at least one objective. So, to translate the design problem into a TO strategy, first combinations of TO objectives and constraints are studied, as shown in Table 1.

Table 1. Combinations of TO objectives and constraints [8].

Objectives → / Constraints ↓	Minimal strain energy	Maximal thermal compliance	Minimal volume
Volume equality	A1	n.a.	n.a.
Volume inequality	A2		n.a.
Maximum stress	n.a.		A4
Maximum stress + volume inequality	A3		n.a.

Combination A1 and A4 represent strategies found in literature, as mentioned above. For the case studied here, only requirements, no objectives, are formulated, and so there is complete freedom in

selecting the objectives. However, minimal volume cannot be used, as two materials are involved, together always occupying the complete TO design space, and the volume of one of the materials is used to control the ratio between the materials. Thus, a weighted sum of the minimal strain energy and maximal thermal compliance is selected, so the trade-off between structural and thermal objectives can be studied. With respect to the constraints, it should be noted that the stiffness requirement and minimal thermal resistance cannot be cast into TO constraints, as their nature is equal to the selected objectives. However, the strength requirement can be represented by constraints, to be presented later. Looking at Table 1, a volume inequality can be used, which defines a minimal or maximal ratio between concrete and insulation, making possible a systematic study of the influence of this ratio. The resulting strategy, here defined as A2, is simple to implement and computationally cheap. As a more advanced alternative strategy, also the stress at each location can be constrained to the maximum allowable stress, strategy A3. This is computationally expensive, however, it relieves postprocessing from checking the strength requirement later. Namely, for both strategies, inevitably results should be checked against the requirements (except for the strength requirement for A3), and adjustments should be made for a following TO attempt. These adjustments may concern: (a) a different geometrical design space, e.g. a thicker panel; (b) a different weighting of the objectives: or (c) a different volume inequality (i.e. more concrete or insulation on average). As a generalization of the above considerations, design problems always have requirements, which can possibly be reformulated as TO objectives and constraints. If no objectives can be found, TO should be driven in an artificial fashion, e.g. by requirement related objectives as used in literature, and preferably in weighted form, so the requirements to be tested afterwards can possibly be met by investigating trade-off solutions. Then, further TO constraints can be formulated to control and study variables that have a strong influence on the requirements: In the above case, the ratio between concrete and insulation was used, via a volume inequality constraint [8].

3. Multi-disciplinary TO for multi-material components

This section presents relevant details of TO strategies A2 and A3. Both strategies use two materials, instead of a more commonly used single material. For a single material, TO defines the so-called relative density x_e, which by a value between 0.0 and 1.0 indicates how much material is thought to be present in each finite element *e* (finite elements explained later). As mentioned before, here the summed relative densities of the two materials always equal 1.0, which allows for the following relation between the ratio of two materials, and the structural and thermal properties of the material mix:

$$E\left(x_e\right) = x_e^p E_{mat1} + (1 - x_e)^p E_{mat2} \tag{1}$$

$$k_{th}\left(x_e\right) = x_e^p k_{mat1} + (1 - x_e)^p k_{mat2} \tag{2}$$

In these equations, x_e is the relative density of material 1 within element *e*; *p* is the so-called penalization factor, an integer to be determined; *E* is the structural Young's modulus [N/mm^2] and *k* is the thermal conductivity [W/(mK)], both for the material mix (no subscript or *th*) or of one of the materials (subscript *mat1* or *mat2*).

The 3D spatial domain, in which TO distributes the ratio between material 1 and 2, is discretised in 3D eight-node orthogonal finite elements, according to the finite element method. Mechanically, each element node has three displacement Degrees Of Freedom (DOF); each finite element is represented by an element stiffness matrix that relates the nodal forces and displacements; and the element matrices are assembled into the structural stiffness matrix, which is part of a linear set of equilibrium equations as follows:

$$\mathbf{K_s u = f} \tag{3}$$

where $\mathbf{K_s}$ is the structural stiffness matrix, **u** the vector of global nodal displacements and **f** the vector of the sum of all nodal forces (from the surrounding elements + external). Thermally, each node has a single DOF, the temperature, and similar reasoning as for the mechanical part results in a linear set of thermal equilibrium equations:

$$\mathbf{K_{th}}\boldsymbol{\varphi} = \mathbf{q} \tag{4}$$

In Equation (4), $\mathbf{K_{th}}$ is the global conductivity matrix, $\boldsymbol{\varphi}$ the vector of nodal temperatures, and **q** a vector in which each term represents the sum of all thermal fluxes (from the surrounding elements + external) at a node. Details on how the mechanical and thermal element stiffness matrices are derived and assembled are given in a report by Youshi [8].

A design can be defined as the discretised spatial domain with for each element a value x_e (implying a certain mix of materials 1 and 2), these values grouped in a vector **x**. With this vector and appropriate loads and boundary conditions, Equations (3) and (4) can be solved, predicting the structural and thermal behaviour of the design. Strain energy c_s, related to the first objective (see Section 2) is then found by:

$$c_s(\mathbf{x}) = \mathbf{f}^{\mathbf{T}}\mathbf{u} = \mathbf{u}^{\mathbf{T}}\mathbf{K_s}(\mathbf{x})\mathbf{u} \tag{5}$$

And thermal compliance c_{th}, related to the second objective (see Section 2) by:

$$c_{th}(\mathbf{x}) = \mathbf{q}^{\mathbf{T}}\boldsymbol{\varphi} = \boldsymbol{\varphi}^{\mathbf{T}}\mathbf{K_{th}}(\mathbf{x})\boldsymbol{\varphi} \tag{6}$$

Finally, a weighted sum of (normalised) objectives is defined; maximal (instead of minimal) thermal compliance is required; and the total amount of material 1 (and so material 2) is controlled via a volume inequality constraint, which together leads to TO strategy A2:

$$\begin{cases} \min f = w_s \dfrac{c_s(\mathbf{x})}{c_{s,max}} - (1-w_s)\dfrac{c_{th}(\mathbf{x})}{c_{th,max}} \\ \text{subject to} \begin{cases} \dfrac{\sum_{e=1}^{n} x_e v_e}{V_f} \le 1 \\ 0 < x_{min} \le x_e \le 1 \end{cases} \end{cases} \tag{7}$$

In this equation (7), f is the function to be minimised, w_s is the weight factor, to be set, $c_{s,max}$ and $c_{th,max}$ the maximal occurring values for the objectives (taken from test runs using w_s = 0.01 and 0.99), n the number of elements, v_e the volume of element e, V_f the required total volume for material 1, to be set, and x_{min} a minimum value to avoid numerical singularities (as the stiffness of material 2, insulation, is very low).

For strategy A3, additionally the stress in each finite element is constrained. As in this paper concrete is used as the structural material, for the constraints the well-known Drucker-Prager yield criterion is used. This leads to a constraint for the stress state in the middle (found via the solution of Equation (3) and precursors of the element stiffness matrix) of each finite element e:

$$\sqrt{\frac{(\sigma_{xx}-\sigma_{yy})^2 + (\sigma_{yy}-\sigma_{zz})^2 + (\sigma_{zz}-\sigma_{xx})^2 + 6\sigma_{xy}^2 + 6\sigma_{yz}^2 + 6\sigma_{zx}^2}{6}} + \alpha(\sigma_{xx}+\sigma_{yy}+\sigma_{zz}) - \beta \le 0 \tag{8}$$

In which σ is the stress, with conventional subscripts for its type and direction, and constants α and β are functions of the concrete's compression and tension strengths. Two issues should be addressed. Firstly, the Drucker-Prager yield criterion is applicable to a finite element fully consisting of concrete (i.e. x_e = 1.0), however, if the relative density is lower, the element can be regarded as porous concrete, for which local stresses will be higher than the average stresses as predicted as explained above. This

can be solved by interpolation, see Duysinx and Bendsøe [9]. Secondly, it can be demonstrated that if the finite element's density becomes very low, local stresses keep a certain value, however, for an element with hardly any material, the stress constraints should not apply, and so stresses are set to zero. This discontinuity (finite vs. zero stress) may lead to solution problems, which can be avoided by the use of so-called relaxation, see Duysinx and Bendsøe [9].

For both strategies A2 and A3, multiple load cases see the objectives being formulated as the sum of the objective values for each load case, and the constraints require that stresses are below the required value for all individual cases. Also, relative densities are filtered, i.e. smoothened across the domain, to reduce the sensitivity of the outcomes for the finite element mesh, and to avoid checkerboard patterns.

The solutions of the linear systems of equations as given by Equations (3) and (4) are found by the proprietary MATLAB functions "mldivide, \", which may use different type of solvers (e.g. QR, LU, Cholesky), depending on the problem. For the optimisation itself, the Method of Moving Asymptotes (MMA) by Svanberg [10] is applied. MMA needs the derivatives of the two objective functions, the total volume, and all stress constraints (one for each finite element) with respect to the element relative densities. Details on the formulation and implementation of interpolation, relaxation, multiple load cases, density filtering, and derivatives can be found in Youshi's report [8], which also includes the complete MATLAB (version 2021b) script used.

4. Case studies

Two case studies are presented, related to the renovation of terraced houses. If these houses have load-bearing party walls, and non-load-bearing façades, they can be renovated by new 3D printed façade panels, either with complete freedom of the concrete/insulation mix across the spatial domain, a case in Section 4.1, or as a sandwich panel with predefined concrete faces, Section 4.2. In the future, it may be possible to completely print houses on site, and a related third case study on a continuous wall-floor system is presented in Youshi's report [8].

4.1. Façade panel

The method presented in Section 3 is used to find an optimal design for a (small part of a) façade panel, for which the design domain, boundary conditions, and loads are shown in Figure 1 on the left. This case is a first academic exploration, and unit loads (1N per node) are taken, which is fine as objectives are normalised, see Equation (7). With respect to the volume inequality, on average max. 50% of concrete can be used for the panel. The Young's modulus of concrete equals 30,000 N/mm^2, and for the insulation it is 19 N/mm^2. Poisson's ratio equals 0.2 for both materials. Equally important, the thermal conductivity of concrete equals 1 W/(mK), and for the insulation 0.06 W/(mK) is taken. Using strategy A2, figure 1 on the right shows the suggested design for w_s = 0.75. Note that elements have an x_e anywhere between 0.0 and 1.0, but for clarity, the visualisation is black-white (in fact: grey-yellow). The exterior surface (shown top right) is almost purely concrete, to distribute the load to the constrained sides in the stiffest way. However, also space is reserved for insulation material, mostly located near the influx of heat, to maximise the thermal compliance. Not shown, but for w_s = 0.99, much more concrete is suggested, e.g. using a thicker exterior face and more concrete along the sides, whereas for w_s = 0.01, a solid piece of insulation is proposed. Figure 2 on the left shows the objectives' values versus the sequence of iterations for w_s = 0.5 and w_s = 0.75. Cleary a trade-off can be seen between the two objectives: If w_s goes from 0.5 to 0.75, the structural compliance decreases (so better performance), whereas the thermal compliance (multiplied by -1) increases from about -1.8 to -1.3, which resembles worse performance. The same case study is also carried out using approach A3, so including stress constraints, with for the concrete's compression and tension strength values of 30 and 3 N/mm^2 respectively. Outcomes are similar, with respect to the TO suggested designs (qualitatively) and convergence behaviour (like in Figure 2 on the left). For a typical example, w_s = 0.75, Figure 2 on the right shows the number of finite elements (on the vertical axis) against the stress constraint function on

the horizontal axis. The stress constraint function's range equals -1 to 0, with "-1" representing zero stress, and "0" indicating that the maximum allowable stress state has been reached.

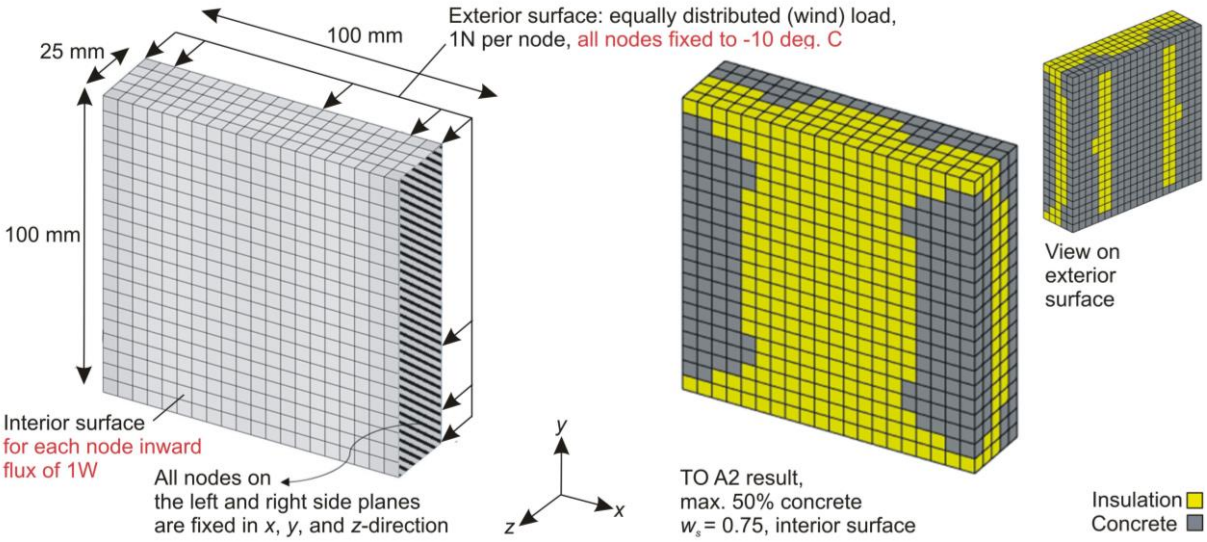

Figure 1. Façade panel case study. Left: finite element model. Right: TO A2 result visualised as a black-white solution (grey "Concrete" if $x_e \geq 0.5$, yellow "Insulation" if $x_e < 0.5$).

As figure 2 shows, all stresses are on the very safe side, and this is also the case for the other A3 simulations (w_s = 0.01, 0.5, and 0.99). This indicates that the maximal allowable average amount of concrete (now 50%) may be reduced in favour of higher insulation performance, or the panel may be designed thinner, all to be presented in the next section.

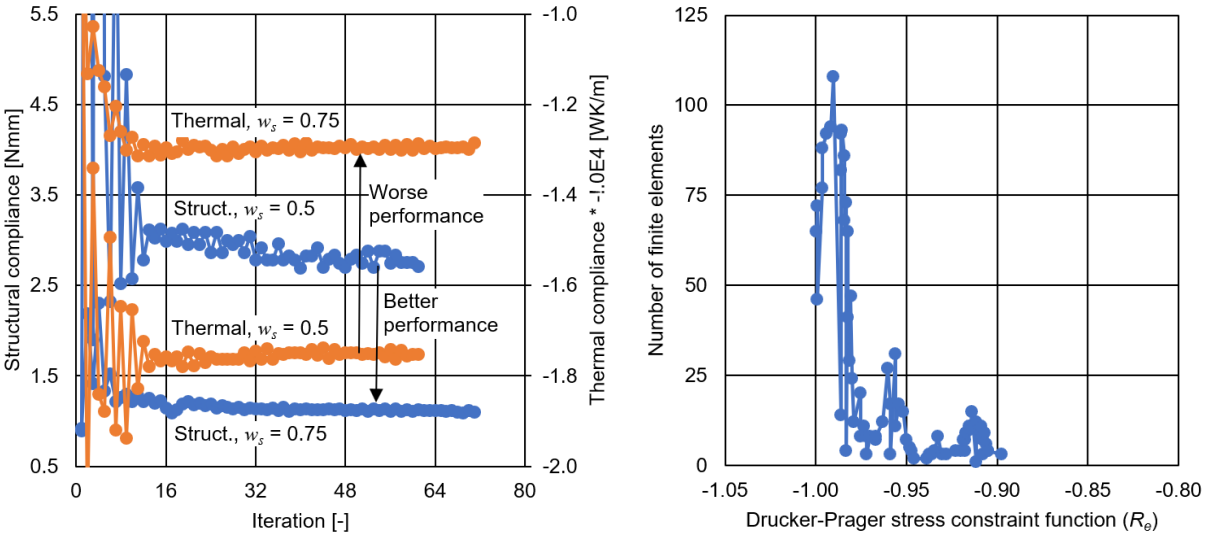

Figure 2. Left: Strategy A2 convergence of structural compliance (blue, left ver. axis) and thermal compliance (orange, right ver. axis) for different weight factors. Right: Strategy A3, w_s = 0.75, number of finite elements vs. the stress constraint function (R_e = -1.0 implies no stress, R_e = 0.0 indicates fully stressed).

As a conclusion, the "multi-disciplinary TO for multi-material components" functions, for it: (i) suggests the multi-material layout of a design; (ii) shows trade-offs between objectives; (iii) accounts for volume and stress constraints.

4.2. Sandwich panel

In Section 3, a design problem was introduced for a sandwich panel, requiring (a) its horizontal deflection being smaller than 1/150 of the height; (b) all concrete stresses being within the limits of 3 MPa in tension and 30 MPa in compression; and (c) a minimal thermal resistance of 4.7 m^2K/W should be achieved. For this problem, the TO (finite element) model is shown in Figure 3 on the left. Pure concrete faces are default for the interior and exterior surfaces, whereas the interior core is subject to TO. The panel is 3 meters wide and 2.5 meters high, including a 1×1 meter window opening, exactly in the middle. The core is modelled by 100×100×100 mm finite elements, and each concrete face by two layers of 100×100×25 mm elements, respecting a 1:4 element aspect ratio. Structurally, on the exterior surface, an equally distributed wind load is put, equal to 2 kN/m^2, together with a line load of 12.5 kN/m^2 on the top side, with an offset of minus 20 mm in *z*-direction following common design standards, representing the load of a floor on top of the panel. The bottom sides of the concrete faces are completely fixed, whereas all nodes along the interior top edge of the concrete face are fixed in *x* and *z*-direction. Thermally, all nodes on the exterior surface are temperature set at minus 10 deg. C., and each node at the interior surface has imposed on it an inward flux of 1W. No further conditions are prescribed for the sides, so fluxes are zero all around there.

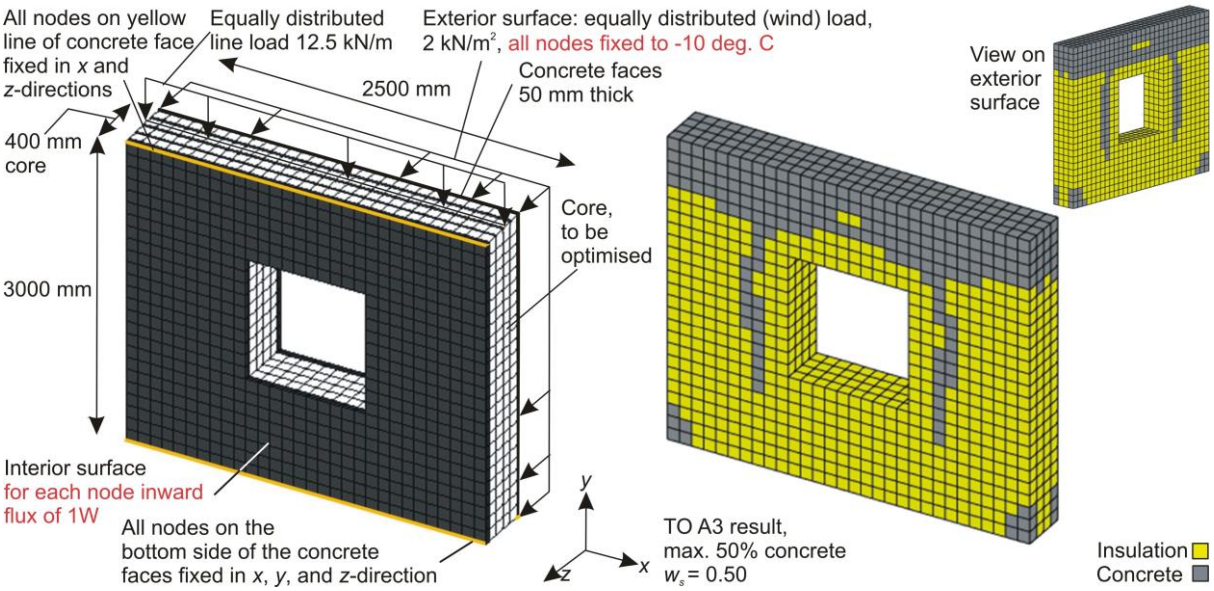

Figure 3. Sandwich panel case study. Left: finite element model. Right: TO A3 result visualised as a black-white solution (grey "Concrete" if $x_e \geq 0.3$, yellow "Insulation" if $x_e < 0.3$).

The initial thickness of the panel (later this thickness will be varied) is determined by simple engineering equations: The sandwich panel is regarded as a linear elastic beam, spanning from top to bottom, with core and faces fully connected. Given the wind and floor loads, the structural requirements (a) and (b) can be plotted as a function of the face thickness versus the core thickness. This shows that the face thickness is (i) dictated by the strength requirement (b); and (ii) a function of the core thickness. Therefore, the core thickness is predicted by the thermal requirement (c), which leads to a thickness of 400 mm. In turn, this leads with requirements (a) and (b) to a face thickness of only 0.5 mm, which is complicating the finite element model setup, impossible to print, and vulnerable in practice, and so for the faces a thickness equal to 50 mm is used.

Similar to the previous case study, strategies A2 and A3 are used, both for the weight factors $w_s = 0.01$, 0.50, 0.75, and 0.99. A typical outcome is shown in figure 3 on the right, for A3 and $w_s = 0.50$. Note that for clarity the solid concrete faces are not visualised, and interior parts of the core, e.g. the second and third layers of elements, are hidden and may have a different layout than as shown for the outer layers.

Not all outcomes can be presented visually here, but strategy A2 shows window opening interior edges of concrete (resulting in stress concentrations). This is avoided by strategy A3, which also results in smoother geometries at other locations. Nevertheless, in general strategy A3 leads to less stiff designs, but for similar insulation performance, see Table 2. Furthermore, this table shows quantitatively the same conclusions as for the first case study: TO is successful in handling the weight factor for a multi-material mix, and results show consistently a clear trade-off between structural and thermal objectives. For the face and core thicknesses initially selected, the stiffness requirement is easily met for all cases, however, the requirement for thermal resistance is only satisfied for a high weight on thermal performance (equals a low weight on structural performance: $w_s = 0.01$). Results in the table are based on successfully finished TO runs, and so for strategy A3 stress constraints are met in all cases.

Table 2. Overview of all TO generated designs for the sandwich panel case [8].

Strategy → / Constraints ↓	A2	A3	A2	A3	A2	A3	A2	A3
Weight factor w_s	0.99		0.75		0.5		0.01	
Maximum deflection [mm] (<16.6)	0.0079	0.0138	0.0409	0.0542	0.1126	0.1238	0.1619	0.1653
Structural compliance [Nmm]	161.6	179.8	465.8	569.4	1010.7	1022.1	1635.1	1918.9
Thermal resistance [m^2K/W] (>4.7)	0.92	0.92	3.47	3.42	4.69	4.67	5.18	5.26

4.2.1. Sandwich panel thickness variations

As Table 2 indicates all requirements can be met (in the last two columns), it can be tried to search for even more efficient designs, by lowering the core thickness (face thickness is fixed, as explained earlier). To investigate this, the previous simulations (total panel thickness 500 mm) are repeated for two other panel thicknesses, 300 and 400 mm, effectively changing the core thickness to 200 and 300 mm respectively. Using strategy A2 and a larger number of weight factors w_s, Figure 4 shows the three resulting Pareto fronts, and for illustrative purposes, three TO suggested designs for thickness = 500 mm. To obtain a classic orientation of the Pareto front, the reciprocal value of the thermal resistance is taken. Again, a too high deflection is not an issue, but the required thermal performance can only be achieved by (a) a sufficiently high weight on its objective in combination with (b) a sufficient thickness, and not by further optimisations, since the solution is optimised already.

Although strategy A2 is used, so stresses are not checked during TO, results still allow for the calculation of the average equivalent Drucker-Prager stress afterwards. As such, it can be shown that for the simulations in Figure 4: (i) the average stress decreases for higher w_s, i.e. structural stiffness is deemed to be more important and more concrete material is used; (ii) average stress increases for thinner panels, for deflections are larger as less material is available; (iii) for all cases the average stress is much lower than the maximal allowable stress, due to the limited load and its distributed character.

5. Fabrication by 3D Printing

Related to the fabrication of multi-material building components by 3D printing, research has been carried out by Herrmann and Sobek [11] on so-called shotcrete printing (for which concrete is sprayed rather than extruded [12]). They used two different concrete mixtures, one with a normal density, and the other one being an ultra-lightweight mixture for insulation purposes. One of their approaches was to blend the two mixtures (allowing variable ratios during printing) before the spray nozzle. Another approach was to apply for each type of mixture a separate spray nozzle. Small concrete prisms were fabricated with controlled densities (and so properties) across their volume. Similar research was carried out by Craveiro *et al*. [13], who followed an approach using extrusion, in which before the single nozzle normal concrete and concrete with cork instead of sand (for insulation purposes) was mixed. Finally,

Ahmed *et al*. [14] experimented with a system to add dry fibres or light-weight granular materials to the wet concrete in the extrusion nozzle, part of several large-scale research projects [15]. Different from the experimental work in academia, in the built environment printing technology is still limited to fabricate components using a single material. Therefore, here two strategies are explored to fabricate multi-material components by 3D printing: (i) functional grading and (ii) printing black-and-white solutions.

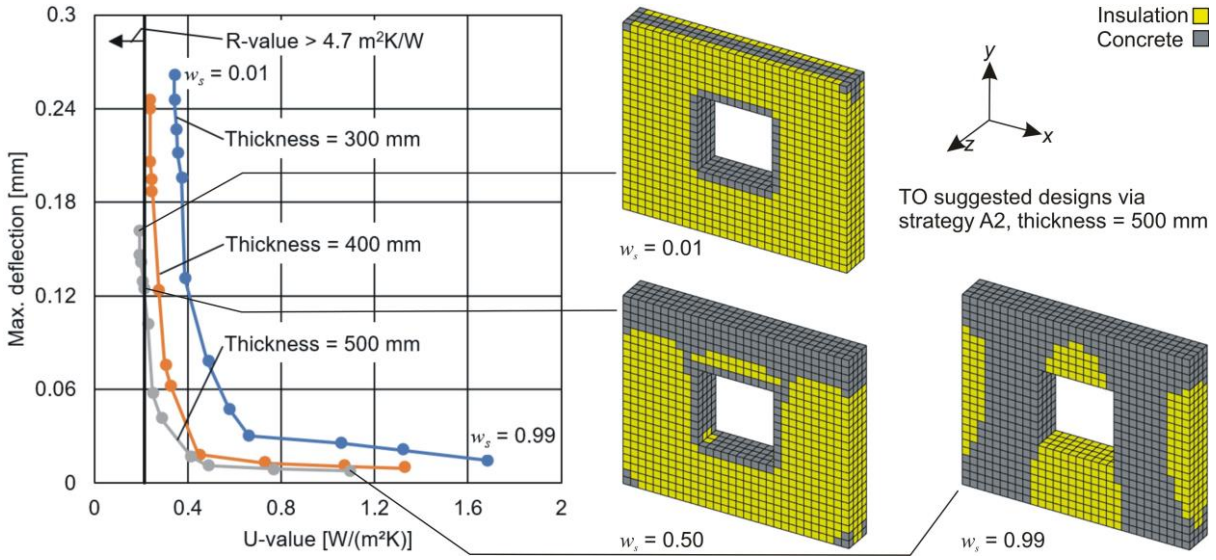

Figure 4. Pareto fronts for different sandwich panel thicknesses, using strategy A2. For all three Pareto fronts, end points refer to w_s = 0.01 and 0.99 respectively (only indicated for the blue curve).

5.1. Functional grading

Relative densities of designs can be shown to all vary continuously between 0.0 (full insulation) and 1.0 (full concrete). Functional grading allows for the printing of all these different densities, by varying the mix of insulation and concrete materials real time during printing. For further study, a TO suggested design is taken based on the problem definition in Figure 3 on the left. Strategy A2 is used, with w_s = 0.75, however, the window opening width is increased to 1.4 m to allow for a circular print path, avoiding 180 degree turns. The resulting finite element mesh is illustrated in Figure 5 on the left for layer 1, with for each element a relative density between 0.0 (full white) and 1.0 (full red).

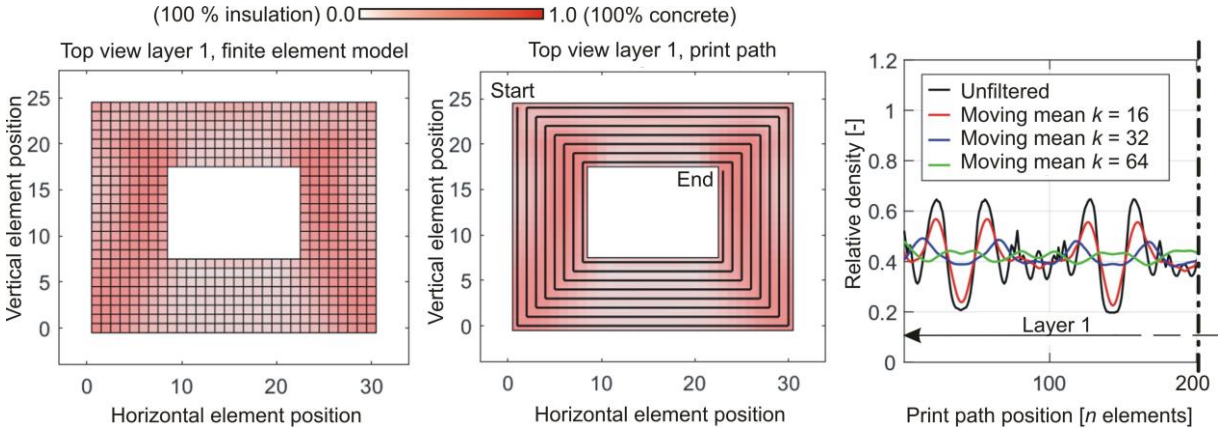

Figure 5. Left: finite element model with continuous relative densities between 0.0 and 1.0. Middle: print path for first layer. Right: required relative densities along the print path (shown for first 200 elements only).

Assuming that the panel is printed in its horizontal (flat) position, a (spiral-like) print path is planned through the entire infill of the panel, see Figure 5 in the middle. Subsequently, the finite elements are sorted along the print path and a graph can made of the relative density vs. the location at the print path, see the black line ("Unfiltered") in Figure 5 on the right. Rapid changes along the print path (and so in time) exist for the relative density, which cannot always be realised due to system dynamics (damping due to mixing, acceleration of the dosing system, etc.). The effects of system dynamics are simulated in Figure 5 on the right by moving mean filters. Practically, the filtered outcomes show that the concrete-insulation mix as fabricated (e.g. green line) is different from the design by TO (i.e. black line), as such compromising the structural and thermal performance. At least, the fabricated distribution should be checked against the design requirements, but better, density filtering, as discussed near the end of Section 3, could be modified to work with a print path shaped inclusion zone, instead of the common spherical inclusion zone [16].

5.2. Printing black-and-white solutions

Similar to the visualisation of densities in Figure 1,3, and 4, for the strategy that prints black-and-white solutions a threshold is used, here 0.50. This practically means that all relative densities equal or above 0.5 are regarded as solid concrete; and everything below 0.5 is solid insulation. There are several strategies to fabricate this type of designs. First, two printing systems, e.g. a gantry printer and a robotic arm, can be used simultaneously or sequentially. However, interference of movements needs to be controlled. Second, like functional grading in the previous section, a print path can be planned (the same as in Figure 5 in the middle) and relative densities can be set along the print path as shown in Figure 6 on the left. Figure 6 uses the same TO suggested design as Section 5.1.

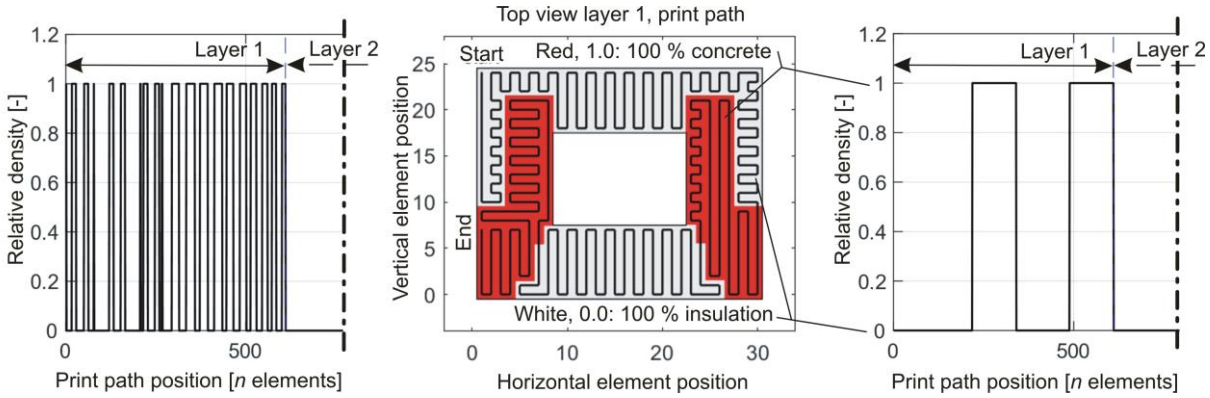

Figure 6. Left: Relative densities on the print path of Figure 5. Middle: optimised print path for black-and-white densities (threshold = 0.50). Right: Required relative densities using the print path of this Figure 6 in the middle.

Even if a printing system is available that can extrude real time the selected materials following the graph (in Figure 6 on the left), the rapid changes in material selection imply issues with system dynamics and fabrication quality. As a possible solution, each layer is divided into different zones based on the element relative densities, and the print path is planned accordingly, as shown in Figure 6 in the middle. The resulting relative densities along the print path clearly show fewer changes, Figure 6 on the right.

5.3. Experiments

Related to the above presented strategies, in 2022 several experiments have been carried out in the Structures Laboratory Eindhoven. First of all, for printing black-and-white solutions, the concrete part was printed of the first layer of the design from Figure 3, with strategy A2 and $w_s = 0.75$, on top of the solid concrete face. This with the assumption that two printing systems are used, and that the concrete system is tested. The result is shown in Figure 7 on the left, where the inset shows irregular printing, caused by the low stiffness of the gantry robot. For functional grading, first the print path was optimised (e.g. avoiding 180 degree turns and reduced flow in 90 degree turns) for the specific gantry robot, by

printing a solid version of the first layer shown in Figure 5. Then calibration prints were carried out, using mortar and a colour dye, instead of insulation material, to tune the flow rate of the dye dosing pump with respect to the print path. Finally, the full interior of four layers of the TO suggested design presented in Sections 5.1 and 5.2 was printed (using a black-white design). A spiral print path similar to Figure 5 was used, since it was more fitting to the used equipment. For practical reasons some scaling was used, projecting each finite element surface to 70×70 mm^2 in practice, and the thickness of each layer of finite elements seen as the printer filament thickness of 10 mm. Results are shown in Figure 7 on the right. Despite a black-white design, gradual transitions occur, and the TO strategy could be advanced by e.g. density filtering using a print path shaped inclusion zone [16].

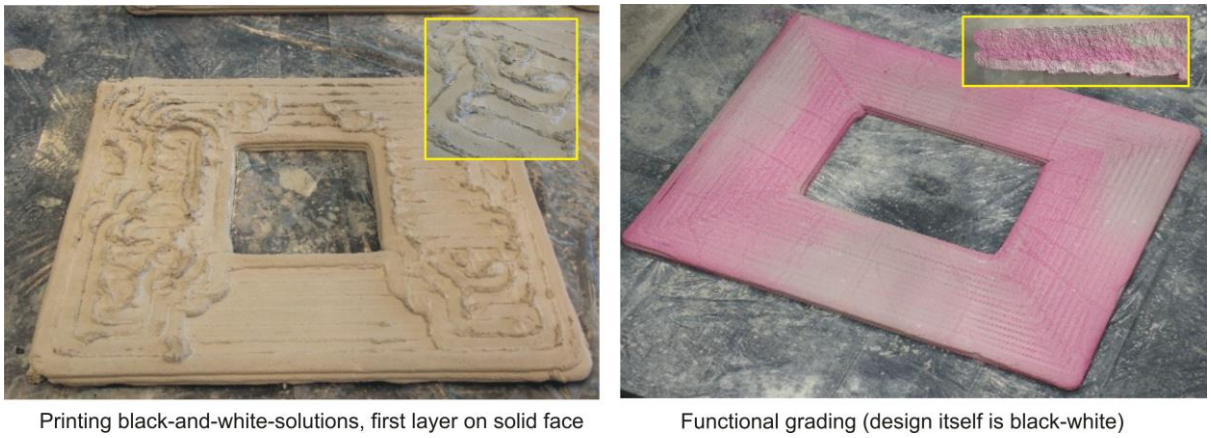

Figure 7. Left: Black-white printing only the first layer's concrete on a solid face. Right: functional grading able printing of a black-white design, full sandwich panel interior.

6. Conclusions and future research

Engineering design problems can be formulated in terms of objectives and constraints. However, if TO is used to create solutions, often the practical objectives and constraints cannot be applied directly. One or preferably more practical constraints should be reformulated as TO objectives, so trade-off solutions can be explored.

Using existing TO strategies with a redefined relative density, multi-disciplinary TO for multi-material components is able to suggest the multi-material layout of a design, to show trade-offs between the objectives, and to account for volume and stress constraints. Mass minimisation with a stiffness constraint [17] can be investigated in the future.

Experiments have revealed that design by TO requires specific print path plans and tweaking of system dynamics for the fabrication by 3D printing. Vice versa, this fabrication requires modifications in the design by TO, e.g by geometrical adjustments (here another window size) or by future density filtering using a print path shaped inclusion zone, both for functional grading and black-white printing [16]. As such, interaction is shown between design by TO and fabrication by 3D printing.

Acknowledgements

This research was financed by the Dutch "RVO" under "Meerjarige Missiegedreven Innovatie Programma's" (MMIP). Jan Blaakmeer (Saint-Gobain Weber Beamix), Marijn Bruurs and Maartje Hoogeveen (Witteveen+Bos), and Sandra Lucas, Theo Salet, and Payam Poorsolhjouy (Eindhoven University of Technology) are acknowledged for their valuable contributions to this project. The authors also thank the staff of the Structures Laboratory Eindhoven for their assistance in setting up the printing system, and Derk Bos and Lauri Hass for their support during printing.

Abstract

This paper explores the development of novel post-tensioned strapping connections for low-cost and high-speed timber framed construction. The strapping is made from a cheap and widely-available polyester packaging material, which can be tensioned and sealed using inexpensive hand tools. The connections are designed conceptually as adaptions of semi-rigid post-tensioned or mortise-and-tenon connections used for permanent timber constructions. Two types of semi-rigid joints were developed which achieve a rotational stiffness via different mechanical behaviours. The first joint uses a force couple between offset straps, developed for a truss frame structure built using utility-grade timber as the component material. The second joint induces a mechanical clamping between adjacent timber elements, developed for a sway frame structure built using engineered timber I-joists as the component material. For both designs, connection rotational stiffness and strength capacity is established with experimental testing. Full-scale prototypes are also built to establish connection suitability for the rapid structural assembly of lightweight timber elements and prefabricated panels.

1. Introduction

1.1. Timber-Framed Construction and Out-of-Grade Timber

Timber is a popular construction material for residential housing as it is renewable, low-cost, and highly workable. In Australia, lightweight timber framing is used for 76% of detached dwelling construction [1]; this building typology comprises sawn timber and engineered wood product structural members, specified to a particular material grade. Grading is intended to classify a timber product into a defined grouping with similar visual and mechanical material characteristics. Grading methods vary by country and resource type; taking Australian sawn pine board as an example, a machine-stress grading process will assign an 'MGP' stress grade, based on allowable thresholds for minimum stiffness and maximum size and frequency of observable defects [2].

The residential timber construction supply chain is highly industrialised; for sawn framing boards, it is also highly optimised to deliver typical rectangular framing sizes in the best attainable structural grade. However, due to the high variability in utilised Australian softwood species, a large volume of sawn softwood fails to attain a structural grade, estimated at 1.2 million m^3 in 2015/16 [3, 4]. These 'out-of-grade' boards have no existing market use and are consequently sold at a loss by millers.

Out-of-grade timber may be classified as such due to low stiffness or due to the large size or higher prevalence of natural defects. These defects could include sloping grain, wane, knots, shakes, splits, checks, or resin. Defects will locally reduce certain structural capacities of a timber member, for example reduced tensile or shear capacity, but the member may otherwise still have excellent performance. More critically though, localised defects prevent the practical connection of out-of-grade timber members. In typical residential housing, timber elements are connected by steel mechanical fixings, such as nails, nail plates, and strapping, which interlock with timber fibres for load transfer. As fibres are more likely to be disrupted or even removed by defects in out-of-grade timber, they are unsuited to assembly using conventional connector types.

1.2. Timber-framed emergency and temporary housing

In a post-disaster context, emergency and temporary housing is used to provide short-term shelter for displaced populations. The frequent and increasing occurrence of worldwide disasters in recent years, including recent bushfire and flood disasters in Australia, has highlighted the need to develop more scalable delivery models for post-disaster housing responses. Scalability of existing systems is limited by their need to access to conventional supply chains for sourcing new construction materials and skilled construction labour, which may be highly limited, and thus expensive, in regional disaster areas. Such systems also have limited ability to integrate or adapt to local material and labour, and thus limited scope for building cost reduction and a high dependence on external support.

Timber framing is beneficial in being lightweight, workable, demountable, and versatile with regards to the structural form and finishing level. These properties make timber stick-framed construction suitable for emergency and temporary housing in tropical and sub-tropical locations with appropriate material availability and climate suitability[5]. Successful recent examples of timber-framed housing systems for low-cost modular construction have also allowed for very rapid assembly, with a single house built in one weekend by a small team of people[6].

The economic viability, transportability, and construction speed of timber housing is strongly dependent on local availability and understanding of connector components. As such, novel connection approaches are frequently proposed to enable a greater flexibility in emergency housing design and delivery, and to make better use of local materials and supply chains. Recent examples have proposed the utilisation of post-tensioned strap joints for high-speed, low-cost, and reversible timber constructions, where reversible refers to a de- and re-constructable structural system [7]. The Liina Transitional Shelter [8] connects individual wooden frames with a nylon hoop strapping, to create an $18m^2$ structure that can be assembled in just 6 hours. A semi-rigid frame structure [9] was proposed by the authors to connect

engineered timber I-joists with polyester (PET) packaging straps, with a 1.5m^2 housing segment assembled in 30 minutes. The connection rotational stiffness in this case was insufficient to meet serviceability requirements for a permanent housing use case.

1.3 Aim

This paper aims to explore two novel connection systems that allow for: i) rapid construction with out-of-grade structural timber; and ii) improved rotational stiffness as compared to existing systems. The new connection methods will also aim to retain the capacity of existing systems in being low-cost, rapidly constructable and de-constructable. The design rationale for the two new 'Strap Truss' and 'Strap Clamp' connection systems are presented in Sections 2 and 3, respectively. For each system, a structural performance assessment is conducted from experimental connection testing, and a constructability performance assessment is conducted from fabrication and assembly of a full-scale building prototype.

2. Strap truss connection system

2.1 Connection design

2.1.1. Out-of-grade timber truss connections

To facilitate a structural assembly of out-of-grade timber, a novel pair of strap-based connection methods was developed as shown in Fig. 2. The first method is based on traditional 'birdsmouth' roof truss connections, which transfer compressive bearing and shear action via a notched recess [10]. These can be additionally reinforced by a metallic binding strip or through-bolt to resist tensile action [4].

The present study introduces a modified form of the strap-reinforced birdsmouth joint, which uses post-tensioned PET packaging strap to connect truss chord and vertical web members as shown in Fig. 2a-b. Inclined truss web members were slightly over-sized, such that they were pre-compressed by the strap tensioning action to remain stable in-plane. Inclined web members also used small double-ended nails at the mitred surfaces for transverse stability.

This connection method is well-suited to assembly of utility-grade timber members, as it relies on pre-compressed bearing action, rather than fibre interlock, for load transfer. For fibre orientation defects such as knot, shake, or resin, the strapping pre-compresses truss chords in the cross-grain direction, reducing the potential for transverse splitting when the member is loaded in axial tension or compression. For geometrical defects such as bowing or twisting, the progressive assembly of strapped locations pulls connected members into structural alignment.

2.1.2. Semi-rigid truss frame connections

A second strapping connection is also introduced to facilitate the semi-rigid connection of adjacent trusses into truss frame structures. With reference to Fig. 2b-c, continuous tensile straps are looped around an entire truss module to anchor to a rigid ground support. When loaded in flexure, semi-rigid load transfer occurs from the force couple between top and bottom anchor locations; due to the applied pre-compression, this will initiate as compressive bearing in both interfaces, and progress to compressive bearing in one interface and tensile strap loading at the other interface. This load transfer mechanism is similar to post-tension timber connection systems for engineered wood products, such as the QuickConnect system [11].

Shear transfer can occur via shear keys located proximate to interface, in the case of connection to a rigid ground support. In the case of connection to an adjacent truss assembly, these shear keys can be introduced as integral notched recesses, similar to that used within the truss for chord and web attachment. These options will be discussed further in below sections.

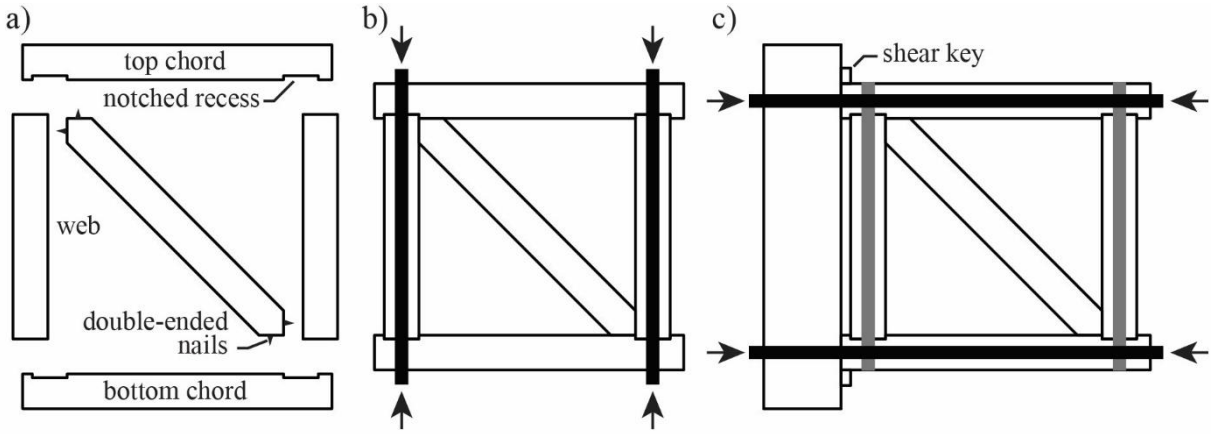

Figure 2: Strap Truss connection system. a) Truss parts. b) Tensioned strap connection of chord and web members. c) Tensioned strap connection to rigid ground support.

2.2 Structural performance assessment

2.2.1 Specimen fabrication and testing

An experimental testing methodology was adopted to evaluate the structural performance capacity of the strap truss connection system. Experimental tests were designed to establish the semi-rigid rotational capacity of truss frame connection straps, which were judged to be the most likely to influence global structure behaviour. With reference to Fig. 3a, specimen geometry was designed to utilise 1.5 full-length (2400mm long) out-of-grade timber boards. Boards was cut into two 795 mm top chords, two 562mm vertical web member, and one 792mm include web member. Parts were assembled into truss modules with two vertical straps, tensioned to 2.7kN and welded with a FROMM P329 strapping tool. Truss modules were then fixed to a pseudo-rigid glue-laminated timber base part, using horizontal straps fixed in the same way. Plywood shear keys were added to the base part at location shown using brad nails.

Three specimen groups were tested, using out-of-grade timber with different Young's Moduli. Specimen Groups A, B, and C utilised boards with average Young's Modulus of 5600 MPa, 7850 MPa, and 11900 MPa, respectively. 90x35 boards were provided by Hyne Timber with average board stiffness values provided based on continuous flatwise bending stiffness measurement. Three samples were fabricated and tested for each specimen group.

Specimens were tested using the apparatus shown in Fig. 3b. The base part was fixed to a rigid steel column and a vertical load was applied at the module end by hydraulic actuator. Side plates were used to prevent lateral instability and force, displacement, and rotation data was recorded by the actuator, a string potentiometer, and an inclinometer, respectively. Load was applied based on European standard EN26891 for timber joints [12], with an initial loading to 40% of predicted peak force (obtained from an initial sample test), an unloading, and a final loading until failure. Force data was multiplied by a 540mm lever arm to convert to a moment about the base support.

2.2.2 Results

Moment-rotation curves for the three tested groups are plotted in Fig. 4a-c. A mean group response curve is obtained as the average of all specimen responses and plotted in Fig. 4d. It can be seen that all specimens exhibit a similar response profile, with an initial pseudo-elastic region with approximately linear stiffness, followed by a non-linear softening behaviour and large rotation. Response values are summarised in Table 1a, with initial stiffness obtained from linear trendlines in pseudo-elastic regions.

The initial region was observed to correspond to the release of the compressive bearing stress on the bottom surface. The only observable material damage in the initial stage is the perpendicular-to-grain crushing where the strap anchors onto the base part during initial pre-tensioning, Fig. 3a. This is consistent with the response shape described in [9] for an I-joist strap joint, which also found that joint

initial stiffness is sensitive to timber flatwise MOE. In the softening region, the truss module underwent a large rotation, with additional progressive material failures. Some samples with material defects at the notched recess in the top chord member showed a shear fracture at the notch location. This caused a sharp force reduction but, in most cases, the vertical web member was caught by the rigid base part to give a force restoration. Ultimate failure then occurred from tensile strap fracture. There was little difference between specimen groups, indicating that out-of-grade timber member stiffness had little impact on connection performance.

2.3. Constructability performance assessment

A full-scale temporary structure was built using the truss strap connection system, to investigate the fabrication effort, assembly effort, and system cost. The structure was designed to use a single repeated truss module, Fig. 5a, comprising four repeating parts: top/bottom chord and vertical/inclined web members. Assembled modules were connected at 600mm spacings with timber battens to create prefabricated wall and roof cassettes. Battens used a small notch to locate frames at the correct transverse spacing and were connected with batten screws.

Prefabricated cassettes were connected side-on in the truss frame strap arrangement shown in Fig. 5b, with semi-rigid connections between roof, wall, and base surfaces. Roof sheeting was screwed onto the outer batten layer and the frame was then tilted up for transport. Upright frames were self-stable and could be transported by using a pallet truck or forklift, lifting from under the floor cassette. A complete structure, Fig. 5c, used two mirrored frames to create a pentagonal envelope, connected by plywood gussets at the apex.

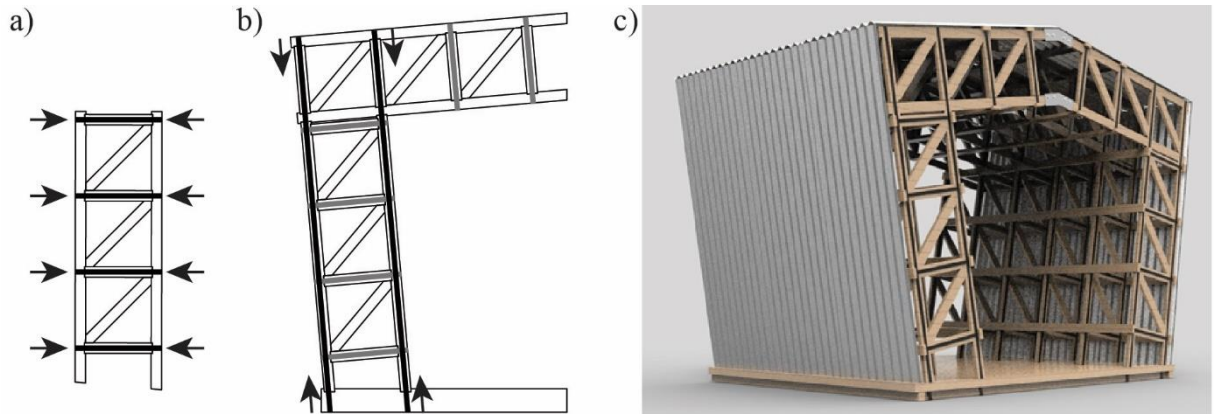

Figure 5: Truss frame temporary structure prototype. a) Repeated truss module (arrows indicate tension strap locations). b) Roof, wall, and floor cassette assembly. c) Complete structure.

The final structure had an internal width and height of 2.66m and 2.46m, respectively, and maximum external width and height of 4.72m and 3.21m, respectively. A single truss module used four 90mm x 35mm x 2400mm out-of-grade timber boards and 6m of strap. A paired frame, Fig. 1a, was 1.2m deep and used 12 truss modules and 36m of strap. Parts were fabricated in approximately 1 day by two people, using typical timber power tools (mitre saw, router). Truss modules were assembled in approximately

ten minutes each by two people; prefabricated cassettes were assembled in approximately four hours by three people; and the full structure took approximately two hours to assemble by four people. The fabrication and assembly effort relative to other systems will be discussed further in Section 4.

3. Strap clamp connection system

3.1 Connection design

In prior strap-based connection designs, both for the truss frame connection above and the system in [9], stiffness is limited by perpendicular-to-grain bearing stiffness and ultimate strength is limited by tensile strap capacity. A new connection system was thus developed to avoid primary load transfer through these components, instead using the strapping elements to facilitate connection assembly.

With reference to Fig. 6, the 'Strap Clamp' connection is an adapted form of a mortise-and-tenon joint, modified to allow low-effort fabrication from engineered timber member. The system considers an entire timber member as the 'tenon'; plywood plates are nailed onto adjected members to build up a 'mortise' to receive the tenon. When subject to flexure, load transfer occurs as shear load into nails and plywood plates, and then compressive bearing between plywood plates and tenon members.

For symmetric load distribution, the connection requires a double-member arrangement in one of the connecting members. Two options for this are shown in Fig. 6. In Fig. 6a, the mortise is split between outer and inner surfaces of a single vertical member, to receive two horizontal tenon members. In Fig. 6b, the mortise is contained within two vertical members, to receive a single horizontal tenon member. Assuming the same plywood width for both cases, the connection bearing area is the same and so joints are expected to have a similar capacity.

The split member arrangement helps to simplify the practical construction of the joint; members can be attached separately in the transverse direction, rather than having to align and insert the full-length member as a pseudo-tenon. Assembly effort and structural performance are also strongly influenced by joint tolerance, controlled here by spacing of the plywood plates. A tighter fit will create a stiffer connection [13, 14], make manual assembly more difficult. Thus, the straps are used to apply a clamping stress that forces parts into a correct and snug-fit alignment, while being removable for disassembly.

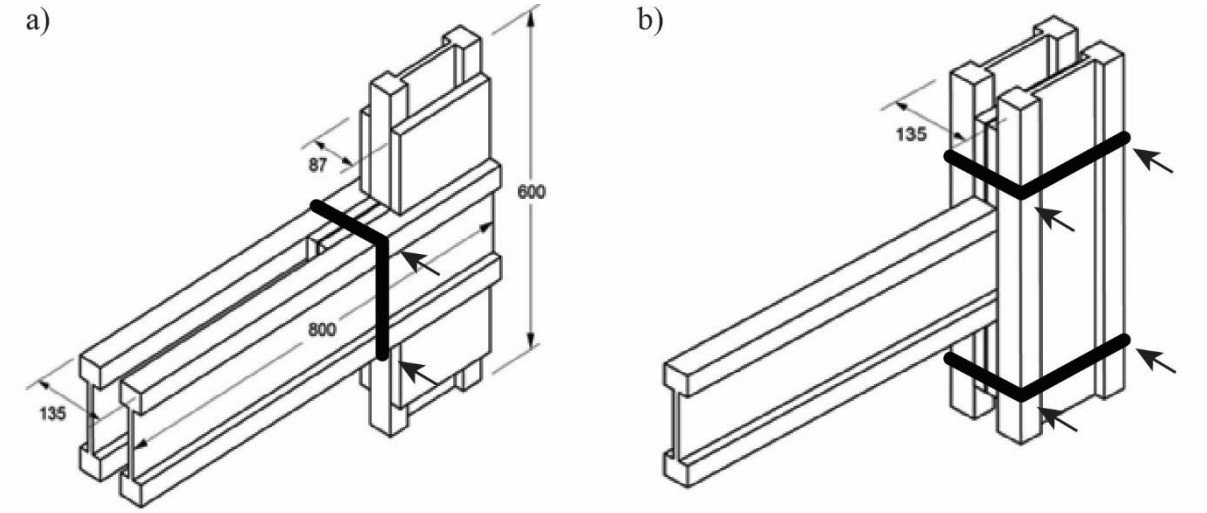

Figure 6: Strap Clamp connection system, with a) double-tenon or b) double-mortise split member arrangement. Strap clamp and assembly direction indicated by arrows.

3.2 Structural performance assessment

3.2.1 Specimen Fabrication and Testing

Strap clamp joints were tested using a similar methodology to that described above for strap truss connections. Three samples each of two specimen groups, A and B, were fabricated to correspond to connection arrangements in Fig. 6a and b, respectively. Connections utilise 'ej20045' timber I-joists, provided by Wesbeam and with flange width w_f = 43 mm, flange height h_f = 38.5 mm, web width w_b = 10 mm and total height h = 200 mm. Plywood plates are 200mm x 150mm x 22.5mm and fixed with six 50mm x 2.87mm D-head strip nails (three nails per I-joist flange). Specimens were hypothesised to be sensitive to this nail arrangement. Three additional specimens were fabricated to conduct a preliminary investigation of this: B0a, B0b, and B0c types with six, four, and ten nails, respectively. Due to time restrictions, only a single specimen for each type was fabricated, noting however that B0a is equivalent to Group B specimens.

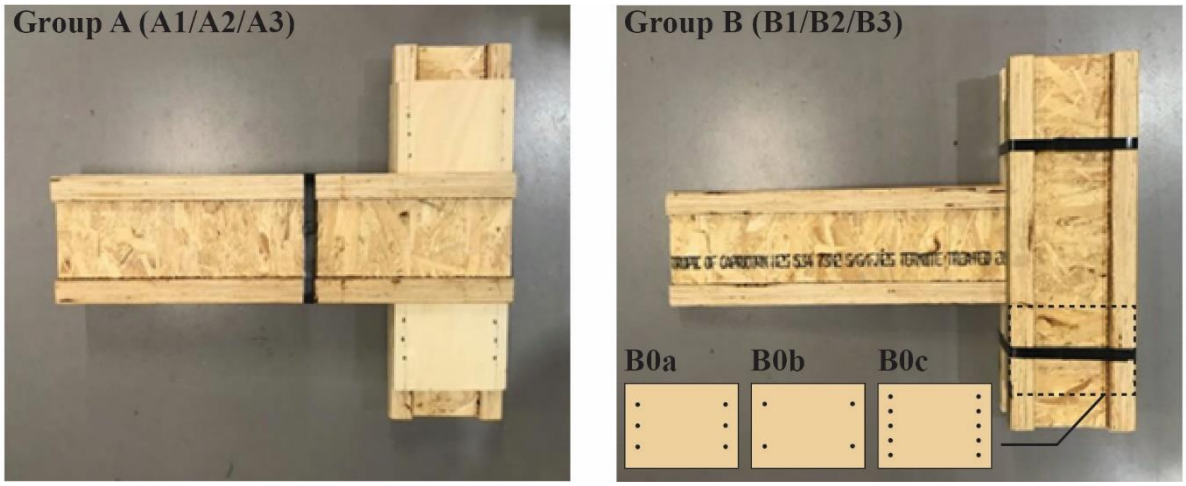

Figure 7: Figure 3: Strap Clamp connection test specimens.

3.2.2 Results

Moment-rotation curves for Strap Clamp connection Groups A and B are plotted in Fig. 8a-b. Curves for nail-varied specimens B0a-c are plotted in Fig. 8c, and alongside all specimens in Fig. 8d. Response values are summarised in Table 1b.

Group A and B responses are very similar, confirming that the distribution of the bearing area, via internal or external attachment, does not strongly influence connection behaviour. Overall, the strap clamps are less stiff than strap truss and prior strap connections; the stiffness range of 62-121kNm/rad for Strap Clamp connections is also smaller than values reported for traditional mortise and tenon connections with similar dimensions[15]. For most specimens, failure occurred as ductile shear failure and rotation of the plywood plates, with local crushing of the timber and some nail withdrawal. In a single specimen, B0c with ten nails, some perpendicular-to-grain crushing was also observed in the flange of the tenon member. The observed response shape is consistent with similar ductile failure modes in direct shear loading of dowel-type timber fasteners [16], with an initial elastic region and subsequent softening. Structural capacity can be seen to be strongly influenced by the nailed plate, with the lowest and highest strength and stiffness recorded for 4-nail B0b and 10-nail B0c specimens, respectively. The performance of the joint could likely be further improved with closer design consideration of these connection components.

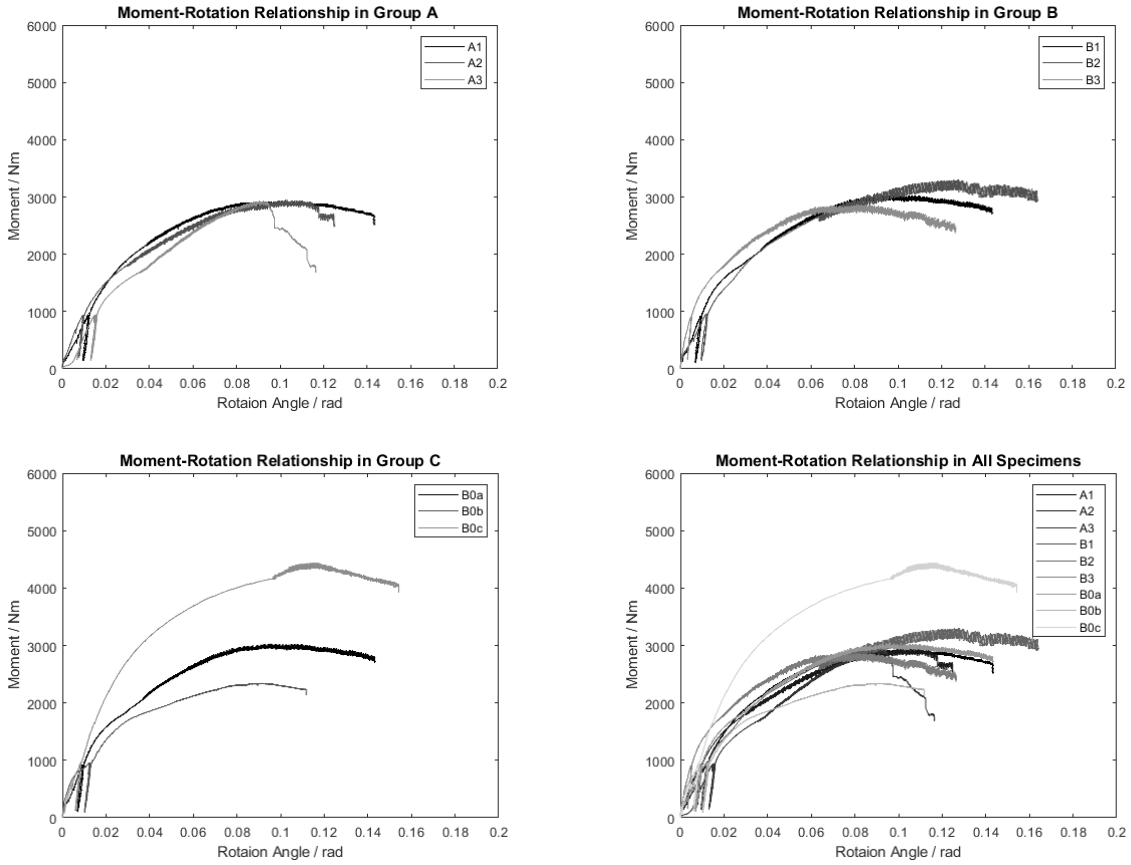

Figure 8: Moment–rotation curves of strap clamp connections. From left-to-right, top-to-bottom: Group A, B, and B0a-c specimens; all specimens.

3.3. Constructability performance assessment

A full-scale temporary structure was built using the strap clamp connection system, termed the 'Bush Hut' and pictured in Fig. 1b. The structure used a sway frame construction, with floor joists connected to wall elements using the double-mortise split member arrangement; and wall elements connected to roof beams using the double-tenon split member arrangement. With reference to the construction sequence shown in Fig. 9, ground anchors and bearers were first installed on a 2400mm x 2400 mm grid. Sway frame parts were fabricated offset, assembled on-site, and lifted onto floor bearers at 1200mm centres. Additional floor joists were placed at 600mm spacing to support floor sheeting and battens were installed at approximately 600mm centres to support wall and roof sheeting. To avoid having to work at height; roof sheeting was pre-fixed to battens while on-ground; a lifting mechanism was then used to lift up the ceiling to slide onto the primary structure. The ceiling was then fixed from underneath using tension straps wrapped around battens and roof beams.

The final structure had an internal width and height of 2.4m and maximum external width and height of 2.9m and 3.1m, respectively. A single sway frame used three 6m long timber I-joists (2.8m + 3.0m floor and wall part; 3.2m + 2.7m roof and wall part; 3.0m + 2.7m wall parts), eight plywood plates as sized for connection tests, and approximately 8m of strap. Frame parts were fabricated in approximately 1 day by 2 people, using typical timber power tools (mitre saw, nail gun). The entire structure was assembled in approximately 1 day by 6 people, including foundations but excluding wall sheeting. Wall sheeting was installed later in 4 hours by 3 people. Frame parts were assembled in 10 minutes each, on the uneven site ground and without issue, as the clamp joint was able to correct for small misalignments.

Figure 9: Construction sequence of 'Bush Hut' temporary housing sway frame structure built with strap clamp connections. From left-to-tight, top-to-bottom: footings and bearers; first strap clamp frame; all strap clamp frames; battens; floor sheeting; roof lifting mechanism; prefabricated roof cassette; lifted roof; installed roof.

4. Discussion

The relative performance of the Strap Truss (ST), Bush Hut (BH) and Strap House (SH) housing prototype previously reported in [9] is summarised in Table 2. Relative material cost, Table 2a, is evaluated using 2023 retail prices of constituent materials. The out-of-grade timber materials used for the ST prototype ($217/m^2) significantly reduce the housing cost as compared to BH ($587/m^2) and SH ($713/m^2) systems. The BH system is also cheaper than the SH system by requiring fewer I-joist components per square meter of building.

Relative labour effort, Table 2b, is evaluated as build time multiplied by the number of required people, and of 1 day being equal to 8 hours. It can see that the lower material cost of out-of-grade stud comes at the expense of a much higher labour effort for the ST (22.6 person-hours/m^2) as compared to the BH (13.2p.h./m^2) and SH (6.3p.h./m^2) systems. The SH system is relatively slower that the BH system as cladding layers could be partially pre-assembled to include structural frame elements. Finally, relative structural performance is summarised in Table 1c from connection experimental test results.

Table 2. Comparison of Strap House (SH) [9], Strap Truss (ST) and Bush Hut (BH) temporary housing prototypes: a) material cost, b) labour effort, and c) structural performance. Note: SH price updated to 2023 material cost.

a)

Element	Material	Cost		
		SH	ST	BH
Structure	I-beam	$ 793	$ -	$ 2,331

	SH	ST	BH
Fabrication	8	16	16
Pre-Assembly (Offsite)		48	-
Final Assembly (Onsite)	1	8	60
Total	*9*	*72*	*76*
Total per sqm	*6.3*	*22.6*	*13.2*

c)

Structural Performance	Connection test		
	SH	ST	BH
Initial Stiffness (kNm/rad)	111-141	114-219	49-121
Ult. Moment (kNm)	1.3-1.4	4.8-5.8	2.9-4.4

5. Conclusion

This study has proposed two new connection systems for low-cost and rapid assembly of temporary timber structures. A Strap Truss connection system enabled connection between out-of-grade timber materials and thus achieved a very low cost overall cost for final building assembly. A Strap Clamp connection system used a strap-fixed, pseudo mortise-and-tenon joint to create a fast, deconstructable, and low-effort assembly system using engineered wood products.

Abstract

Developing new solutions from the historical and traditional experience, in order to provide superior performance, is currently become a priority in civil engineering research. The most important features of sustainable building are represented by materials derived directly from surroundings, obtained from local, often family-run businesses, supporting the local development and cultural independence of the region. The objectives are to build with simple techniques that do not further pollute the environment, do not consume more fossil fuel, and do not extract unnecessarily resources. Earthen architecture can be linked to a technological continuity common all over the world, dating back to ancient periods. In this aim, clay mixtures are able to be successfully used to build masonry bricks, mortars, plasters and finishes. The paper presents experimental studies and results made in the field of eco-friendly building materials, emphasizing significant contributions for revaluation of traditional and local construction materials, along with conservation of natural resources, protection of landscape and bionetwork.

Keywords: sustainability, natural resources, eco-friendly building materials, recycling, environmental compatible structures, structural materials

1. Introduction

The present global economic and social context has a high impact on the built environment. The full life-cycle of a building has to be considered from early design phase [1], with reference to: integration in the urban environment, planning with regard to economical land use and inclusion of green spaces, placing and shaping the building in relation to natural light, wind effects and passive solar heating, using local, traditional building materials, preservation of the site and vegetation integrity during all construction activities, along with the selection of native plants in landscape design. This approach involves and sustains protection of natural resources, minimizes emission levels and waste production, by achieving energy efficiency, and allowing materials and equipment to be reused.

An ever-increasing turn towards tradition arises from the need of society to have its own identity, to keep in touch with the identity of the nation it originates from, and not to lose the traditions that define it [2]. Constructions made of earthen materials can be found all over the world, mainly in rural areas, both in less developed countries as well as in economically developed ones [3], therefore, many countries have proposed and implemented standards and regulations for earth housing construction.

The recent trend of green-building construction concept underlines the importance of an environment-friendly management of materials throughout their entire life-cycle [4], from resource extraction, during the fabrication phase, on-site installation, use, maintenance and post- utilization. By supporting the local development and cultural independence of the region, the use of these materials meet the objectives to build with simple techniques that don't further pollute the environment, don’t consume more fossil fuel, or unnecessarily extract resources. For the ease of recycling, as well, the natural materials are preferred.

2. Materials and methods

The terms related to natural building refers to any sort of construction that is accomplished with the use of materials, and techniques with reduced environmental impact, as well as building measures that minimize the use of products that require considerable embodied energy for their manufacture or transportation.

Earthen architecture can be linked to a technological continuity common all over the word, dating back to ancient periods. Incorporating ancient and traditional construction techniques into contemporary sustainable building practices offers several opportunities to address modern challenges in the construction industry, the reason why many countries have proposed and implemented standards and regulations for earth housing construction [5], [6], [7]. By understanding the advantages of these time-tested methods, architects, engineers, and other professionals can develop innovative, environmentally friendly, and culturally sensitive building solutions:

- Climate-responsive design: Ancient construction techniques have evolved to suit specific local climates and environmental conditions. By studying these techniques, designers can develop climate-responsive buildings that efficiently regulate indoor temperatures, reducing the reliance on mechanical heating and cooling systems and minimizing energy consumption.

- Local material sourcing: Traditional construction methods often employ locally sourced materials, reducing the need for transportation and associated carbon emissions. Embracing these practices can support local economies, minimize environmental impacts, and promote the use of sustainable, low-impact building materials.

- Bioclimatic architecture: By analyzing ancient building methods, designers can learn how to create structures that harmonize with their natural surroundings. Bioclimatic architecture integrates passive design strategies, such as natural ventilation, day lighting, and solar gain, reducing energy consumption and enhancing occupant comfort.

- Community engagement and empowerment: Ancient construction techniques often involve community participation, fostering social cohesion and empowering communities in the building process. Integrating these practices into modern construction projects can promote affordable, inclusive, and culturally sensitive housing solutions.

- Preservation and adaptation of traditional skills: Integrating ancient techniques into contemporary building practices helps preserve traditional knowledge and craftsmanship. By adapting these techniques to modern requirements and materials, designers can develop innovative solutions that merge the best of both worlds, creating durable, sustainable, and culturally relevant structures.

- Circular economy in construction: Ancient techniques often employ biodegradable and recyclable materials, minimizing waste and promoting resource efficiency. Incorporating these practices into modern construction projects can support the transition towards a circular economy in the industry [8], where materials are reused, repurposed, or recycled at the end of their life cycle.

- Resilience and durability: Traditional building techniques have proven their durability and resilience over time [9]. By integrating these methods and principles into modern sustainable construction, designers can create structures that withstand the test of time and adapt to changing environmental conditions.

Advantages of clay based compositions are mentioned in literature [10], [11], [12], as being environmentally friendly, easy obtained with little financial and energy effort, adaptable to users' needs, helping to regulate indoor air relative humidity, with no toxic emissions, being fire resistant, as well as resistant to insects, rodents and mold attack. Clay mixtures can be successfully used to build masonry bricks, mortars, plasters and finishes. There are various benefits and advantages of traditional clay-based construction techniques in the context of sustainability and environmental concerns:

- Local and natural material sourcing: Traditional clay-based construction techniques often utilize locally sourced materials, reducing the need for transportation and their associated carbon emissions. This approach supports local economies and minimizes the environmental impact of material extraction and production.

- Low-cost and community-driven construction methods: Traditional clay-based construction techniques are often cost-effective and rely on community participation, making them accessible to a wide range of people. This promotes social cohesion and empowers communities to be involved in building their own homes and public spaces.

- Adaptation to local climate and environmental conditions: Traditional clay-based construction techniques have evolved over time to suit specific local climates and environmental conditions. This adaptation ensures that buildings are resilient and well-suited to their surroundings, minimizing the need for additional energy inputs and reducing the overall environmental impact of the building.

- Energy efficiency and thermal properties: Clay-based materials have good thermal properties, providing natural insulation and temperature regulation. This helps to maintain comfortable indoor environments with minimal reliance on mechanical heating and cooling systems, reducing energy consumption and greenhouse gas emissions.

- Biodegradable and recyclable materials: Clay-based construction materials are often biodegradable and recyclable, making them an environmentally friendly choice. They can be easily reused or repurposed at the end of their life cycle, reducing waste and promoting the circular economy in the construction industry.

Despite of many advantages, some shortcomings and limitations are indicated by the literature [13], [14], [15], including the reduced resistance to water and moisture, being susceptible to erosion and damage, requiring proper site selection, drainage, and maintenance to ensure durability, the reduced resistance to seismic actions, being not suitable for regions with high seismic activity, as they can be prone to structural damage during earthquakes, the necessity of more frequent maintenance and repairs than in case of industrial construction materials, as well as the effort to establish the optimal composition of clay-sand-additions, which are varying from one extraction site to another [16], [17].

The research was performed in order to improve the mechanical performance of adobe bricks and the workability of local fresh clay mixtures. In this intend, a wide span of natural additives was studied, and different samples of clay mixtures material have been used in adobe bricks, mortar, and plaster for eco-friendly construction elements, made with products and resources from the nearby geographic area [18]. The clay material extracted from a natural deposit, usually referred to as loam, is a product of erosion of feldspar and other minerals, and as expected, does not represent a standardized composition. In order to determine the suitability of loam for a specific application, it is necessary to know its composition.

Depending on the site of extraction it contains varying amounts of clay, silt, sand, aggregate and water, resulting in specific properties. According to their ratio there are defined several types of clay based compositions and consequently, different samples of clay mixtures material have been used in adobe bricks, mortar, and plaster for eco-friendly construction elements.

The clay mixtures were made with products and resources from the nearby geographic area. The experimental mixes were made with soil extracted from a Transylvanian site. The granulometric analysis was determined according to prescriptions [19], by sieving method.

The granulation characteristics in correlation with data from the literature indicate that this soil is in accordance with the chosen purpose, having a sandy loam-type composition [20], as pointed out in Figure 1.

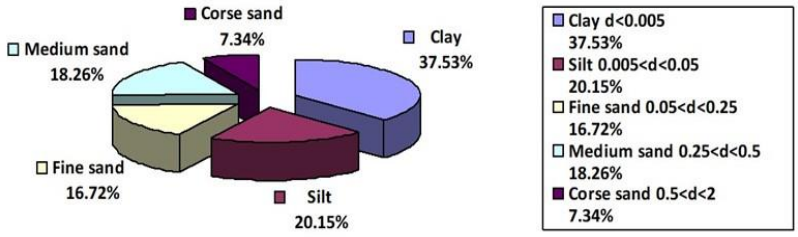

Figure 1. Characteristic texture and size distribution of the clay composition, see Călătan et al. [20]

The sand has a bulk density of 1500 kg/m3 and a size distribution presented in Table 1:

Table 1. Sand size distribution, determined by sieving method

Sieve size [mm]	0.063	0.125	0.25	0.5	1	2	4	8
Past [%]	0.5	1.6	8.8	28.5	59.6	82.4	98	100

A wide range of additions were studied, both theoretically and experimentally, throughout more than 50 mix recipes, and the use of following was highlighted: paste lime, bone glue, sodium hydroxide (NaOH), and salt (NaCl). In this regard, paste lime was analyzed according to SR EN 4592 [21], bone glue was purchased in granular form and dissolved in water, while sodium hydroxide (NaOH) and salt (NaCl) were procured as maximum purity substances, which are routinely used in the laboratory.

Experimental studies regarding the effectiveness of natural fiber disperse reinforcement in adobe bricks were conducted previously [2], [18], [20], [22]. The primary clay mixture was modified by introducing the vegetal fibers (hemp fibers and wheat straw, Figure 2).

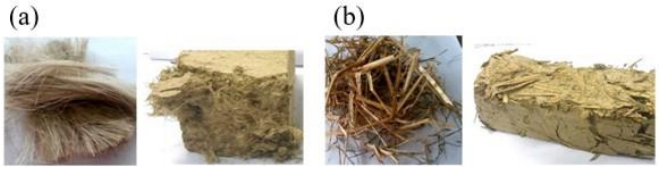

Figure 2. Fibers used in the preparation of clay mixtures: a) Hemp fibers; b) Wheat straw fibers, see Călătan [18]

Hemp (industrial hemp) is a species of plant that is grown specifically for the industrial uses of its derived products. It can be refined into a variety of commercial items including paper, textiles, clothing, biodegradable materials, paint, insulation, bio-fuel, food, and animal feed. The fibers are extracted from the hemp stem which is straight and has branches at the bottom. The stem's length varies between 1 and 3 m, and the thickness ranges from 4 to 8 mm. Hardness, durability and resistance to decay are included among the many characteristics of the hemp fibers.

Wheat straw is a harvesting agricultural by-product, rich in cellulosic fibers, available from the annually renewable crops, produced in large quantities, in numerous regions all over the world. Used as addition to building materials' composition, neither their production nor their use, even at the end of their life service, does harm the environment or health. Having high water absorption capacity, straw fibers have to be immersed in water in advance to avoid the phenomenon of water absorption from the clay matrix.

In order to determine the physical - mechanical parameters, samples have been made by casting in molds. Prismatic specimens of 40x40x160 mm were used to determine the bulk density of the material reached to equilibrium moister, the axial contractions, the flexural tensile strength and the compressive strength. Also prismatic specimens of 300x300x40 mm were used to determine the thermal conductivity based on the heat transfer property of the samples, through the thermofluxmetric method, for an average temperature between plates, of 10ºC, as shown in Figure 3.

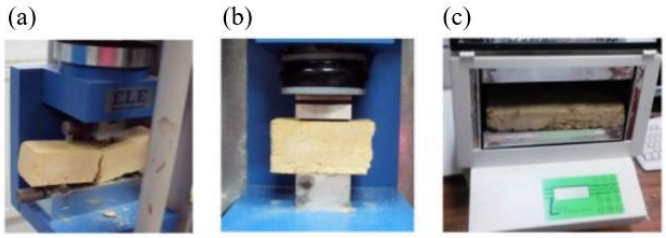

Figure 3. Specimens in test devices: a) Testing of the flexural tensile strength (Rf); b) Testing of the compressive strength (Rc); c) Determination of the thermal conductivity, see Călătan [18]

The witness specimen was conceived from the established composition, as the optimal one from the experimental research. The mix included sandy loam, sand, bone glue and paste lime, in proportions of 35% sand and 65% binder (composed of 79% sandy loam, 1% bone glue and 2% paste lime). The required water was established as 33% reported to the dry material mass. There were made three sets of witness specimens: optimal mixture, optimal mixture with straw addition and optimal mixture with hemp fiber addition. The proportion of vegetal fibers was determined as well, during experimental research [18], [22]. The composition was prepared by hand mixing of raw materials. After preparation the mix was placed in molds, in form of successive layers, each layer was then rammed until its thickness was reduced to half. After unmolding, the specimens were stored under laboratory conditions, at +23 ^{o}C, until reaching the equilibrium moister.

The specimens tested for mechanical strength were evaluated in following combinations: mixture of recycled clay material without vegetal fibers, mixture of recycled clay material with straw addition and mixture of recycled clay material with hemp fiber addition. The flexural tensile strength (Rf), was determined by applying a concentrated load at half of the distance between the supports, and the compressive strength (Rc), on the two resulted halves of the specimen.

The research aims to determine furthermore the optimal addition of vegetal materials, hemp fibers or straw, taking into account the main factors that must be observed in the production of sandy clay bricks: axial contractions, eventuality of appearance and evolution of cracks, bulk density, mechanical strength and thermal performance. For this purpose, vegetal materials were introduced into the clay matrix in various amounts, expressed as percentage by volume of the clay mixture. Thus, 3%, 8%, 9%, 10%, 12% or 15% volume of hemp fiber, respectively 10%, 20%, 30%, 40%, 50% or 60% volume of straw. Hemp fibers were used as such. Straws, having a high water absorption capacity, were used after being immersed in water for an hour, in order to avoid the water absorption phenomenon from the clay matrix.

From each mixture, a set of three prismatic specimens of 40x40x160 mm was made, to determine the bulk density, axial contractions and mechanical resistances. Another set of prismatic specimens, of 300x300x40 mm was dried in an oven until to a constant mass, and then placed in the apparatus to determine and to record the thermal conductivity. All specimens were kept under laboratory conditions until equilibrium humidity was reached. The workability of the mixture was tracked during the preparation of the mixtures and during the manufacture of the specimens. The appearance and evolution of the cracks was visually tracked as well.

3. Experimental data and results

By comparing the experimental results obtained for clay mixtures with paste lime, with the admissible limit values indicated in the literature [23], [24], it has been found that an addition of up to 3% paste lime in the mixture keeps the compressive strength within limits that meet the required conditions. The addition of paste lime has positive influences by reducing the axial contractions and thus, the risk of cracks, as the amount of paste lime used in the mixture increases. All these achieved mixes had axial contractions falling within the range of values recommended in the literature.

Gathering the obtained experimental results, it can be remarked that in the case of the using paste lime as a single additive material, the results are not satisfactory for more than 2% of paste lime because it induces significant reduction of the mechanical resistances. Bulk density is negatively influenced in this case; none of the tested mixtures reached the minimum density limit indicated in the literature.

From the view of mechanical strengths recorded in case of replacement of the mixing water with solutions of NaOH and/ or bone glue, it can be said that an improvement was generally found, with peak values for the mixtures made with 0.7% to 1.25% bone glue, as well as for the mixture made with 1.5% bone glue and 2% sodium hydroxide (NaOH) solution. Comparing the obtained experimental results with the admissible limit values indicated in the literature, it has been found that all mixing variants analyzed are in this case higher in value than the minimal compression resistance specified in the literature, which indicates that they are suitable for the intended purpose.

Following the analysis of the obtained results, it may be appreciated that in the case of sandy clay materials, for the identification of an optimal composition meant for building masonry elements of vernacular structures, it is advisable to consider the use of additions of sand and paste lime, along with the possibility of substituting the mixture water with a solution of bone glue and NaOH. This combination of several additive materials creates the possibility of identifying the mix to meet at best the criteria of thermal resistance by a satisfactory bulk density, and the criteria for the strength and durability (mechanical strength, axial shrinkage and water resistance), along with the need of minimum effort (in terms of energy consumption and resource efficiency) required in production and utilization.

The research emphasizes that the most beneficial additives were the bone glue and sodium hydroxide (NaOH). The optimal concentration of bone glue is 1.25% to achieve compressive strengths of about 4.1 MPa at 40 days (higher concentrations leads to mold grow). Bone glue was purchased in granular form and dissolved in water. An addition of 2% sodium hydroxide (NaOH) provides a better workability of the mixture and helps dissolve the bone glue faster. Also, the research revealed that the variation of the observed physical-mechanical parameters is influenced by the type of the organic material, hemp fiber or straw, and of the amount entered in the mixture. In conformity with literature [2], [3], [20], [22] an amount of minimum 5% but no more than 50% clay in the loam extracted from the natural deposit is optimal for obtain proper adobe bricks. By analyzing simultaneously all watched physical-mechanical parameters, for the used clay mixture, it was set an optimum addition of hemp fibers, of 9-10% by volume, respectively an optimal straw addition, of 30-40% by volume. Thus, it contributes to the completion of the information reported up to date in literature, and indicates the possibility of diminishing the dimensions of earthen walls, as well as maintaining the safety operation characteristics along with the thermal efficiency. The variation of compressive strength, flexural tensile strength, and thermal conductivity, depending on the amount of vegetal fibers included in the clay mixture is presented in Figure 4.

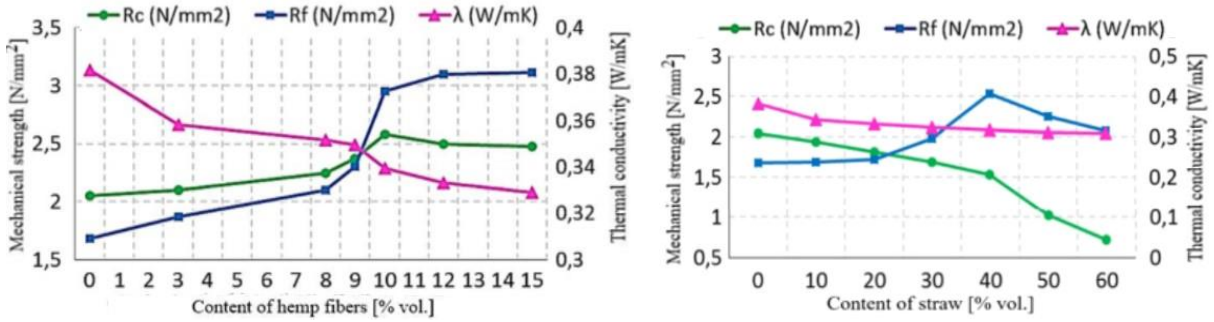

Figure 4. Variation of compressive strength, flexural tensile strength, and thermal conductivity (depending on the content of hemp fibers and straw), see Călătan et al. [22]

4. Conclusion:

In recent years, the circular economy has been endorsed as a policy to minimize burdens to the environment and stimulate the economy, and especially to reduce the redundant resource exploitation. There are promoted innovative business models that go beyond product preservation, along with strategies for multifunctionality [25], or use intensification of products, in order to prevent the unreasonably consumption of new products and consequently to prevent the unnecessarily exploitation of resources and generation of waste. Life Cycle Assessment should be used as a technique for determining the potential environmental aspects associated with products, processes and activities, through production, usage, and disposal, by identifying and quantifying energy and materials used, and wastes released to the environment [1], [26], [27].

Constructions made of earthen materials can be found all over the world, mainly in rural areas, and an ever-increasing turn towards tradition arises from the need of society to have its own identity, and not to lose the origins that define it. In this reason, the use of organic waste in building materials' production takes part directly in the field of sustainable construction. Adobe bricks composition for masonry contains different proportions of clay (as main row material, extracted from natural deposit), sand and various organic matter additive of animal or vegetal provenience, being dispersed reinforced with animal or vegetal fibers.

Using low cost materials and vegetal by-products, which are as well located close to the production centres, along with the possibility of recycling and introducing them again into the manufacturing processes (through the use of waste), could become an opportunity for improvement and sustainable development. The research contributes to the completion of the information reported up to date in literature, and indicates the monitoring possibility of earthen walls dimensions, along with the maintaining of safety operation characteristics, and their thermal efficiency. Integrating ancient construction techniques into contemporary sustainable building practices offers a wealth of opportunities for addressing modern challenges. By embracing the wisdom and expertise of the past, professionals can develop innovative, environmentally friendly, and culturally sensitive solutions that promote a more sustainable future for the construction industry.

Abstract

Current design for disassembly strategies largely rely on geometry relations between parts, with little thought given to the potential of inherent material properties to foster reversibility. This study investigates low-tech and low-energy methods for the assembly and disassembly of timber only structures, utilising reclaimed timber and wood's swelling and shrinkage to create reversible connections. The paper contributes with experimental data to demonstrate ideal assembly, in-use, and disassembly conditions, with significant changes in joint tightness between conditions. This practical approach is then applied in a truss structure, a component-based typology that is reconfigurable to different spans, geometries and scales. This specific design is evaluated using diagrammatic Statistical Entropy as well as reflections/considerations of the approach's opportunities and challenges. Finally, the paper offers insights into how the project can contribute to a more sustainable building practice, in balance with the resources it depends on.

Keywords: timber only structures, reclaimed wood, timber trusses, design for disassembly , timber connections

1. Introduction

Current pressures on the building sector to reduce its impact have provoked a necessity for materials to last longer than building lifetimes, requiring effective design for disassembly strategies [1]. This is important for materials like wood, that require relatively long regeneration periods compared to faster growing bio-based materials, such as hemp and straw. Therefore, design strategies that work towards material lifetimes in harmony with forest renewal is essential for creating regenerative building practices.

Structural parts of buildings are considered the most culturally and technically long lasting, as highlighted by Stewart Brand's Layers of Change principle [2]. This durability makes structural functions an ideal application for materials such as timber that require long service lives. The demolition and disassembly of long-lasting components invokes the dilemma of predicting future technologies, priorities, and scarcities. Therefore, design strategies that recognise this, and enable the greatest variety of future scenarios through either the direct reuse of entire components, their elemental parts, or through cascading are optimal for enabling extended material lifetimes.

Effective examples of biomass cascading succeed in keeping material in its solid form for as long as possible [3]. The cascading of timber in practice is currently limited, with the associated challenges of fixings, fasteners, adhesives, and contaminants contributing to low material yields in investigations applying salvaged material to structural applications [4] [5]. Furthermore, these aspects have contributed to low motivation from current industry to introduce reclaimed material to their existing timber product production [6].

Today's popular environmental impact assessments, such as LCA (Life Cycle Assessment) prioritise material volumes as a metric to evaluate impact, offering little indication of how effectively materials can be reused or repurposed. The types of interfaces and fixings between materials are more important parameters than volumetric quantities when assessing disassembly potential of building parts [7]. An alternative approach, Statistical Entropy, is a method that models how intertwined materials are, and subsequently a quantifiable indication of their separability [8]. The method models how material is distributed within a component or structure, therefore enabling recyclability to be assessed. This promotes mono-material design solutions and mechanical connections as an alternative to the predominant irreversible complications of multi-layered, multi-material, and adhesive oriented construction.

Today, the predominant focus in research into design for disassembly has revolved around geometric relations between parts. This is exemplified in the *design for dissassemly alphabet*, that outlines a series of interfacing strategies for enabling components to be separated from one another [9]. More radical architectural investigations include the complex spatial assemblies of discrete parts by Retsin et, al. and Kunic et, al. [10], [11]. Whilst these offer rich tectonic taxonomies and morphological potentials, they regard components as neutral, neglecting the capacity for materials to morph over time in response to their environment.

The investigative foundation of this study is two-fold. Firstly, to investigate the potential role of timber's inherent properties in design for disassembly strategies. Secondly, to investigate the potential of timber only connections for enabling the reconfigurability and reversibility of components, providing a greater material availability in future scenarios. The study is centred around trusses and multi-shear connections, both existing typologies that already demonstrate potential for utilising reclaimed timber in its solid form [12].

2. Swelling and shrinking in timber design

Swelling and shrinking occurs in timber during changes to relative humidity (RH) due to its hydroscopic properties, finding moisture content (MC) equilibrium with its environment. This phenomenon is well studied from science to craft and is included as a consideration in many applications for wood. In typical buildings, the most significant changes to RH are seasonal, however, there are also daily fluctuations. Wood is well known for its anisotropic structure, significantly impacting its mechanical properties. Anisotropy also causes non-uniform swelling and shrinkage during changes in MC, as a consequence of fluctuating RH. This trait is typically regarded as a deficiency in the design of timber structures and components. The Engineered Wood Product (EWP) Cross Laminated Timber (CLT) is an example where anisotropic movement is mitigated through the perpendicular laminating of lamellae. This works against rather than with a fundamental material characteristic, arguably leading to inefficient allocation of timber in building design.

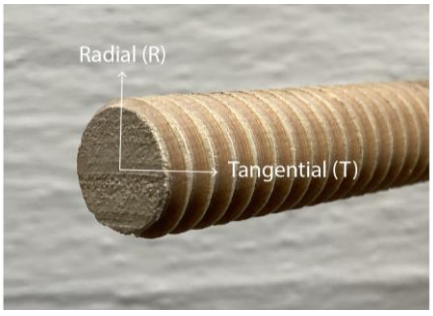

Figure 1. The radial and tangential axes of a threaded wood dowel, each with their own expansion coefficients.

3. Threaded timber dowel connections

Threaded timber dowels are less commonplace in building design than regular timber dowels and threaded steel dowels. They have however been applied to many technologies, such as early forms of fruit press, and remain in some examples of adjustable height timber stools today. In buildings, the *Nur Holz* product is an example of a deck type EWP utilising threaded dowels as an alternative to adhesives [13]. Whilst this succeeds in delivering a single material component, it is unclear as to whether this system is designed to be reversible, enabling dowels and boards of two different wood species to return to their component parts.

Steel bolts are well established as an optimal solution for reversible connections, as well as offering high strength to weight ratio and ductile structural behaviour. However, design contexts featuring large quantities of connections are disadvantaged by steel's high environmental impact.

This study aims to combine the reversibility made possible by threads with the renewability and low embodied energy of wood. Today, threaded timber dowels are available commercially, often intended for machines where metals must be avoided. Alternatively, they can be produced using simple, inexpensive tap and die hand tools in a variety of diameters (Figure 2). Earlier explorations have demonstrated the variety of possible threaded dowels, as well as their application in connecting irregular timber feedstock [12].

Figure 2. The tap and die set for wood used in this study.

4. Design Context

This study investigates the potential of threaded timber dowels for connections in structural members from reclaimed timber. Multi-shear truss connections are the specific focus, motivated by a need to develop alternatives to the adhesive dependent EWPs common today, and the steel connections typical in traditional trusses. Furthermore, the paper expands on the potential of reversible threaded dowel connections in full scale component design. This demonstrates how reclaimed timber can be efficiently allocated to timber trusses, and later reconfigured for second and third building applications.

Previous studies investigating the potential of reclaimed timber for structural applications have demonstrated the potential of threaded dowels to connect elements with irregular surface geometries. Many of today's EWPs are dependent on reliable material feedstock, toxic adhesives, and centralised fabrication; each of which have an impact on environmental performance. The proposed multi-shear truss layup (Figure 3) aims to challenge these three aspects by featuring irregular timber feedstock, mechanical timber fastenings, and low-tech fabrication techniques.

Geometric irregularities, physical contaminants, and short lengths often determine timber's rejection from EWP production, leading to significant quantities meeting premature energy recovery. Strategies for utilising this material for EWPs with minimum processing have shown potential at a prototype level [12]. This demonstrates that the accurate interfaces required for adhesive connections can be alternatively achieved with threaded dowel fastenings, that lock elements along the fastener, as well as in shear. A system can be designed to work with a domain of element cross section dimensions. This domain can be calibrated with a constrained stock, especially as reclaimed material typically falls into dimension categories informed by sawing standards, as opposed to being completely randomised [14].

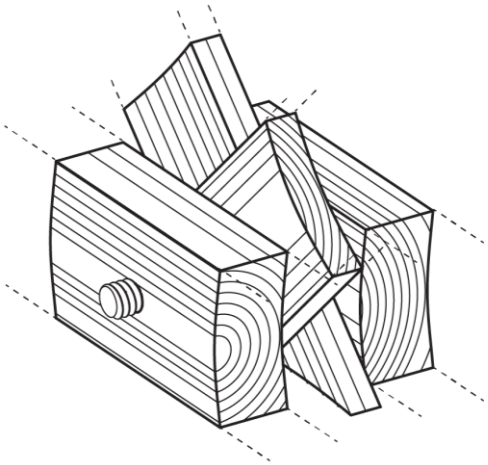

Figure 3: Truss elements with irregular timber stock featuring *cupping*, preventing proper interfacing.

At the component scale, maintaining the inherited properties and qualities of salvaged timber has two aims. Firstly, processing of imperfect geometry is minimised, meaning the volume of material yielded from the waste stream is as high as possible. This provides optimum carbon storage, reduced energy usage, minimal processing infrastructure, as well as maximising the volume of material available for future uses. Secondly, the spectrum of tones and textures inherent to timber and developed over time is retained. This presents the opportunity for components to express the diversity of material origins, offering a visual representation of salvaged timber's provenance- a notion that contrasts to the relative aesthetic homogeneity of single specie EWPs.

Furthermore, short lengths are a common attribute of undervalued reclaimed timber, aligning well with truss typologies. This further enables salvaged timber to be utilised in its inherited from, without the need for processing and finger jointing to elongate elements.

Despite the general functioning of threaded dowels in previous studies, inserting dowels demanded inconsistent torque and in some cases resulted in spiral fractures of dowels, causing them to be immobile and presenting a production problem for the remainder of the component. These challenges, and unpredictable behaviours motivate a need to develop a more calculated production approach to utilising threaded dowels, with calibrated relations between the parts and the varying stages of a components' lifetime: assembly, in-use, and disassembly.

Lastly, the development of structural components that are optimised based on a constrained stock is gaining momentum. Bruttning et, al have developed numerous studies on structurally optimal morphologies from a constrained stock of steel elements [15], [16].

5. Materials and testing method

A method was devised to measure the torque of threaded dowels in multi-shear connections after exposure to contrasting environmental conditions. Through testing, the study intends to determine ideal conditions for the assembly, in-use, and disassembly of connections. With the in-use condition resembling the domain of typical indoor RH, where tight connections are considered optimal.

Capitalising on the dimensional change occurring when exposed to varying RH and temperature environments, threaded dowels can be assembled with a designed level of torque. To reduce variables in the study, virgin single species timber for the truss elements combined with single species and dimension dowels was selected.

Grade C14 spruce samples and 19mm birch dowels were conditioned at (20 ± 2) °C and (65 ± 5) % relative humidity until they reached constant mass. This conditioning space is hereafter referred to as *ambient* for the duration of the study. The spruce was planed and cut into pieces to resemble single multi-shear connections (Figure 4), followed by a 16mm hole drilled into the centre. The birch dowels settled at an average of 12.3% MC during conditioning. These dowels were cut into 200mm lengths, before having threads cut with the die. The die is adjustable and was calibrated after initial assembly tests. It is important to note the limited accuracy of the tool's adjustability, making precise thread sizes challenging to define. Lastly, threads were cut into the spruce connection samples with two passes of a tap.

Torque was measured using a customised attachment between the birch dowels and a torque wrench with a measurement range of 1.6-14 newton meters (Nm). Ca. 2Nm is considered hand tight, and therefore an optimal target for assembly and disassembly readings. During assembly, an oven at 60c was used to induce shrinkage. This temperature reduced RH to ca. 10%, and ensured dowels were cool enough to handle. Measurements were taken every 15 minutes, recording maximum torque and distance from complete assembly if torque exceeded 6Nm prior to full assembly. This maximum is introduced due to drier, more brittle dowels splitting under torque higher than 6Nm during pre-experiments.

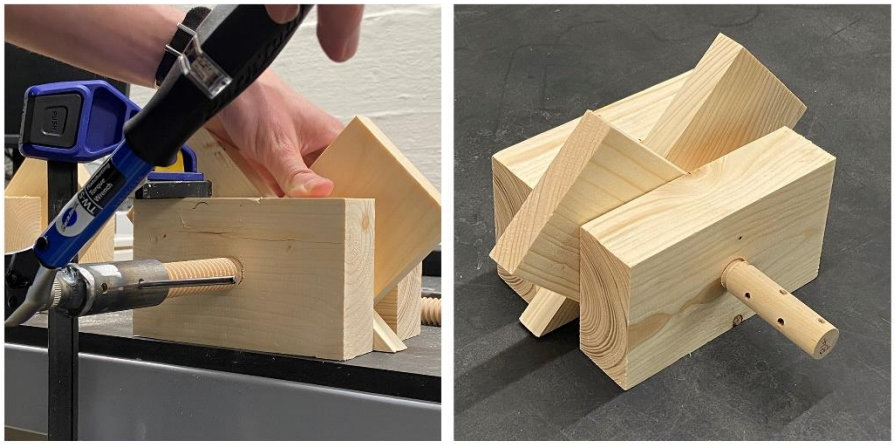

Figure 4. Torque measuring setup (left) and assembled sample (right).

During in-use, the assembled samples are returned to ambient condition. Timing is less critical in this stage, as the conditions are less extreme, and a production scenario needn't require an instantaneous tight joint during equilibrating with ambient conditions.

For disassembly, the oven's temperature was reduced to 45c, as the dowels are insulated by the spruce and are expected to require a more extended and slower drying period prior to dowel removal.

6. Results

6.1 Initial experiments (Figure 5)

After determining the average MC of a batch of uniform dimension birch dowels, an assessment was made of how quickly the MC would decrease. Initial tests, recording moisture content changes, by weighing samples at 15-minute intervals when exposed to 60c, demonstrated that significant moisture losses occur in the first 30-45 minutes. It is also shown that this is where the most significant dimensional change takes place, although reductions in the transverse direction are minimal, and undetectable in the radial direction.

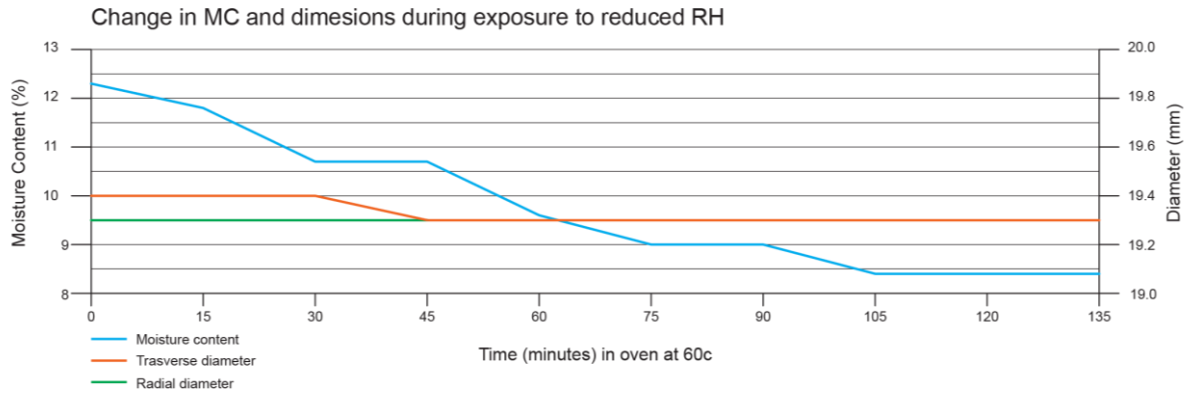

Figure 5: Change in MC and dowel diameter dimensions during exposure to reduced RH.

6.2 Assembly results (Figure 6)

The 5 sets of spruce samples with corresponding dowels each show the same trend despite noticeable torque variation between sets. Some samples required longer drying times to reach the target torque of 2Nm, such as B2. Earlier tests demonstrated slowed reduction in MC after 90 minutes, this corresponds with the torque reduction shown in the assembly tests, exemplified by B2 and B4.

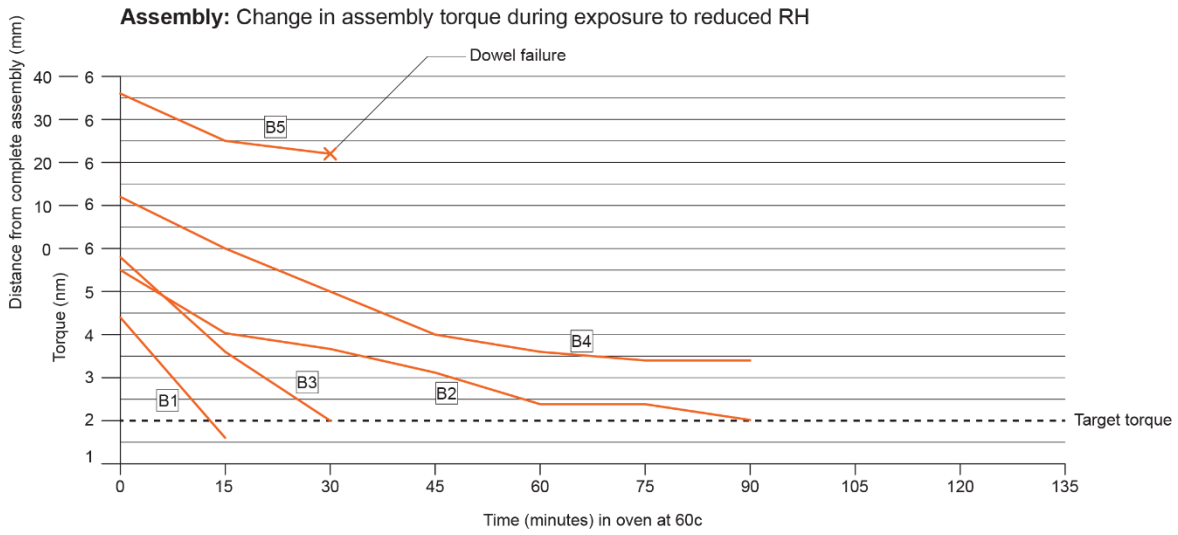

Figure 6. Change in dowel assembly torque during shrinkage due to exposure to reduced RH. Dowel B5 failed in torsion at the third measurement. The y axis shows two scales as some samples could not be fully assembled with 6Nm of torque.

6.3 In-use results (Figure 7)

Upon returning the samples to the ambient environment previously used for conditioning, the threaded dowels swelled, returning the torque readings to a similar value shown in beginning of assembly. A single dowel sample that had followed the environments of B1-B4 returned to its original MC after 1 day. The four assembled samples follow a similar trend, though the highest recorded torque is inconsistent, and almost all samples showed a reduction in tightness towards the end of the measurement period.

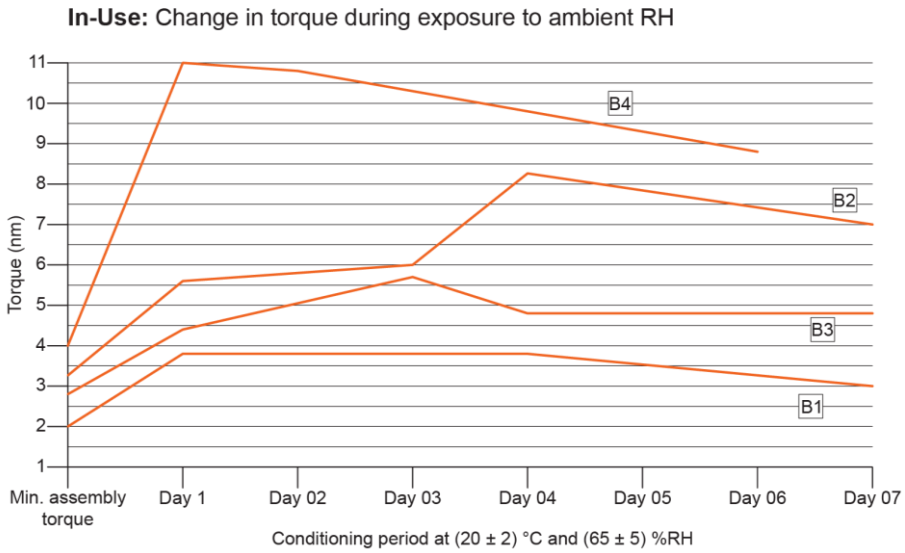

Figure 7. Change in dowel torque during swelling due to ambient exposure to RH. The first values correspond to the last values in figure 6.

6.4 Disassembly results (Figure 8)

The disassembly results show that all samples reached the target torque of less than 2Nm after 3 days.

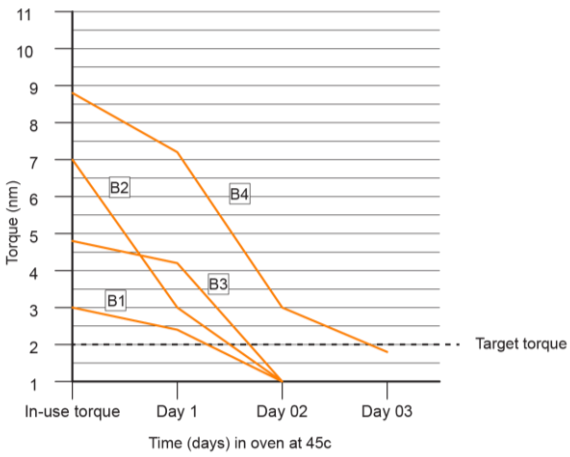

Figure 8. Change in dowel torque during shrinking in oven at 45c. The first values correspond to the last values in figure 7.

7. Applying the connection to a component

The reversible connection is contextualised in multi-layer truss type structures, Figure 9 shows a truss concept that applies the multi-shear threaded dowel connection. Truss component typologies can be applied to a spectrum of scales and building types, subsequently making them appropriate for applying a variety of reclaimed wood dimensions.

Figure 9. Truss concept with threaded dowel connections, featuring a variety of timber tones and geometries, assimilated into a rectilinear component. - Rendered elevation

MC is a crucial parameter to the success of the approach and can be challenging to accurately record and monitor in an industrial context as devices depending on probes and surface readings are not always reliable.

To overcome this, a *tracer* element with a known weight and MC can be continuously weighed to monitor fluctuations in MC of the dowels, providing that the tracer is always exposed to the same conditions as the dowel group. This would enable fabrication staff to know when MC is optimum for cutting dowel threads, and for how long they should be dried prior to assembly. The reliability of this approach would require a further study, as well as an investigation of its suitability in production environments.

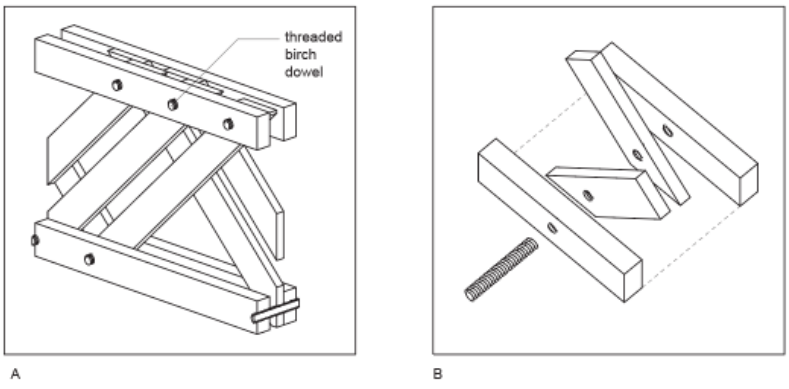

Figure 10. A: Multi-layered truss – isometric. B: Truss connection, using threaded wood dowels – exploded isometric.

The truss concept utilises semi-standard web elements, each of which are cut to the same length with 45° end angles. This intends to negotiate a balance between the irregular characteristics of timber waste streams and the standardisation preference of current production practices. Furthermore, as the assembly system is forgiving of variability, it can be applied to a variety of production methods, from low-tech crafting to full automation. This responds to the introductory problematic of predicting the future

technologies, priorities, and scarcities that ultimately determine how components are assembled, used, and disassembled.

7.1 Evaluating reversibility- Statistical entropy

A study by Roithner et, al., presents methods for making a recyclability assessment of two case study buildings [8]. This introduces methods for quantifying how materials are spatially distributed, how they are connected, and ultimately how easily they can be recovered for future applications. They apply Statistical Entropy (SE) as a means to measure how *mixed* materials are, and therefore their recoverability potential. A lower SE corresponds to fewer parts or materials, and a higher SE the opposite, the former being considered more ideal for recyclability.

SE is applied in this study in diagrammatic form (Figure 11) to make a comparison between the truss concept and a conventional glulam element from three perspectives: Complexity, Disassembly, and Material Concentration. From a complexity perspective, the truss is shown to have higher SE, due to its larger number of parts. From a disassembly perspective, glulam is shown to have higher SE due to the parts being inseparable. Finally, from the perspective of material concentration, the glulam is shown to have higher SE due to the two different materials, wood and glue, being intertwined, whereas the truss is a mono-material component. These three perspectives provide an alternative method to conventional LCA for approaching the reversibility of building elements, as well as what might be prioritised. For example, the truss's complexity may require significant steps to take a part, but it is made possible due to the type of fastening.

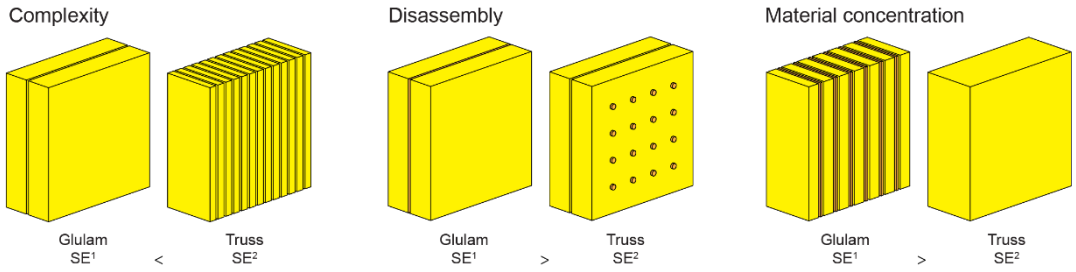

Figure 11. Statistical entropy diagrams of the truss concept compared to a glulam, from the perspective of Complexity, Disassembly, and Material Concentration.

8. Reconfigurability in context

To further the contextualisation of the reversible joints, the study continues to demonstrate how reconfigured elements might work in practice. The same stock of component parts can be applied to a range of structural requirements, with each truss retaining the same exterior component geometry. This contrasts to conventional glulam practises, that although graded, generally require geometric changes to match design loads. Here, web elements can be allocated to create distributions of material and quality to meet specific functional demands. This approach can be applied to a series of components, each with the same geometry, that have varying load cases within a single building. Alternatively, as a series of load cases across a series of buildings over time.

Reconfigurability can take place during changing requirements to a building's programme, or after disassembly, to reallocate material for a future structural function. This approach enables the same

material to cater to multiple building applications over time, each with their own specific performance demands, and with little or no loss of material between applications. Below, two examples are given showing the same component type with unique load cases. These load cases define how a varied stock of material is allocated, and due to the flexibility of the truss concept, each web member can be of a different dimension. The two examples could represent individual components within the same building, or two components produced from the same elements, a building lifetime apart.

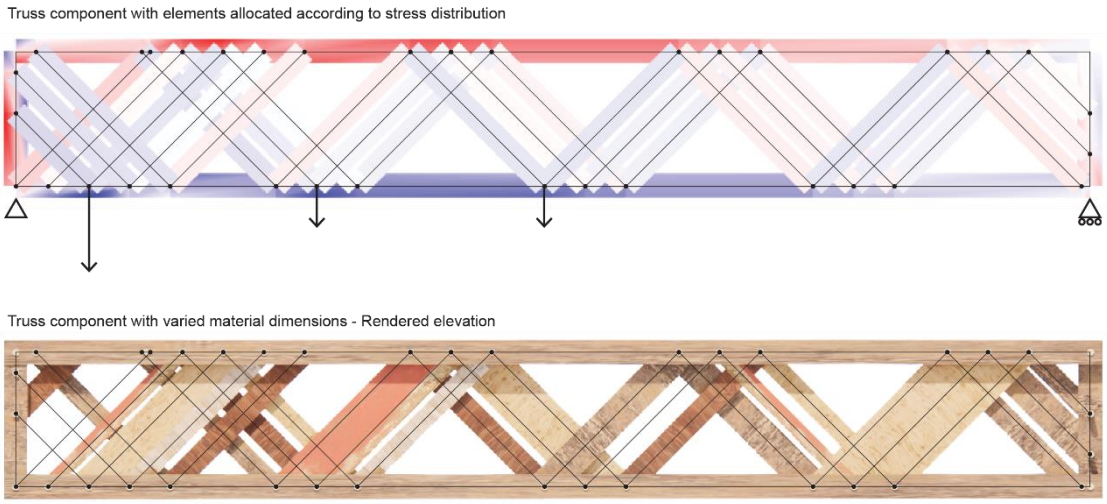

Figure 12. Building application 01- optimum material distribution for a specific load case

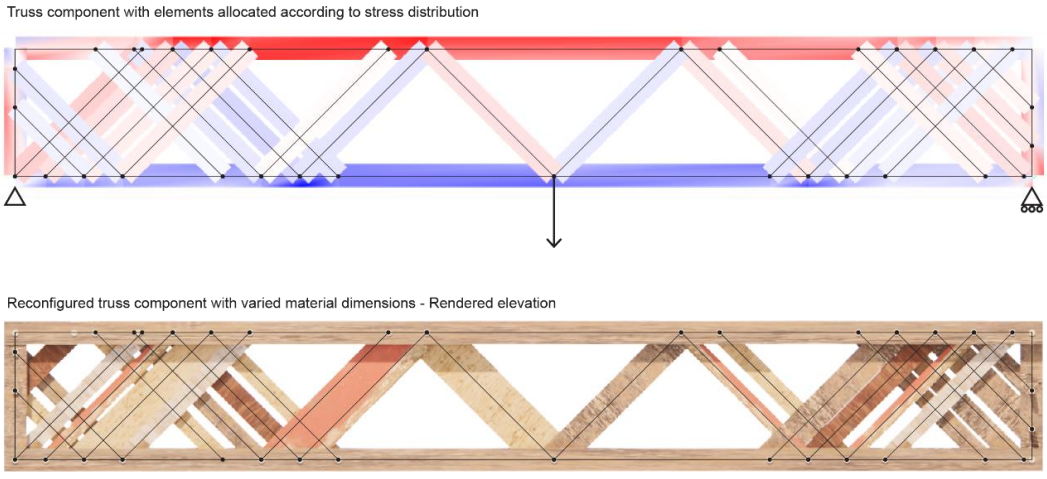

Figure 13. Building application 02- optimum material distribution for a second specific load case

9. Discussion

The study offers an initial investigation into a method for applying reclaimed timber to structural applications. This combines the opportunities of integrating timber's movement in joints with a reconfigurable component design. Together, these intend to enable components to meet the specificity of their function, in close dialogue with the inherited forms of secondary materials.

Within the presented project, the principle aim of harnessing timber's geometry fluctuations to create reversible connections has been demonstrated. The investigation achieved an increased understanding of optimum drying times, swelling 'tightness', and the reversibility of threaded dowel joints. It is important to state that the time periods required to create effective geometry changes are within practical domains. For example, a drying period of less than 2 hours is required prior to assembly, and joints become tight after only one day. Furthermore, disassembly is achievable within a short period, increasing the feasibility of such an approach to be adopted at a larger scale.

Working with fundamental material properties, that have been known and utilised for centuries, leads to the conclusion that the relevant knowledge to reverse these connections will be available in the future. This challenges design for disassembly solutions that require new technologies or highly specific knowledge, often becoming obsolete after a time period relatively short compared to a potential building's lifetime.

Further work would benefit the reliability of the approach, that showed surprising variability considering the consistency of materials and method. This may include other impacting parameters not found or considered in this investigation. Reliability is likely to be more challenging when applying the approach to reclaimed material, where material heterogeneity is more acute. The range of properties occurring in waste materials is likely to present varying performances. A future study with increased scope would benefit from longer term monitoring of dowel joints, with comparisons between controlled conditioning environments and the real-life RH fluctuations of a building's interior- ideally tested over the course of 1 year, to include the full spectrum of RH conditions.

This investigation proposes an alternative to the recent traditional paradigms of efficiency, that tend to prioritise a reduction of material volumes, an increase in material strength, and focus on a single application. In contrast, the approach investigated and presented in this paper demonstrates a strategy to effectively apply materials for current and future applications by considering the required material footprint, how they are combined (SE), and how they can be adapted for future uses. Whilst this may lead to components that are over dimensioned, it intends to offer effective utilisation of available reclaimed material, as well as maximise the material availability for future scenarios.

Furthermore, aspects other than structural performance are important considerations for material allocation in structures. Aesthetics, partitioning, light, acoustics, servicing, and fire are equally involved parameters in the design of components and their arrangement in buildings. Future investigations of the approach would benefit from diversifying optimisation parameters to include aspects other than structural performance and material utilisation, leading to more holistically considered applications for waste timber materials.

10. Conclusion

This research demonstrates that rethinking the scope of design for disassembly, structural components from reclaimed timber can be designed with timber only reversible joints. This enables discarded material to be utilised in high value building parts, with a situated relationship between discarded materials and a building's needs.

The results show that the principle of defining assembly, in-use, and disassembly conditions for timber only joints is practical and feasible. This integration of principles from wood science can be further enhanced to achieve more reliable production. For the purpose of this study, these joints have been applied to a hypothetical building application in the form of a truss, a component-based structural system.

Lastly, the study contributes with a general approach to sustainability, where undervalued materials are utilised, allocated as they are needed, and designed to achieve service lives that extend beyond the regeneration periods of the ecosystems they depend upon.

takayama.naoyuki@takenaka.co.jp

Abstract

Normally, timber is used for compression or bending members, where the allowable stress can be evaluated to be high. However, for a structural frame in which the axial forces are dominant, this material can also be fully utilized as tensile members because the entire sections of the members can be effectively used. This paper presents the structural design of a club house with a catenary-shaped wooden roof. Use of a catenary shape for the roof has created a column-free space for the training room by making use of the small section of wood and ensuring that the main stresses in the members are axial forces. The author has determined the roof shape by considering the creep deformation properties of wood, and parametrically verifying the shape with a computer, to meet various constraints such as the required roof drainage slope and smoke exhaust area, building height restrictions, and effective ceiling height requirements. Furthermore, the application of a system that combines tensile bolts and timber to the member joints that tend to be complicated minimizes the partial losses of the member areas at the joints to improve the architectural design, productivity, and structural performance of the building.

Keywords: catenary-shaped wooden roof, triangular grid, computational design, geometric nonlinear analysis, computer numerical control (CNC) machining

1. Introduction

In this project, we relocated the boathouse of the Mukogawa Women's University's canoe club known for its strong canoe racing team and built a new building ("Building"). The project site is located in the residential area where the canoe club has been active for years, and very close to the old boathouse used by the club. The Building was required not only to provide an easy-to-use club room and boathouse, but also to create a memorable space that brings the club members back the memories of their club activities. To meet the requirements, we took a structural approach using generally available lumber.

2. Building overview and structural planning

2.1. Architectural planning and design

The Building is two-storied with a plane shape of 17.34 meters by 13.65 meters. It has a boathouse at the first-floor level and a training room at the second-floor level. The Building can accommodate up to 20 club members for training and store up to 77 canoes (2.95 to 11 meters long each).

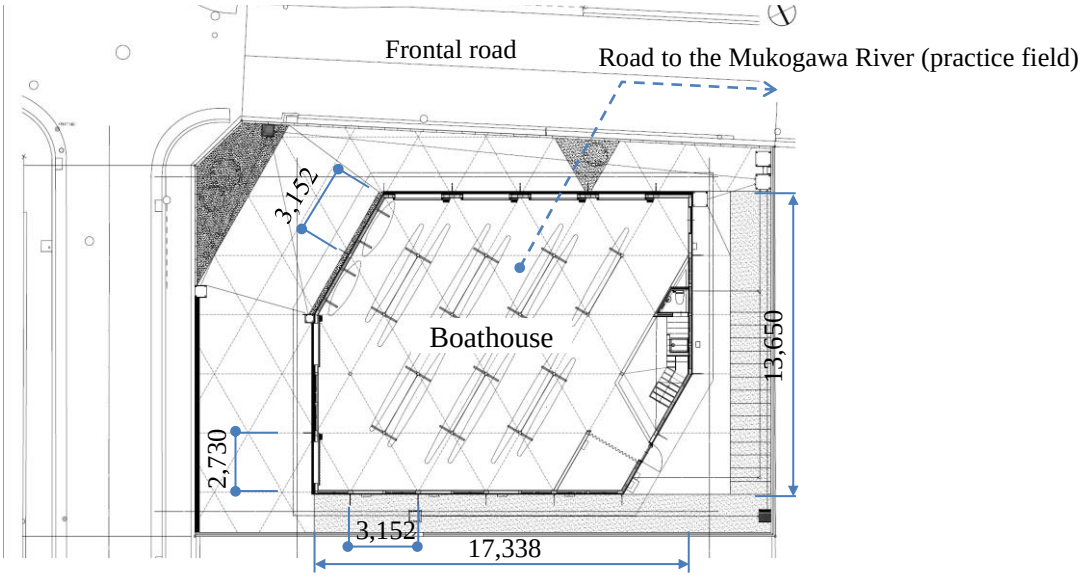

Figure 3. Site plan / first floor plan

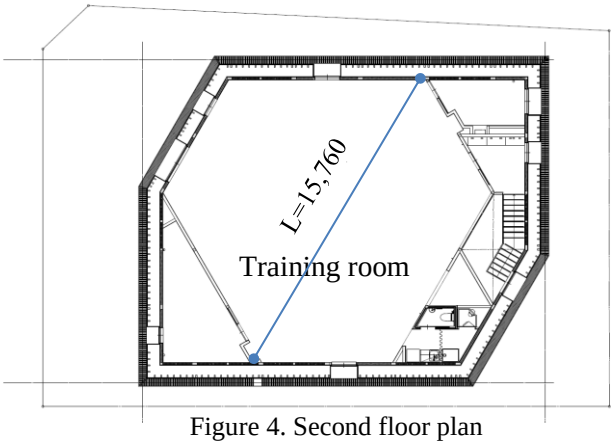

Figure 4. Second floor plan

Figure 5. Exterior view of Building (north side)

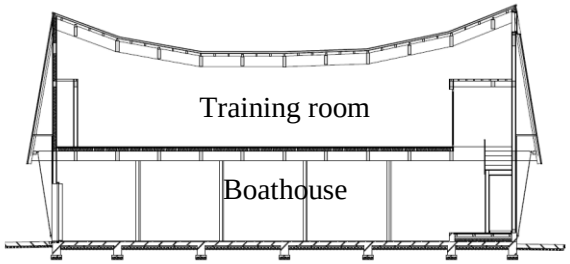

Figure 6. Section

2.2. Structural planning

In planning the Building, we used three distinctive planning elements: "timber," "triangular grid," and "catenary-shaped roof" to solve the issues faced in the planning. The details of the elements are as follows.

2.2.1. Timber

In recent years, the promotion of using timber has attracted attention because it requires less energy for processing than other materials and is an environmentally friendly material. There was another reason for choosing timber. The club house is not only a place for training but also a place for the girls to relax after practicing on the river. Therefore, we designed a wooden structure with small section members as used in ordinary houses so as to make them feel at home on a human scale, aiming to create a space with a friendly ambience rather than a place for strict training.

2.2.2. Triangular grid

The first-floor boathouse was required to be easy to maintain because canoes are frequently taken out of and into it. Therefore, we adopted a triangular grid (Figure 7), instead of the conventional orthogonal grid, in consideration of the narrow road in front of the boathouse. The triangular grid, inclined at 30 degrees to the frontal road, has made it possible to move them from the boatyard to the Mukogawa River, then to the canoe maintenance area, and back to the boatyard in a single uninterrupted movement. The triangular grid also enhances the rigidity of the wooden floor.

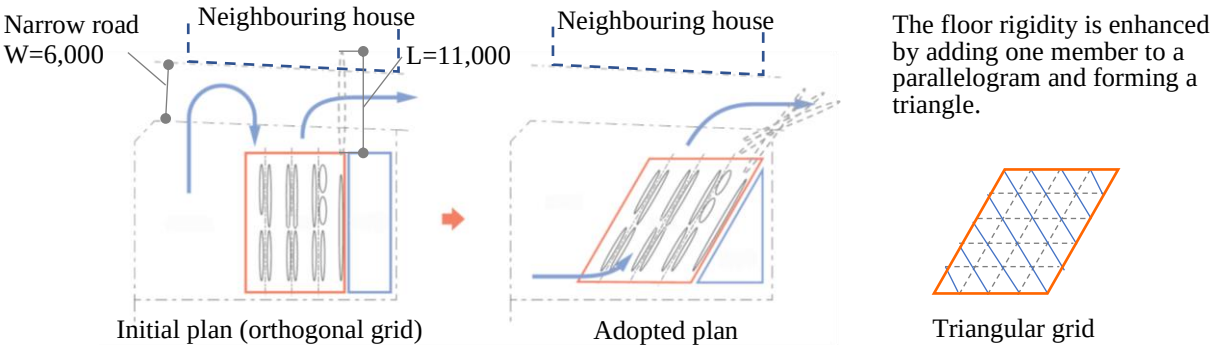

Figure 7. Planning of grid

2.2.3. Catenary-shaped roof

The training room required a large column-free, partition-free space to accommodate various types of training activities. It was also necessary to minimize the pocket created by the structural framework in order to secure the required training room space while meeting the building height limitations in the residential area although truss beams and string beams are often used when planning a long-span wooden structure. Accordingly, we considered the use of a wooden catenary structure to meet the required spatial shape while reducing the member heights as much as possible to meet the building height limitations.

Figure 8. Selection of roof structure type

Thus, we planned to place a wooden catenary structure, derived from the "timber," "triangular grid," and "catenary-shaped roof," over a structure with wooden seismic walls all around the building. Figure 9 shows a diagram of the structural frame.

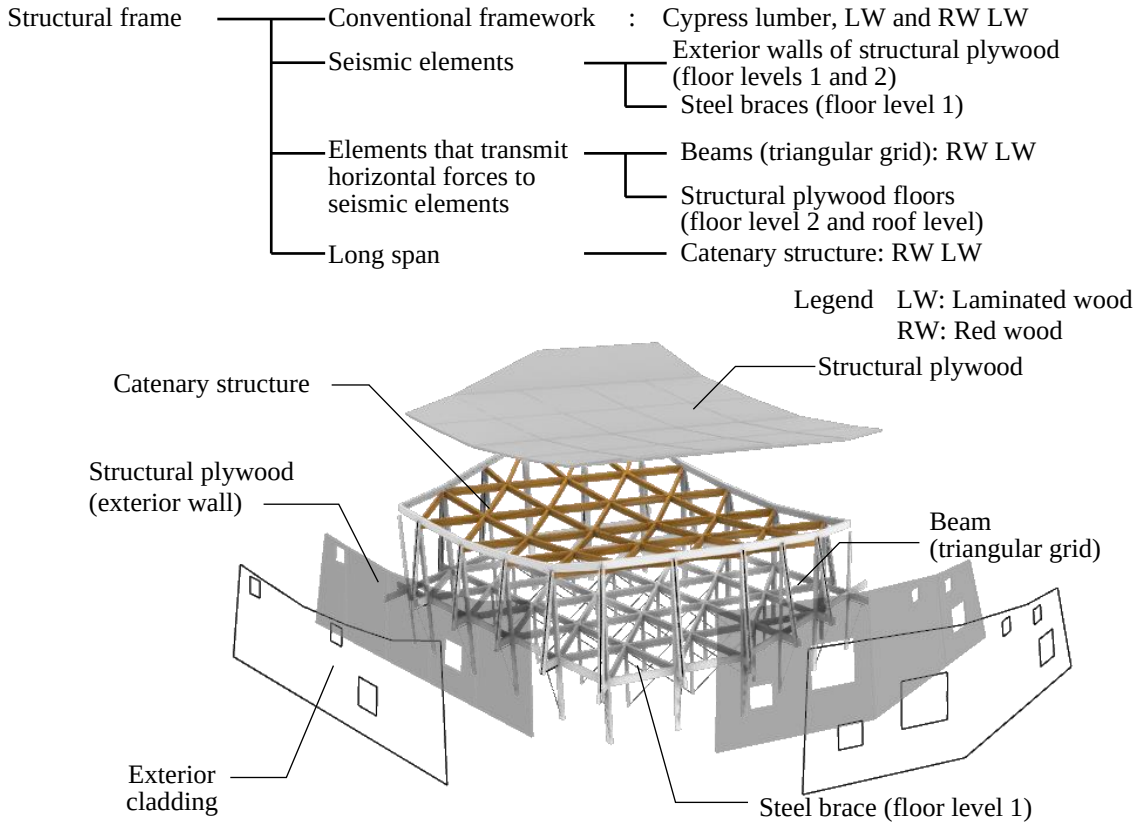

Figure 9. Diagram of structural frame

3. Catenary-shaped wooden roof

3.1. Determination of roof shape by simulation

A catenary-shaped wooden roof needed to be established under the constraints including the building height restrictions on the site, required ceiling height for the training room, opening dimensions and location required for smoke extraction, and required roof drainage slope. The computational design method using "grasshopper" was helpful in the situation where many conditions had to be validated concurrently. We used the following structural validation flow to determine the roof shape.

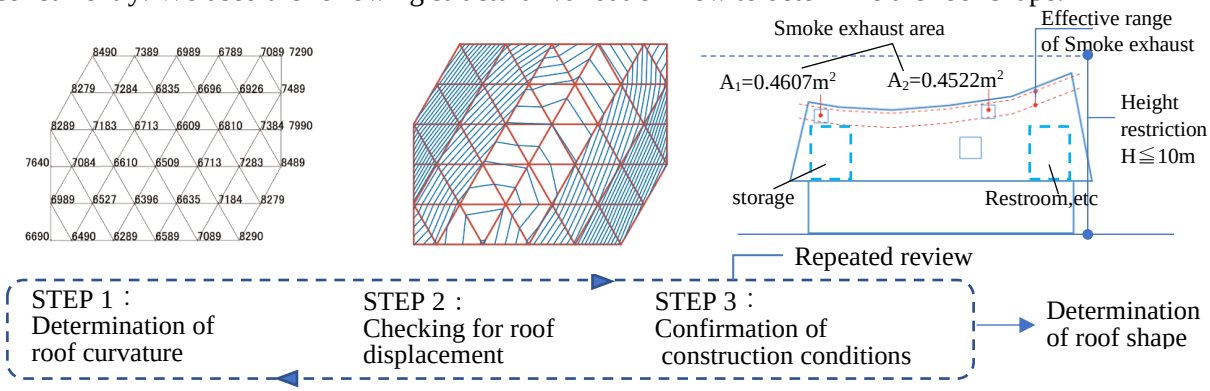

Figure 10. Structural validation flow

3.2. Study on application of wooden catenary beam structure consisting of wooden members and tensile bolts

The sizes of locally sourceable lumber ranged from [120 mm by 120 mm] to [120 mm by 390 mm]. In the architectural planning, the roof span was as long as 15.7 meters when the beams were planned in a grid pattern. Therefore, there was an issue that if the beams were planned in a usual way, the roof beams would have been large to the extent that the beam height would be about 140 cm.

First, we explored possibilities of using a suspended wooden roof with small timber beams for the Building.

Then we considered the use of a catenary-shaped wooden frame with a combination of tensile bolts and a wooden member for each grid of no more than 4,000 mm in order to use local timber with a maximum length of 4,000 mm.

3.3. Invention and design of wooden catenary beam structure consisting of wooden members and tensile bolts

Normally, the allowable stress of wood is lower in the tensile direction than in the bending direction. Therefore, it is generally considered inefficient to apply members against tensile forces. In this project, however, the stresses of the roof structure are designed to be axial, which makes it possible to use the entire sections of the members, bringing a larger effect. Moreover, the pin-joined structure using tensile bolts at the joints between wooden members has created a wooden frame conforming to the roof curvature, suspended from the two ends of the roof like a string of beads.

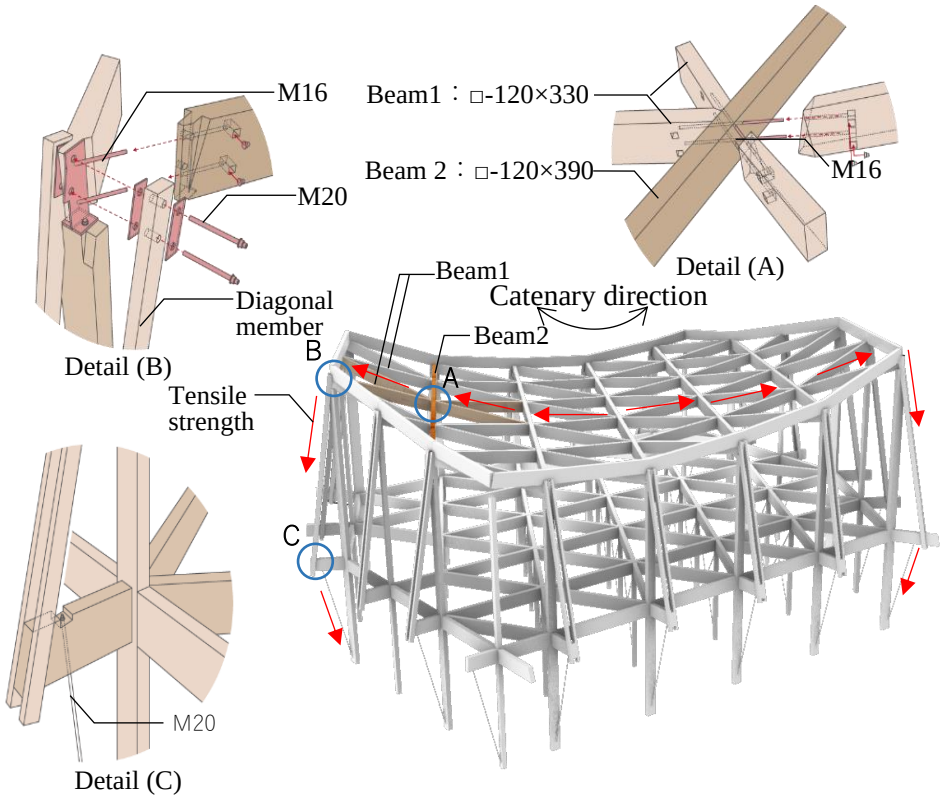

Figure 11. Structural frame

3.4. Analytical results of catenary-shaped wood frame

The author performed a static geometric nonlinear incremental analysis of the catenary-shaped wood frame and obtained the data concerning the deformation and stresses of the members, considering the geometric nonlinearity caused by the roof deformation. The results of the analysis have revealed that approximately 70% of the loads were transferred by axial forces in a suspended roof structure (Beam 1 in Figure 11), and the remaining loads were transferred in an orthogonal beam framing structure (Beam 2 in Figure 11).

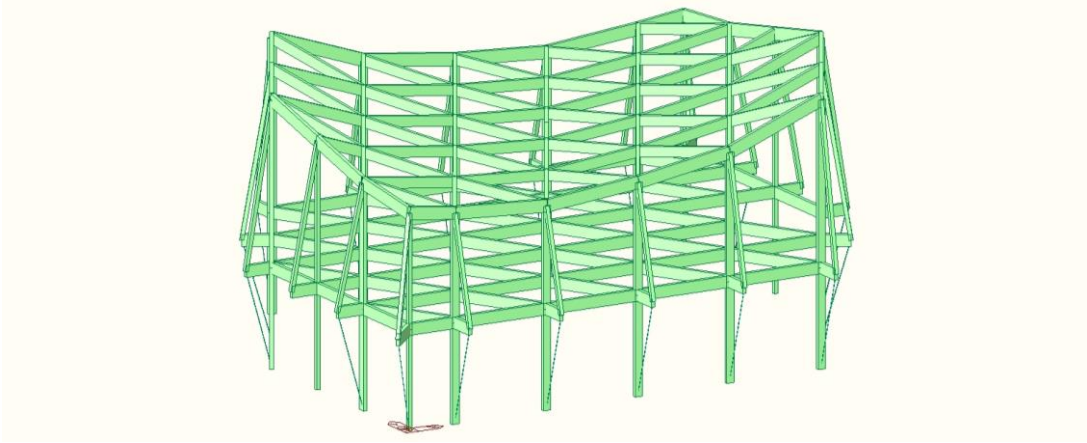

Figure 12. Analysis model

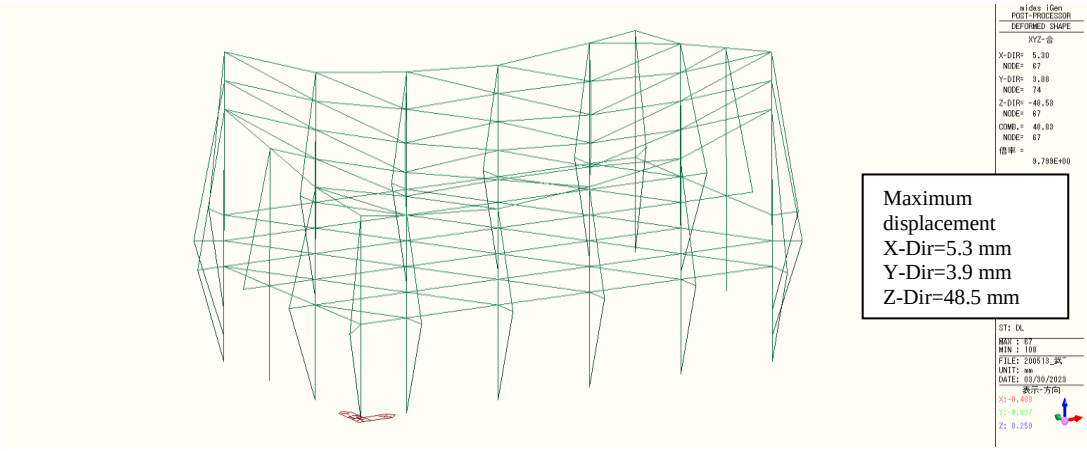

Figure 13. Deformations under dead load

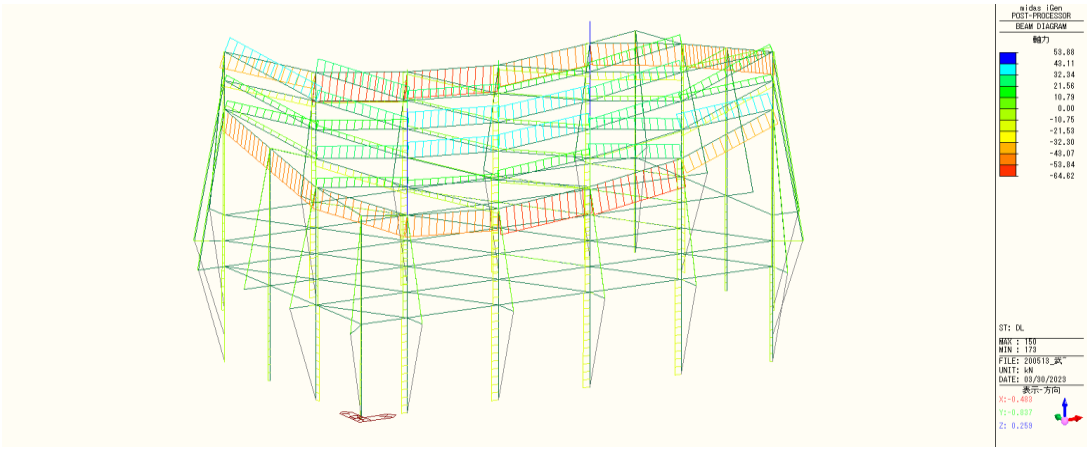

Figure 14. Axial forces under dead load

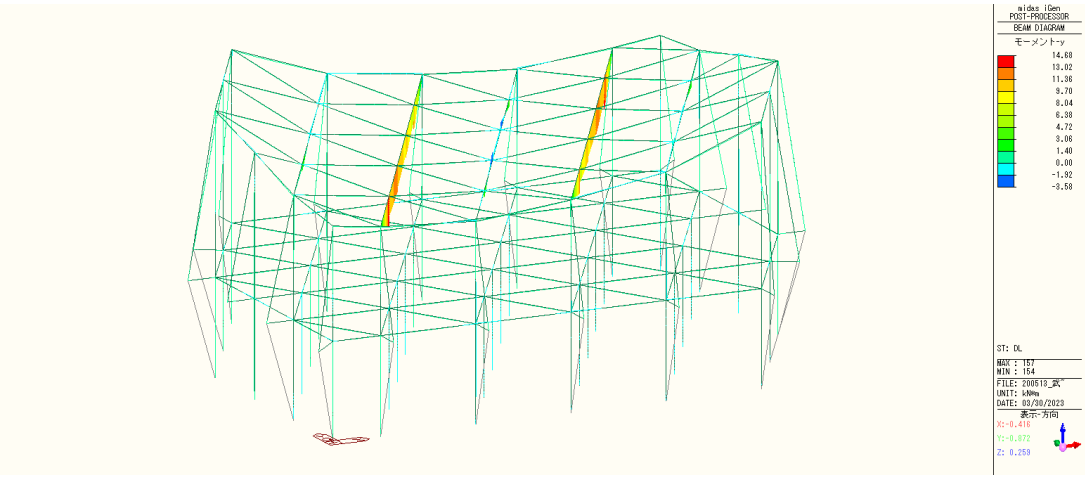

Figure 15. Bending moments (My) under dead load

4. Computational design and handwork

4.1. Digital fabrication and handwork

In the catenary structure used in this project, the shapes of intersecting members vary from joint to joint. Since the main force to be transmitted is a tensile force in this structure, the author has invented a simple rule for the joints that the sectional area of a member should be secured up to a position of 190 mm from a tensile bolt fixing point. The parts exceeding 190 mm are treated as a finishing material. We have developed an interior elevation of every member joint as shown in Figure 17. Although CNC machines were used for processing the members as much as possible, the parts that could not be shaped by machining were processed by hand.

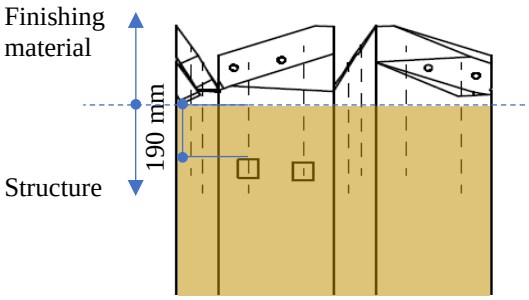

Figure 16. Joint rule

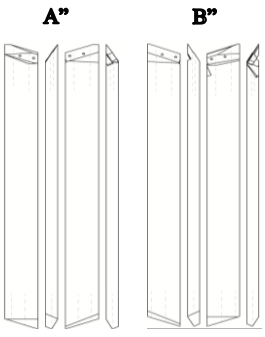

Figure 17. Interior elevation of processed shapes

Since the continuous beam (Beam 2 in Figure 11) material passing through joints was as long as 15.7 meters, it was necessary to join two timbers after transportation. The Japanese traditional joint system called *Okkake Daisen* (Figure 17), which can transmit bending stress, was used for the joints. We upgraded the traditional system by inserting an oblique plug in the centre of each joint as the measure against the axial shrinkage over time and filling the gaps which may be generated between the members.

Figure 18. Processed shapes

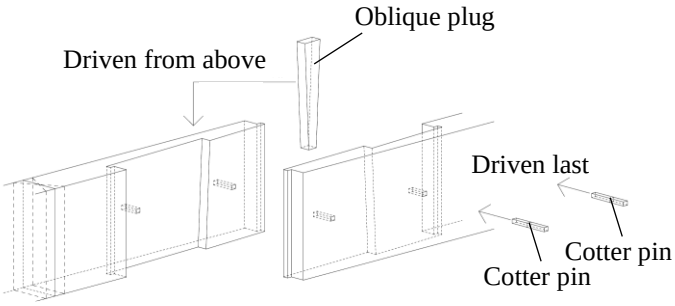

Figure 19. *Okkake Daisen* joint detail

4.2. Erection

Prior to erection, we assembled members temporarily at the fabricator's factory to check the processing accuracy of the members (Figure 20). We erected members on scaffolding, assembling the roof structural frame members and then purlins (Figures 21-23).

Figure 20. Verification of assembled members

Figure 21. Bird's-eye view of erection

Figure 22. Erection: Timber joints ((A) in Figure 11)

Figure 23. Erection: Timber joints (triangular grid)

5. Conclusion

We have developed a catenary-curved roof with a triangular grid of wood for roof structures. Generally available lumber will do to achieve this special system. In addition, a hybrid combination with tensile bolts allows forces to be transmitted only in the direction of the wood fibres, which is helpful against future creep deformation specific to wood and enables simple member joining. Our analysis and measurements verified that the developed beams have sufficient strength and stiffness to meet the requirements.

Abstract

There has been a growing interest in advancing the use of mycelium composite in recent years, due to their eco-friendliness, affordable cost, low density, and excellent acoustic and thermal insulation properties. This study compares various mycelium composites manufactured using different fungal species and provides a decision-making guide for selecting the most suitable material of secondary structure member for built environment applications. To determine the most important variables in the selection process, the analytic hierarchy process (AHP) was employed, revealing that tensile strength is the most critical factor (52%), followed by flexural strength (19%), manufacturing period (17%), density (9%), and water absorption (3%). It shows that both the mechanical properties and manufacturing duration significantly affect project delivery, emphasizing the need to consider these factors in the selection process. This study also used the Fuzzy Comprehensive Evaluation (FCE) approach to establish a rational rating system for making the decision of material selection. The FCE results indicate that Ganoderma lucidum is the most promising material, as it has an optimal balance of material performance and material manufacturing time. The combination of AHP and FCE methods is shown to be an effective tool for establishing a comprehensive evaluation for selecting mycelium composites for specific purposes in construction.

Keywords: circular economy, sustainability, living materials, analytic hierarchy process, fuzzy comprehensive evaluation

1. Introduction

In recent decades, there has been a growing focus within the international community on reducing energy usage and achieving universal sustainable development [1]. According to recent studies, approximately one-third of all global carbon emissions can be attributed to the built environment, with fossil fuel combustion accounting for 71% of these emissions [2, 3]. In Australia, the construction sector alone accounts for 36% of the country's carbon balance [4]. As a result, decarbonization of the built environment has become a crucial undertaking in achieving sustainable urbanization and climate neutrality [5]. Traditional building materials, such as concrete and steel, are not conducive to environmental conservation, since their production increases energy consumption and contributes around 10 percent of the world's carbon dioxide emissions [6, 7]. Therefore, it is crucial to encourage the adoption of “green engineering materials” that can minimise non-renewable energy consumption, greenhouse gas emissions, and land and water contamination during the fabrication, transportation, and

deconstruction process [8]. Mycelium-based composites (MBC), a type of renewable and biodegradable engineering material, have attracted considerable interest as a sustainable alternative to conventional synthetic materials in the field of civil engineering (Figure 1) [9]. It is a biomaterial formed from the development of fungi on diverse substrates, such as agricultural waste, forestry leftovers, and cellulosic materials at the end of their useful life [10, 11]. In the sector of construction, MBCs provide various benefits over conventional materials. For example, it has a reduced carbon footprint, which presents an opportunity to improve the sustainability of built environments while also ensuring aesthetic appeal [12]. In addition, their low density, excellent acoustic and thermal insulation, reasonable cost, and minimal environmental effect make them highly competitive in the material market for non-primary structural members [13].

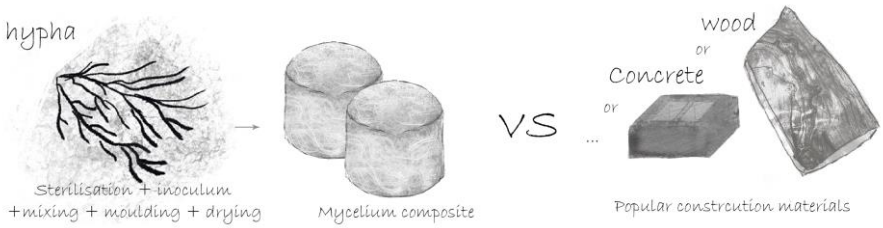

Figure 1. Different construction materials.

Mycelium-based composites are gaining prominence in facade construction owing to their exceptional material properties. For example, the production of the exterior facade panel of the Growing Pavilion by Pascal Leboucq and Erik Klarenbeek involved the use of MBCs [14]. However, despite the increasing popularity of mycelium-based composites in the construction industry, there remains a dearth of comprehensive evaluation guides that thoroughly assess the properties of different types of MBCs manufactured with various fungal species. This poses significant challenges for architects in selecting appropriate materials, as they may lack sufficient foresight regarding the balance of product satisfaction and construction period. To address this gap, this study aims to compare and contrast the key characteristics of different mycelium composites produced from a range of fungal species, while also offering a decision-making guide for the selection of materials used as the secondary structural members in the construction of facades. In this paper, fuzzy comprehensive evaluation (FCE) technique will be employed to provide a systematic ranking of different MBCs. Throughout this process, the study will consider and assess the key properties of MBCs, including density, water absorption, tensile strength, and flexural strength, as well as manufacturing periods. Also, the weight proportions of these evaluation factors in the context of facade applications will be evaluated using the analytic hierarchy process (AHP).

2. Research methodology

2.1. Analytic hierarchy process

The AHP decision-making approach [15] can facilitate an accurate and straightforward determination of the weight vector for multivariable systems, particularly those with more than three variables. Instead of performing a laborious and ill-defined process of cross-comparison, this technique enables the creation of a pairwise comparison matrix, which can then be used to evaluate the relevance of each aspect that was taken into consideration [16]. Discovering the primary key factors for assessment, building the pairwise comparison matrix using the Saaty scale (Table 1), calculating the eigenvector and major eigenvalue and transferring the result to the weight vector are the five procedures that are necessary to generate the weight fraction. Following the calculation of the weight fraction, the

consistency of the created matrix must be evaluated by determining its value using the consistency ratio (CR). The calculation for CR can be found in Equation 1, as indicated. If the value of CR is more than the restriction of 0.1, it is possible that a mistake caused by poor human judgement occurred during the building of the matrix. In every other case, the outcome is considered rational [17].

$$\mathrm{CR} = \frac{CI}{RI} = \frac{\sum_{i=1}^{n} \frac{(A\vec{\omega})_i}{n\omega_i} - n}{RI\ (n-1)} \leq 0.1 \tag{1}$$

where A is the formed pairwise matrix, ω_i is the weight vector, n is the number of variables, RI is an average random index and CI is the consistency index.

Table 1. Saaty scale used to form comparison matrix.

The number for A/B	Definition
1	Factor A has the SAME importance as B in the assessment.
2	Factor A is SLIGHTLY more important than B in the assessment.
3	Factor A is MODERATELY more important than B in the assessment.
4	Factor A is MODERATELY PLUS more important than B in the assessment.
5	Factor A is STRONGLY more important than B in the assessment.
6	Factor A is VERY STRONGLY more important than B in the assessment.
7	Factor A is DEMONSTRATED more important than B in the assessment.
8	Factor A is VERY VERY STRONGLY more important than B in the assessment.
9	Factor A is EXTREMELY more important than B in the assessment.

2.2. Fuzzy comprehensive evaluation

Fuzzy comprehensive evaluation was created based on Zadeh's fuzzy mathematics theory [18, 19]. The benefit of this technique is delivering the quantified full evaluation for each choice without needing exact numerical criteria and resources. The complete technique might be separated into three steps: (i) establishing the variable set and scale set, (ii) building the fuzzy evaluation matrix, and (iii) determining the rank by applying the weight vector obtained in the AHP. The evaluation level with the greatest likelihood of the outcome reflects the final projected grade of assessment [16]. The detailed process is summarised in Figure 2.

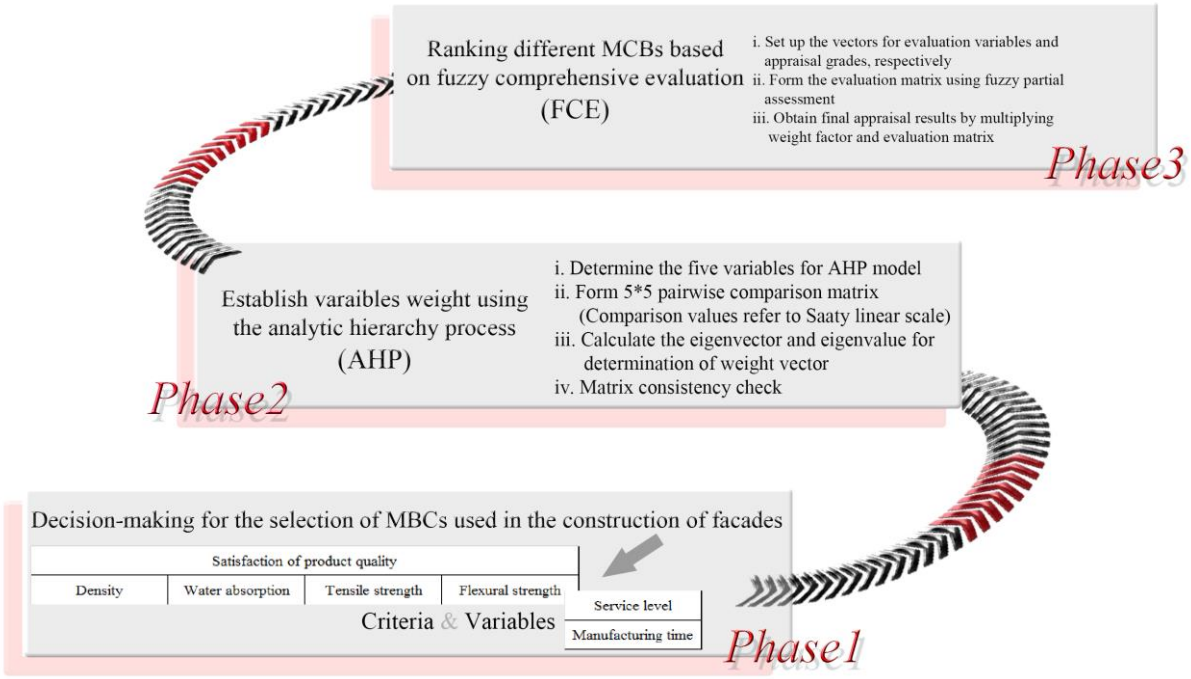

Figure 2. Systematical scoring process for different MBCs.

3. Result and discussion

3.1. Weight vector determination for multi-variables

The Analytic Hierarchy Process (AHP) allows to divide complex cross-comparisons into a series of pairwise evaluations. By adopting a numerical scale for pairwise comparison, it is feasible to establish the degree of significance of each variable through an easy, methodical, and accurate technique. The steps required to acquire the weight vector that will be used to evaluate the various realignment methods are outlined below.

At the variable determination phase, which is the initial stage, all five variables needed for decision-making - density, water absorption, tensile strength, flexural strength, and manufacturing period - are acquired from existing research to evaluate and compare properties of different MBCs. The second phase focuses on the development of matrices for pairwise comparisons. This study focus to evaluate the overall performance of mycelium composites as a material for secondary structural members in both outer-frame and inter-frame configurations, whose findings provide significant insight into the possibilities of each mycelium composite as the material for facade construction

The AHP approach provides the option to break down complicated cross-comparisons into a series of pairwise assessments. It would be possible to determine the degree of significance of each variable using a procedure that was straightforward, methodical and exact if one used a numbering scale for pairwise comparison. The following process is used to obtain the weight vector that will be used for rating the different realignment methods. The pairwise relationship between every two variables for both conditions is defined based on the studies conducted by Chen [20], Patnaik et.al. [21] and Lee et al.[22]. The matrix is created following the procedure outlined in Table 2. To assess the relative relevance of each variable, it is compared with its counterpart. Using the Saaty linear scale, this relative relevance is then mapped onto numerical data, as illustrated in Table 3 [17].

Table 2. Pairwise comparison matrix.

Matrix Framework		Satisfaction with product quality				Service level
		Density (D)	Water absorption(WA)	Tensile strength (TS)	Flexural strength (FS)	Manufacturing period (MP)
Satisfaction with product quality	Density (D)	1	D/WA	D/TS	D/FS	D/MP
	Water absorption (WA)	WA/D	1	WA/TS	WA/FS	WA/MP
	Tensile strength (TS)	TS/D	TS/WA	1	TS/FS	TS/MP
	Flexural strength (FS)	FS/D	FS/WA	FS/TS	1	FS/MP
Service level	Manufacturing period (MP)	MP/D	MP/WA	MP/TS	MP/FS	1

Table 3. Pairwise comparison matrix with data input.

Matrix Framework		Satisfaction with product quality				Service level
		Density (D)	Water absorption(WA)	Tensile strength (TS)	Flexural strength (FS)	Manufacturing period (MP)
Satisfaction with product quality	Density (D)	1	5	1/7	2	1
	Water absorption (WA)	1/5	1	1/9	1/9	1/9
	Tensile strength (TS)	7	9	1	4	4
	Flexural strength (FS)	3	9	1/4	1	1
Service level	Manufacturing period (MP)	2	9	1/4	1	1

The third phase involves calculating the eigen system and weight vector for each variable. The eigenvector (ν) and principal eigenvalue (λ_{max}) are determined to be (0.436, 0.143, 2.599, 0.949, 0.873) and 5.276, respectively. Additional transformations can be performed to determine the weight proportion of each consideration factor: 8.772% for density, 2.857% for water absorption, 51.978% for tensile strength, 18.979% for flexural strength, and 17.464% for manufacturing period. The result shows the selection of suitable materials for secondary structure members in facade construction is a crucial aspect of engineering design. Among the various factors considered in this process, mechanical properties hold a key significance due to their impact on the structural integrity and safety of the built environment. In addition to mechanical properties, AHP results highlight the manufacturing period of a material also plays a significant role in project delivery. The duration of the manufacturing process can have considerable impacts on the timeline of a project. Hence, it is essential to consider the manufacturing period of a material during the material selection process, to ensure that the selected material can be manufactured and delivered within the project's timeframe, while also meeting the required performance specifications during its expected lifetime.

The fourth stage of matrix consistency inspection entails calculating the CR (*CR = CI/RI*) to validate the precision of the comparison matrix. The consistency index, also known as CI, can be calculated using Equation 2. The RI, or average random index, is 1.12, as shown in Table 4 [23]. The calculated CR is 0.062, which is below the threshold of 0.1. Therefore, it is possible to conclude that the matrix's consistency level is sufficient.

$$\mathrm{CI} = \frac{\lambda_{max} - n}{n - 1} = 0.069 \tag{2}$$

where *n* is the size of the matrix.

3.2. Fuzzy comprehensive evaluation model

The FCE approach offers a comprehensive analysis of the fuzzy evaluation of each criterion, making it a valuable tool for cross-comparisons across various methodologies. In this study, the FCE approach was employed to establish a logical ranking system for suitable mycelium composites used as material of secondary structural members in facade construction. The factors/variables set (U) in this study comprised density, water absorption, tensile strength, flexural strength, and manufacturing periods. The assessment levels (V) were categorized as excellent, very good, good, fair, or poor according to the established scale. The specific ranking criteria are presented in Table 4 along with the corresponding assessment levels. By considering both mechanical properties and the manufacturing period during the material selection process, architects can make informed decisions that ensure the optimal balance between performance and time for their projects.

Table 4. Evaluation scale used in FCE.

Level	Excellent	Very Good	Good	Fair	Poor
Density, D (kg/m3)	D<100	100 ≤D<200	200≤D<300	300≤D<500	D≥500
Water absorption, WA (%）	WA<100	100 ≤WA<150	150≤WA<200	200≤WA<300	WA≥300
Tensile strength, TS (MPa)	TS>1	0.5<TS≤1	0.1 <TS≤0.5	0.05 <TS≤0.1	TS≤0.05
Flexural strength, FS (MPa)	FS>1	0.5<FS≤1	0.1 <FS≤0.5	0.05 <FS≤0.1	FS≤0.05
Manufacturing period, MP (days)	MT<15	15 ≤MT<20	20≤MT<25	25≤MT<30	MT≥30

This study aimed to evaluate seven different types of mycelium composites for their suitability as facade construction materials. These tested composites were composed of *trametes multicolor*, *pleurotus ostreatus*, *ganoderma fornicatum*, *ganoderma williamsianum*, *lentinus sajor-caju*, *schizophyllum commune*, and *ganoderma lucidum*, respectively. Physical and mechanical properties of these composites as well as their production time were collected from relevant literature sources, which are summarized in Figure 3 [24-34]. The results indicate that there is a high degree of uncertainty regarding all five properties of mycelium composite with *pleurotus ostreatus*, while the behaviour of *ganoderma williamsianum* is relatively stable. Additionally, the difference in physical properties between the seven different types of mycelium composites is less significant compared to the difference in mechanical properties.

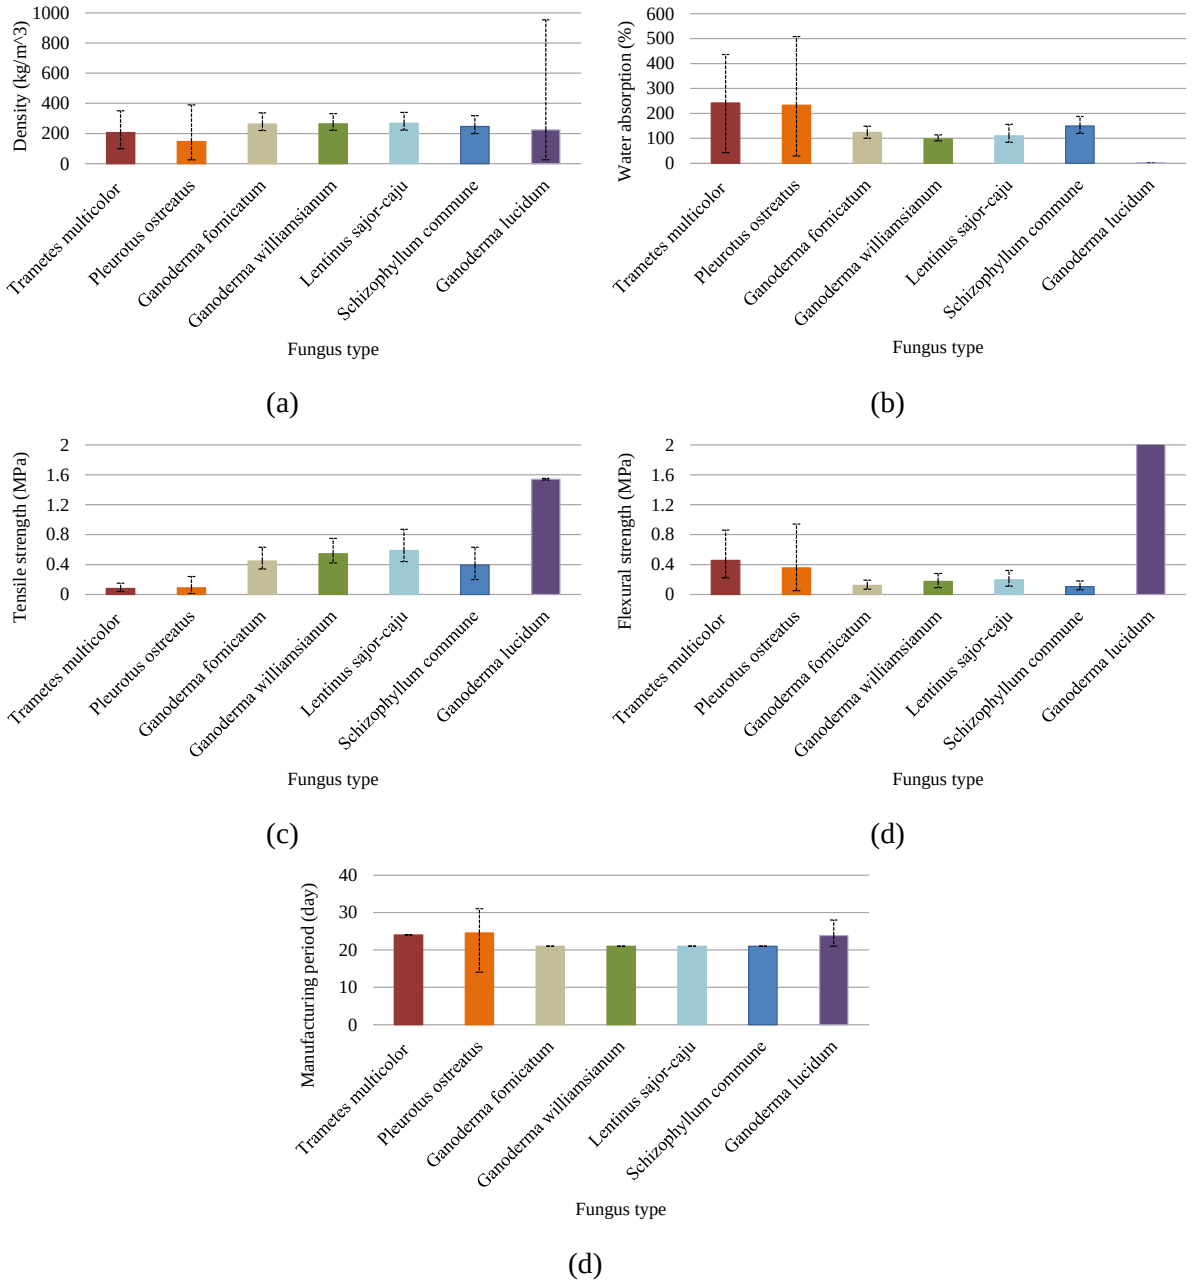

Figure 3. Five characteristics of mycelium composites manufactured with different fungi: (a) Density, (b)Water absorption, (c) Tensile strength, (d) Flexural strength and (e) Manunfacturing period.

The fuzzy matrix R, which includes entries $u_i v_i$, was constructed using the findings from existing literature. The dot product of the weight vector and the fuzzy matrix presented in Figure 4 was used to create the complete assessment set. According to the results, *ganoderma lucidum* appears to be the most promising fungus for the manufacture of mycelium composites used in facades. This type of MBC boasts outstanding water resistance and tensile strength, relative light density but longer production period. However, given the limited data available in the literature, this study acknowledges the

uncertainty of the range for each variable. Future studies can improve upon these findings by expanding the database.

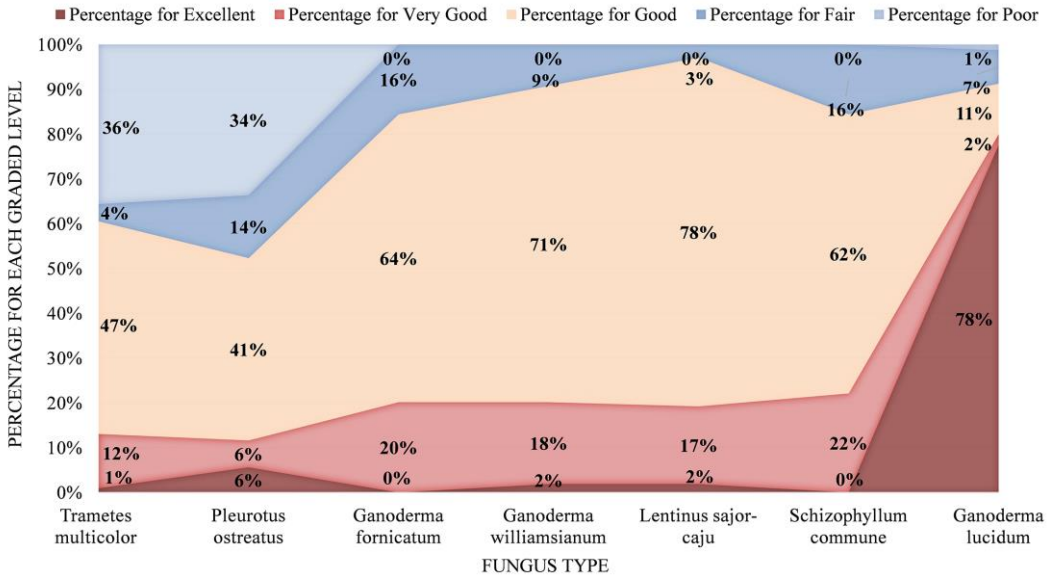

Figure 4. Evaluation results for mycelium composites manufactured with a different fungus.

4. Conclusions

This research employs the Analytic Hierarchy Process and Fuzzy Comprehensive Evaluation methods to identify the most suitable mycelium composites for use in facade construction. The research presents a comprehensive evaluation to assess the suitability of each typed mycelium composites and their potential to enhance practical application in civil engineering. The AHP results reveal the weight proportion of each variable considered in the study, with density accounting for 8.8%, water absorption for 2.9%, tensile strength for 52.0%, flexural strength for 19.0%, and manufacturing period for 17.5%. The study underscores the significance of mechanical properties in the selection of materials for secondary structure members, as these properties have a crucial impact on the structural integrity and safety of the built environment. Moreover, the analysis emphasizes that material manufacturing duration and mechanical properties are two significant factors that affect project delivery.

The FCE approach has been utilised to establish a rational rating system for mycelium composites used in facade construction. This study examines five key factors that influence the suitability of mycelium composites. Architects and engineers can use the FCE results to make informed decisions that balance performance and time while ensuring optimal material selection. Based on the FCE findings, Ganoderma lucidum appears to be the most promising fungus for mycelium composites for built environment applications, for both external and internal spaces. This typed MBC has excellent water resistance and tensile strength, a relatively light density, but takes longer to produce. Nevertheless, this analysis acknowledges the range uncertainty for each variable due to the limited literature available. Therefore, future studies can improve upon these findings by expanding the database. However, it is clear to show that the FCE approach can provide a reasonable rational ranking system for the selection of mycelium composites used for the specific purpose of construction. This study improves the architect's predictive abilities in material selection, resulting in better control over both structural and aesthetic features during the early stages of design. In addition, the proposed methodology is adaptable, allowing for a variety of material selection purposes by modification of factors and alternative material assessments.

Abstract

Glulam arches have promising in-plane stability due to the high compression efficiency of wood. As the span becomes large currently, well attention should be paid to the out-of-plane mechanical property of the structure. In some cases, several arches are connected with each other with members, where the connections between web members and arches come into place. This paper studies the mechanical properties of a type of embedded steel-tube glulam joint applied in a real arched glulam structure. Experimental tests were conducted on three full-scale joint specimens with two dimensions of steel tubes. Two loading protocols were considered, i.e. the monotonic and cycling loading. Tshe failure mode, force-displacement responses, shearing capacities, shearing stiffnesses, and ductility factors of the specimens were compared. The test results proved the shearing capacity to be reliable compared to the design forces. The enhancing screws effectively restricted the crack propagation which enabled the specimens to fail in a ductile manner. Finally, standard codes were utilized to calculate the theoretical capacities of the specimens. The theoretical results prove to be too conservative mainly because such large steel tubes in glulam joints were seldom considered.

Keywords: arched glulam structures, steel-tube glulam joints, mechanical performance, experimental tests, analytical models

1. Introduction

Arched glulam structures are widely used for the construction of gymnasiums, industrial and agricultural buildings, etc. Such structural systems possess superiorities in aesthetical attractions and structural efficiency, which is associated with the unique arch-type configuration that reduces the bending moment demand on structural members. Recently, glulam arched structures are gaining increased popularity owing to the positive environmental impact of wood, and the high strength-to-weight ratio of glulam. The exposure of wood members can further improve the aesthetic appearance of the structure. As the span of glulam arches becomes large, the length challenge of glulam members associated with the manufacturing and transportation limits needs to be well addressed. For example, for the Tianfu Botanical Garden project, which includes five large-span glulam arches ranging from 11 m to 50 m in height and 88 m to 128 m in diameter (one of them shown in Figure 1(a)), it is quite challenging for a single arch to resist various loads. For this reason, several arches are connected to each other with steel triangles to become an arch truss. This has raised concerns regarding the mechanical performance of the connection properties between the steel members and the glulam arch since they may greatly influence the response of the entire structure, especially in shearing force.

Various connection techniques have been developed to connect timber elements or sometimes even steel members. These techniques involve the use of slotted-in steel plates and dowels [1, 2], glued-in steel

rods or plates [3, 4], direct adhesive bonding [5, 6], self-tapping screws (STSs) [7, 8], lagscrewbolts [9], long threaded rods (LTRs) [10, 11], etc. Each splice connection technique has pros and cons, as discussed in [12]. From the perspectives of aesthetic appearance and on-site assembly efficiency, using a steel tube to embed into the glulam arch from one side is preferred in the project. In such a joint, the embedment performance of the glulam material is challenged. The embedment performance of dowel-type connections have been investigated sufficiently [13–17] for small diameter fasteners. Previous work elaborately considered the influence of diameter of fasteners, wood density, loading degree, moisture etc. to the embedment strength. Many equations have been refined from tests and theoretical studies and been proved to be feasible within common range in practice.

However, previous work mainly focused on dowel-type fasteners whose diameters are mostly within a limited range where the diameter of fasteners is commonly small. There is not enough research as to large-sized fasteners or even large steel-tubes as mentioned in this paper. Therefore, this paper carried out a series of steel-tube embedded glulam joint with three replicates taken from a real large-span arched glulam project to investigate the shear performance of this kind of joint.

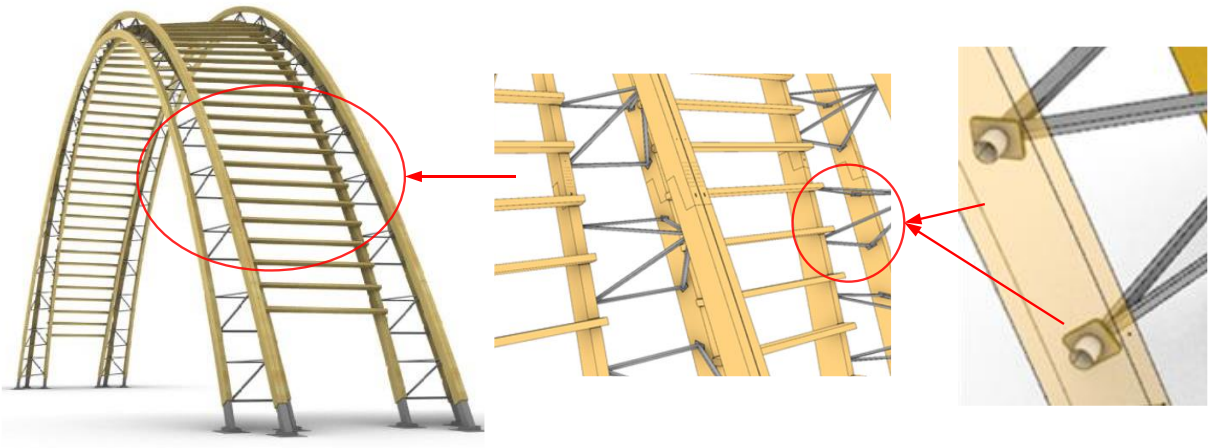

Figure 1. The joint sketch in real structure

2. Test program

2.1. Specimen design

In order to investigate the shear performance of the steel-tube glulam joint, three specimens were tested under quasi-static load. The specimens were full-scale replicates extracted from a real long-span arched glulam structure - Tianfu Agricultural Expo. project. The three specimens were labelled as AM, BM and BC. The first letter in the label represents the cross section and the second letter refers to the loading type. Thus, there were two types of cross-sections and two types of loading modes in the testing program. All the wood in three specimens were glulam in grade GL-24h, with an average density and moisture contents in 460 kg/m3 and 12.6%. The steel tubes were manufactured with Q235B low-carbon steel. Furthermore, self-tapping screws (STS) were set in the direction perpendicular to grain near the joint area to restrict the crack propagation. The product in the type of VGS from a famous company Rothoblaas [18] was adopted. Specimens are designed as shown in Figure 2.

Specimen AM has a glulam cross section in 660mm x 200mm. A prefabricated hole was cut in the middle of the specimen by 135mm in diameter. The steel tube was 133mm in diameter, slightly smaller than the hole for installation convenience. The specimen was 2.5m in length. The specimen design of AM is shown in Figure 3(a), along with the STS configuration. Specimen AM was loaded with a monotonic mode.

Group B contains two specimens, both of which were made of glulam in cross-section of 920mm x 200mm, with a prefabricated hole in the middle of the specimen by 275mm in diameter. The steel tubes were 273mm in diameter. The specimens were 2.5m in length and the design was shown in Figure 3(b), (c), along with the detailed STS configuration. Similar to AM, specimen BM was loaded monotonically, while BC was loaded with a cyclic mode.

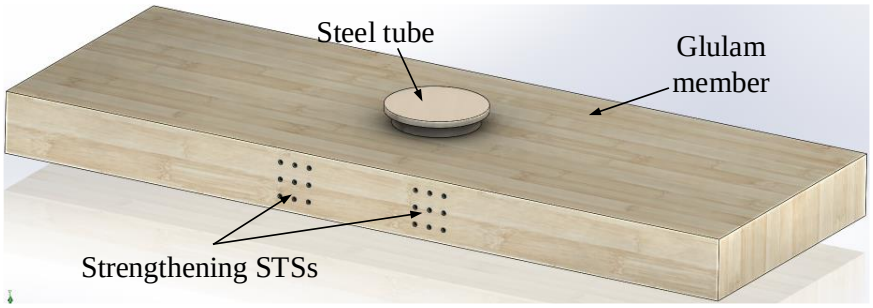

Figure 2. Joint appearance

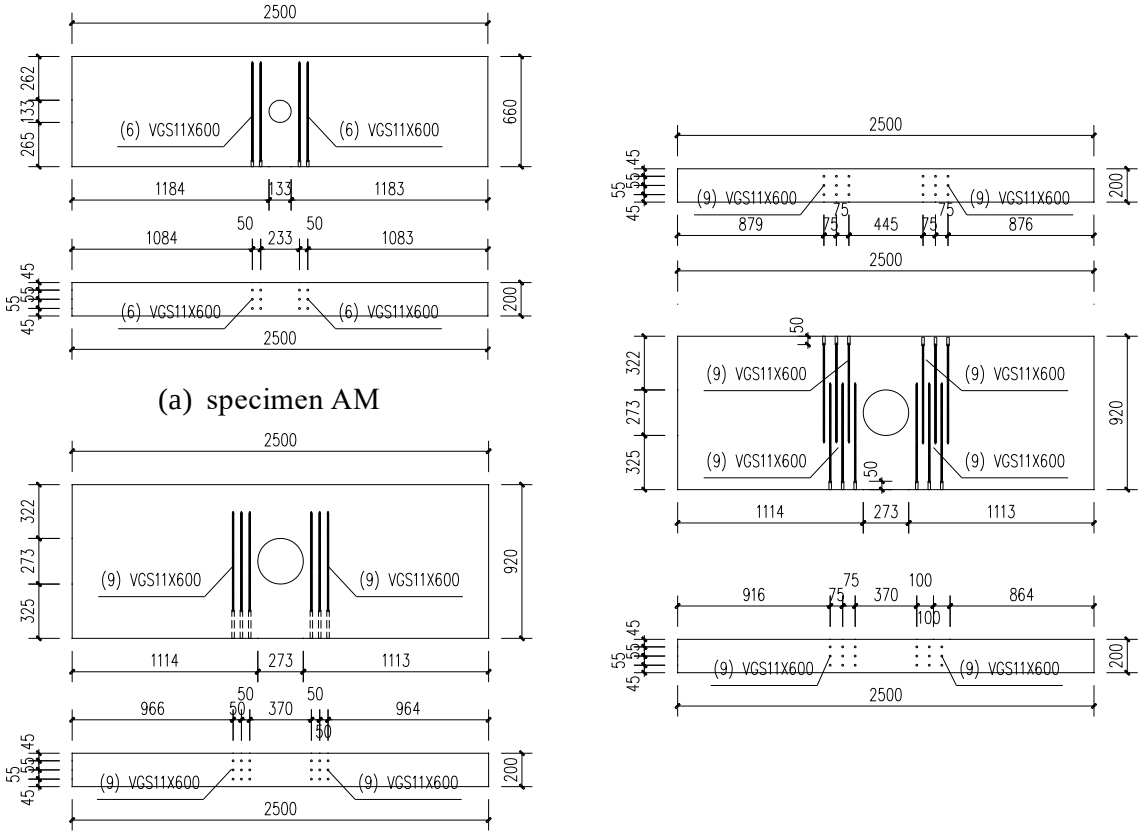

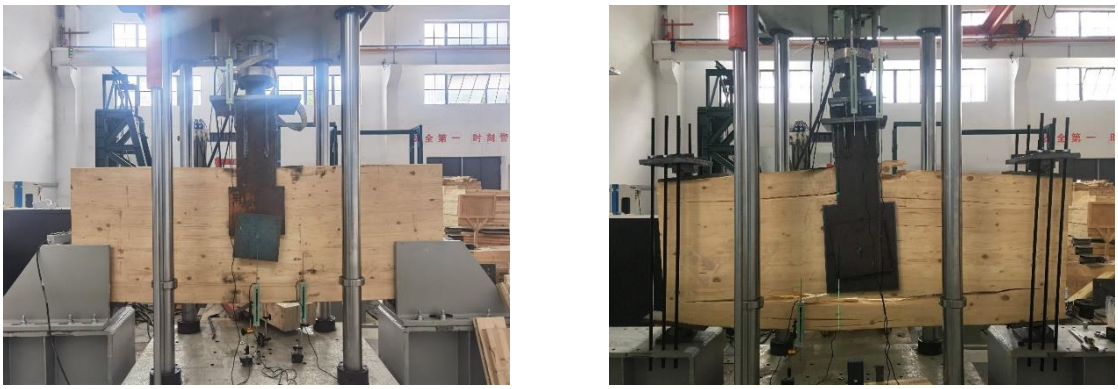

Figure 3. Specimen sketches

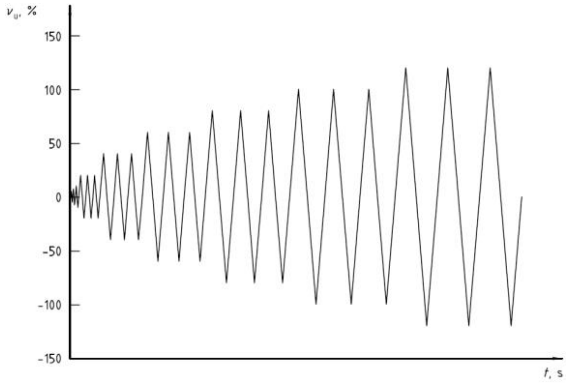
2.2. Test setup



Generally speaking, the mechanical properties for wood in the direction perpendicular to grain was often challenged. Therefore, the loading direction follows this way perpendicular to grain, namely vertical according to the set of the actuator. Figure 4 shows the test installation. There was a difference between the specimens BM and BC, as to the loading device between the steel tube and the actuator. The difference simply came from the loading mode between the two specimens, namely monotonic or cyclic loading.

In the monotonic loading mode, the loading speed was set to be 3mm/min. If the force drops suddenly or it decreases to 80% of the peak load. In the cyclic loading mode, the quasi-static reversed-cyclic test method was adopted which follows the standard ISO-16670-2003, as shown in Figure 5 and Table 1.

(a) Group A (b) Group B

Figure 4. Test installation

Step	No. of cycles	Amplitude
1	1	1,25 % of v_u
2	1	2,5 % of v_u
3	1	5 % of v_u
4	1	7,5 % of v_u
5	1	10 % of v_u
6	3	20 % of v_u
7	3	40 % of v_u
8	3	60 % of v_u
9	3	80 % of v_u
10	3	100 % of v_u
11	3	increments of 20 % of v_u
NOTE Some of the initial steps (1,25 % to 10 % v_u) may be omitted or repeated (or new steps may be added) depending on the stiffness of the joint or accuracy of the measurement system, as long as the principles given in 6.2 are satisfied. Clause A.2 identifies cases where modification of the standard cyclic displacement schedule may be warranted.		

(a) Displacement-time curve (b) Amplitude of each loop

Figure 5. ISO cyclic loading program

Since the specimen BM and BC are same replicates as to dimensions and material. Therefore, BM can be the monotonic reference specimen for BC. The predicated ultimate displacement $v_u = 148mm$ as obtained by the curve of BM. In this way, the loading protocol of BC can be determined as Table 1.

The arrangement of the Linear Voltage Displacement Transducers (LVDTs) were displayed in Figure 6 L1 and L2, L3 and L4. L2, L3 detect the moment of the steel-tube, and the displacement can be the average of the results of L2 and L3. L1 and L2 separately record the displacement of the wood, within which L1 on the top and L2 the bottom.

Table 1. Detailed loading protocol

Step	Amplitude(%)	displacement(mm)	No. of cycles	Speed(mm/min)
1	1.25	1.85	1	5
2	2.50	3.7	1	5
3	5	7.4	1	10
4	7.50	11.1	1	20
5	10	14.8	1	20
6	20	29.6	3	40
7	40	59.2	3	60
8	60	88.8	3	60
9	80	118.4	3	60
10	100	148	3	60
11	120	177.6	3	60

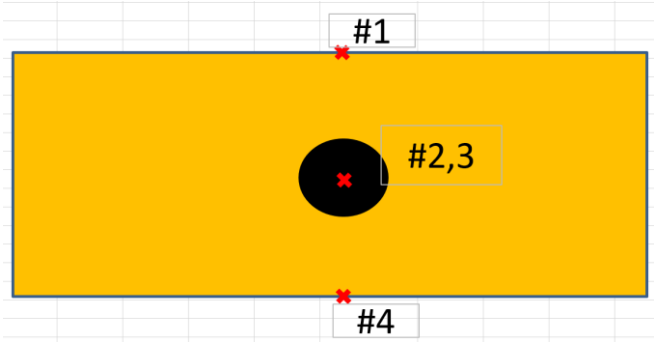


Figure 6. LVDT arrangement

3. Test results

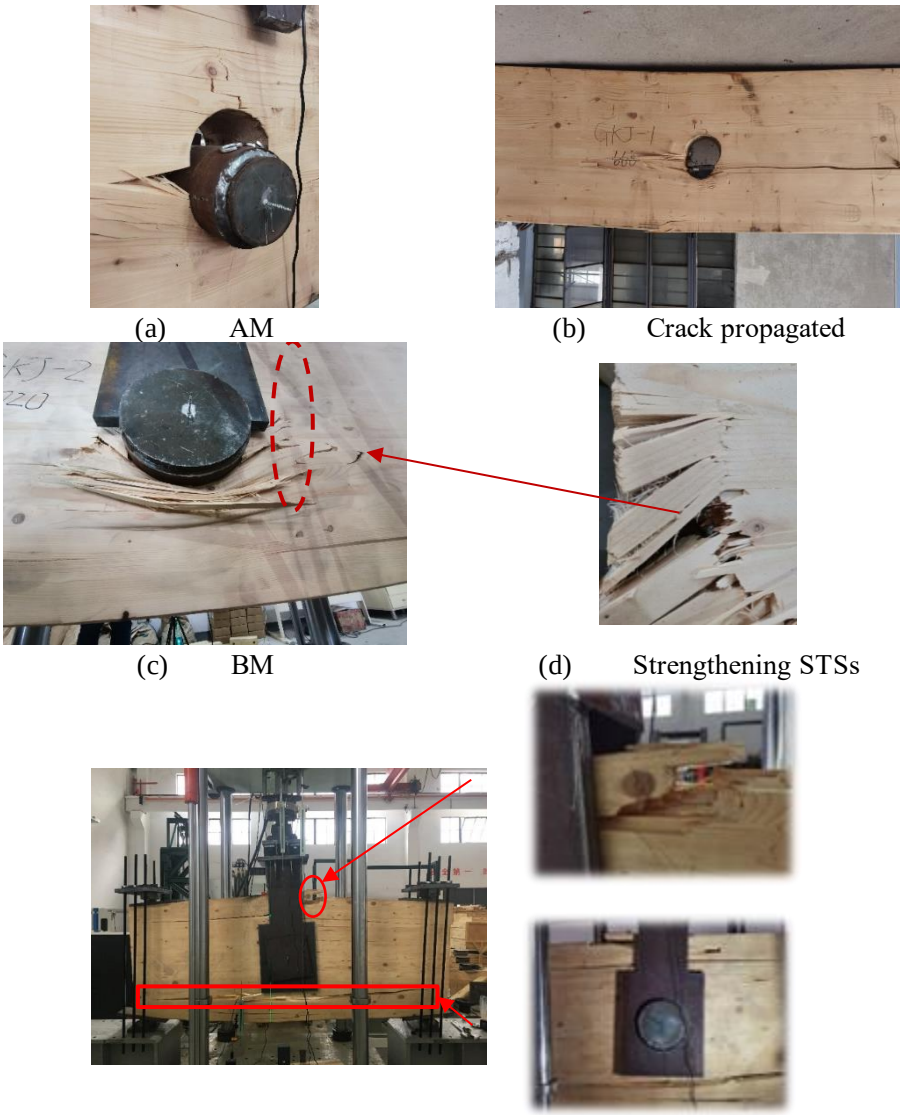
3.1 Experimental observations

The photos of the specimens AM and BM which were both loaded monotonically are shown in Figure 7, respectively. It was observed that for specimen AM, a longitudinal crack initiated in the middle of the hole, when the load reached about 300kN and the displacement of the steel tube was about 40mm. As the load increased, the crack propagated along the longitudinal grain, which inevitably met with the strengthening screws perpendicular to the grain, as shown in Figure 7(a),(b). At the meantime, with the continuing vertical movement of the tube, the squeezing deformation at the embedded area was simultaneously observed. When the load approached the peak load (around 340kN), an obvious longitudinal crack was formed throughout the whole specimen to the end of one side, leading to a significant damage in the specimen as shown in Figure 7(b).

As for specimen BM, similar pattern at the early stage of the loading was observed, where some cracks caused from the squeezing of the steel tube initiated at the hole. With the increasing of the load, similar squeezing area as that of specimen AM was noticed at the embedded region. However, when the load continued to increase, no obvious brittle failure was observed except that the embedded region continued to be squeezed. Figure 7(c),(d) indicated that the cracks around the hole were restricted by the strengthening screws perpendicular to the grain.

The pictures exhibiting the failure mode of specimen BC were listed in Figure 7(e). At a low magnitude of loading when the force was around 50% of the peak load, the steel tube kept squeezing the embedded region of the hole, causing small cracks to propagate. When the peak load was reached (about 450kN),

a longitudinal crack below the hole was observed, as shown in Figure 7(e). The crack continued to open as the actuator continued to move down at the seventh cycle level (i.e. 59.2mm). When the actuator moved in the reverse way, namely upward, another crack symmetrically occurred at the upper region of the wood member above the hole, as shown in the photo. Since the wood member has some initial defect near the upper crack, the crack was observed to propagate to the uppermost layer of the member. With the loading continued to progress, the upper and lower cracks alternatingly propagated until the capacity decreased to 80% of the peak load, which was popularly viewed as the failure point of wood joints.



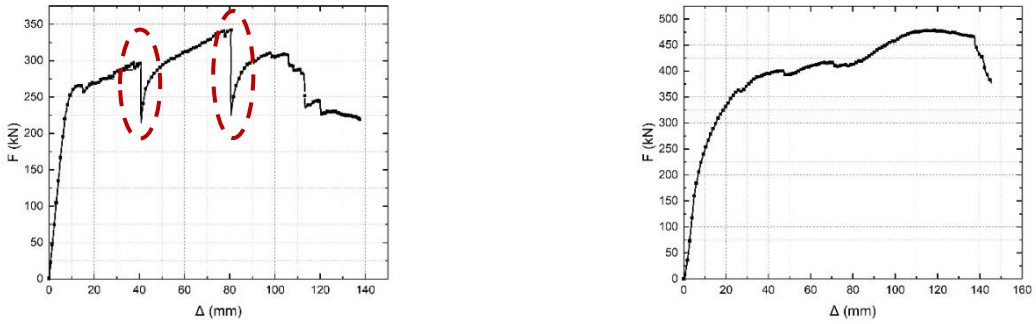


Figure 7. Test observations

3.2 Load-displacement curves

The load-displacement curves for the specimens under monotonic loading were plotted in Figure 8,. Figure 8(a) represents the curve of specimen AM, which is consistent with the experimental observation. At the early stage of loading, the curve progressed linearly when the joint deformed in an elastic way. Then the curve experienced two sudden declines in sequence. The first decline happened at the point where the displacement of the steel tube was 40mm and the shear force reached about 300kN, which corresponds to the first crack initiated at the hole. The capacity continued to increase until the displacement reached 80mm when the peak load of 342.6kN was reached. The second decline

corresponds to the perfoliate crack as stated in section 3.1. After the summit point, the curve increased to a certain rate lower than the summit and then decreased gradually.

As is shown in Figure 8(b), the curve of specimen BM showed a different characteristic than specimen AM. No obvious decrease was observed in the curve. At the early stage of the loading, the force increased linearly along with the displacement of the steel tube before the yield point (about 20mm, 350kN). Then the stiffness decreased significantly after the yield point. The force increased slowly along with the displacement. After the joint reached the peak load (478.2kN), the curve began to decline gradually until 80% of the peak load.

(a) GKJ-1 (b) GKJ-2

Figure 8. Monotonically loaded specimens (i.e. AM, BM)

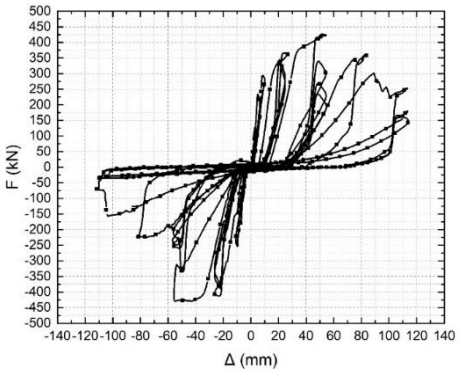

Figure 9. Cyclically loaded specimen BC

Table 2. Connection properties matrix

Specimen No.	Stiffness kN/mm	Yield point		Peak point	
		displacement(mm)	shear(kN)	displacement(mm)	force(kN)
AM	33.0	5.2	171.4	77.7	342.6
BM	27.9	7.9	220.2	118.4	478.2
BC	28.3	7.5	212.6	90.4	428.9

Figure 9 shows the force-displacement hysteretic curve of specimen BC, which was loaded cyclically. The early hysteretic loops showed relatively high and stable stiffness. The later loops were relatively full, which indicates that the energy dissipation ability was good for specimen BC. During the declining

stage of the loading, the curve decreases gradually after the peak load of the certain loop and decreases to zero when the loading direction reverses. The specimen failed at the nineth hysteretic loop, where the capacity of the joint decreased to 80% of the peak load.

All of the connection properties are listed in Table 2.

3.3 Capacity calculation method

Many countries have already put design codes into practice that provide the specific equations to calculate the embedment capacity of wood in various cases. This section arranges these calculating approaches together and compare them with each other, in order to investigate the feasibility of the calculating methods in current codes.

Chinese standard GB50005-2017 provides the calculation for the embedment strength in the direction perpendicular to grain as Eq. (1)

$$f_{e,90} = \frac{212G^{1.45}}{\sqrt{d}} \tag{1}$$

Where G represents the total dry relative density of the wood (10^3kg/m^3), d represents the diameter of the fastener (mm). The equation provided here is similar to that in American code [19].

In European standard EN1995-1-1:2004 [20], embedment strength at an angle α to grain is obtained according to Eqs. (2)~(3):

$$f_{e,\alpha} = \frac{f_{e,0}}{K_{90}\sin^2\alpha + \cos^2\alpha} \tag{2}$$

$$K_{90} = \begin{cases} 1.35 + 0.015d\,(soft\ wood) \\ 1.30 + 0.015d\,(LVL) \\ 0.90 + 0.015d\,(hard\ wood) \end{cases} \tag{3}$$

Furthermore, Canadian standard [21] CSA(O86-09-2009) provides the embedment strength relative to the density as well as the diameter of fasteners as follows:

$$f_{e,90} = 22G(1 - 0.01d) \tag{4}$$

As is easily noticed that, for European and Canadian standards, the embedment strength of wood is directly or indirectly relative to the diameter of the fastener And it can be inferred that no embedment strength can be calculated using current equations with diameter over 100mm since the part (1-0.01d) can't be negative obviously. Therefore, only Chinese or American standards can currently calculate the embedment strength for such large steel-tube joints discussed in this paper. Calculation results are listed below in Table 3 and the comparison with test results are also obtained.

Table 3. Calculation and test results

d(mm)	Test results(kN)	GB50005-2017/NDS-2005(kN)	Error(%)
133(for group A)	342.6	158.6	53.7
273(for group B)	478.2	227.2	52.5

According to Table 3, even if some certain standards can calculate the shear performance for large steel-tube connections, the accuracy is doubted with an error up to 50%. This error means that the test results can be almost two times over calculation results, which indicates that for large steel-tube joints, the capacities are over underestimated.

4. Conclusion

A series of three embedded steel-tube glulam joint have been tested and the results have been compared to the current standards. The conclusions are listed as follows:

(1) The embedded steel-tube glulam joints applied in arched timber structures can achieve high shear capacity and stiffness, which can be a good method of connecting arches together in the out-of-plane direction;

(2) It can be a valuable approach to apply self-tapping screws (STSs) near the joint area perpendicular to the wood grain to help the joint to perform in a more ductile way;

(3) The current standards cannot exactly predict the capacity of large embedded steel-tube glulam joint since the embedment strength cannot be applied to fasteners larger than 100mm in diameter.

Abstract

This article presents a framework for topology optimisation in unbounded media. The air in electromagnetic and acoustic problems and the soil in soil-structure interaction problems are examples of unbounded media. Unbounded media have characteristics that require special methods to describe them properly. Domain discretization methods such as the classical Finite Element Method (FEM) resort to truncation of the unbounded domain, which not only results in computational cost issues, but also violates radiation conditions for the unbounded domain. In this paper, we focus on the case of a soil-structure interaction problem and present a strategy to design via topology optimisation. The unbounded region surrounding this domain is modelled via Boundary Element Method (BEM). Coupling between the two methods is obtained by imposing continuity and equilibrium conditions at their interface. We also present a strategy to describe this coupling in the case in which the finite and boundary element meshes have different orders. The paper discusses the derivation of sensitivity and filtering schemes based on the coupled FEM-BEM equilibrium equation. As an illustrative example, this framework is used in this paper to compute optimised designs for buried foundations. In order to show the flexibility of the framework, we have used both the Solid Isotropic Microstructure with Penalization (SIMP) and the Bi-Directional Evolutionary Structural Optimisation (BESO) methods to solve this foundation optimisation problem. The results show that the present framework is computationally efficient and yields physically consistent results.

Keywords: soil-structure interaction, topology optimisation, coupled methods, foundations

1. Introduction

Topology optimisation (TO) algorithms have become widely used in recent years. The popularisation of these powerful design tools has occurred in conjunction with intense research in different methods [1,2] and applications [3,4], culminating in the possibility of applying topology optimisation to a wide range of engineering problems. However, problems involving unbounded domains, such as soil-structure interaction, have not been studied as extensively as those with finite domains.

Most works involving the structural optimisation of structure-soil systems focus on the problem of a completely buried structure, specifically, deep buried tunnels and excavations [5,6]. More recently, the work of [7] expanded the set of applications of TO in soil-structure interaction by investigating the structural optimisation of buried foundations. All these works have in common that the soil is represented through a large finite element mesh that needs to be truncated at a significant distance from the design domain.

The recent works of [8] and [9] have utilised boundary-element formulations to accurately model the soil and avoid the use of huge meshes in problems of soil-structure interaction. By coupling a finite-element-modelled design domain with the unbounded soil response, they were able to demonstrate that the presence of the soil strongly affects the optimisation of structures on the soil surface. Although these results are encouraging, there is still room for further investigation and improvements in the current approaches.

The present work aims to expand the use of coupled formulations in topology optimisation of soil-structure systems by investigating the optimisation of half-buried structures. Classical four-noded isoparametric finite elements are used to model the optimisation design domain, which is defined at a specific portion of the soil that surrounds the buried part of the structure. The soil is modelled as a semi-infinite elastic medium using an Indirect Boundary Element formulation based on the superposition of influence functions. The two formulations are coupled through the imposition of continuity and equilibrium conditions at the interface. The optimisation is carried out using the BESO and SIMP algorithms. The present results illustrate the effect of applied load position, available material and the coupling scheme on the optimisation final solution.

2. Numerical model

2.1. Problem statement

Consider a linear-elastic, two-dimensional structure of Young's modulus E_c and Poisson ratio ν_c, which has an arbitrary shape and is partially buried in a linear-elastic layer of Young's modulus E_s and Poisson ratio ν_s. The layer extends horizontally without bounds, has a depth of H, and is placed on a rigid bedrock. The optimisation problem can be stated as: given a static load applied over the structure, determine the optimal topology for the buried section of the structure that maximises the stiffness of the soil-structure system, while keeping the volume of material fixed.

2.2. Soil-structure interaction model

The methodology employed in this study involves utilising a boundary-finite element coupling scheme to model the interaction between the soil and the structure. The proposed method employs classical four-noded finite elements to model a rectangular-shaped domain denoted by Ω, which encompasses the embedded portion of the structure (Fig. 1b). This allows each finite element within Ω to be assigned material properties of either the structure (denoted by the sub-index *c*), the surrounding soil (denoted by the sub-index *s*), or to represent voids in the structure. The remaining portion of the semi-infinite soil layer is modelled using an Indirect Boundary Element Method formulation, in which the interface $\Gamma=\Gamma_1+\Gamma_2+\Gamma_3$ (Fig. 1c) is discretized with piecewise constant boundary elements representing a superposition of non-singular influence functions.

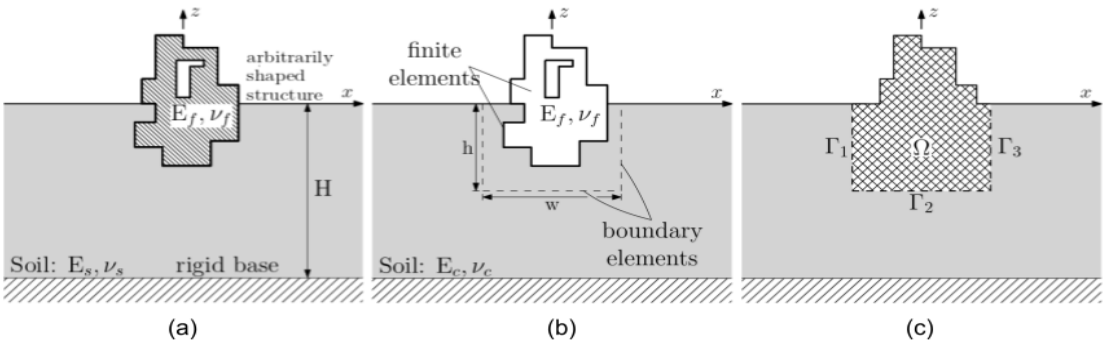

Figure 1. Problem statement: (a) arbitrarily shape half-buried in the soil, (b) subdomains used in the finite- and boundary-element models and (c) subdomain notation.

2.3. Model of the structure

The optimizable domain Ω is modelled with linear-elastic, isoparametric quadrilateral finite elements (FE), with four nodes and two degrees of freedom per node. A plane-strain condition is assumed. The elemental stiffness matrix is given by $\mathbf{k}_c = \int_{-1}^{+1} \int_{-1}^{+1} \mathbf{B}\mathbf{C}^T\mathbf{B} \det[\mathbf{J}] d\xi d\eta$, where **B** is the strain–displacement transformation matrix, **C** is the constitutive matrix for the plane-strain case and **J** is the Jacobian operator of the transformation between natural $(x - z)$ and parametric $(\xi - \eta)$ domains. The global stiffness matrix $\mathbf{K}_c$ of Ω is assembled from $\mathbf{k}_c$ according to the classical assembly algorithm [10]. The equilibrium equation for Ω is given by:

$$\mathbf{K}_c \mathbf{u}_c = \mathbf{f}_c, \tag{1}$$

in which $\mathbf{u}_c$ and $\mathbf{f}_c$ are the vector of nodal displacements and forces, respectively.

2.4. Model of the soil layer

To model the unbounded soil layer, the IBEM formulation involves the discretization of the interface Γ by piecewise constant boundary elements (BE). These elements have a single node located at their center, and the displacements and tractions measured at these nodes are connected via a series of fictitious loads. In the present model, Γ is discretized by $N_s = N_h + 2N_w$ elements, in which N_w is the number of vertical elements at Γ_1 and Γ_3, and N_h is the number of horizontal elements at Γ_2. The displacements and tractions for each element can be written as

$$\mathbf{u}_b = \mathbf{U}\mathbf{q}, \tag{2}$$

$$\mathbf{t}_b = \mathbf{T}\mathbf{q}, \tag{3}$$

in which $\mathbf{u}_b = \{u_x^1\ u_z^1\ u_x^2\ u_z^2 \ldots u_x^{Ns}\ u_z^{Ns}\}^T$ is the vector of nodal displacements, $\mathbf{t}_b = \{t_x^1\ t_z^1\ t_x^2\ t_z^2 \ldots t_x^{Ns}\ t_z^{Ns}\}^T$ is the vector of nodal tractions, $\mathbf{q} = \{q_x^1\ q_z^1\ q_x^2\ q_z^2 \ldots q_x^{Ns}\ q_z^{Ns}\}^T$ is the vector of fictitious loads, and **U** and **T** are displacement and traction influence matrices that incorporate the response of the soil layer. A general term $u_{r,s}^{i,j}$ of matrix **U** represent the displacement of an element *i* of the BE mesh in the *r*-direction due to a unit load uniformly distributed over an element *j* in the *s*-direction $(i, j = 1, \ldots, N_s; r, s = x, z)$. The same convention holds for a general term $t_{r,s}^{i,j}$ of matrix **T**. The solution for the unknown contact loads **q** is obtained by imposing prescribed continuity and equilibrium conditions throughout the element nodes at the Γ interface.

2.4.1. Influence functions

General solutions for stress and displacements in the semi-infinite soil are expressed in terms of non-singular Green's functions, which are commonly referred to as influence functions. The solutions proposed by [9], which take into account loads applied within the soil, are employed in this study. The displacement and stress inside the soil layer are written in terms of improper integrals in the Fourier transformed space:

$$u_i(x, z) = \int_{-\infty}^{\infty} \bar{u}_i\ e^{i\zeta x} d\zeta \tag{4}$$

$$\sigma_{ij}(x, z) = \int_{-\infty}^{\infty} \bar{\sigma}_{ij}\ e^{i\zeta x} d\zeta, \quad i, j = x, z, \tag{5}$$

where $\underline{u_i}$ and $\underline{\sigma_{ij}}$ are functions of the constitutive properties of the soil and load depth. These solutions are computed numerically, as they do not have an explicit solution, demanding a high computational cost. This is due to the integrands containing regions with singularities, and an oscillatory-decaying tail which necessitate the use of specific integration techniques. Details of the numerical evaluation of these functions are presented in [9].

To account for the geometric orientation of the boundary in the problem, the stress terms calculated in Eq. (5) need to be converted into traction terms. This can be achieved with the Cauchy's formula $t_{rt}^{i,j} = \sigma_{rst}^{i,j} n_r^i$, $(r,s,t = x,z;\ i,j = 1,\ldots,N_s)$, in which $\mathbf{n}^i = \{\boldsymbol{n_x^i}\ \boldsymbol{n_z^i}\}^T$ is the unit normal vector at the BE where the traction is being determined, and pointing outward from the soil domain. At Γ_1, Γ_2 and Γ_3, $\mathbf{n}^i = \{1\ 0\}^T$, $\mathbf{n}^i = \{0\ 1\}^T$, $\mathbf{n}^i = \{-1\ 0\}^T$, respectively. Influence functions for loads that are uniformly distributed in the vertical direction are computed for elements located at $\Gamma_{1,3}$, while influence functions for loads that are uniformly distributed in the horizontal direction are computed for elements located at Γ_2.

2.5. Coupling scheme

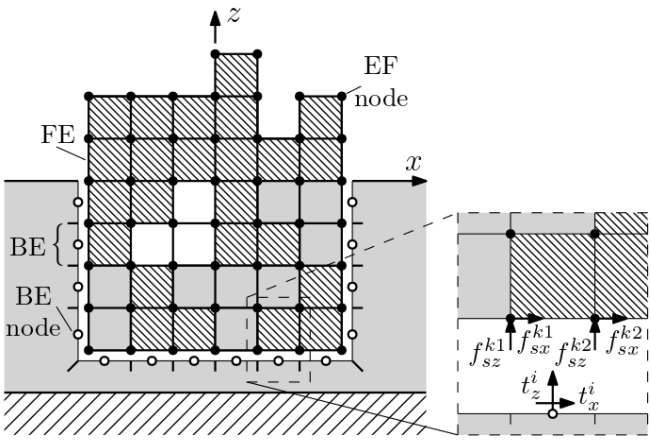

Figure 2. Coupling.

To incorporate the soil response on the design domain, one can implement a finite-boundary coupling scheme. The unbounded soil response over Ω can be expressed in terms of a set of equivalent nodal contact forces $\mathbf{f}_s$ (Fig. 2), acting on the finite element nodes at the Γ interface. Thus, the equilibrium equation of Ω can be written as:

$$\mathbf{K}_c\mathbf{u}_c = \mathbf{f}_c - \mathbf{f}_s. \tag{6}$$

The coupling of Ω and the surrounding soil is achieved by imposing continuity and equilibrium conditions at the interface Γ. The equilibrium condition represents that the equivalent nodal contact force over a finite element can be expressed in terms of the fictitious loads applied over the corresponding boundary element. As the elements used have different orders of approximation, a nodal equivalence transformation given by $\mathbf{f}_s$=**ATq**, is used to represent equilibrium. In this equation, $\mathbf{f}_s = \{f_{sx}^1\ f_{sz}^1\ f_{sx}^2\ f_{sz}^1 \ldots f_{sx}^{n\prime}\ f_{sz}^{n\prime}\}$, **A** is a transformation matrix and *n'* is the number of nodes at the interface Γ. Considering this nodal equivalence transformation, Eq. (6) can be rewritten as

$$\mathbf{K}_c\mathbf{u}_c + \mathbf{ATq} = \mathbf{f}_c. \tag{7}$$

The continuity condition ensures kinematic compatibility of the correspondent FE-BE. This can also be achieved by a linear transformation such as:

$$\mathbf{u}_b = \mathbf{D}\mathbf{u}_c, \tag{8}$$

where **D** is a transformation matrix. In view of Eq. (2), the continuity condition yields

$$\mathbf{D}\mathbf{u}_c - \mathbf{U}\mathbf{q} = \mathbf{0}. \tag{9}$$

Rewriting Eq. (7) and Eq. (8) into a single matrix equation gives

$$\begin{bmatrix} \mathbf{K} & \mathbf{AT} \\ \mathbf{D} & -\mathbf{U} \end{bmatrix} \begin{Bmatrix} \mathbf{u}_c \\ \mathbf{q} \end{Bmatrix} = \begin{Bmatrix} \mathbf{f} \\ \mathbf{0} \end{Bmatrix}, \tag{10}$$

which represents the equilibrium for nodes at the interface Γ. Extending to the entire domain Ω, yields

$$\begin{bmatrix} \mathbf{K} & \begin{Bmatrix} \mathbf{AT} \\ \mathbf{0} \end{Bmatrix} \\ \{\mathbf{D} \quad \mathbf{0}\} & -\mathbf{U} \end{bmatrix} \begin{Bmatrix} \begin{Bmatrix} \mathbf{u}_c \\ \mathbf{0} \end{Bmatrix} \\ \mathbf{q} \end{Bmatrix} = \begin{Bmatrix} \begin{Bmatrix} \mathbf{f} \\ \mathbf{0} \end{Bmatrix} \\ \mathbf{0} \end{Bmatrix}, \tag{11}$$

in which **0** are matrices of zeros of compatible dimensions. Equation (11) represents the present coupled IBEM-FEM formulation, and its solution for a set of applied forces **f** yields the nodal displacements $\mathbf{u}_c$ of Ω, as well as the set of fictitious loads **q**.

3. Topology optimisation

In this work, the focus is on optimising the topology of the buried part of the structure in order to obtain the structure-soil system with the maximum possible stiffness, thus resulting in an optimal foundation design. This is addressed by considering the optimisation problem as one of compliance minimization with a prescribed volume constraint. In the sense of the present IBEM-FEM implementation, this problem can be formulated as

$$\begin{aligned} &\text{Minimise } C(\boldsymbol{x}) = \mathbf{f}^T\mathbf{u}_c, \\ &\text{Subject to } V^* - \textstyle\sum_{i=1}^{Nd} \quad V_i x_i = 0, \\ &\qquad x_i \in \{1,0\}, \\ &\qquad \begin{bmatrix} \mathbf{K} & \mathbf{AT} \\ \mathbf{D} & -\mathbf{U} \end{bmatrix} \begin{Bmatrix} \mathbf{u}_c \\ \mathbf{q} \end{Bmatrix} = \begin{Bmatrix} \mathbf{f} \\ \mathbf{0} \end{Bmatrix}, \end{aligned} \tag{12}$$

in which x_i is the vector of design variables, V^* is the specified maximum of the structure material, N_d is the number of elements in the design domain, and $C(x)$ is the structural compliance, which is the objective function. A value of x_i = 1 corresponds to a structure element and x_i = 0 corresponds to a soil element. In this article, the BESO algorithm [11] is mainly used for the optimisation process.

Considering the problem's two-phase nature, the material interpolation scheme applied is defined by the following power law [12]:

$$E(x_i) = E_s + x_i^p (E_s + E_c), \tag{13}$$

where $p = 3$ is a penalty coefficient.

3.1. Sensitivity numbers

Sensitivity numbers represent the gradient of the objective function with respect to the design variables. The influence matrices **U** and **T**, as well as the transformation matrices **A** and **D**, are not dependent on the elastic properties of the optimizable domain Ω. This implies that the sensitivity analysis is solely dependent on the coupled structural stiffness. For a two-phase material problem, the elemental sensitivities can be written as [11]

$$\alpha_i = \begin{cases} \left[1 - \dfrac{E_s}{E_c}\right] \mathbf{u}_i{}^T \mathbf{k}_i \mathbf{u}_i, & \text{for structure element} \\ 0, & \text{for soil element,} \end{cases}, \tag{14}$$

where $\mathbf{k}_i$ and $\mathbf{u}_i$ are the elemental stiffness matrix and the vector of nodal displacements of element *i*, respectively. These numbers are derived considering the hard-kill BESO algorithm, in which the penalty factor *p* in Eq. (13) approaches infinity.

3.2. BESO algorithm

The Bi-directional Evolutionary Structural Optimisation method (BESO) [11] is a well-established optimisation algorithm [3] that consists of an iterative material removal scheme based on the ranked elemental sensitivity numbers (Eq. (14)). The method applies a binary approach, in which, starting from a given initial design, elements with the lowest sensitivities are iteratively removed (switching x_i from 1 to 0). Elements that have been removed from the design domain can also be reintroduced (switching x_i from 0 to 1) to prevent local minimum solutions. The net amount of material removed at each iteration is controlled by an evolutionary ratio (*ER*), given as a percentage of the design domain volume. The maximum of added material is also controlled by a maximum admission ratio (AR_{max}) parameter.

Traditional structural optimisation problems like checkerboard patterns and mesh-dependent solutions are avoided by applying a smoothing filter to the elemental sensitivities. In this work, the filtered sensitivity number of element *i* is given by:

$$\hat{\alpha}_i = \frac{\sum_{j=1}^{N_d} \alpha_i H_{ij}}{\sum_{j=1}^{N_d} H_{ij}}, \tag{15}$$

Where $H_{ij} = \max\{0, r_f - r_{ij}\}$, r_f is the filter radius and r_{ij} is the distance between the centers of the *i*-th and *j*-th elements.

A historic stabilisation scheme is also employed in order to enhance optimisation convergence properties [11]. This is obtained by taking the average sensitivity number of two consecutive iterations:

$$\hat{\alpha}_i^k = \frac{\hat{\alpha}_i^k + \hat{\alpha}_i^{k-1}}{2}, \tag{16}$$

in which *k* denotes the current iteration. It is assumed that optimisation reaches convergence when the value of the objective function remains stable for at least 10 consecutive iterations. This is formulated by the following equation

$$\text{error} = \frac{\left|\sum_{i=1}^{N}(C_{k-i+1} - C_{k-N-i+1})\right|}{\sum_{i=1}^{N} C_{k-i+1}} \leq \tau, \tag{17}$$

where the relative convergence error must be less than a small value $\tau = 10^{-4}$, and $N = 5$.

4. Numerical results

This section presents some numerical examples of the present implementation. The problem considered is that of the foundation of a rigid strip footing resting on the soil surface. The footing has a width of *a* and is subjected to vertical symmetric and eccentric static loads (Fig. 3). The optimizable domain Ω was defined as a square with $w = h = 4a$. The plate and the design domain are discretized with a homogeneous mesh of quadrilateral finite elements with size of $0.04a$ (total of 10^{-4} elements). All results consider a rigid base with depth of $H = 40$, a foundation 100 times stiffer than the soil, $E_c = 100E_s$, and with the same Poisson ratio of $\nu_c = \nu_s = 0.25$. The BESO parameters used were $ER = 0.02$ % and $AR_{max} = 0.05$ %, with a filter radius of 2.5 times the size of the element. The SIMP algorithm was applied with a continuation method following the approach proposed by [7]. Results illustrate the effect of the foundation volume, applied load position and coupling scheme on the optimisation results.

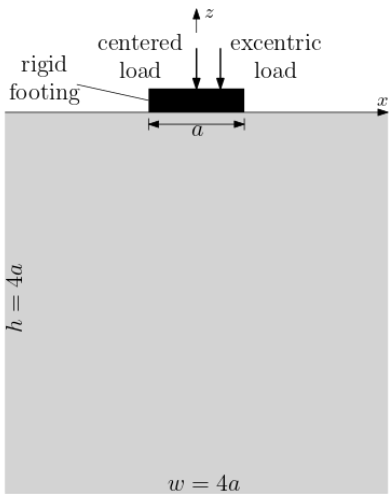

Figure 3. Design domain.

4.1. Effect of the applied load position

Figure 4 shows the final optimisation solution for a foundation under the effect of a symmetric and an eccentric applied load. The target volume for the foundation is 4.5 % of the design domain volume for both scenarios. In the symmetrical load case, the foundation material is concentrated symmetrically at both footing edges, which is physically consistent, as at these points the stress reaches its maximum value over the entire domain. The final topology of the foundation resembles the shape of a traditional piled-foundation, but with a slight inclination from the vertical. In the eccentric load case, the pile-like structures are not symmetrical, and it is observed that there is a noticeable greater concentration of material at the most demanded end of the footing.

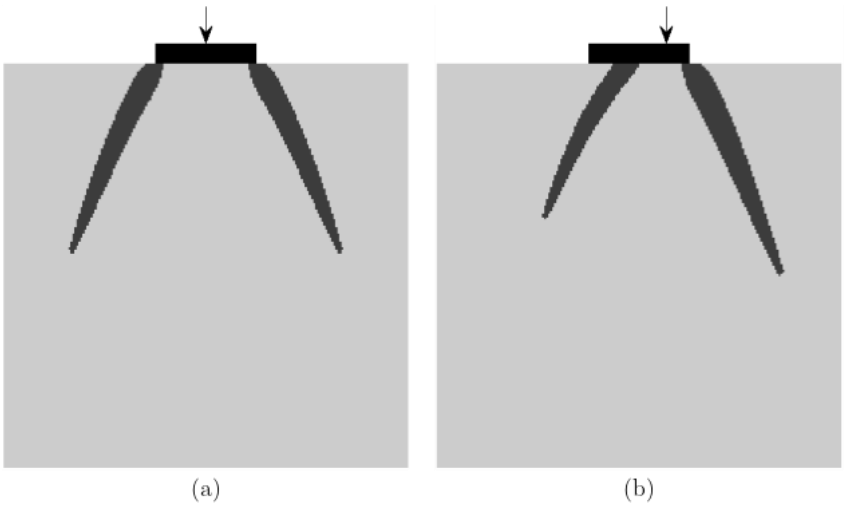

Figure 4. Effect of the applied load position on the optimisation solution: (a) symmetrical load and (b) eccentric load.

The evolution of the objective function for both load cases is presented in Fig. 5. Note that the structural compliance value is significantly increased throughout the iterations as the foundation material is replaced by soil. The objective function value for the centered load case is C = 0.1905 and for the eccentric load case is C = 0.2111, which indicates that the asymmetrical foundation configuration is more flexible than the symmetric configuration.

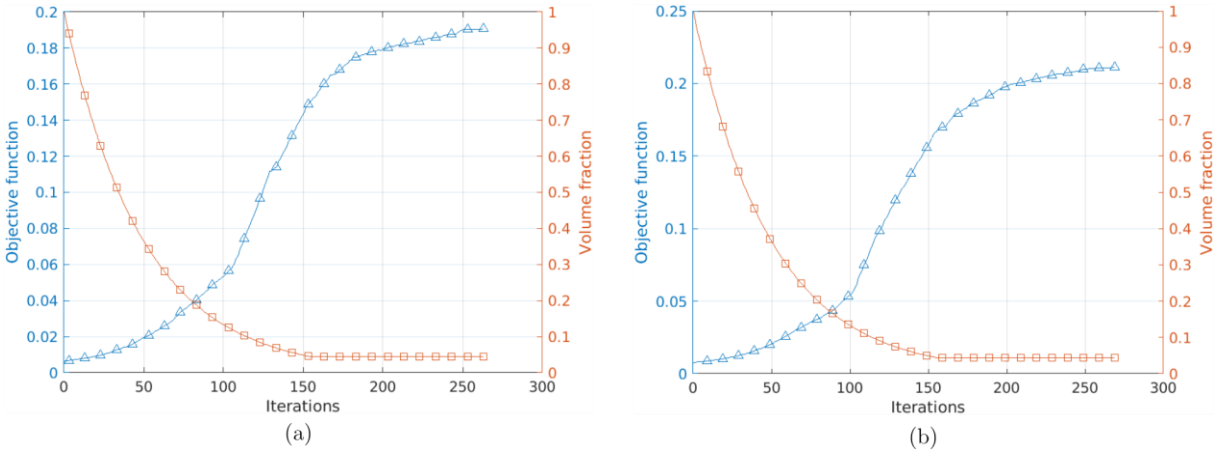

Figure 5. Objective function evolution: (a) symmetrical load and (b) eccentric load.

Figure 6 illustrates the final solution obtained for both load cases using the SIMP method. These results are mostly similar to the results obtained with the BESO method, but with the difference of the formation of thin horizontal bars at the soil surface around the footing, which are absent in the BESO solution. Also, the pile-like structures obtained with the SIMP method are a little more deeper and straighter than those obtained with BESO. The final solutions obtained with the SIMP method present a stiffer configuration than those obtained with BESO method, as the objective function value for the centered load case is C = 0.1590 and for the eccentric load case is C = 0.1824. This is directly related to the fact that the solutions obtained by the SIMP are deeper.

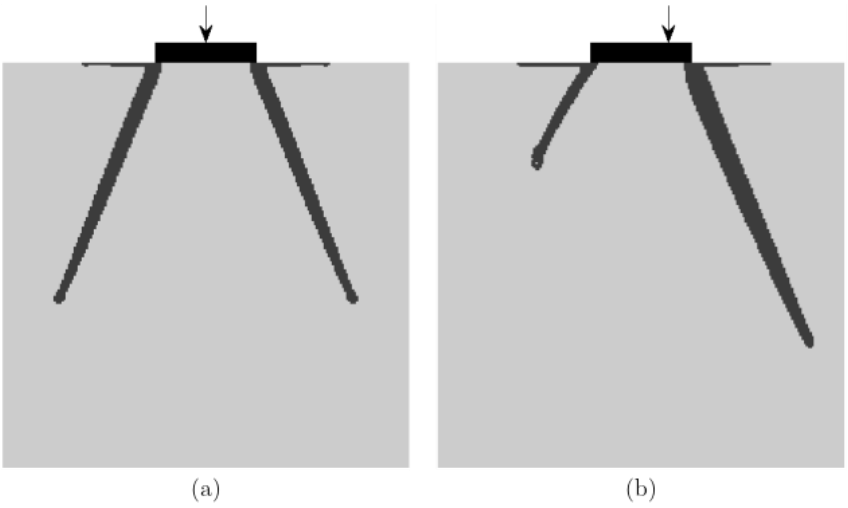

Figure 6. Final solutions obtained with the SIMP method: (a) symmetrical load and (b) eccentric load.

4.2. Effect of foundation volume

Figure 7 shows the influence of the foundation prescribed volume. The results consider a footing under centered load and two prescribed foundation volumes of 4.5% and 10% of the design domain, respectively. It is observed that the more material available, the deeper the optimised foundation is. This is physically consistent with the engineering practice, as deeper foundations present more contact area with the soil which increases the capacity of load transfer from the structure to the soil.

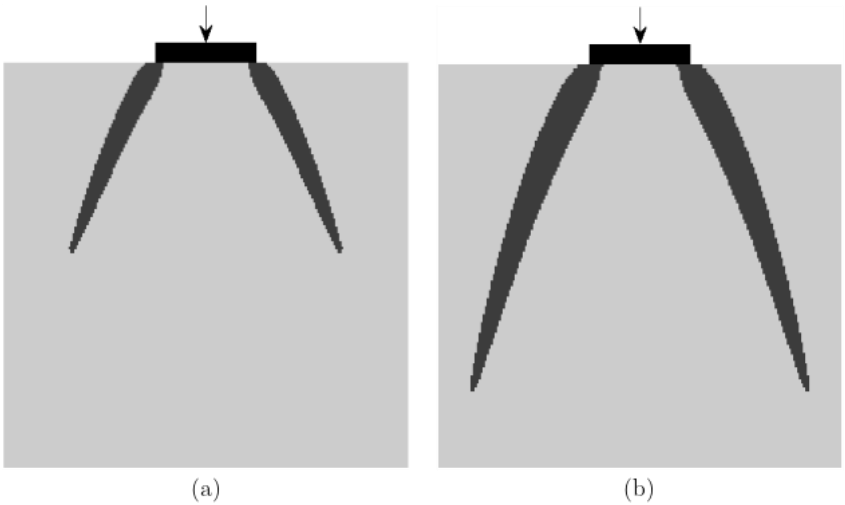

Figure 7. Effect of prescribed foundation volume on the optimisation solution: (a) foundation with a volume of 4.5% of design domain and (b) foundation with a volume of 10% of design domain.

4.2. Effect of coupling

In general, coupling a single finite element to a single neighbour boundary element provides the accurate solution to Eq. (11), but one can use different orders of mesh correspondence to reduce the computational cost at the expense of some accuracy. Figure 8 presents the difference between the final optimised solution for the foundation of a rigid footing subject to a centered vertical load using a 1-1 FE-BE and a 2-1 FE-BE correspondence. The foundation prescribed volume is 4.5% of the design domain volume. Note that both solutions are nearly identical, but the solution obtained with the 2-1 correspondence is on average five times faster, demonstrating the advantage of this approach for computational efficiency.

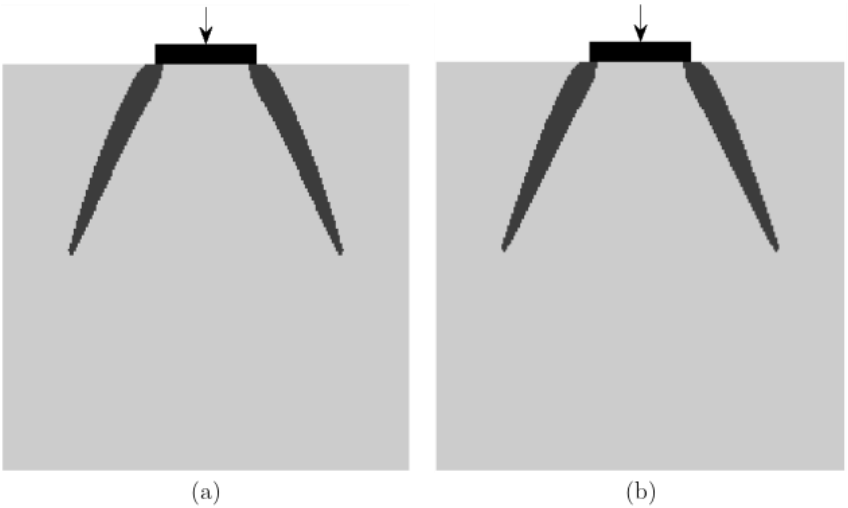

Figure 8. Effect of different orders of coupling correspondence on the optimisation solution: (a) one finite element coupled with one boundary element and (b) two finite elements coupled with one boundary element.

5. Final remarks

This work investigated the topology optimisation of buried foundations. The soil-structure system was modelled via an IBEM-FEM formulation which was used in conjunction with BESO and SIMP algorithms to optimise the material distribution of the buried structure. The soil was modelled through

an Indirect-BEM formulation and was considered a homogeneous semi infinite linear-elastic layer resting over a rigid bedrock. The optimisation domain was defined as a square region in the soil, modelled via classical quadrilateral finite elements. The representative case of the foundation of a rigid strip footing under vertical static loads is investigated. The optimised structure topology resembles that of a piled-foundation, indicating consistency with the engineering practice. It was observed that the position of the applied load significantly affects the optimisation solution. Additionally, increasing the available material resulted in a deeper optimised foundation. Lastly, results have shown that one can choose different coupling configurations to improve the algorithm efficiency without compromising the optimisation results.

Abstract

The level set-based optimisation method generally uses the rectangular/hexahedral mesh in finite element analysis despite its zero-level contour crossing these elements. The work uses adaptive triangular mesh to improve the similarity of the finite element model with the smooth structure presented by the level set method. Also, the level set function is a linear combination of cubic B-spline basis functions to increase optimisation flexibility and structural smoothness. The edges of the triangular mesh are equivalent to a balanced truss network, with its adaptivity adjusted by the distance between the nodes to the boundaries. The sensitivity of design variables, the coefficients of the B-spline basis functions, is analysed using the adjoint variable method. Their values should be interpolated from the nodes of the body-fitted mesh to the nodes of rectangular elements. A reaction-diffusion method and void elements-excluding scheme are used to update and reduce the design variables. Numerical examples illustrate that elegant structures with ultra-smooth boundaries can be generated with high efficiency.

1. Introduction

Structural topology optimisation involves the computational layout of material within a design domain based on minimising a costing function and fulfilling various constraints. The approach to structural representation is a critical factor in optimisation as it greatly impacts the final results. The homogenisation method [1] controls material occupancy in an element by using the size of a rectangular void. The solid isotropic material with the penalisation (SIMP) method [2, 3], and bi-directional evolutionary optimisation method (BESO) [4–7] all use the volume ratio of solid material in a local element to represent the structure. The SIMP method imposes a penalty factor greater than or equal to 3 to allow for either complete material occupancy or void in an element, while the grey element with a volume ratio between 0 and 1 is sometimes necessary. In contrast, the level set method [8–10] assumes the structural profile as the zero-level contour of a higher-dimensional level set function. Although this guarantees continuous boundaries, the application of rectangular/tetrahedral elements in finite element analysis makes it meaningless. Therefore, automatic adaptive mesh generation is essential for topology optimisation, as a high-quality body-fitted mesh can accurately describe and discretise the design domain geometry. In the past, various techniques have been proposed for adaptive mesh generation, including polygonal mesh [11], fluid relaxation analogy [12], and feature-aware smoothed particle hydrodynamics [13]. More recently, level-set-based mesh adaptation methods [14, 15] have been proposed and applied in topology optimisation. Closed-source re-meshing tools like MMG, Rhino, and ZBrush have been used to generate body-fitted meshes.

In addition to body-fitted mesh, a proper structural representation method can also be considered to provide smooth boundaries. For example, B-spline and non-uniform rational basis spline (NURBS) are widely used methods for expressing geometry in computer-aided design/manufacturing (CAD/CAM). They offer global control over the design domain while allowing for local adjustments. In the pursuit of bridging structural topology optimisation with CAD/CAM, researchers have explored using spline functions in structural topology optimisation. One such attempt involved Wall et al. [16], who combined isogeometric analysis (IGA) with shape optimisation, using NURBS to create an exact geometry model. However, the quality of the mesh deteriorated as optimisation progressed due to the high reliance on control points. To address this issue, researchers have turned to parametric representation on the level set function, rather than on the structure directly, to achieve clear and smooth boundaries.

Therefore, the B-spline level set representation method and body-fitted mesh are combined in this article. We propose a reaction diffusion-based B-spline level set method that uses a body-fitted mesh and nonlinear diffusion regularisation. The algorithm updates the positions of vertices iteratively by finding a solution to force equilibrium in the bars, generating a high-quality triangular mesh that captures the boundaries. Delaunay triangulation is used to connect the nodes, forming the body-fitted mesh. The sensitivities generated by adaptive mesh are interpolated to produce B-spline coefficients of sensitivities. Simultaneously, the B-spline coefficients of the level set function is regarded as the designed variables, updated by the reaction-diffusion method. Numerical examples illustrate that elegant structures with ultra-smooth boundaries can be generated with high efficiency.

2. Problem statement

2.1. Optimization problem

The objective of this study is to minimise the mean compliance in order to showcase the advantages of using a B-spline-based level set function using adaptive mesh for structural topology optimisation. The mathematical representation of this optimisation problem, illustrated in Figure 1, can be expressed as:

$$\begin{cases} -\mathrm{div}(\boldsymbol{\sigma}(\mathbf{u})) = f_a(\mathbf{x},\mathbf{u}) & \text{in } D \\ \mathbf{u} = 0 & \text{on } \Gamma_D \\ \boldsymbol{\sigma}(\mathbf{u})\cdot\mathbf{n} = f_b(\mathbf{x},\mathbf{u}) & \text{on } \Gamma_N \\ \boldsymbol{\sigma}(\mathbf{u})\cdot\mathbf{n} = 0 & \text{on } \Gamma_H \end{cases} \tag{1}$$

where $\mathbf{x}$ represents a point situated in the design domain D, $\mathbf{n}$ is the outward normal to the boundary, $\mathbf{u}$ is the displacement field, Γ_D is the Dirichlet boundary that indicates the fixed displacement, Γ_N is the non-homogeneous Neumann boundary that implies the imposed surface traction load with Γ_H being the homogeneous Neumann boundary.

Hooke's law allows us to calculate the stress tensor $\boldsymbol{\sigma}(\mathbf{u})$ and is expressed as:

$$\boldsymbol{\sigma}(\mathbf{u}) = \mathbf{C} : \boldsymbol{\varepsilon}(\mathbf{u}) = 2\mu_1\boldsymbol{\varepsilon}(\mathbf{u}) + \mu_2\mathrm{tr}(\boldsymbol{\varepsilon}(\mathbf{u}))\mathbf{I} \tag{2}$$

where the strain tensor $\boldsymbol{\varepsilon}(\mathbf{u})$ is calculated as 0.5 times the sum of the gradient of displacement $\mathbf{u}$ and its transpose, which is represented as $\boldsymbol{\varepsilon}(\mathbf{u})=0.5(\nabla\mathbf{u}+(\nabla\mathbf{u})^T)$. The fourth-order elasticity tensor $\mathbf{C}$ is used in Hooke's law to calculate the stress tensor $\boldsymbol{\sigma}(\mathbf{u})$. The Lamé coefficients μ_1 and μ_2 are related to Young's modulus E and Poisson's ratio v. The term $\mathrm{tr}(\boldsymbol{\varepsilon}(\mathbf{u}))$ represents the trace of the strain tensor $\boldsymbol{\varepsilon}(\mathbf{u})$.

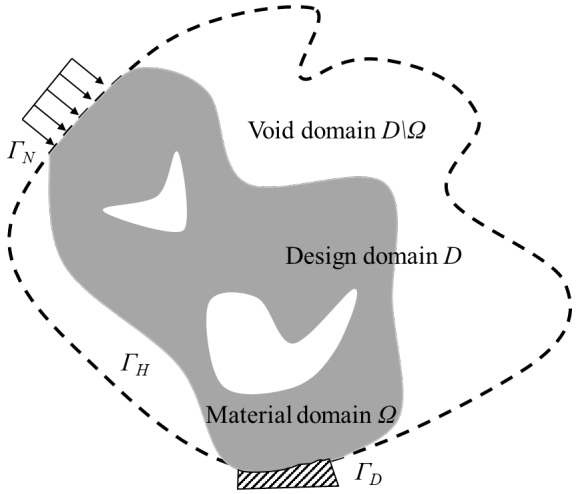

Figure 1. Schematic of the optimisation problem.

An optimisation problem with an objective functional F subject to a volume constraint functional G can be generally represented as:

$$\begin{aligned} &\inf_{\chi_\Omega} F(\chi_\Omega(\mathbf{x})) = \int_D f_a(\mathbf{x},\mathbf{u})\chi_\Omega(\mathbf{x})d\Omega + \int_{\Gamma_N} f_b(\mathbf{x},\mathbf{u})\chi_\Omega(\mathbf{x})d\Gamma_N \\ &\text{subject to } G(\chi_\Omega(\mathbf{x})) = \int_D \chi_\Omega(\mathbf{x})d\Omega - V_{\max} \le 0 \end{aligned} \tag{3}$$

The material distribution problem can be transformed using a characteristic function $\chi_\Omega \in L^2$, which is defined as follows:

$$\begin{cases} \chi_\Omega(\mathbf{x}) = 1 & \text{if } \mathbf{x} \in \Omega \\ \chi_\Omega(\mathbf{x}) = 0 & \text{if } \mathbf{x} \in D \setminus \Omega \end{cases} \tag{4}$$

Then, the analysis in Section 2.1 shows that the characteristic function $\chi_\varphi(\varphi)$ is generated by a level set function expressed by B-splines.

The Lagrange function for the classical level set-based topology optimisation method can be constructed as follows:

$$\inf_{\varphi} L(\chi_\varphi(\varphi),\varphi) = F_d(\chi_\varphi(\varphi),\varphi) + \lambda\left(\int_D \chi_\varphi(\varphi)d\Omega - V_{\max}\right) \tag{5}$$

where L represents the Lagrangian, λ is the Lagrange multiplier of the volume constraint, and F_d is the objective function with a fictitious interface energy term:

$$F_d(\chi_\varphi(\varphi),\varphi) = \int_D f_a(\mathbf{x},\mathbf{u},\chi_\varphi(\varphi))d\Omega + \int_{\Gamma_N} f_b(\mathbf{x},\mathbf{u},\chi_\varphi(\varphi))d\Gamma_N + \int_D \frac{1}{2}\tau\left|\nabla\varphi\right|^2 d\Omega \tag{6}$$

2.2. Structures representation

The conventional level set method utilises a level set function to represent a structure in higher dimensions. Figure 2 illustrates how the zero-level contour $\partial\Omega$ of the level set function φ ($\mathbf{x}$, t) divides the design domain D into regions Ω and $D\backslash\Omega$ based on its sign. This can be expressed mathematically as:

$$\begin{cases} \varphi(\mathbf{x},t) = 0 & \forall \mathbf{x} \in \partial\Omega \\ \varphi(\mathbf{x},t) < 0 & \forall \mathbf{x} \in D \setminus \Omega \\ \varphi(\mathbf{x},t) > 0 & \forall \mathbf{x} \in \Omega \end{cases} \tag{7}$$

where $\mathbf{x}=(u, v)\in R^2$ denotes the global coordinates of a point in Ω and t represents the pseudo-time for the evolution of the level set function.

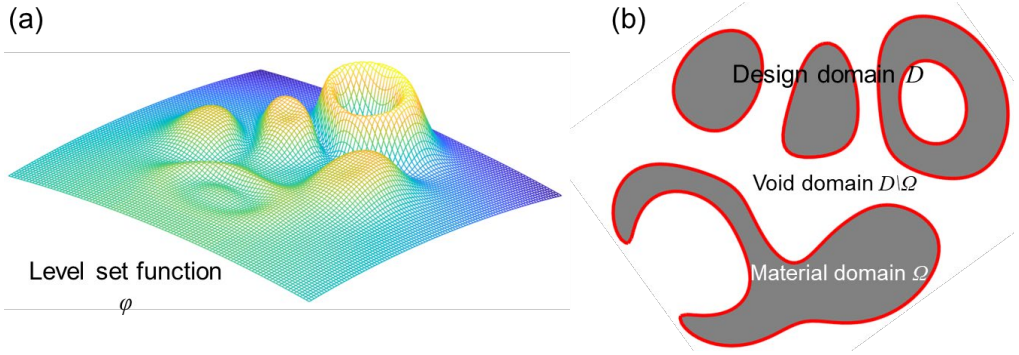

Figure 2. (a) The level set function and (b) its zero-level contour.

The characteristic function χ can be used to represent material presented at a local point and is defined as:

$$\begin{cases} \chi_\varphi\left(\varphi(\mathbf{x},t)\right) = 1 & \text{if } \varphi(\mathbf{x},t) \geq 0 \\ \chi_\varphi\left(\varphi(\mathbf{x},t)\right) = 0 & \text{if } \varphi(\mathbf{x},t) < 0 \end{cases} \tag{8}$$

According to the tensor product of B-spline functions, the level set function is implicitly expressed as the linear combination of cubic B-spline basis functions in our work as:

$$\varphi(\mathbf{x},t) = \sum_{i=1}^{m}\sum_{j=1}^{n} c_{ij}(t)\cdot N_{ij}(\mathbf{x}) = \sum_{i=1}^{m}\sum_{j=1}^{n} c_{ij}(t)\cdot B_i(u)B_j(v) \tag{9}$$

Where the bivariate B-spline function N_{ij} can be expressed as $B_i(u)\ B_j(v)$, where $B_i(u)$ and $B_j(v)$ are the B-spline basis functions defined on the knot vectors in the x and y directions. The coefficient c_{ij} parameterises the level set function.

The standard B-spline shape function in an element can be generated by the Cox-de-Boor formula, the corresponding curves are shown in Figure 3. The detailed generation process can be referred to [17].

$$\begin{aligned} B_1(\xi) &= \frac{1}{6}\left(1-\frac{\xi}{a}\right)^3 \\ B_2(\xi) &= \frac{1}{6}\left[3\left(\frac{\xi}{a}\right)^3 - 6\left(\frac{\xi}{a}\right)^2 + 4\right] \\ B_3(\xi) &= \frac{1}{6}\left[-3\left(\frac{\xi}{a}\right)^3 + 3\left(\frac{\xi}{a}\right)^2 + 3\left(\frac{\xi}{a}\right) + 1\right] \\ B_4(\xi) &= \frac{1}{6}\left(\frac{\xi}{a}\right)^3 \end{aligned} \tag{10}$$

The $B_j(\eta)$ has similar formulae to $B_i(\xi)$, so they are not presented herein.

With 4×4 B-spline shape functions of x and y directions, Eq. (9) in each element becomes:

$$\varphi^e(\xi,\eta,t) = \sum_{i=1}^{4}\sum_{j=1}^{4} c_{ij}(t)\cdot N_{ij}(\xi,\eta) = \sum_{i=1}^{4}\sum_{j=1}^{4} c_{ij}(t)\cdot B_i(\xi)B_j(\eta) = \mathbf{N}(\xi,\eta)\cdot\mathbf{C}_\varphi(t) \tag{11}$$

where $\underbrace{\mathbf{N}(\xi,\eta)}_{1\times16}$ is the row vector form of $\underbrace{\mathbf{N}_0(\xi,\eta)}_{4\times4}$ and $\underbrace{\mathbf{C}_\varphi(t)}_{16\times1}$ is the column vector of $\underbrace{\mathbf{C}_{0\varphi}(t)}_{4\times4}$. Thus, the design variables become the coefficients c_{ij}.

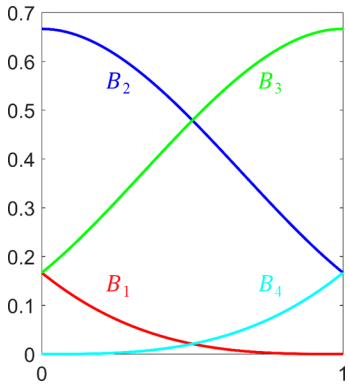

Figure 3. Standard B-spline shape function in an element of x direction.

3. Numerical implement

3.1 Body-fitted mesh generator

In this paper, the adaptive triangular mesh generation method proposed by Persson and Strang [18] is utilised to improve the quality of the boundaries. The node sensitivity field obtained from the bi-sectioning method is not only utilised for redistributing the solid and void domain but also for determining the material boundaries based on its zero-level isosurface. A 2D Gaussian filter is applied to further refine the material boundaries within the design domain. To generate a point set on the boundary, the MATLAB function "contour" is used, and the spacing between these nodes is adjusted before being fixed as the element vertices. Points with narrow spacing are merged to avoid singularity, and additional points are inserted between points with ample spacing to capture the smooth interface accurately.

An initial pattern is generated using Delaunay triangulation with uniformly distributed nodes located on the boundaries. To satisfy user-defined mesh density, the positions of nodes are iteratively changed by solving the force-displacement function for the edges. Hooke's law is used to calculate the repulsive force in bars F_e, based on the current length l and the expected unextended length l_0 of each bar, as follows:

$$F_e(l,l_0) = k_0(l_0 - l) \tag{12}$$

where k_0 is the modulus of elasticity. The expected bar length l_0 specified by the user is used to control the mesh density. The resultant force $\boldsymbol{F}_p$ for each node is the sum of force vectors from the connected bars, except for the fixed nodes where the force is zero to prevent movement. With the node coordinate matrix $\boldsymbol{p}$, the ODE system can be expressed as follows:

$$\frac{d\boldsymbol{p}}{dt} = \boldsymbol{F}_p(\boldsymbol{p}) \tag{13}$$

The approximate solution can be updated iteratively using the forward Euler method starting from the regularly distributed nodes as:

$$\boldsymbol{p}_{n+1} = \boldsymbol{p}_n + \Delta t \boldsymbol{F}_p(\boldsymbol{p}_n) \tag{14}$$

where Δt is the artificial time, set to 0.2 in the MATLAB code. After a prescribed maximum number of iterations, an elegant triangular mesh with the desired density is generated by the unstructured mesh generator, as shown in Figure 4. The red curve represents the smooth interface between the solid

(yellow) and void (grey) domains, with each triangular element being either fully solid or fully void to avoid intermediate densities in the design domain. For a detailed description of the mesh generation process, please refer to [19, 20].

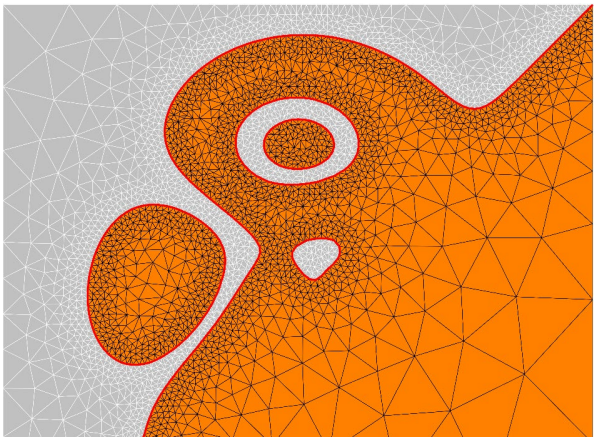

Figure 4. The adaptive triangular elements produced by the unstructured mesh generator.

Then, finite element analysis and sensitivity analysis are both launched based on the generated adaptive triangular mesh. To integrate with the B-spline level set method, the shape sensitivities must be interpolated to generate the corresponding B-spline coefficients.

3.2 Update scheme

In order to minimise the number of iterations and manage the geometrical complexity of the optimised structure, the reaction-diffusion equation is applied to modify the design variables, specifically the B-spline coefficients. This methodology is detailed below.

It is assumed that the variation of the level set function is proportional to the derivative of Lagrangian L' with a coefficient of K=1, resulting in the following equation.

$$\frac{\partial \varphi}{\partial t} = -K \cdot L' = -L' \tag{15}$$

Substituting Eqs. (5) & (6) into Eq. (15) yields:

$$\frac{\partial \varphi}{\partial t} = -(\bar{F}' + \tau \cdot \nabla^2 \varphi) \tag{16}$$

The finite difference approach can be employed to discretise Eq. (16) in the time direction as follows:

$$\frac{\partial \varphi}{\partial t} = \frac{\varphi(t+\Delta t) - \varphi(t)}{\Delta t} = -(\bar{F}' + \tau \cdot \nabla^2 \varphi) \tag{17}$$

where Δt is the step for fictitious time t. Then, substitute Eq. (11) into the reorganised Eq. (17) in weak form, the B-spline based reaction-diffusion equation is generated as:

$$\mathbf{T} \cdot \mathbf{C}_{\varphi}(t+\Delta t) = \mathbf{Y} \tag{18}$$

where $\mathbf{T}$ and $\mathbf{Y}$ are:

$$\mathbf{T} = \frac{1}{\Delta t} \underbrace{\int_V \mathbf{N}^T \mathbf{N}_g dV}_{\mathbf{NN}} + \tau \underbrace{\int_V \nabla^T \mathbf{N} \nabla \mathbf{N}_g dV}_{\mathbf{dNdN}} \tag{19}$$

$$\mathbf{Y} = \underbrace{\int_V \mathbf{N}^T \mathbf{N}_g dV}_{\mathbf{NN}} \cdot \underbrace{\left(-\mathbf{C}_{\bar{F}'}(t) + \frac{\mathbf{C}_\varphi(t)}{\Delta t} \right)}_{\mathbf{C_Y}} \tag{20}$$

NN and **dNdN** can be pre-calculated when parameters Δt and τ are decided, thus resulting in saving time when updating B-spline coefficients iteratively. Detailed updating process can be referred to [17].

4. Numerical examples

In both cases, the time step size for fictitious time t is set to 2, and all initial B-spline coefficients are initialised to 1. The initial body-fitted mesh is created using a uniform-distributed pore pattern. The convergence check is performed after reaching the minimum number of iterations, and the optimisation stops if the previous five iterations of the objective function differ by less than 1%. The precision of l_1 and l_2 in the bi-section method is set to 10^{-6}.

The first example involves a Messerschmitt-Bölkow-Blohm (MBB) beam with 240×80 B-spline elements, and symmetric boundary conditions are applied. The optimisation result for the MBB beam is presented in Figure 5. A regularisation parameter τ of 0.6 is used for the diffusion term, and a volume fraction upper limit of 0.5 is applied. The mean compliance problem converges within 20 iterations and takes 707.4 seconds to complete.

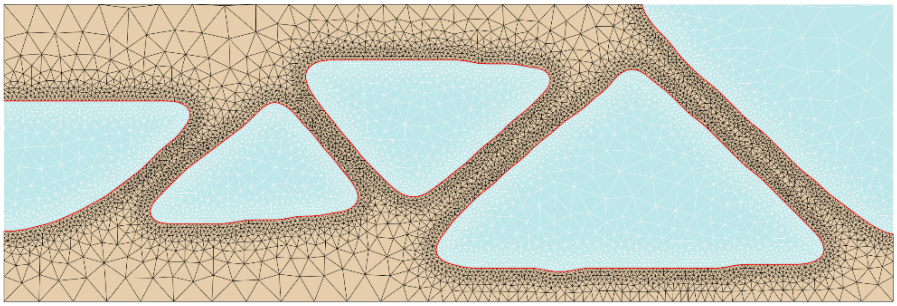

Figure 5. The optimised MBB beam.

The second example deals with a cantilever beam consisting of 200×100 B-spline elements. The optimisation result for the cantilever beam is shown in Figure 6, with a volume fraction upper limit of 0.3. The regularisation parameter τ for the diffusion term is set to 0.1, and the program converges within 20 iterations, taking 1026.0 seconds to complete.

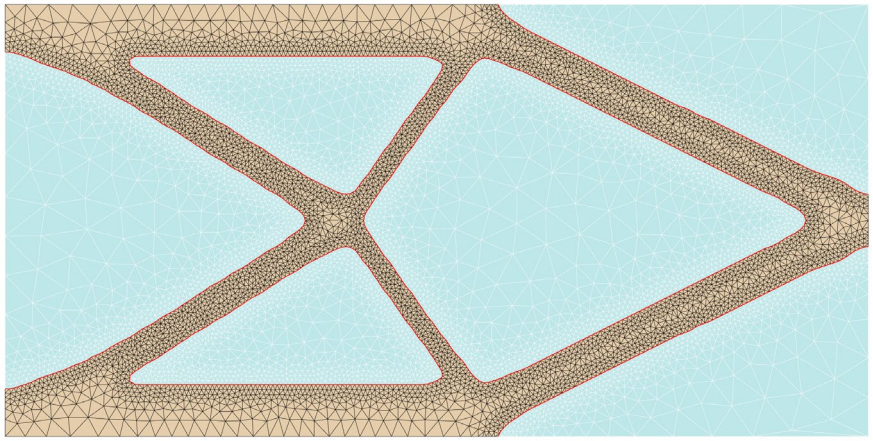

Figure 6. The optimised Cantilever beam.

5. Conclusions

In conclusion, the combination of RDBLS and body-fitted mesh is a promising approach for topology optimisation problems. RDBLS provides a powerful parametric representation method that allows for precise control of the level set function through B-spline coefficients, while the body-fitted mesh with an adaptive mesh generator can efficiently increase the flexibility of topology optimisation with a denser mesh around boundaries and a coarser mesh away from them. The synergy of these two methods has demonstrated significant improvements in the accuracy and efficiency of topology optimisation and it has the potential to be applied to fluid and optic problems, which require smooth boundaries for accurate physical performance calculations. Therefore, we believe that this combined approach will have a significant impact on the field of topology optimisation and will be beneficial for future research and practical applications.

Abstract

Recent years have seen rapid developments in advanced concrete construction techniques, such as 3D-printed moulds and 3D concrete printing, enabling the construction of free-form concrete structures. However, due to the poor tensile capacity of concrete, it has been a great challenge to design structurally efficient concrete structures that are applicable to automated construction. To address this challenge, the multi-material bi-directional evolutionary structural optimisation (MBESO) method, which arranges two different materials suitable for tension and compression in the respective tensile and compressive regions of the structure, can be used to design efficient composite structures. In this study, an 800 mm × 800 mm × 120 mm steel cable-supported concrete slab is designed using the MBESO method. Furthermore, the structural analysis confirms the efficiency of the composite slab, demonstrating its potential for use in future practical engineering. The proposed steel-concrete composite model in this paper maximises concrete's compressive properties and circumvent its poor tensile ability, offering an innovative and efficient structural design strategy for concrete structures and potentially other materials such as clay and gypsum.

Keywords: topology optimisation, concrete slab, multi-material topology optimisation, composite structure, form finding

1. Introduction

Structural optimisation is crucial for architectural structural design, particularly for the design of concrete structures [1]. Reasonable design and optimisation of concrete structures can effectively reduce the amount of concrete used, lower the structural self-weight, save material usage, and reduce carbon emissions [2]. Since the application of concrete materials in architecture, designing efficient concrete structures has been an important research topic [3, 4]. The ancient Roman Pantheon, constructed in 120 AD, is an excellent example of a large-span dome built using concrete materials, fully utilizing the compressive performance of concrete [5].

Since the 19th century, with the continuous improvement of concrete technology, it has been widely used in construction. Thin slab structures are a common type of architectural structure that differs from other structures, such as arches and shells. They can achieve large-span coverage within a limited height range. The design of efficient concrete slabs has different methods and solutions in different eras, and it remains an important area of research in the field of structural engineering.

In the Gatti Wool Factory, Nervi and Arcangeli [6, 11] collaborated to design a rib-reinforced concrete floor system based on the curved isostatic pattern of the factory floors (Figure 1a). This method has similarities with some of the modern construction practices. Based on stress trajectories, Yuan's team

at Tongji University designed ribs on the opposite side of the floor prototype and used a 3D concrete printing method assisted by a robotic arm for construction (Figure 1b). Similarly, Dillenburger's research group [8] at ETH Zurich designed and constructed "Smart Slabs" using 3D-printed sand casts, laser-cut timber formwork, and concrete spraying (Figure 1c). In addition to stress trajectory-based optimisation, topology optimisation technology is also a very effective tool for concrete slab optimisation design. For example, Dillenburger's research group [12] used the Solid Isotropic Material Penalization (SIMP method [13, 14], a type of topology optimisation method) to obtain an optimized design for a 1.8 m × 1 m × 0.15 m slab and used a template for concrete casting (Figure 1d). Combining the modified BESO method, Xie's group from RMIT University developed a digital design and construction process for large-scale ribbed floor systems [10].

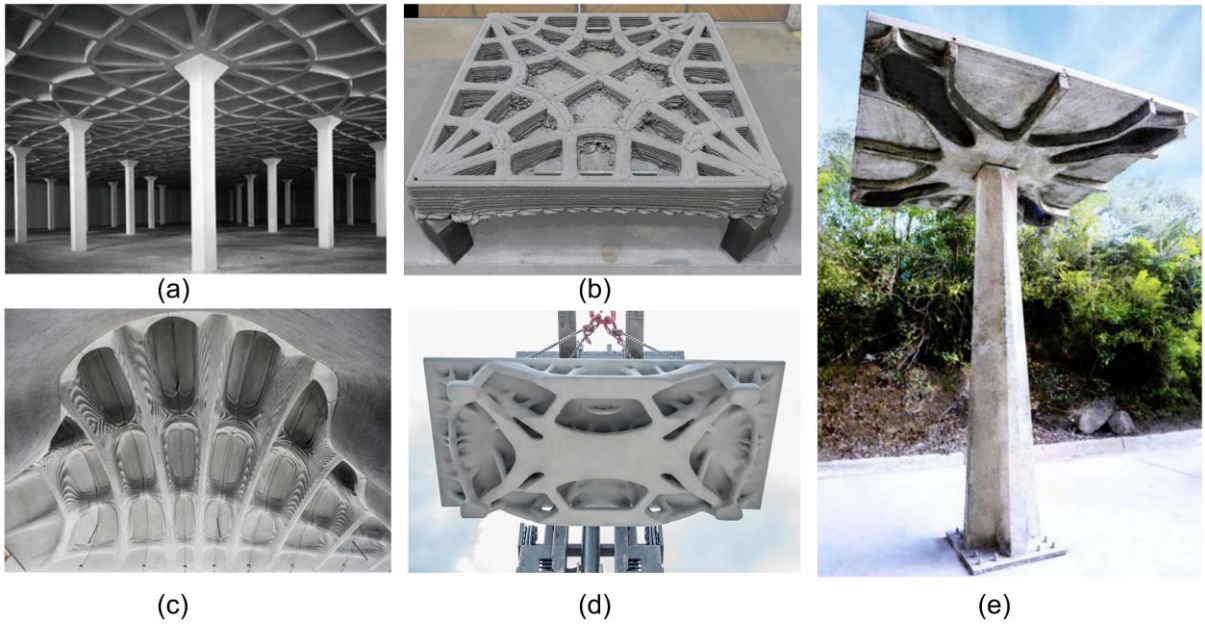

Figure 1. Concrete slabs designed based on structural performance: (a) The Gatti Wool Factory designed by Nervi [6]; (b) a 3D-printed high-performance concrete slab designed and constructed by Yuan's team at Tongji University [7]; (c) "Smart Slabs" designed by Dillenburger's research group at ETH Zurich [8]; (d) concrete slab designed based on topology optimisation, also by Dillenburger's research group at ETH [9]; (e) ribbed floor system designed and constructed by Xie's team at RMIT University using topology optimisation [10].

It is evident that both methods are effective in achieving lightweight design for slab structures, ensuring structural strength while maximizing material efficiency. Among these methods, topology optimisation based on continuum models can present more intricate 3D structural details while optimizing the structure, making it more suitable for intelligent construction methods such as 3D concrete printing or concrete casting with 3D-printed moulds.

Most studies on topology optimisation have been developed for single-material structures, which are effective for materials like metals that exhibit similar mechanical properties in both tension and compression. However, for concrete, which has significantly better compressive performance compared to its tensile performance, single-material topology optimisation algorithms that do not consider the performance differences between the two stress states are not applicable.

Recently, developed from the single-material BESO method based on stress, Li and Xie [15, 16] proposed the MBESO method. By considering the performance differences of materials in tension and compression, this technique has shown great potential in improving the structural efficiency of multi-material structures, such as steel-concrete structures. This method is very simple but effective for the

form-finding of composite structures, providing a new approach to concrete structure design [17]. In this paper, this method is used for the topology optimisation design of a thin steel-concrete slab prototype, which is then constructed using digital fabrication methods.

2. Design of the steel-concrete slab based on multi-material topology optimisation

2.1 Multi-material topology optimisation

In this research, we adopt the relative stress level of a structure as the standard for evaluating the importance of each element to the entirety of the structure. To this end, we use the utilization of material as an indicator. For the *i*-th element in the design domain, its utilization η_i can be determined as follows:

$$\eta_i = \begin{cases} \sigma_{i,Mises}/[\sigma_s^t] & \text{(for steel)} \\ \sigma_{i,Mises}/[\sigma_c^c] & \text{(for concrete)} \end{cases}, i = 1, 2, \dots, N \tag{1}$$

where $[\sigma_s^t]$ and $[\sigma_c^c]$ indicate the allowable tensile stress for steel and the allowable compressive stress for concrete, respectively. The von Mises stress of the *i*-th element is denoted by $\sigma_{i,Mises}$, and *N* represents the total number of elements in the design domain.

Regarding how to determine the tensile or compressive stress state of the elements in the structure, this study utilizes a complex stress indicator: the first invariant of the stress tensor. In terms of physic meaning [18, 19], the first invariant I_1 of the stress tensor represents the change in volume of the element. $I_1 \geqslant 0$ indicates that the volume of the element has increased, which can be considered as a tensile stress. Conversely, $I_1 < 0$ signifies that the volume has decreased, indicating a compressive stress state. In composite structures with intricate stress states, this approach facilitates the classification of each element as a tensile or compressed element based on whether the sum of the principal stresses exceeds 0. To represent the variable, I_1 is calculated as:

$$I_1 = \sigma_{11} + \sigma_{22} + \sigma_{33} \tag{2}$$

where σ_{11}, σ_{22} and σ_{33} denote the maximum principal stress, the second principal stress, and the minimum stress, respectively.

This method allows for the easy classification of elements in composite structures into two distinct types that match two different materials, such as steel and concrete. Although this approach is heuristic, it has been demonstrated to be effective in identifying a more suitable material for each element between two distinct materials.

To describe the solid-void design and the material properties of each element in our study, we define two variables x_i and m_i as follows:

$$x_i = \begin{cases} 1 & \text{(solid)} \\ x_{min} & \text{(void)} \end{cases}, i = 1, 2, \dots, N \tag{3}$$

$$m_i = \begin{cases} 1 & \text{(steel)} \\ 2 & \text{(concrete)} \\ 0 & \text{(void)} \end{cases}, i = 1, 2, \dots, N \tag{4}$$

where $x_i = 1$ or x_{min} (0.001 is used in this study) means that the *i*-th element is solid (including steel and concrete) or void, and $m_i = 1$, 2 or 3 indicates the type of the material. For void elements, material 3 with a small Young's modulus is introduced, and its Young's modulus is calculated as

$$E_{min} = x_i^p E_2 \tag{5}$$

where *p* is the penalty coefficient set as 3 in our study. Huang and Xie [20] have shown that the contribution of a material like material 3 in solid-void design can be ignored when $p \geqslant 3$.

To address the mesh-dependency problem and checkerboard patterns [21, 22], filter techniques can be employed for raw utilization. Besides, to enhance the convergence of the process, it is possible to incorporate historical data into the topology optimisation, similar to some previous work [23, 24]. One approach is to calculate the average utilization value by combining the current utilization with the historical data obtained in the previous step. The details of the filter and stabilisation processes can be found in [16, 17].

To begin the optimisation process, the volume of the solid elements in the *k*-th iteration, denoted as $v^{(k)}$, can be calculated using Equation (6).

$$v^{(k)} = v^{(k-1)} \times (1 - er) \ \ (v^{(0)} = 1, k = 1, 2, \dots) \tag{6}$$

Here, $v^{(k)}$ represents the volume of solid elements in the (*k*-1)-th iteration, and *er* is the evolutionary ratio, which is set to 0.001 in this study. Initially, the volume of solid elements is set to 1 in the first iteration, i.e., $v^{(k)} = 1$, and for all subsequent iterations, the volume is updated using Equation (6).

Once the volume of solid elements is determined, all the elements are ranked based on their utilizations, from maximum to minimum. The top $v^{(k)}$ elements are designated as solid elements, represented by $x_i = 1$, while the elements ranked after top $v^{(k)}$ are set as void, represented by $x_i = x_{min}$. This step-wise reduction in the volume of solid elements gradually decreases the volume of solid material from 1 to the preset volume fraction v_f.

After the updating of inefficient solid elements and efficient void elements in each iteration, the material type of each solid element can be determined as follows:

$$m_i = \begin{cases} 1 & (\sigma_e > 0, \ x_i = 1) \\ 2 & (\sigma_e \leq 0, \ x_i = 1) \\ 0 & (\ x_i = x_{min}) \end{cases}, i = 1, 2, \dots, N \tag{7}$$

where only the solid elements with $x_i = 1$ need to be classified. This process results in a new multi-material design for the structure.

The optimisation calculation stops when the volume of the optimized structure is reduced to the volume fraction v_f, and the compliance satisfies the following condition:

$$\frac{|C^{(k)} - C^{(k-1)}|}{C^{(k)}} \leq \tau \tag{8}$$

Where $C^{(k)}$ and $C^{(k\text{-}1)}$ are the compliance of the optimized structure calculated in the *k*-th and the (*k* -1)-th iterations, respectively, and τ is a small preset value set to 10^{-4} in this study.

2.2 Topology optimisation and post-design process of the steel-concrete slab.

2.2.1 Material properties

The mechanical properties of the two materials, steel and concrete, used to construct the composite concrete slab in this study are shown in Table 1. Based on the MBESO algorithm, the steel material only exists in the tensile region of the structure, while the concrete is only subjected to compression. Therefore, only the mechanical properties of the steel in the tensile state and the concrete in the compression state are included as the actual properties of the two materials in Table 1. For the void element (Material 3), there are two allowable stress values because, similar to the solid element, the void elements are also divided into tensile and compressed elements in the multi-material topology optimisation calculation, respectively serving as candidate elements for steel and concrete elements. Therefore, the material utilization calculation standards and the threshold for becoming a solid element differ between these two types of elements [25].

Table 1: Material properties of the structures (material 3 is introduced to represent void elements).

Material	Young's modulus E (GPa)	Poisson's ratio μ	Allowable stress $[\sigma]$ (MPa)
Steel	E_1 = 200	μ = 0.3	$[\sigma_s^t]$ = 250 (in tension)
Concrete	E_2 = 20	μ = 0.3	$[\sigma_c^c]$ = 50 (in compression)
Material 3	$E_3 = E_{min}$	μ = 0.3	$[\sigma_{m3}] = [\sigma_s^t]$ = 250 (in tension)
(void elements)			or $[\sigma_{m3}] = [\sigma_c^c]$ = 50 (in compression)

2.2.2 Topology optimisation process and results

As shown in Figure 2(a), the experimental prototype in this study is a rectangular slab with four corners simply supported, where only one corner is fixed as a hinge support, and the other corners are only fixed in the vertical direction. The size of the slab design domain is 800 mm × 800 mm ×120 mm, where the upper surface with a thickness of 20 mm is set as a non-design domain. The elements in this area will always be reserved during the topology optimisation process to ensure the effective transmission of the uniform load above.

Due to the symmetry in both the structural model and load conditions, 4 symmetric planes are set in the design domain to accelerate calculations. With the presence of symmetry boundaries, only a minimum of 1/8 of the structure needs to be computed to achieve the topology optimisation of the rectangular concrete slab. In this study, 1/4 of the structure is actually used for calculation and subsequently reassembled into a complete slab.

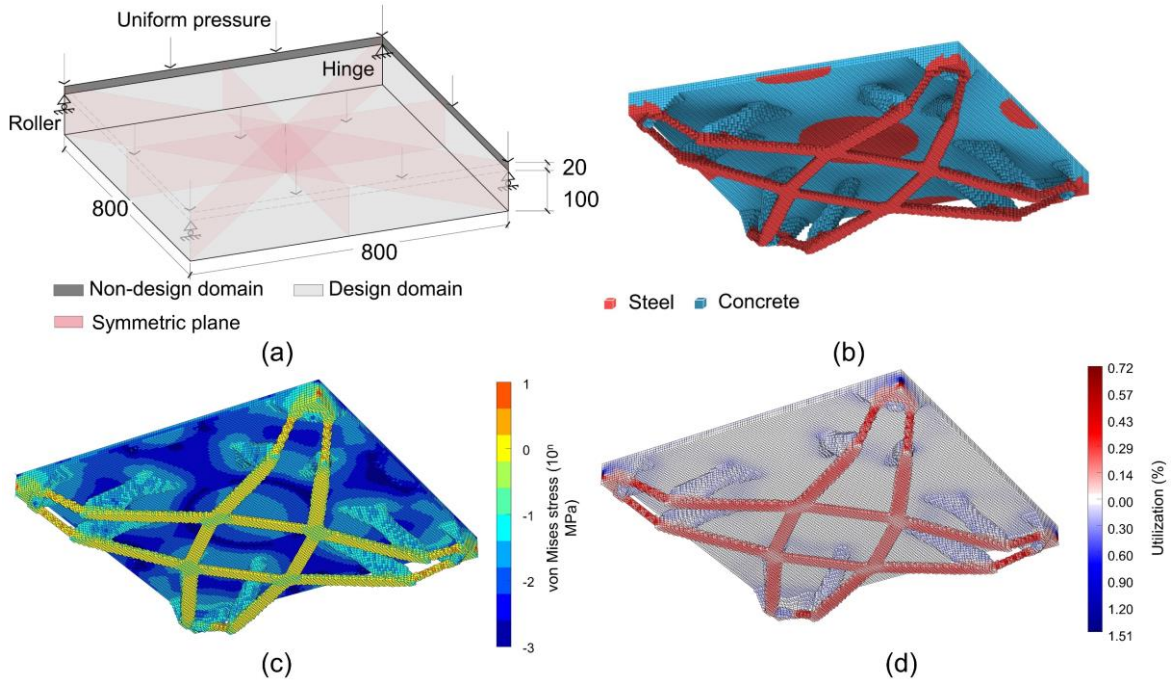

Figure 2. Topology optimisation settings and corresponding results of the multi-material concrete slab: (a) design domain, loads, and support conditions; (b) optimized material layout of the multi-material slab; (c) von Mises stress distribution; (d) material utilization distribution.

For the design domain shown in Figure 2(a), one quarter of it is discretised using 66 × 66 × 20 eight-node hexahedral elements. A total of 348,480 finite elements are used to represent the whole structure. The target volume fraction for the final structure is set at 0.2, meaning that the solid material in the final structure occupies 20% of the initial design domain. Other topology optimisation parameters are set as follows: uniform load q = 1 kN/m^2, evolution rate er = 0.01, and filter radius $r_1 = r_2$ = 45 mm.

The topologically optimized slab obtained based on the above settings is shown in Figure 2(b). In this structure, the concrete material is mainly distributed in the upper part, and 8 inclined short columns are supporting the red steel components beneath the concrete part. The steel material mainly forms 4 intersecting cable-like components below the superstructure, with each cable end connected to one support point. The cable turns at the lower end of each inclined short column. In addition to the steel material in the lower part of the structure, there is also a small amount of steel material below the mid-span area, indicating tension in this area. During the topology optimisation of the concrete slab, the stress distribution (Figure 2c) and material utilization distribution (Figure 2d) in the structure can be calculated simultaneously. From these two figures, it can be seen that, except for the stress concentration at the 4 support points, the stress in the bottom cable is much higher than that in the upper concrete slab. However, from the distribution of material utilization, the maximum material utilisation of the steel and concrete parts is similar, indicating both materials are well utilised.

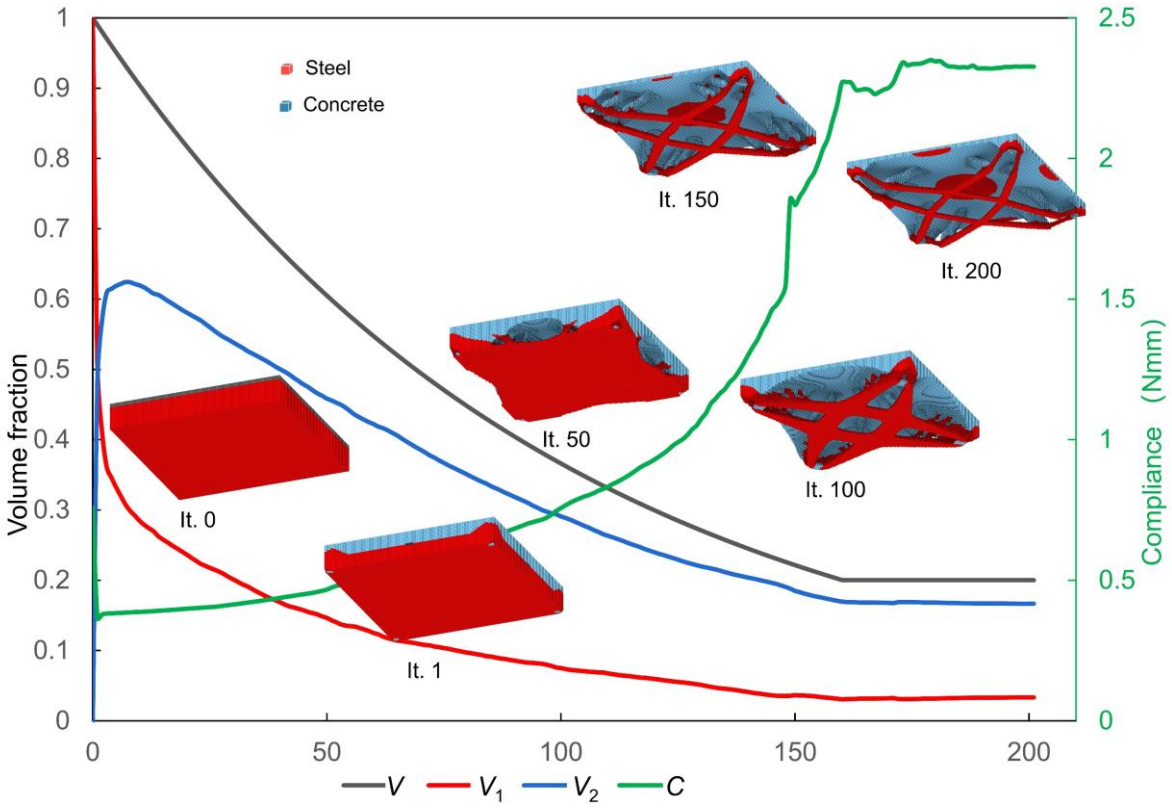

Figure 3. Evolution history of the relevant parameters during the topology optimisation of the composite slab (where V represents the total volume of the material, v_1 represents the volume of steel, v_2 represents the volume of concrete, and C represents the compliance of the structure).

The evolution history of the relevant parameters during the topology optimisation of this composite slab is shown in Figure 3. The entire design domain consists solely of steel in the initial stage of topology optimisation (Iteration 0). In the first iteration, steel or concrete materials are assigned based on the tension or compression state of each element, and 2% of solid materials are removed simultaneously.

The iteration continues until the material volume reaches the target volume fraction and the structural compliance converges. It can be observed that the volume fraction of steel gradually decreases from 1 and finally stabilizes at around 0.033, while the volume fraction of concrete rapidly increases from 0 to a peak of about 0.624, and then gradually decreases to 0.167. The total material volume fraction gradually decreases from 1 to the target volume fraction of 0.2 and remains stable. In this process, the compliance of the structure first decreases rapidly (the all-steel structure becomes a dual-material structure in the first iteration), then gradually increases, and finally reaches a relatively stable state.

2.2.3 Comparison of slabs with different thicknesses

Topology optimization outcomes for composite slabs exhibit considerable variation across varying thicknesses. In this regard, exploring slabs with distinct thicknesses can aid in identifying the suitable thickness for topology optimization results in post-design procedures. Figure 4 showcases the topology optimization outcomes for four different thicknesses of steel-concrete composite slabs: 80, 120, 160, and 200 mm.

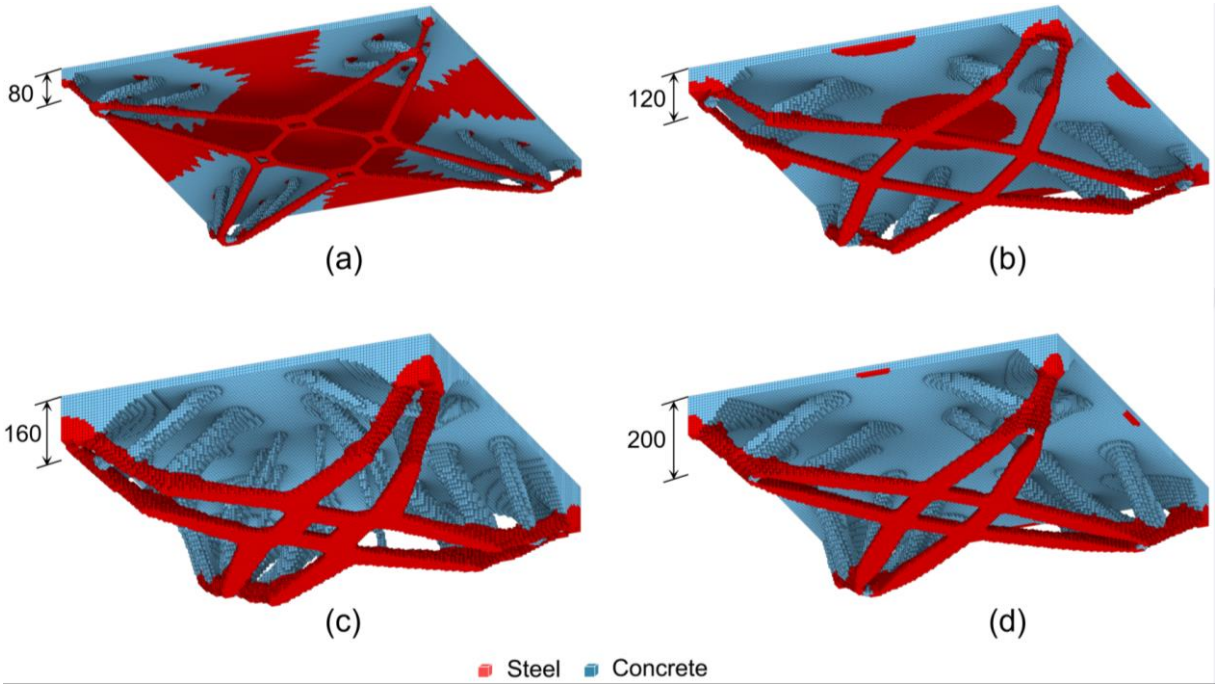

Figure 4. Topology optimization results for steel-concrete composite slabs with different thicknesses: (a) h = 80 mm; (b) h = 120 mm; (c) h = 160 mm; (d) h = 200 mm.

The results reveal both commonalities and differences among them. For instance, in the composite slab with an 80 mm thickness (Figure 4a), the steel parts and inclined columns used to reinforce the slab are inadequate to provide sufficient support for the thin slab. As a consequence, there are significant proportions of tensile regions (in red) and compression regions (in blue) in the upper structure of the slab. Given this situation, relying solely on concrete for the construction of the upper slab is inappropriate.

On the other hand, by increasing the thickness to 120 mm (Figure 4b), the proportion of tensile regions in the upper slab decreases, and a large surface area of the upper structure comes under compression. Consequently, in such a scenario, it is possible to employ concrete reinforcement measures to construct the upper slab. As the thickness increases further to 160 mm (Figure 4c) and 200 mm (Figure 4d), the tensile regions in the upper structure fade away, and the superstructure transforms into a pure

compressed component. Thus, in these models, the upper slab is suitable for construction using unreinforced concrete.

Following a comprehensive comparison and analysis of these outcomes, the topology optimization result with a thickness of 120 mm (Figure 4b) was selected as the prototype for further design and analysis. This prototype meets the fundamental requirement of ensuring that the upper plate is mostly under compression while maintaining a relatively thin thickness.

2.2.4 Post-design process

As shown in Figure 5(a), although the upper structure is not purely under compression, it mainly consists of compressed concrete. If the upper concrete components are constructed as a whole, they can, to some extent, satisfy the local bending conditions. Therefore, in this paper, the upper structure is simplified as a complete concrete slab (Figure 5b), and the eight inclined short columns are also made of concrete. The lower tensioned steel structure is simplified as four intersecting steel cables, each of which is connected to the two diagonal support bases.

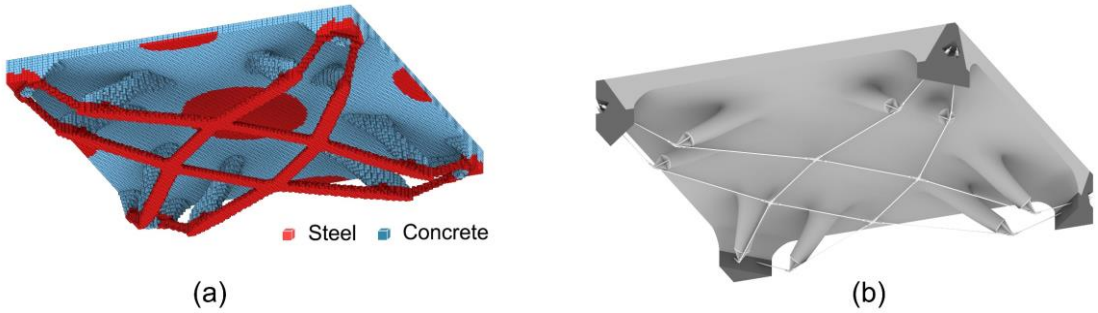

Figure 5. Post-design process based on the multi-material topology optimisation result: (a) dual-material topology optimisation result; (b) constructible model after the post-design process.

4 Structural analysis

In this structural model, the cable-support system formed by intersecting steel cables and inclined columns is the key component that reduces the deformation of the concrete slab. To validate the strengthening effect of this system, the stress and strain distributions of two concrete slabs, one with cable support and one without, are compared in Figure 6.

Figures 6(a) and (b) show the von Mises stress distribution of the two slabs without and with cable support, respectively, with the same legend values in both figures. While little difference is observed in the stress distribution of the upper concrete portion, in the slab with cable support (Figure 6b), the stress in the tension cable at the bottom of the slab is very high but still within the safety range of the steel material. Figures 6(c) and (d) present the vertical deformation distribution of the two slabs, also with the same legend values in both figures. In Figure 6(c), due to the lack of reinforcement components, the deformation of the concrete slab mainly depends on itself, and there is a significant deformation in the mid-span area of the slab. On the contrary, in Figure 6(d), due to the support of steel cables and inclined columns, the deformation of the central part of the concrete slab is relatively reduced, with the maximum deformation being 36% lower than that in Figure 6(c).

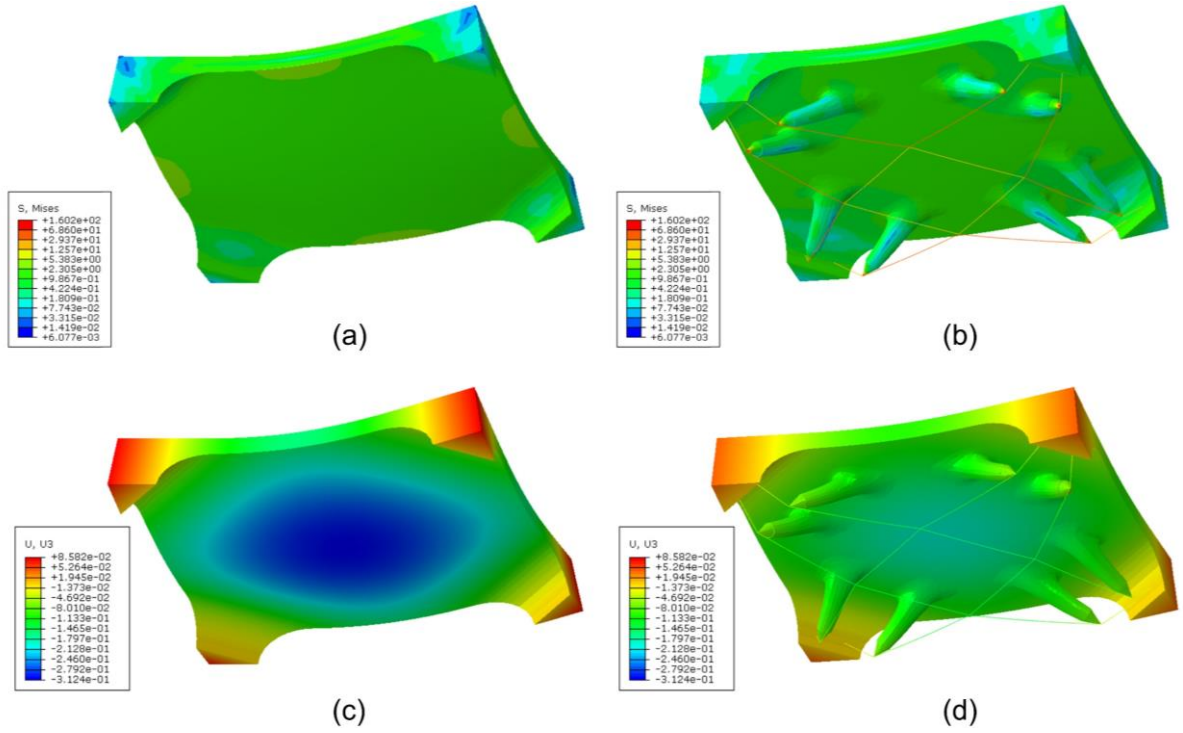

Figure 6. Comparison of stress and strain analysis results of two concrete slabs with and without cable-support systems (units: mm, MPa): (a) von Mises stress distribution of the concrete slab without cable-support system; (b) von Mises stress distribution of the concrete slab with the cable-support system. (c) deformation distribution of the concrete slab without a cable-support system; (d) deformation distribution of the concrete slab with a cable-support system.

5 Conclusions

In this study, the multi-material bi-directional evolutionary structural optimisation (MBESO) method was applied to design an efficient steel-concrete slab, resulting in a composite structural system that effectively utilises steel for tension and concrete for compression. During the post-design process based on the multi-material topology optimisation result, the tensile portion of the structure was simplified into crossed steel cables that connected diagonal support bases, and the compressed upper portion was streamlined into freeform concrete casting components. The connection between the steel cables and the concrete was reinforced by metal nodes to accommodate the transmission of significant forces. Furthermore, the numerical analysis comparing the stress and strain of slabs with and without cable-support systems showed that cable reinforcement reduced the maximum deformation of the concrete slab by about 36%, effectively enhancing its structural rigidity. This innovative approach simplifies the design process, and provides valuable guidance for digital design and intelligent construction of complex-shaped concrete structures in the future. The development of the steel-concrete composite slab model highlights the immense potential and significance of utilising multi-material topology optimisation methods for efficient structural design of similar materials such as gypsum, clay, or concrete. The process demonstrated how these techniques can assist in streamlining the construction of complex-shaped structures while optimising their performance.

Abstract

This work aims to conduct the topological design for the natural frequency maximization problems using non-penalization Smooth-Edged Material Distribution for Optimizing Topology (SEMDOT) algorithm. Pin-pin, fix-pin, and clamped beams are used to demonstrate the effectiveness of the proposed non-penalization SEMDOT algorithm in solving natural frequency maximization problems. Comparisons with Evolutionary Topology Optimization (ETO) and Floating Projection Topology Optimization (FPTO) algorithms, which are capable of generating smooth boundaries, are conducted, showing that non-penalized SEMDOT can obtain comparable results.

Keywords: natural frequency maximization, non-penalization, smooth boundary, topology optimization

1. Introduction

Topology optimization is a powerful virtual tool that can find the optimal material distribution and geometry within a predefined design domain [1]. Topology optimization, an important branch of the light-weight design, has been extensively used in mechanical design, weight reduction in industry and multiple other physics fields [2-4]. Element-based topology optimization algorithms are the most widely used methods because of their easy implementation and ability to remove materials freely across the design domain. There are some representative element-based topology optimization algorithms, including Solid Isotropic Material with Penalization (SIMP) [5], Evolutionary Structural Optimization (ESO) [6], Bi-directional Evolutionary Structural Optimization (BESO) [7], and Floating Projection Topology Optimization (FPTO) [8-11].

Traditional element-based methods such as SIMP and BESO will generate zigzag or blurry boundaries, which will require the post-processing method such as shape optimization to obtain smooth boundaries before fabrication. To avoid extra efforts, Da et al. [12] proposed an elemental volume fraction-based approach named Evolutionary Topology Optimization (ETO) algorithm in which the smooth topological boundaries can be formed during optimization. Since ETO is developed based on the BESO framework, only the Optimality Criteria (OC) method can be used as the optimizer. However, the Method of Moving Asymptote (MMA) proposed by Svanberg [13] performs better than OC in solving some complicated optimization problems [14]. Therefore, Fu et al. [15,16] proposed a new elemental volume fraction-based method named Smooth-Edged Material Distribution for Optimizing Topology (SEMDOT) based on the SIMP framework, and hence the MMA optimizer can be used in SEMDOT. Since the use of the material penalization scheme will artificially change the relationship between material properties and elemental values, the authors developed a non-penalization SEMDOT algorithm using discrete variable sensitivities [17]. Compared to penalized SEMDOT, non-penalized SEMDOT can generally lead to better performance and stronger convergence [17]. Another advantage of non-penalized SEMDOT is that the complexity of the algorithm is reduced. Therefore, non-penalization SEMDOT will be used as the optimization platform in this work.

Natural frequency is an important performance index for numerous engineering structures. Compared with stiffness optimization, topology optimization for natural frequency is more challenging due to the possible localized modes [18], and hence the natural frequency maximization case is a representative problem used to validate the effectiveness of a topology optimization algorithm [18-20]. To date, non-penalized SEMDOT is not yet used for maximizing natural frequency.

This work aims to conduct the topological design for the natural frequency maximization problems using the non-penalization SEMDOT algorithm. In addition, comparisons with existing element-based algorithms (i.e., ETO and FPTO) will be presented.

2. Topology optimization for maximizing natural frequency

The smooth boundary strategy of SEMDOT is schematically illustrated in Figure 1 where X_e is the elemental volume fraction (design variable), $\rho_{e,g}$ is the density (value) of the grid points, and $\rho_{\min}$ is a small value, for example, 0.001. SEMDOT pursues the solid and void design of grid points, and then the obtained solid and grid points will be used to assemble the elements. As the number of grid points is higher than that of elements, the smooth topological boundary can be formed. As shown in Figure 1, the solid element ($X_e = 1$) is full of solid grid points ($\rho_{e,g} = 1$); the void element ($X_e = \rho_{\min}$) is full of void grid points ($\rho_{e,g} = \rho_{\min}$); and the boundary element ($\rho_{\min} < X_e < 1$) is a mixture of solid and void grid points.

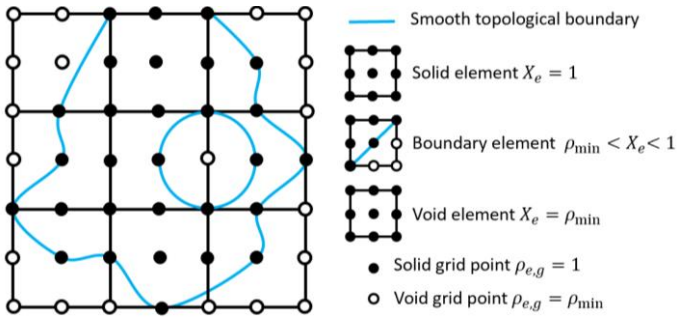

Figure 1. Smooth boundary representation in SEMDOT.

The relationship between X_e and $\rho_{e,g}$ is

$$X_e = \frac{1}{N}\sum_{g=1}^{N} \rho_{e,g} \tag{1}$$

where e is the number of the element, g is the number of the grid point in the eth element, and N is the total number of grid points in each element.

This work focuses on maximizing the first natural frequency of the structure. The optimization problem is therefore mathematically stated as:

$$\begin{aligned} &\min: C = -\varphi_1 = -\omega_1^2 \\ &\text{s.t.}: \begin{cases} (\mathbf{K} - \varphi_1 \mathbf{M})\mathbf{u}_1 = 0 \\ \dfrac{\sum_{e=1}^{n} X_e V_e}{\sum_{e=1}^{n} V_e} - V^* \le 0 \\ 0 < \rho_{\min} \le X_e \le 1; \quad e = 1,2,\cdots,n \end{cases} \end{aligned} \tag{2}$$

where C is the objective function, φ_1 and ω_1 are the first eigenvalue and natural frequency, respectively; $\mathbf{u}_1$ is the eigenvector related to φ_1; $\mathbf{K}$ is the global stiffness matrix; $\mathbf{M}$ is the global mass matrix; V_e is the volume of the eth element; V^* is the target volume; and n is the total number of elements.

According to the Rayleigh quotient, the first eigenvalue can be calculated by

$$\varphi_1 = \frac{\mathbf{u_1^T K u_1}}{\mathbf{u_1^T M u_1}} \tag{3}$$

The linear interpolation in non-penalization SEMDOT is used to calculate the global stiffness matrix $\mathbf{K}$ such that

$$\mathbf{K} = (1 - X_e)\rho_{\min}\mathbf{K}^1 + X_e\mathbf{K}^1 \tag{4}$$

where $\mathbf{K}^1$ is the stiffness matrix of solid elements.

Using the same form, the global mass matrix $\mathbf{M}$ is given by

$$\mathbf{M} = (1 - X_e)\rho_{\min}\mathbf{M}^1 + X_e\mathbf{M}^1 \tag{5}$$

where $\mathbf{M}^1$ is the mass matrix of solid elements.

The sensitivity analysis is then calculated by

$$\frac{\partial \varphi_1}{\partial X_e} = \mathbf{u_1^T}\left(\frac{\partial \mathbf{K}}{\partial X_e} - \varphi_1 \frac{\partial \mathbf{M}}{\partial X_e}\right)\mathbf{u_1} \tag{6}$$

where

$$\frac{\partial \mathbf{K}}{\partial X_e} \approx (1 - X_e)\frac{\partial \mathbf{K}}{\partial X_e}\Big|_{X_e=\rho_{\min}} + X_e \frac{\partial \mathbf{K}}{\partial X_e}\Big|_{X_e=1} \tag{7}$$

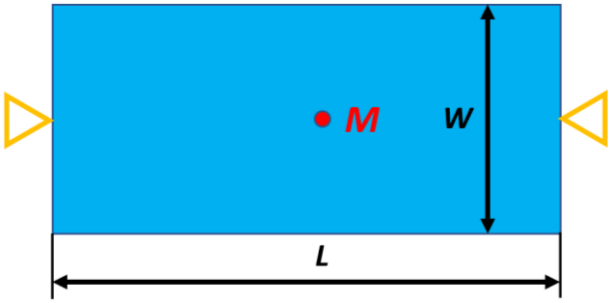
$$\frac{\partial \mathbf{M}}{\partial X_e} \approx (1 - X_e)\frac{\partial \mathbf{M}}{\partial X_e}\Big|_{X_e=\rho_{\min}} + X_e \frac{\partial \mathbf{M}}{\partial X_e}\Big|_{X_e=1} \tag{8}$$

It should be noted that the sensitivity analysis in SEMDOT is very different with traditional methods such as SIMP and BESO. In SEMDOT, the sensitivity is approximated using the linear combination of solid and void phases. More details can be found in [17].

3. Numerical examples

This section will use pin-pin, fix-pin, and clamped beams to demonstrate the effectiveness of non-penalization SEMDOT in solving natural frequency maximization problems. Unless otherwise stated, the parameters of SEMDOT in [15] and default MMA parameters are adopted. It is noted that the default move limit in MMA is 1. Different versions of the MMA optimizer will result in different results. For all numerical cases, the Young's modulus is set to 1, and the Poisson's ratio is set to 0.3.

The first optimization case is the pin-pin beam whose design domain and boundary conditions are shown in Figure 2. In Figure 2, M represents the concentrated mass, and L and W represent the length and width of the design domain, respectively. Here, M is set to 1×10^{-4}; the mass density ρ_M is set to 1×10^{-9}; L is set to 240; and W is set to 60. The filter radius $r_{\min}$ is set to 2, and the final volume V^* is restricted to be 30% of the design domain.



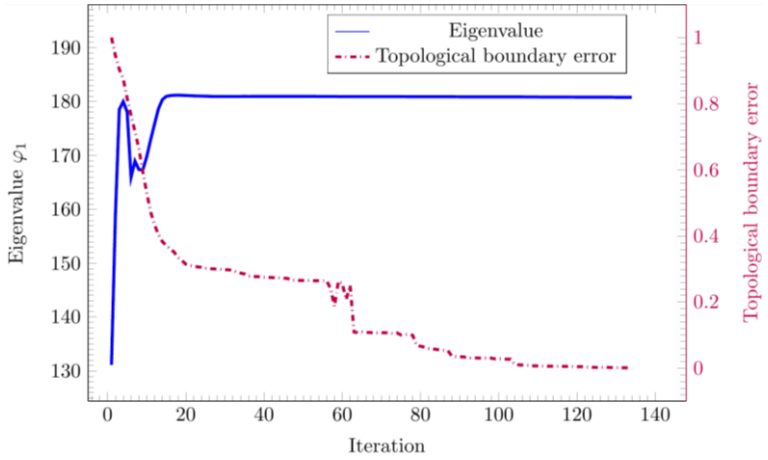


Figure 2. Design domain of a pin-pin beam.

Figure 3a shows that the optimization process converges at the first eigenvalue of 180.7897 after 134 iterations, and the topological boundary error value reaches zero. Figure 3b,c shows the element and smooth designs of the optimized topology, respectively.

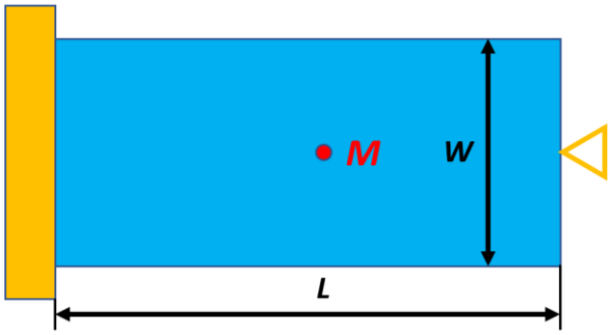
(a) Convergence process

(b) Element design

(c) Smooth design

Figure 3. Convergence process and element and smooth designs of a pin-pin beam.

The second optimization case is the fix-pin beam whose design domain and boundary conditions are shown in Figure 4. It is noted that the fix-pin beam case uses the same parameter setting as the pin-pin beam case.



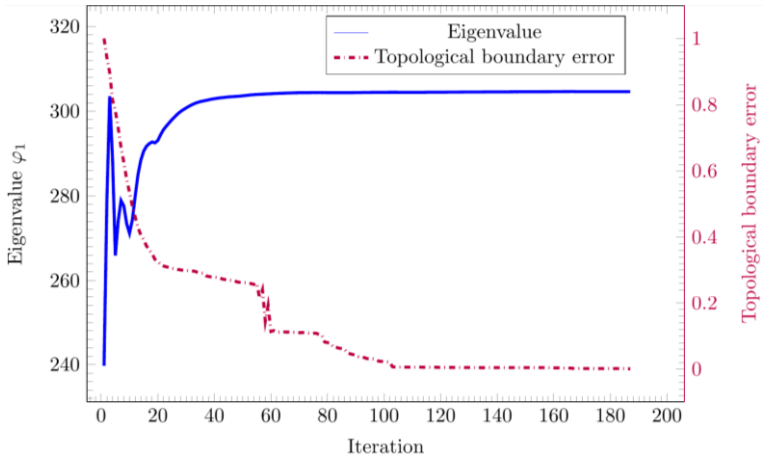


Figure 4. Design domain of a fix-pin beam.

Figure 5a shows that the optimization process converges at the first eigenvalue of 304.6251 after 187 iterations, and the topological boundary error value reaches zero. Figure 5b,c shows the element and smooth designs of the optimized topology, respectively.

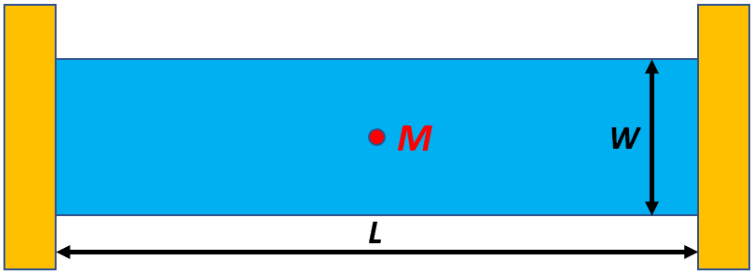
(a) Convergence process

(b) Element design

(c) Smooth design

Figure 5. Convergence process and element and smooth designs of a fix-pin beam.

The third optimization case is the clamped beam whose design domain and boundary conditions are shown in Figure 6. The clamped beam case is used to compare SEMDOT with two representative smooth topological design algorithms (ETO and FPTO) with the purpose of further showing the capability of non-penalization SEMDOT. It is noted that FPTO is also a non-penalization topology optimization algorithm.



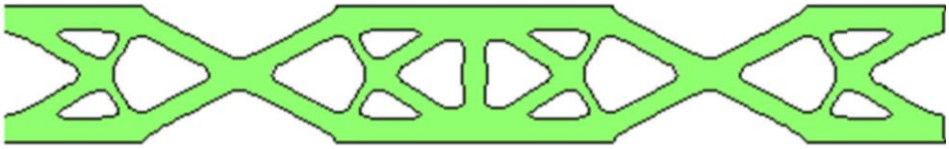


Figure 6. Design domain of a clamped beam.

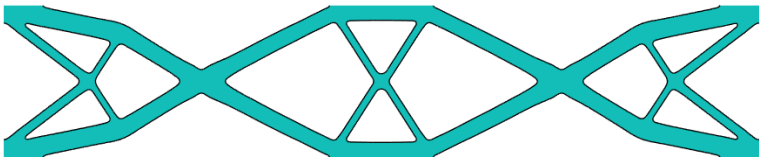
To make a fair comparison with ETO, the same parameters are used, namely, $L = 140$, $W = 20$, $M = 1 \times 10^{-3}$, $\rho_M = 1 \times 10^{-9}$, $r_{\min} = 2$, and $V^* = 0.5$. The optimization process of SEMDOT converges at the first eigenvalue of 21.7045 after 235 iterations, and the optimization process of ETO converges at the first eigenvalue of 21.75 after 61 iterations [12]. Although ETO performs better than SEMDOT in both performance and convergence, the topology obtained by SEMDOT (Figure 7a) is smoother than that obtained by ETO (Figure 7b). Similar topologies can be observed in Figure 7.



(a) SEMDOT with $\varphi_1 = 21.7045$

(b) ETO with $\varphi_1 = 21.75$ [12]

Figure 7. Comparison between SEMDOT and ETO [12] for a clamped beam.

To ensure the fairness of the comparison with FPTO, the parameters are set to $L = 500$, $W = 100$, $M = 0.1$, $\rho_M = 1 \times 10^{-6}$, $r_{\min} = 3$, and $V^* = 0.3$. The optimization process of SEMDOT converges at the first eigenvalue of 0.2340 after 149 iterations, and the optimization process of FPTO converges at the first eigenvalue of 0.23289 after 186 iterations [11]. The SEMDOT performs better than FPTO in both performance and convergence. The topology obtained by SEMDOT (Figure 8a) is almost the same with that obtained by FPTO (Figure 8b).

(a) SEMDOT with $\varphi_1 = 0.2340$

(b) FPTO with $\varphi_1 = 0.23289$ [11]

Figure 8. Comparison between SEMDOT and FPTO [11] for a clamped beam.

Based on the above discussion, it can be concluded that non-penalization SEMDOT can obtain comparable results and similar topological layouts compared to ETO and FPTO. However, it is hard to determine which algorithm is better as a systematic comparison is required.

4. Concluding remarks

This work used the newly developed non-penalization SEMDOT algorithm to solve the natural frequency maximization problems. Maximizing the first natural frequency of the structure is the focus of this study. Pin-pin, fix-pin, and clamped beams are used to demonstrate the effectiveness of non-penalization SEMDOT. Comparisons with ETO and FPTO show that non-penalized SEMDOT can obtain comparable results and similar topologies. Future work will consider the 3D cases.

Acknowledgements

The authors would like to thank Prof. Krister Svanberg for providing the MMA optimizer code. Dr. Yun-Fei Fu would like to thank Prof. Xiaodong Huang from Swinburne University of Technology (Australia) for the discussion on non-penalization topology optimization.

Abstract

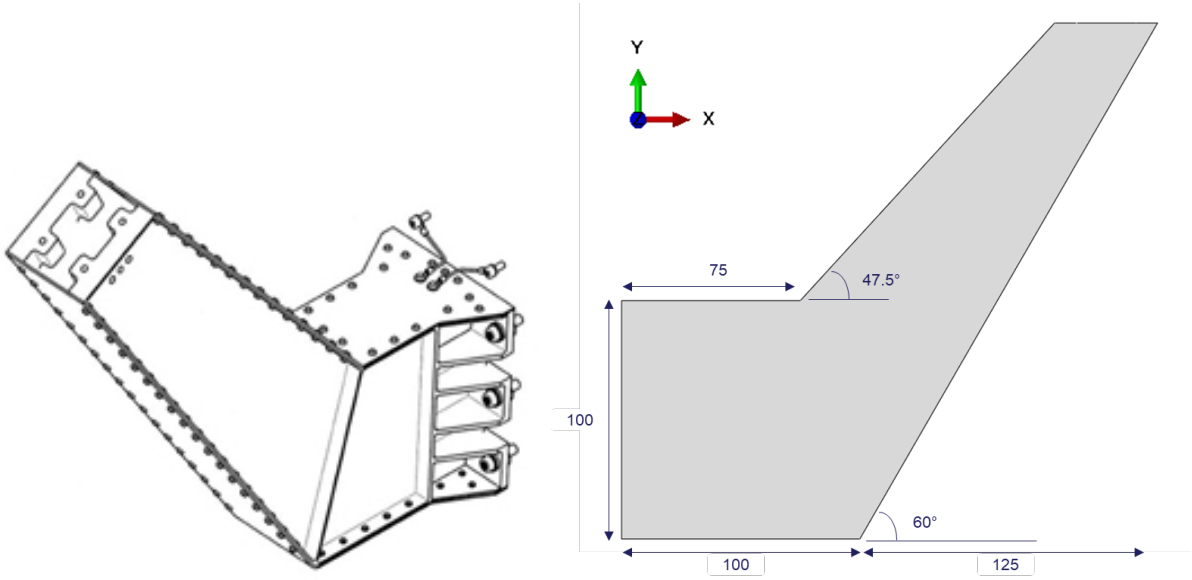
Structural optimisation plays a significant role in the development of innovative structures for the aerospace and space sectors. The advancement of technology and research in the space domain has sparked interest towards increasing the efficiency and duration of satellite operations for Earth-orbit missions. The ability to reduce the weight of structures by removing inefficient material whilst maintaining essential strength and stiffness qualities is highly advantageous in such weight-conscious applications. Structural optimisation combined with the deployment of additive manufacturing technology further enables the production of these highly optimised and complex structures. This paper presents a case study for the optimisation of a non-tertiary, satellite antenna bracket structure using the bi-directional evolutionary structural optimisation (BESO) method. It is observed that the BESO method can reduce the weight of a structure through inefficient material removal whilst maintaining critical strength and stiffness qualities. The findings of this study inform the ability of the BESO method as a functional tool for the future design optimisation of spacecraft structures.

Keywords: satellite antenna bracket, topology optimisation, BESO, finite element method, additive manufacturing

1. Introduction

Satellite bracket structures are essential to the design and functionality of satellite systems. Various types of brackets are used to support satellite components including electronics, batteries, cameras and antennae [1]. The primary function of these structures is to support the load and ensure the stability of these systems during various operational phases including launch, deployment and service. Antennas are fundamental to satellites for communication and navigation purposes through sending and receiving signals. The size and mass of the antenna significantly influences the supporting bracket structure required. Whilst the bracket must have the required strength and stiffness to bear the mass of the antenna, conventional supporting brackets are often simplistic and utilise unnecessary and excessive material in their design. With mission costs known to exceed €10,000 (approximately AUD $15,000) per kilogram, minimising the use of non-essential material can enable more efficient structures and hence overall mission profiles [2].

Additive manufacturing (AM) is a fabrication method that creates structures through a sequential layering process. A variety of AM processes exist that can be understood as consisting of two main actions; the first being material deposition followed by material solidification [3]. Various types of metal AM processes are used in the aerospace field including powder bed fusion and directed energy deposition. The generative nature of AM enables significant design freedom to be achieved by removing constraints often imposed by traditional, subtractive manufacturing methods [4]. This further extends to providing fine control over the shape, composition and functionality of structures that is unparalleled by other methods [5].



Copyright © 2023 by Joshua RODRIGUES, Simon BARTER and Raj DAS. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

The realisation and potential of AM technology have led to significant research in methods and application of structural optimisation techniques. As structures with complex, porous and internal features can now be manufactured with relative ease, methods of structural optimisation have become widely utilised across various industries including the automotive, civil and aerospace sectors. Structural optimisation refers to a technique where the material distribution of a structure is spatially changed (such as the elimination of excess material or the addition of new material) to increase structural efficiency for a given application. This is quite appealing to the space sector where weight-conscious designs are paramount. Common methods of optimisation include size, shape and topology changes, with associated levels of complexity [6]. Topology optimisation focuses on determining the optimal layout of material within a structure whilst considering a set design objective(s) and constraint(s) [7]. The bi-directional evolutionary structural optimisation (BESO) method is a finite element-based topology optimisation technique that is an extension of the evolutionary structural optimisation (ESO) method [8, 9]. Compared to ESO which is limited in its approach to material removal, the BESO method not only removes inefficient material from a structure but can simultaneously add efficient material to regions that require strengthening, making it much more material efficient [10].

In this paper, we apply the BESO algorithm to optimise a realistic satellite antenna bracket through finite element modelling using Abaqus software (ver. 2020). The original design of the satellite antenna bracket will be presented and used as inspiration for the design domain. Relevant loading and boundary conditions will then be applied to the structure, where it will be meshed and the BESO method will be performed, specifically using the compact 100-line Python code as presented in [8] due to its simplicity and use for educational purposes. The outcome of this study will be used to assess the applicability of such a method for the design optimisation of satellite components, in this case, an antenna bracket structure.

2. Satellite antenna bracket design

Here the applicability of the BESO algorithm is demonstrated to obtain an improved material layout for a satellite antenna bracket. This optimisation aims to produce a lighter bracket structure whilst still adhering to the geometric and strength requirements. The structure of choice is based on the antenna bracket used in the RUAG Sentinel 1 radar satellite as per Fig. 1a. The structure is simplified to a 3D plate model in which complicated features, such as the rivets and fasteners, were neglected as their effects on the main analysis results of interest were negligible. It is also noted that the exact parameters of the RUAG bracket are not publically available, hence representative dimensions are used, as per Fig. 1b. The thickness of the structure is assumed to be 1 mm.

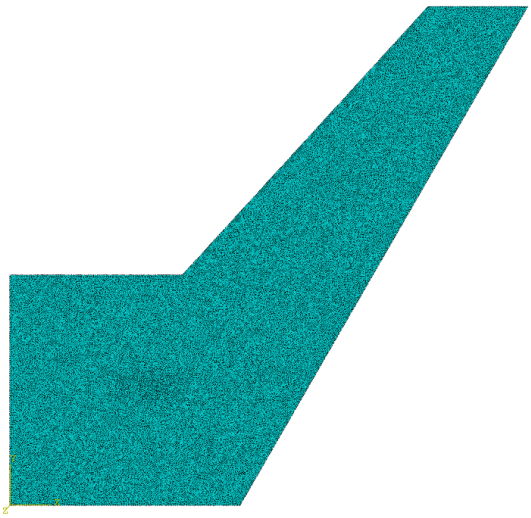
(a) (b)

Figure 1. (a) RUAG Sentinel 1 satellite antenna bracket and (b) representative structure with dimensions in millimetres (mm) [11].

A lightweight AM aluminium alloy (AlSi10Mg) is used as the material for this analysis as it is common in AM processes. The Poisson's ratio (v) was taken as 0.33. Prior tensile testing of AM coupons has been completed on this alloy, giving a Young's modulus (E) of 58.571 GPa, assuming a vertical build direction. The density of this material is 2.597 g/cm^3. Typically aluminium alloys such as 6061-T6 and 6063-T6 extrusions are used for this application, which have comparable density and mechanical properties. A linear-elastic finite element analysis was performed throughout.

3. Finite element modelling

The bracket structure was created in finite element software Abaqus as a solid, 3D model using the graphical user interface (Abaqus CAE). The aluminium alloy AlSi10Mg material was created and the properties were assigned as a homogeneous, solid section. A static general step was applied to the structure with an increment size between 0.01 and 1. Optimisation problems require a fine mesh to achieve accurate results. In this analysis, the solid model was meshed with a seed size of 2.0 mm which resulted in 100,138 elements and 201,730 nodes. Type C3D8 elements were used, which are 8-node linear brick elements. This is due to the BESO code requiring hexahedral elements to perform the optimisation process. The meshed part is displayed in Fig. 2.



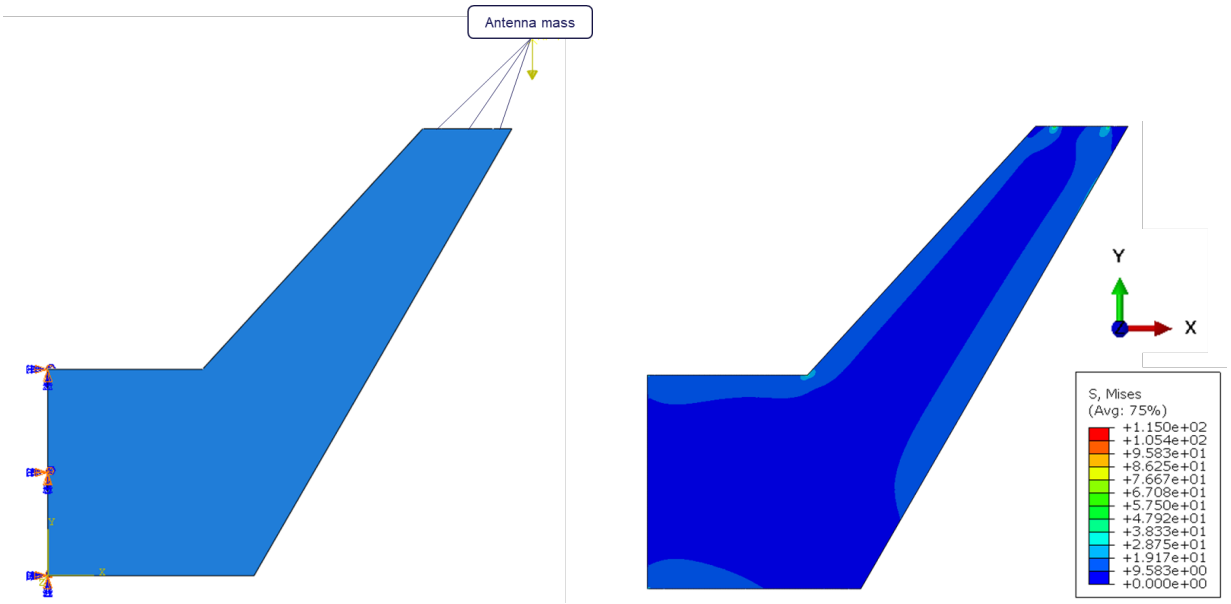


Figure 2. Meshed antenna bracket structure.

The purpose of this bracket structure is to support the load of an antenna system. To enhance the simplicity of the computational model, the antenna is considered as a singular point mass of 1.00 kg at the location of its centre of gravity. A simple static case is considered for this analysis where the weight of the antenna is considered to be under the force of gravity (10g). Therefore, a singular point load of 100 N is applied vertically downwards (the negative y-direction). As seen in Fig. 1a, the antenna is mounted to the original bracket using fasteners. In this analysis, it is assumed that the loading of the antenna is applied evenly across the middle area of this section. A 25 mm partition along the top surface of the model is applied to represent potential fasteners at this location. A multi-point constraint (MPC) of type beam is used to constrain the mass load evenly across this partitioned region of the structure.

The original structure is also fixed to the main satellite body using fasteners at the base of the bracket. The precise locations of these mounting points, however, are not fundamental to the design and optimisation process. Therefore, this entire edge of the bracket is considered fully fixed (encastre) to the satellite in all six degrees of freedom but is still part of the overall design domain. The results from this optimisation can then inform the potential location of these fastener interfaces, rather than excluding unnecessary regions from the optimisation. The von Mises stress is chosen as the criterion for this optimisation and will hence be used throughout. Fig. 3a exhibits the loading and boundary conditions applied to the structure and Fig. 3b displays the initial von Mises stress analysis of the applied load.

(a) (b)

Figure 3. (a) loading and boundary conditions applied to the finite element model and (b) the von Mises stress distribution of static analysis.

The von Mises stress distribution of the structure under a static analysis is depicted in Fig. 3b, where a maximum stress of 100.970 MPa is observed occurring at the corner of the edge where the antenna load is applied. It is observed that the fixed edge of the structure has elevated stress at the top and bottom locations along the edge. An elevated stress region is also seen at the oblique corner angle in the bracket. The majority of the structure has minimal stress of approximately 5 MPa throughout, represented by the deep blue region. This suggests that there is a large portion of inefficient material used to transfer the load in the part, indicating that a more optimum layout of the material will be beneficial to saving weight.

4. Optimisation using BESO

Once the model was developed, the BESO method was performed by running the Python code in Abaqus. Abaqus CAE was used to monitor the progress of the iterative jobs. This study considers a compliance minimisation objective (stiffness maximisation) with respect to a volume constraint. The BESO method used in this analysis is based on the 'soft-kill' approach. This treats elements as relative densities as either being 1.0, which indicates the presence of a solid element, or a small prescribed value of 0.001, to indicate void elements. In contrast to a 'hard-kill' approach that completely removes the elements from the model, the soft-kill can filter between each material type instead of entire element deletion. The void material can then be excluded when viewing the results whilst remaining in the part, which is the case for the results presented in this paper. The von Mises stress field was used to modify the topology of the structure. At each iteration, the von Mises stress was calculated, whereby elements were deemed void if they were lower than a reference stress value. A target volume fraction was set to 0.3, with a minimum filter radius of 3 mm and an evolutionary ratio of 2%. The gradual evolution of the optimisation process is presented in Fig. 4 by a few intermediate topologies. A volume fraction (W/W_0) is also denoted, representing the current iteration volume (W) to the initial volume of the structure (W_0).

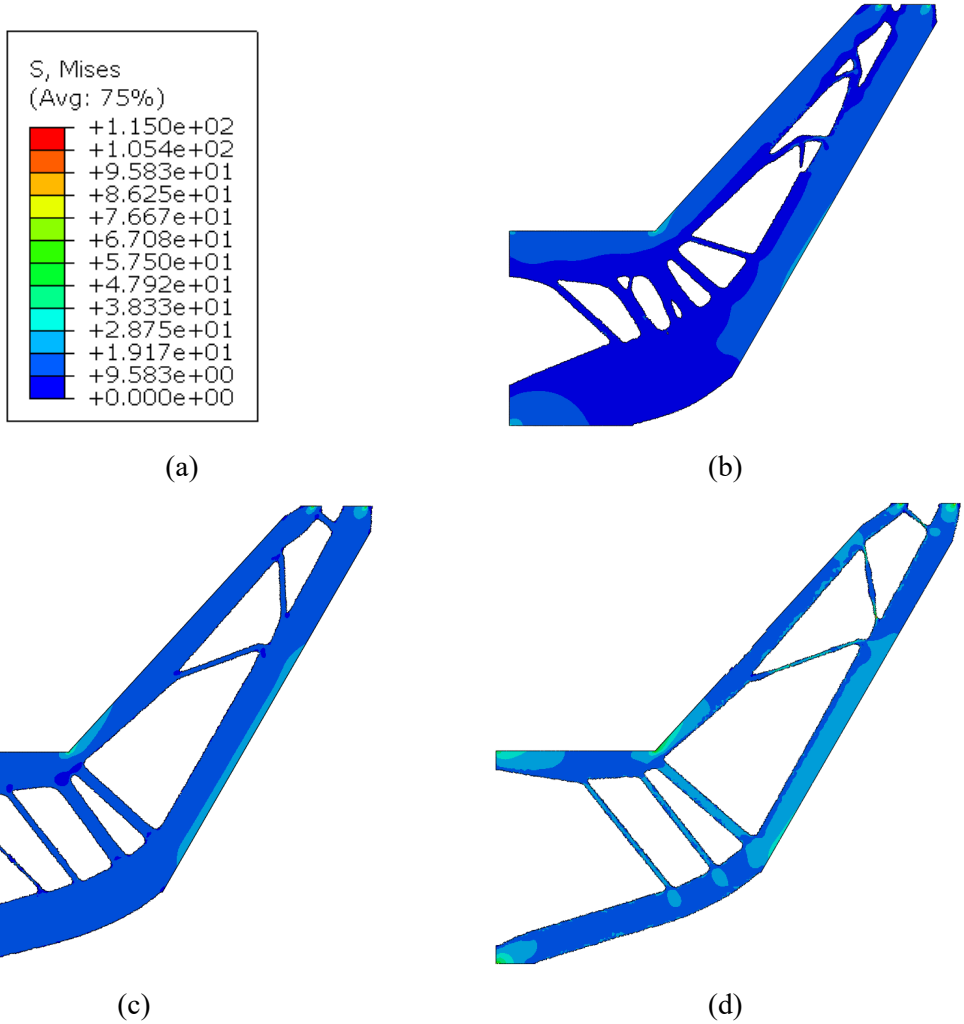

Figure 4. Intermediate results of the satellite antenna bracket optimisation process using the BESO method including (a) von Mises stress legend, (b) iteration 17: $W/W_0 = 70.93\%$, (c) iteration 34: $W/W_0 = 50.32\%$ and (d) iteration 53: $W/W_0 = 34.28\%$.

The 'optimum' solution was determined based on the maximum stress of the structure and the weight savings achievable within a prescribed domain. As described in [7], a maximum design allowable stress (σ_a) was selected that is usually based on failure criteria, material properties and operating conditions. In this analysis, the maximum allowable stress was set to 110 MPa, which is approximately 10% greater than the maximum initial von Mises stress. The iteration with the greatest weight savings whilst remaining under σ_a is considered to be the optimum solution for this analysis. Fig. 5a and Fig. 5b show the variation of the maximum von Mises stress and volume fraction, respectively, of the satellite antenna bracket with a change in topology layout (iteration number). A dashed horizontal line is drawn to represent the prescribed maximum allowable stress of 110 MPa. The topology layout of the structure that immediately precedes the point of intersection between this line and the stress history curve represents the most optimum solution. This was determined to be the 43rd iteration, represented by the red dot denoted as the 'design point'.

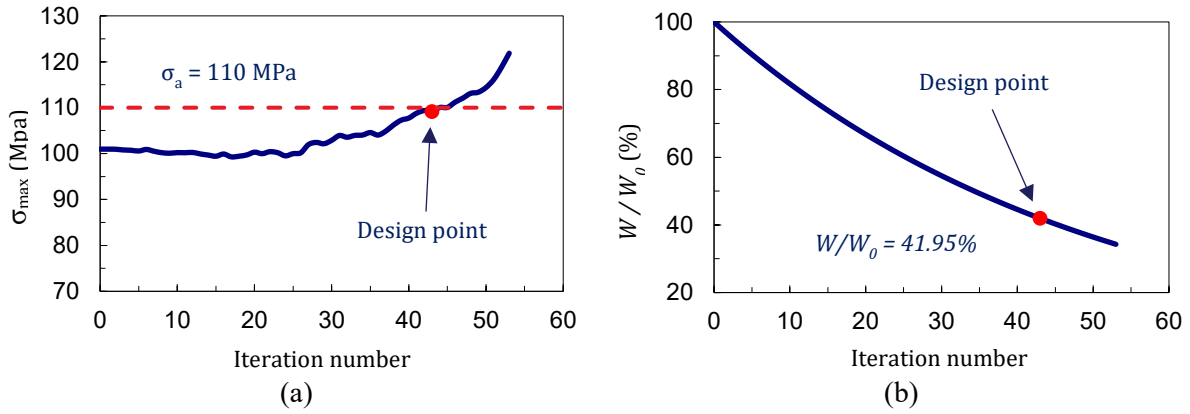

Figure 5. (a) Variation of the maximum von Mises stress in the antenna bracket with change in topology layout, and (b) change in volume fraction of the bracket with change in topology layout.

Under the prescribed loading and boundary conditions, the topology layout at this iteration resulted in a maximum von Mises stress of 109.142 MPa. The next iteration had a maximum von Mises stress of 110.036 MPa, which exceeds the allowable limit of 110 MPa. This design point also yielded a weight fraction of 41.95% compared to the weight of the original structure. This implies that the optimum design yielded a weight reduction of around 58%, whilst only increasing the maximum von Mises stress by approximately only 8 MPa. This weight saving could have a significant impact on the efficiency and performance of, not only this sub-component but the holistic satellite structure, signifying the importance that design optimisation can have for spacecraft structures.

The resultant optimal topology is exhibited in Fig. 6, where several layout and stress changes can be observed compared to the initial design in Fig. 3b. The key features of the optimal topology are listed below:

- The bulk of the lowly stressed material that was present in the middle of the initial structure has been removed and replaced with strut-like connections between the upper and lower edges of the bracket.
- The top and bottom sides of the fixed edge remain whilst the middle section has been removed. This indicates that potential fasteners should be applied at the top and bottom corners of the fixed edge and that no fasteners are required in the middle.
- The highest stress occurs at the location where the antenna mass is constrained to the partitioned edge at the top of the antenna bracket. The material on either side of this partition was inefficient as it did not support much load and was hence removed.
- The average lowly stressed regions have increased from 5 MPa in the initial structure to approximately 15 MPa in the optimum design.
- The inclined portion of the bracket where the antenna is mounted appears to represent a truss section with diagonal struts present between the upper and lower edges.
- In the original design, an oblique 60° angle was present at the lower edge of the bracket. Whilst this incline remains, the bottom edge of the structure appears to have a more filleted section with a more gradual transition radius that reduces the stress concentrations in this corner. This further reduces the potential for crack initiation at this location due to launch vibrations.

It is noted that the derived optimal design using BESO is a conceptual design and requires significant post-processing to effectively implement this design. This can be in the form of local modifications to the geometry, shape optimisation of features and more accurate geometries for fastener interfaces.

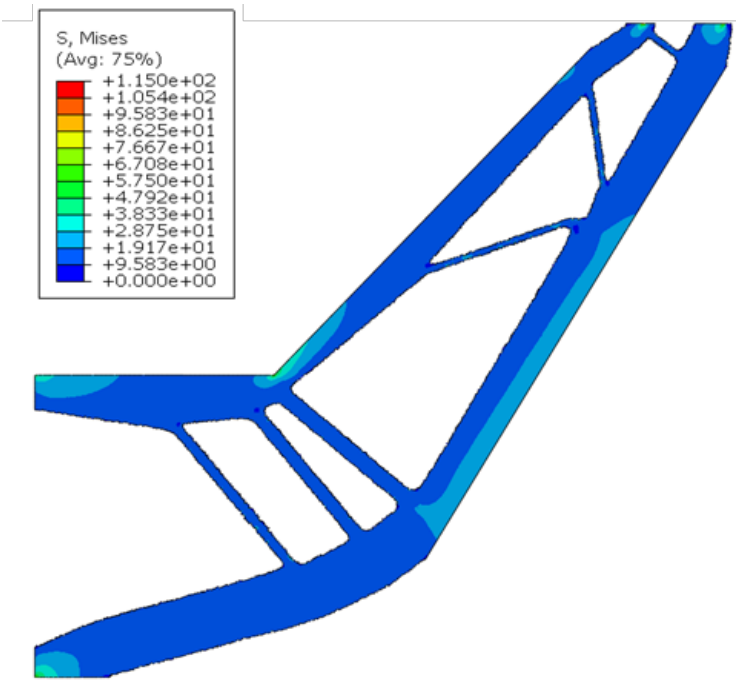

Figure 6. Optimal topology layout of the satellite antenna bracket with von Mises stress distribution.

6. Conclusions

This paper investigated the use of the BESO method for the topology optimisation of a spacecraft structure. The capabilities of the BESO algorithm were demonstrated by considering the design optimisation of a satellite antenna bracket structure. The BESO algorithm was applied to the initial design of the structure to generate an improved topological layout by the gradual removal and addition of material using the soft-kill approach. An approximate 58% decrease in the weight of the structure was achieved whilst having a maximum stress below the allowable design stress limit of 110 MPa that was set for this optimisation. The BESO algorithm was found to be an efficient and practical tool for the optimisation of realistic spacecraft structures. This technique can serve as a valuable starting point for further design considerations and other optimisation techniques that are not easily realised using conventional methods. The BESO method can be applied to various spacecraft applications to reduce the weight of structures without compromising their critical strength and stiffness characteristics. Variations in stress levels can also be reduced and lead to a more uniformly stressed structure with more optimum material usage.

Abstract

Topology optimisation techniques have been increasingly employed in architectural designs to achieve efficient and elegant structures with minimal material. Current architectural applications of topology optimisation typically consider structural stiffness as the main design objective. However, buckling is a critical phenomenon that should not be ignored in structural designs, as it could lead to catastrophic failure of a structure. In this study, a buckling-constrained bi-directional evolutionary optimisation (BC-BESO) algorithm is presented for designing buckling-resistant structures. The proposed algorithm aims to minimise the compliance of a structure under predefined buckling constraints, thus ensuring both stiffness and stability of the structure. To validate the proposed algorithm, a benchmark example is presented to compare the numerical result with the analytical solution. The application of the proposed method in the structural design of high-rise buildings demonstrates that the algorithm can significantly enhance buckling resistance with a slight sacrifice of stiffness.

Keywords: topology optimisation, bi-directional evolutionary structural optimisation, architectural design, buckling, structural stability

1. Introduction

Topology optimisation has emerged as a powerful tool in the architecture community over the past few decades, enabling the design of high-performance structures with minimal material [1]. Among various topology optimisation techniques, the bi-directional evolutionary structural optimisation (BESO) method is one of the most commonly used methods, which removes inefficient material from a structure and adds material to the most-needed locations [2, 3]. The BESO method has been employed to design buildings and bridges that are optimised for efficiency, environmental sustainability, and aesthetical appeal [4–10].

Notwithstanding the growing interest of architects in topology optimisation, practical applications of this technique in large-scale projects remain limited [1]. One of the main reasons is the fact that the current BESO algorithm for architectural design primarily focuses on maximising structural stiffness, generating forms that may be susceptible to buckling issues. The lack of consideration for the buckling effect in topology optimisation can lead to poor stability and unexpected structural failures [11]. To address this issue, this paper introduces a buckling-constrained BESO (BC-BESO) algorithm for architectural design, allowing architects to obtain more practical solutions with improved stability and buckling-resistant performance.

The BESO algorithm benefits from having only two discrete states (solid and void) for the design variables, which helps alleviate the issues related to so-called pseudo-buckling modes that often occur in other density-based topology optimisation algorithms [12, 13]. In this study, the proposed BC-BESO algorithm is validated through a benchmark example, where the numerical result obtained by the algorithm is compared to the analytical solution presented by Haftka and Gürdal [14]. Besides, this

paper presents an example of topology optimisation considering buckling effect in the design of a high-rise building, highlighting the importance of this consideration for achieving practical and buckling-resistant solutions.

The rest of the paper is organised as follows. In Section 2, the formulas and the procedure of the BC-BESO algorithm are given. Section 3 studies a benchmark example that demonstrates the effectiveness of the BC-BESO algorithm. In Section 4, the application of the algorithm in the design of a high-rise building is presented, and a comparison is made between the results obtained from the BC-BESO and the conventional BESO methods. Lastly, concluding remarks are given in Section 5.

2. Buckling-constrained BESO method

In this section, the BC-BESO method for architectural optimisation is presented. By considering buckling constraints in topology optimisation, the proposed method enables architects to achieve more efficient and buckling-resistant structures for their designs.

2.1. Problem statement

The topology optimisation for minimising compliance subject to buckling constraints can be stated as follows:

$$\begin{aligned} &\text{min: } C = \boldsymbol{F}^T \boldsymbol{u} \\ &\text{s.t.: } \begin{cases} \boldsymbol{K}\boldsymbol{u} = \boldsymbol{F} \\ V(x) = \sum x_i v_i - V^* = 0 \\ x_i = x_{min} \text{ or } 1,\ i = 1,\ 2,\ ...,\ N. \\ \lambda_1 \geq \underline{\lambda} \end{cases} \end{aligned} \tag{1}$$

where C is the mean compliance, $\boldsymbol{K}$ and $\boldsymbol{u}$ are the global stiffness matrix and the displacement vector, respectively. $\boldsymbol{F}$ is the load applied to the structure. v_i is the volume of the corresponding element and V^* is the predefined volume fraction. λ_1 is the lowest buckling load factor (BLF) and $\underline{\lambda}$ is the prescribed buckling constraint. x_i is the binary design variable of an individual element, which equals to either x_{min} (void) or 1 (solid).

2.2. Optimisation procedure

Linear buckling analysis is used to conduct sensitivity analysis to save computational cost. Linear buckling analysis is defined as

$$\mu_j = -\frac{\boldsymbol{\varphi}_j^T \boldsymbol{G} \boldsymbol{\varphi}_j}{\boldsymbol{\varphi}_j^T \boldsymbol{K} \boldsymbol{\varphi}_j} \tag{2}$$

where $\boldsymbol{G}$ is the stress stiffness matrix. μ_j and $\boldsymbol{\varphi}_j$ are the inverse value of the j-th BLF λ_j and its corresponding buckling mode vector, respectively. Two different material interpolation schemes are used for stiffness and the stress stiffness matrix to restrain pseudo-buckling modes [15], which are given as follows.

$$\begin{cases} E_K(x_i) = \left[\dfrac{x_{min} - x_{min}^p}{1 - x_{min}^p} (1 - x_i^p) + x_i^p \right] E \\ E_G(x_i) = x_i^p E \end{cases} \tag{3}$$

The sensitivity of BLF is calculated as

$$\frac{\partial \mu_j}{\partial x_i} = -\left[\boldsymbol{\varphi}_j^T \left(\frac{\partial \boldsymbol{G}}{\partial x_i} + \mu_j \frac{\partial \boldsymbol{K}}{\partial x_i} \right) \boldsymbol{\varphi}_j - \boldsymbol{v}_j^T \frac{\partial \boldsymbol{K}}{\partial x_i} \boldsymbol{u} \right] \tag{4}$$

The second term on the right side is the adjoint term, which can be solved by

$$\boldsymbol{K}\boldsymbol{v}_j = \boldsymbol{\varphi}_j^T \frac{\partial \boldsymbol{G}}{\partial \boldsymbol{u}} \boldsymbol{\varphi}_j \tag{5}$$

Multiple buckling constraints are aggregated into a single one by the KS function. The KS-aggregated buckling sensitivity is written as [16]

$$\frac{\partial \mu^{KS}}{\partial x_i} = \frac{\sum_{i=1}^{q} e^{\rho(\mu_j - \mu_1)} \frac{\partial \mu_j}{\partial x_i}}{\sum_{i=1}^{q} e^{\rho(\mu_j - \mu_1)}} \tag{6}$$

The above sensitivity of buckling constraints is added to compliance sensitivity via an augmented Lagrangian multiplier Λ reported in the literature [11]. The overall sensitivity can be found as

$$\frac{\partial f}{\partial x_i} = \frac{\partial C}{\partial x_i} + \Lambda \frac{\partial \mu^{KS}}{\partial x_i} = -\frac{1}{2}\boldsymbol{u}^T \frac{\partial \boldsymbol{K}}{\partial x_i}\boldsymbol{u} - \Lambda \frac{\sum_{i=1}^{q} e^{\rho(\mu_j - \mu_1)} \left[\boldsymbol{\varphi}_j^T \left(\frac{\partial \boldsymbol{G}}{\partial x_i} + \mu_j \frac{\partial \boldsymbol{K}}{\partial x_i} \right) \boldsymbol{\varphi}_j - \boldsymbol{v}_j^T \frac{\partial \boldsymbol{K}}{\partial x_i} \boldsymbol{u} \right]}{\sum_{i=1}^{q} e^{\rho(\mu_j - \mu_1)}} \tag{7}$$

Therefore, the sensitivity of element *i* in the BESO method is calculated as

$$\alpha_i = -\frac{\partial f}{\partial x_i} = \frac{1}{2}\boldsymbol{u}^T \frac{\partial \boldsymbol{K}}{\partial x_i}\boldsymbol{u} + \Lambda \frac{\sum_{i=1}^{q} e^{\rho(\mu_j - \mu_1)} \left[\boldsymbol{\varphi}_j^T \left(\frac{\partial \boldsymbol{G}}{\partial x_i} + \mu_j \frac{\partial \boldsymbol{K}}{\partial x_i} \right) \boldsymbol{\varphi}_j - \boldsymbol{v}_j^T \frac{\partial \boldsymbol{K}}{\partial x_i} \boldsymbol{u} \right]}{\sum_{i=1}^{q} e^{\rho(\mu_j - \mu_1)}} \tag{8}$$

To avoid a mesh-dependent solution, the sensitivity values are averaged by a filtering scheme, which is determined as [17]

$$\tilde{\alpha}_j = \frac{\sum_{i=1}^{N} \omega_{ij} \alpha_i}{\sum_{i=1}^{N} \omega_{ij}} \tag{9}$$

where $\tilde{\alpha}_j$ is the averaged sensitivity value of the *j*-th element. *N* denotes the number of neighbouring elements. ω_{ij} is the linear weight factor related to r_{ij}, which is the distance between the centroids of the centred element *j* and its neighbouring elements *i*

$$\omega_{ij} = r_{min} - r_{ij} \left(j = 1, 2, ..., \mathrm{N} \right) \tag{10}$$

where r_{min} is the filter radius. To enhance the optimisation stability and convergence, the sensitivity value is averaged by the previous three historical information as

$$\tilde{\alpha}_j^k = \frac{\tilde{\alpha}_j^k + \tilde{\alpha}_j^{k-1} + \tilde{\alpha}_j^{k-2}}{3} \tag{11}$$

where *k* is the current iteration number, and afterwards, the design variables are updated according to the scheme described in [11].

The optimisation process is conducted until buckling constraints, the volume constraint and the convergence criterion are all met. The convergence criterion is defined as the change in the objective function over the last ten iterations being sufficiently small, e.g., 10^{-3} to 10^{-5}. The overall procedure of the proposed BC-BESO method is illustrated in Figure 1.

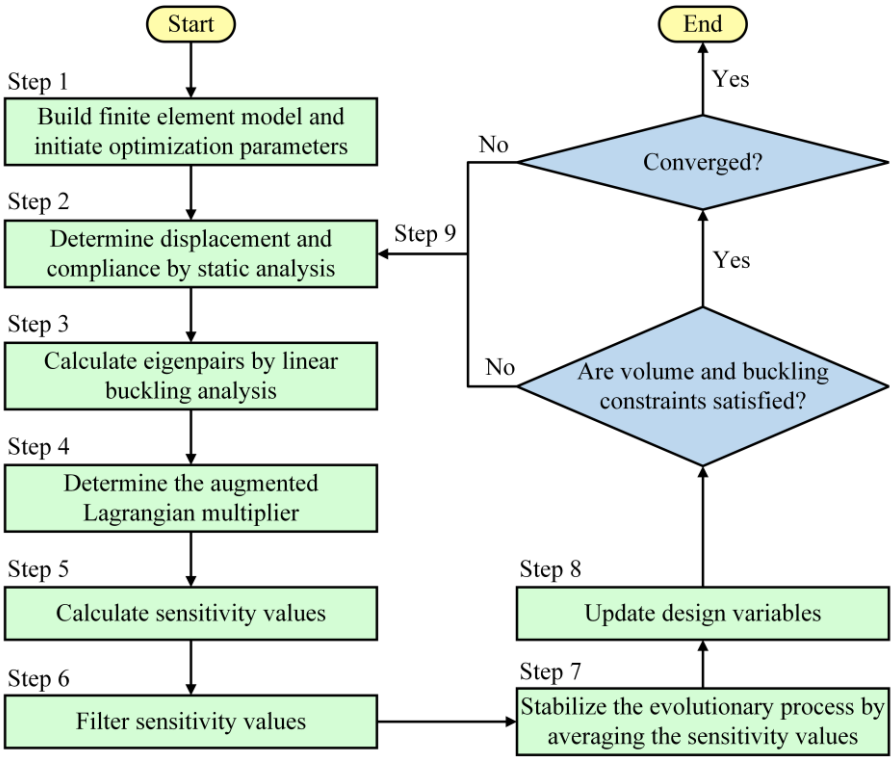

Figure 1. Flowchart of the BC-BESO method.

3. Benchmark example

To validate the BC-BESO algorithm, a benchmark example reported by [14] is studied in this section. The objective of this example is to maximise the lowest BLF λ_1 of a simply supported column with a length of L subjected to the constant volume constraint (Figure 2a). The optimum analytical column from the literature has zero cross-sectional areas at both ends, and the cross-sectional area gradually increases towards the middle section. The analytical solution of the lowest BLF of the optimised column is given as follows [14].

$$\lambda_1^{opt} = \frac{125}{9}\frac{EI_0}{L^2} = 1.407\frac{\pi^2 EI_0}{L^2} = 1.407\lambda_1^0 \tag{12}$$

where I_0 and λ_1^0 are the moment of inertia and the lowest BLF of the initial constant area column, respectively.

In this study, a continuum model is employed, which has a discretised rectangular design domain with a high aspect ratio. Shape optimisation is performed with a constant volume. The parameters are set as $E = 1$, $\nu = 0$, $p = 3$, $x_{min} = 10^{-6}$, and $r_{min} = 2 \times$ the element side length. The ideal slender column has an approximately infinite aspect ratio, whereas different aspect ratios (L_x/L_y) are adopted for the rectangular design domain, i.e., 20, 30, 50 and 80. Besides, it was reported by [18] that the discretisation could influence the accuracy of λ_1 approximations. Thus, different discretisation levels are used in this study. The numerical results obtained from the proposed buckling-constrained BESO method are compared with the analytical solution [14] in Table 1.

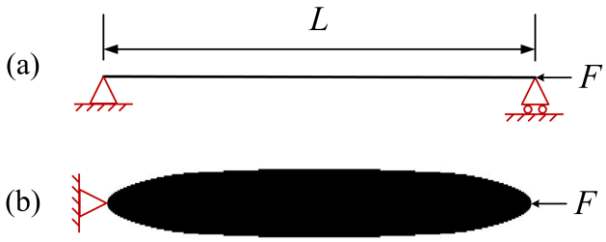

Figure 2. Benchmark example: (a) boundary conditions of the simply supported column, and (b) optimum design obtained from the continuum model. Note that the length of the optimum design is scaled for easy viewing.

Table 1. λ_1 obtained based on different discretisation levels and aspect ratios of the design domain. (Both λ_1 and $\lambda_1^{uniform}$ are the numerical results obtained with the discretisation shown in the same row.)

Aspect ratio L_x/L_y	Discretisation	$\lambda_1/\lambda_1^{uniform}$	Error (%)
20	200×10	1.339	-4.9
	400×20	1.368	-2.8
	600×30	1.370	-2.6
	800×40	1.376	-2.2
30	600×20	1.372	-2.5
	900×30	1.380	-1.9
	1200×40	1.381	-1.9
50	1500×30	1.390	-1.2
	2000×40	1.392	-1.1
80	4800×60	1.396	-0.8

The shape of the optimum column (Figure 2b) exhibits consistent characteristics with the analytical solution, i.e., infinitesimal widths at the ends and wider dimensions in the middle. Such a width-tapered column leads to a higher moment of inertia and stronger resistance to buckling. Nevertheless, as shown in Table 1, the accuracy of the numerical results is dependent on the discretisation level and the aspect ratio of the design domain.

The error decreases when a finer discretisation level is applied. For instance, when the aspect ratio is 20, the error reduces from -4.9% for 200 × 10 elements to -2.2% for 800 × 40 elements; when the aspect ratio is 30, the error reduces from -2.5% for 600 × 20 elements to -1.9% for 1200 × 40 elements.

The aspect ratio of the design domain also affects the accuracy of the optimisation results. With a discretisation of 30 × the aspect ratio $=$ 30, the errors are -2.6%, -1.9% and -1.2% when the aspect ratios are 20, 30 and 50, respectively. With a large aspect ratio of 80 and an extremely fine mesh of 4800 × 60, an error of only -0.8% can be achieved. Besides, it is worth mentioning that the same numerical results are obtained with $\nu = 0.3$.

The comparison between the analytical solution and the numerical results indicates that satisfactory results can be obtained with a small error margin. The proposed algorithm has been demonstrated to be valid and accurate.

4. Numerical examples

A high-rise building with a width of 20 m and a height of 100 m is considered, as illustrated in Figure 3a. It is assumed that the building is subjected to lateral wind loads at five different heights, where the wind load *P* at the height of 20 m is 1000 kN and increases linearly with height. Two wind load cases

are considered. In the first case, the building is subjected to the wind load from the left, while in the second case, it experiences the wind load from the right. The design domain is discretised into 80 × 400 elements.

The stiffness optimisation is firstly conducted with $V^* = 50\%$, $ER = 1\%$, and $r_{min} = 1$ m. The corresponding stiffness design is presented in Figure 3b. The design exhibits a concentration of material in the lower part of the structure, while the upper part features thinner structural members. Upon applying the wind load on both sides, the first buckling modes are observed in Figure 3c and 3d, where a localised buckling is clearly evident at the top of the structure (indicated by the red circle). Additionally, a high level of strain energy density is observed in the upper part of the structure, while the lower part possesses relatively low strain energy density. The lowest BLF λ_1^C of the stiffness design is only 0.127, corresponding to a critical load $P_{cr} = \lambda_1^C \times P = 127$ kN. Therefore, the obtained stiffness design cannot be used in practical architectural applications, as it may be susceptible to severe buckling issues.

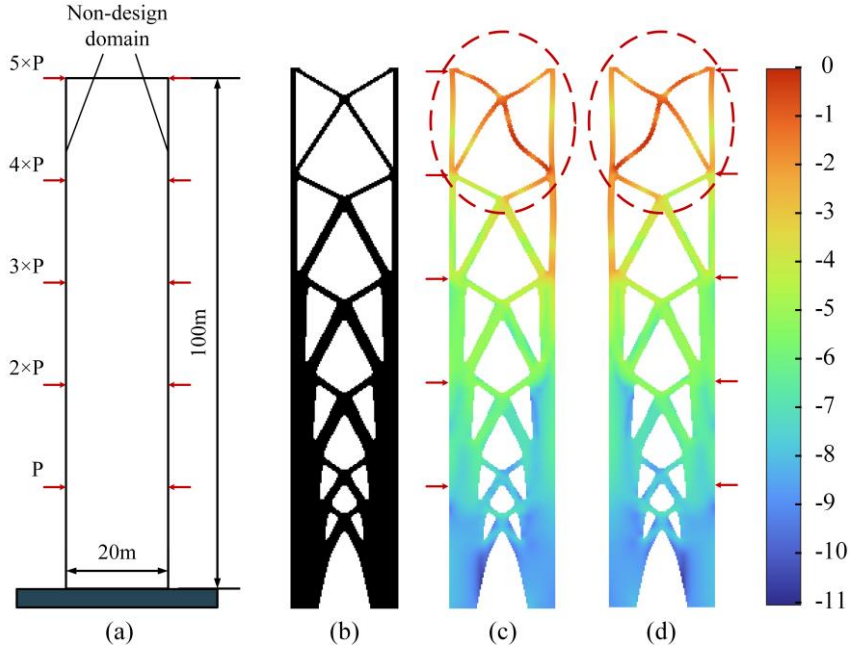

Figure 3. High-rise building: (a) boundary conditions; (b) stiffness design; (c) first buckling mode under left wind load; and (d) first buckling mode under right wind load. Buckling modes are coloured from blue to red, corresponding to the logarithm of normalised strain energy density from low to high.

To achieve a structure resistant to buckling, the buckling-constrained optimisation is then conducted based on the stiffness design with $ER = 0.1\%$, $r_{min} = 0.75$ m, and $\underline{\lambda} = 10 \times \lambda_1^C = 1.27$. The resulted buckling-reinforced structure is shown in Figure 4a, where the material is relocated from the lower part of the structure to the upper part. Thin members in the upper part are separated, and additional members are generated to resist buckling (as indicated by the red circle). The first buckling modes, illustrated in Figure 4b and 4c, show that the buckling-reinforce structure exhibits a more global buckling mode, and the strain energy density distributes more evenly compared to that of the stiffness design (Figure 3c and 3d). The lowest BLF λ_1^B of the buckling-reinforced design is increased to 1.27, corresponding to a much higher critical load $P_{cr} = \lambda_1^B \times P = 1{,}270$ kN. Moreover, the stiffness of the buckling-reinforced structure is decreased by only 1.0% compared to that of the stiffness design.

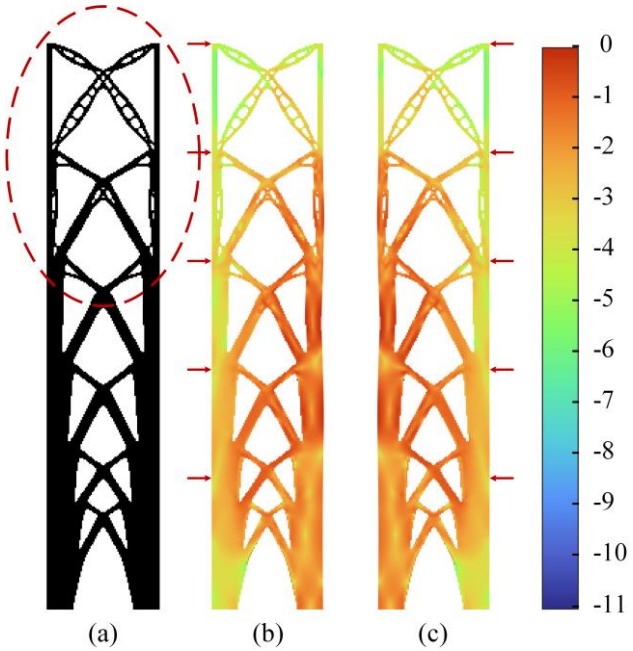

Figure 4. Buckling-constrained optimisation: (a) optimisation result and (b) first buckling mode under left wind load; and (c) first buckling mode under right wind load. Buckling modes are coloured from blue to red, corresponding to the logarithm of normalised strain energy density from low to high.

This example highlights the importance of considering the buckling effect in architectural design, as the stiffness design generated by conventional BESO can face severe buckling issues. The proposed BC-BESO algorithm offers a promising solution to achieve more efficient and stable architectural designs by incorporating buckling constraints in the optimisation process.

5. Conclusion

In this study, a buckling-constrained bi-directional evolutionary structural optimisation (BC-BESO) algorithm is presented for architectural design to enhance structural stability. The algorithm is validated through a benchmark example, demonstrating its effectiveness in generating efficient and buckling-resistant structures. The application of the algorithm to the design of a high-rise building demonstrates its ability to significantly improve buckling resistance with minimal stiffness reduction. Furthermore, the research contributes to the body of knowledge on topology optimisation with buckling constraints in architectural design. In future research, it is worthwhile to investigate the inclusion of additional constraints, such as vibration or thermal performance, and to apply the algorithm to optimise different types of structures, such as bridges and large-scale infrastructure.

Topology optimisation considering subjective preferences: current progress and challenges

Zhi LI [a], Ting-Uei LEE[a], Yi Min XIE[a,*]

Abstract

Topology optimisation techniques can redistribute given materials to their most-needed locations to generate efficient and innovative structural designs. However, these techniques are typically performed based purely on structural performance. Hence, the solutions could be of low value in specific practical applications, as they may not always satisfy all design requirements, including factors like aesthetic quality. Recently, a few studies have reported that introducing subjective preferences into topology optimisation techniques can result in more satisfying structural designs so that users do not need to passively accept the conventional optimisation results. This paper provides a brief overview of the state-of-the-art in topology optimisation techniques that consider subjective preferences. The techniques are classified into three groups based on when subjective interventions are introduced: pre-processing, post-processing and interactive processing strategies. The advantages and limitations of each group are discussed, as are the technical challenges involved in extending these new techniques. Overall, this paper aims to serve as a helpful guide for future developments of topology optimisation techniques that consider subjective preferences, hoping to create more practical and customised structural designs that better meet the needs of users.

Keywords: topology optimisation, subjective preferences, structural design, interactive design

1. Introduction

Topology optimisation is an effective strategy to generate lightweight, efficient and innovative structural designs by redistributing underutilised materials to their most-needed locations in continuous design domains [1]. Conventional topology optimisation techniques are typically performed based on finite element analysis (FEA) with the elements used to represent the given materials. A widely used topology optimisation technique is the bi-directional evolutionary structural optimisation (BESO) method; it allows inefficient and efficient elements to be simultaneously removed and added, generating clear 0/1 designs to represent material density distributions [2]. As shown in Figures 1(a)–(e), the BESO method has been employed in numerous novel practical applications, including bridges [3], furniture [4] and architectural designs [5,6].

According to [7], topology optimisation that focuses only on improving structural performance may not achieve solutions that meet all design requirements, such as aesthetics. Therefore, recent studies have extended the BESO method (i.e., multi-solution strategies) to produce diverse and competitive solutions, offering users a variety of design choices [7]. Specifically, such strategies trade off a minor decrease in the structural performance (e.g., 3% stiffness) of the 'best design' in exchange for multiple topologically different and structurally efficient solutions. Multi-solution strategies include parameter-based [8,9], sub-domain-based [5,10,11], constraint-based [12,13] and weight-based strategies [10,11,14].

It should be noted that design options generated from multi-solution strategies may include many undesired candidates due to differences in personal preferences [15]. Hence, designers must spend

Copyright © 2023 by Zhi LI, Ting-Uei LEE and Yi Min XIE. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

significant time and effort to evaluate each option to select a satisfactory one, leading to a costly design exploration process [15]. As reported in [16], a piece of design work can reflect the designer's personality, taste and thoughts, emphasising the need to introduce subjective preferences into the design process rather than selecting from multiple options. To this end, recent studies have developed various computational design methods incorporating subjective preferences [16–19]. However, only a few studies have implemented the concept of 'subjective preferences' into topology optimisation [5,14,16]. In this context, a comprehensive review of the current topology optimisation methods considering subjective preferences is necessary to better understand the progress, potential and challenges.

The objective of this paper is to offer a clear understanding of topology optimisation methods that incorporate subjective preferences. To achieve this goal, we conduct a critical review of state-of-the-art research in this field. By examining the progress made so far, the potential and challenges of these methods can be better understood. This will help to improve the development of future topology optimisation techniques that can produce structural designs that better reflect subjective preferences and ultimately lead to more efficient and effective design processes. Section 2 provides a detailed review of these methods, while Section 3 discusses the existing challenges and future possibilities. Finally, Section 4 presents a conclusion.

2. Topology optimisation techniques considering subjective preferences

2.1. Selection criteria

Shortlisted research papers discussed in this paper are selected based on the following criteria:

- The underlying computational design method must be topology optimisation, such as the BESO, SIMP and level-set methods.
- The topology optimisation method must allow users to input their subjective preferences, such as aesthetics, design concepts and artificial intervention, among others.
- The incorporation of subjective preferences must have an impact on the generation of optimal structural topologies.

Note that the term 'subjective preferences' may be expressed in different ways in different studies. A few phrases were useful in finding the shortlisted research papers: 'topology optimisation based on artificial intervention', 'preference-based topology optimisation' and 'topology optimisation considering aesthetics'.

Based on the above criteria, we have found three most-related research papers about 'topology optimisation considering subjective preferences', including [5], [14] and [16]. The three interrelated studies put forward a total of five topology optimisation methods that incorporate subjective preferences. These methods can be classified into three groups based on the conditions of subjective interventions in topology optimisation, as shown in Figure 2. They include 'pre-processing', 'post-processing' and 'interactive processing' strategies, corresponding to subjective interventions 'before', 'after' and 'during' topology optimisation, respectively. Details of each group are summarised in Sections 2.2–2.4.

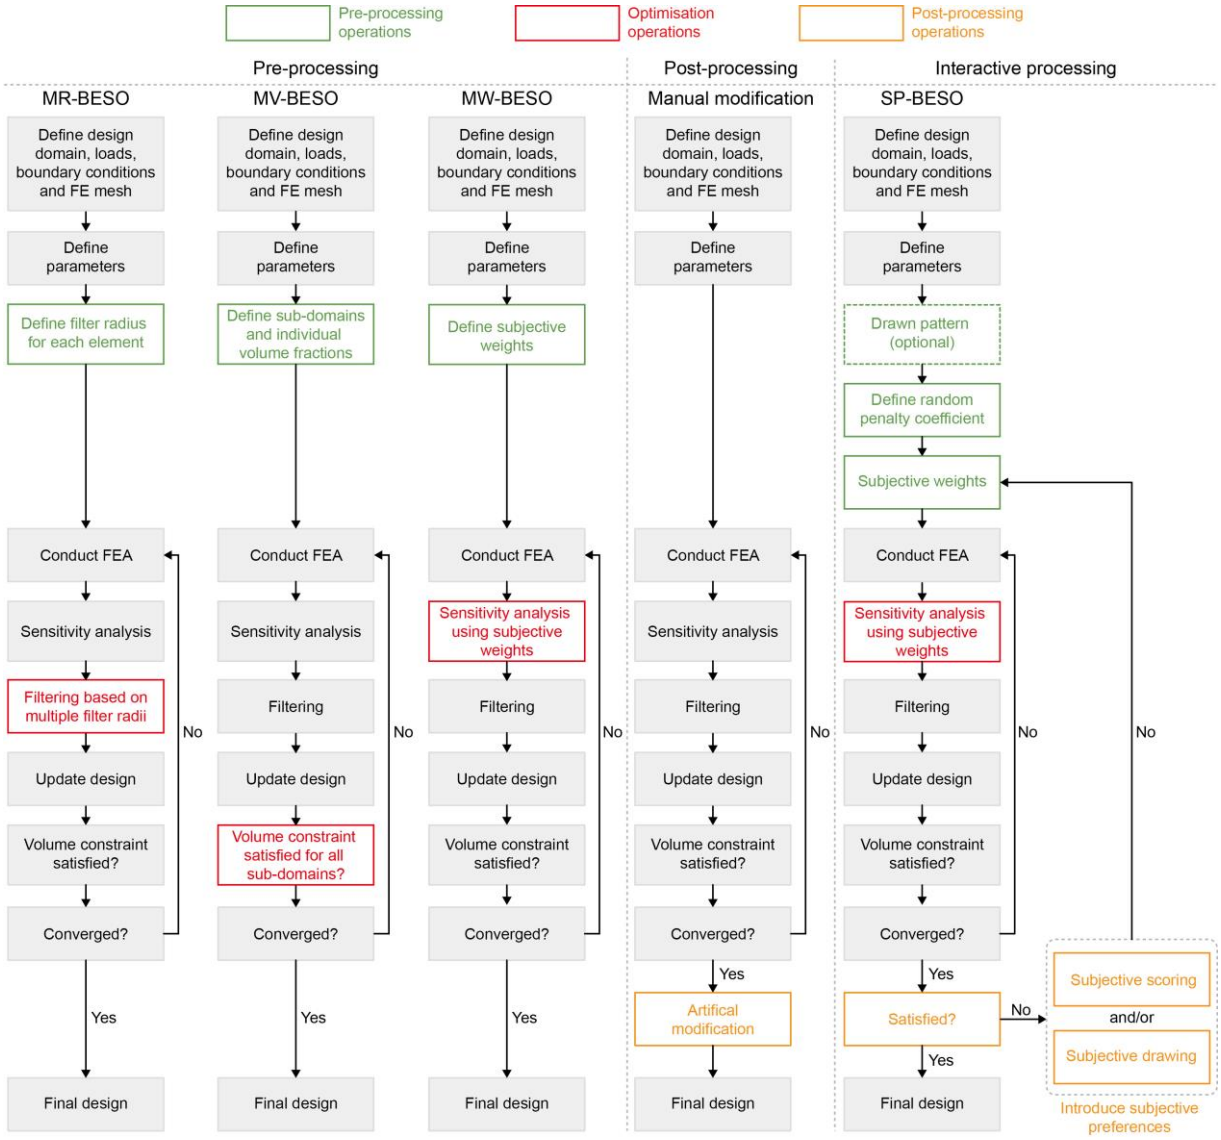

Figure 2. Computational workflow of topology optimisation methods considering subjective preferences. These five methods can be categorised into three groups: pre-processing, post-processing and interactive processing strategies.

2.2. Pre-processing strategy

In the pre-processing strategy, users are required to subjectively define local settings, such as weights of elements and optimisation parameters, before carrying out topology optimisation. Yan et al. [5] proposed three extensions of the BESO method based on the pre-processing strategy to consider subjective preferences, including multi-radius BESO (MR-BESO), multi-volume BESO (MV-BESO) and multi-weight BESO (MW-BESO). Figure 3 provides a clear graphical comparison of these three

methods with the original BESO method. Note that in the original BESO method (see Figure 3(a)), there is only a uniform filter radius, a global volume constraint and equal weights for all elements (i.e., one weight). However, in [5], the number of these optimisation parameters is increased to expand design freedom to include subjective preferences.

- MR-BESO (see Figure 3(b)) empowers designers to specify multiple filters of different sizes in different areas of the design domain. This feature enables designers to regulate the minimum sizes of structural members based on their subjective preferences and ensure that the design requirements of member sizes at specific regions are met.
- MV-BESO (see Figure 3(c)) first divides the design domain into multiple sub-domains, where the elements in each sub-domain are independently added or removed during topology optimisation in the same evolutionary iteration [10]. Using MV-BESO, designers can pre-define different local volume fractions for each sub-domain based on their subjective preferences or design requirements, resulting in customised structural designs.
- MW-BESO (see Figure 3(d)) allows designers to adjust the importance of elements by introducing elemental weights based on subjective preferences. By assigning higher weights to specific elements, users can influence the outcome of the optimisation process and potentially achieve a design that better meets their needs. These weighted elements are given a higher rank during sensitivity analysis, which increases their likelihood of being retained in the final topology. Notably, the importance level of subjective preferences in MW-BESO is controlled by two weighting coefficients, enabling the final structural topology to be subjective- or performance-driven, depending on the design requirements.

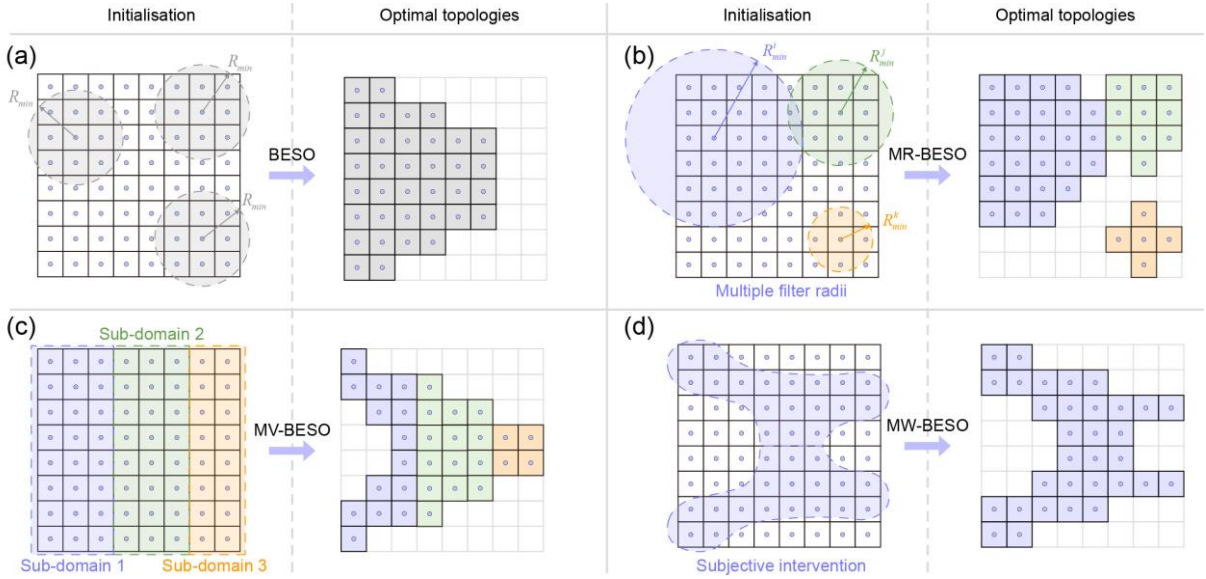

Figure 3. Comparison of the BESO method with its extensions developed based on pre-processing strategies to include subjective preferences: (a) original BESO; (b) MR-BESO; (c) MV-BESO; (d) MW-BESO [5].

The pre-processing strategies can produce efficient structural designs while including subjective preferences, as the final structural topologies are ultimately determined by the optimisation algorithm. However, there are a few limitations to this strategy. For example, as discussed in [5], MR-BESO cannot control the locations of high-stressed areas in a specific topology because the filter radius can only control the minimum sizes of structural members. As for MV-BESO and MW-BESO, although they can directly manipulate locations of high-stressed regions by altering the topologies, the use of subjective preferences may result in significant performance losses because the preferred topologies may deviate from the global optimum. Moreover, the pre-processing strategies are all performed only once, hoping to produce satisfactory designs. However, designers may wish to further refine their subjective

preferences to find a better design option. Therefore, modification based on existing designs is considered a necessary process in design exploration, which is beyond the capability of the pre-processing strategies.

2.3. Post-processing strategy

The post-processing strategy involves manual processing of the optimal topologies to align with the Unity-in-Variety design principle [16]. Specifically, subjective preferences are introduced after topology optimisation is performed. Unity refers to the level of coherence that can be perceived in a design, while variety serves as a source of inspiration for designers by arousing their interest [20]. Striking a balance between unity and variety in a design can enhance the aesthetic quality and meet the design requirements of subjective preferences [21].

The manual modification involves extracting the optimised structures' contours and editing the control points to adjust the design based on subjective Gestalt principles, such as similarity, closure and continuity [16,22]. This process allows for the incorporation of subjective preferences into the optimal topology, resulting in designs that align with the desired aesthetic qualities.

In Figure 4, two pairs of optimal topologies (i.e., chairs) and their modified counterparts are reproduced from [16]. The highlighted areas demonstrate that the modified designs are edited by designers according to the continuity and similarity principles. As reported in [16], their survey claim that artificial modification can significantly improve the unity of the designs. Specifically, a majority of participants perceived the modified designs as visually more appealing. This instance exemplifies how the integration of optimal topologies with subjective preferences can further enhance structural forms to meet design requirements.

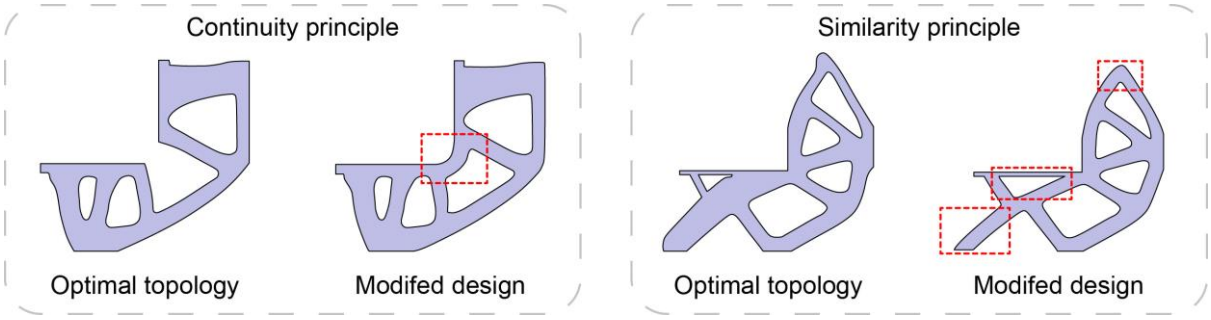

Figure 4. Two 2D chairs designed using the post-processing strategy. The highlighted areas are artificially modified based on the continuity and similarity principles. The figures are modified versions of [16].

It is worth noting that applying overly subjective intervention may be contrary to the original goal of topology optimisation, as the manual post-processing method is purely based on designers' preferences, which ignores the volume constraint and compromises structural performance. Therefore, the obtained designs may fail to fulfil objective design requirements, such as structural efficiency.

2.4. Interactive processing strategy

The two strategies above (pre-processing and post-processing) create structural designs through 'single-execution topology optimisation'. However, these strategies still face challenges in exploring satisfactory designs. In detail, while the pre-processing strategies can generate efficient structural topologies considering subjective preferences, they do not support designers in further explorations based on these results. On the other hand, the post-processing strategy requires strong artificial intervention, which ignores the volume constraint and structural performance. To address these issues, Li et al. [14] proposed an interactive topology optimisation method, SP-BESO, which considers subjective preferences (SP). This strategy introduces scoring and drawing systems that allow users to iteratively explore desired designs by alternately inputting quantified subjective preferences and

performing topology optimisation. The interactive approach enables designers to balance their subjective preferences and structural performance by refining the design through an iterative process.

The SP-BESO method employs three weight-based approaches to generate preference-driven designs by affecting the ranking of elemental sensitivity numbers in BESO:

- SP-BESO uses a random perturbation technique to generate unexpected initial structural topologies (i.e., before introducing subjective preferences), enhancing the design diversity [9].
- Subjective evaluation of an existing design can be converted into weights by integrating design variables and artificial scores; these scoring weights can be used to alter the subsequent topology optimisation outcomes.
- Drawing weights are introduced that translate hand-drawn sketches into weights, guiding the next topology optimisation process to produce efficient designs similar to the inputted pattern.

It should be noted that the scoring and drawing systems can be independently executed during optimisation. Adjusting parameters, λ_e, λ_s and λ_d, can control the importance level of *structural performance*, *subjective scoring* and *drawing*, respectively. Repeatedly running the SP-BESO method allows designers to dynamically adjust subjective preferences and create improved solutions based on existing designs. However, designers may need to make refinements more than once, so the entire interactive design exploration process can be time-consuming.

Figure 5 shows a 2D chair example designed by the authors using SP-BESO. The optimisation problem is shown in Figure 5(a), with details described in [14]. For comparison purposes, the reference design (see Figure 5(b)) is obtained from the standard BESO method without considering subjective preferences. Each optimisation produces four child designs as potential design options. After optimisation, zig-zag boundaries of the child designs are smoothed to improve visual quality, assisting subjective evaluation of design options [23]. The iterative design exploration process is detailed as follows.

A preferred pattern is first drawn to connect the two supports and the backrest as the initial subjective preferences to generate the first set of solutions, as shown in Figure 5(c), where the optimisation parameters are $\lambda_e = 1$, $\lambda_s = 0$ and $\lambda_d = 0.3$. Among the four solutions shown in Figure 5(c), solutions C and D are subjectively selected as preferred designs, so they are imparted with higher scores (2 and 4); undesired solutions have lower scores (-5 and -2). From here, the optimisation parameters are updated to $\lambda_e = \lambda_s = 1$ and $\lambda_d = 0.3$ to generate a new set of designs, as shown in Figure 5(d). If one wishes to further modify the preferred design in Figure 5(d) (i.e., solution A), the drawn pattern can be modified to include the key geometrical features of solution A, with optimisation parameters adjusted to $\lambda_e = 0.8$, $\lambda_s = 0$ and $\lambda_d = 1$. Among the four solutions shown in Figure 5(d), Solution D may be selected as the final solution due to the best structural performance with the highest stiffness (i.e., the lowest C); the final 3D simulation is shown in Figure 5(f). Compared with the original BESO result (see Figure 5(b)), the final design has a 42% of performance loss (see Figure 5(e)). Nevertheless, it is still structurally efficient due to the use of topology optimisation, and the shape can fulfil subjective design requirements based on an iterative design exploration process.

3. Discussion

3.1. Other topology optimisation methods

The abovementioned pre-processing and interactive processing strategies are based on the BESO method, whereas the post-processing strategy is independent of the method of topology optimisation. It is worth noting that the key advantage of using the BESO method is its simplicity in employing discrete design variables. However, the use of discrete design variables may not be sufficient to address some mathematically more complex structural design problems, such as multi-objective optimisation problems.

The pre-processing and interactive processing strategies are straightforward. They can be easily integrated into other element-based topology optimisation methods that use continuous design variables. For example, multiple filters (MR-BESO) and multiple local volume constraints (MV-BESO) can be combined with other topology optimisation methods, such as SIMP and level-set methods, to produce solutions considering subjective preferences. The same concept can be applied to MW-BESO and SP-BESO, where the weights of elements are a scalar field to penalise the sensitivity numbers independent of the underlying element-based topology optimisation method. Together, it can be understood that these potential extensions sacrifice the simplicity of the BESO method in exchange for the capability of solving complex structural design problems; future studies are needed to develop such possible extensions.

3.2. Objective functions

For certain practical applications, the overall stiffness of the structure may be less important, as the designers could be more concerned about the local performance, such as local displacement, stress and buckling. Existing topology optimisation methods that consider subjective preferences only focus on compliance minimisation (i.e., stiffness maximisation) problems. There is potential to extend these methods for optimisation of local performance while ensuring subjective preferences. The key challenge is to formulate the objective function of local performance, but mathematically possible. Furthermore, some structural designs are sensitive to minor local changes, making it crucial to carefully apply subjective interventions. Therefore, future research is needed to investigate the influence of subjective interventions in sensitive areas. Overall, there is a need for future research to consider different design objectives than just compliance minimisation to develop topology optimisation techniques that can be applied to diverse real-world scenarios while ensuring subjective preferences.

3.3. Structural complexity control

To enhance the effectiveness of pre-processing and interactive processing strategies, quantified subjective preferences can be supplemented with additional geometric constraints, similar to the structural complexity control technique [12]. For instance, the number and location of holes can be explicitly pre-defined before carrying out topology optimisation, which enables users to manage manufacturing difficulty and costs according to fabrication limitations. However, too many holes can pose significant challenges in fabrication [13]. Besides, some designers consider the number of holes a valuable aesthetic contribution as they can modify how light interacts with the structure, creating unique lighting and shadow effects that enhance the design's visual appeal.

It is worth pointing out that existing topology optimisation techniques that consider subjective preferences do not yet use geometric constraints to impact the complexity of final outcomes based on fabrication limitations or functional aesthetic requirements. Therefore, future research could explore ways to utilise geometric constraints to address diverse demands in practical applications while ensuring other subjective preferences are met.

3.4. 3D applications

Designing a structure in 3D space provides more flexibility and richer geometric details, resulting in more accurate real-world representations [24]. It should be noted that the three strategies outlined in this paper have not yet been extended to 3D cases. Addressing this goal requires overcoming three technical challenges.

The first challenge is visualisation. Specifically, accurately observing and evaluating a given 3D structure can be difficult for inexperienced designers, as it requires strong spatial awareness skills to look at many 3D geometric details. Therefore, precisely determining subjective preferences based on these observations becomes a demanding task.

The second challenge is interaction. Some manual-based interactive operations, such as drawing, struggle to work in 3D. That is because 3D structures often include numerous internal elements that cannot be directly visualised and edited from the outside. That is to say, concisely and accurately interacting with 3D structures to include specific subjective preferences can be a complex task.

The third challenge is structural performance. Subjective intervention in 3D topology optimisation may result in more significant performance losses than in 2D cases. The increased design degrees of freedom provide greater opportunities for subjective intervention to deviate from the globally optimal solution, meaning that even minor modifications may severely compromise the structural performance.

These three technical challenges require further exploration in future research, aiming to develop a practically useful 3D topology optimisation tool that can create appealing, efficient and reliable structures based on subjective preferences.

4. Conclusion

This paper presents a review of the latest topology optimisation methods considering subjective preferences. Existing methods are classified into three groups, pre-processing, post-processing and interactive processing strategies, depending on the conditions of subjective interventions in topology optimisation. The pre-processing strategies can generate diverse and competitive structural designs, but they may not be able to obtain a satisfactory solution. This is because the optimisation is performed only once, with subjective preferences specified beforehand without allowing any further refinement, leading to the hope of achieving satisfactory designs in a single attempt. The post-processing strategy involves manual modifications to the optimal structural topologies based on subjective design principles, resulting in highly preferred customised designs. However, this approach may overlook objective design requirements such as volume constraints and structural performance, potentially compromising the overall effectiveness of the optimisation. The interactive processing strategy enables designers to iteratively explore desired designs by inputting quantified subjective preferences and performing topology optimisation in alternation. This approach forms an iterative design exploration process that strikes a balance between structural performance and subjective preferences. However, refinements of subjective preferences may be made more than once, so the entire process can be time-consuming.

This paper also proposes four potential extensions of the strategies discussed above. Firstly, all existing strategies have the potential to be extended to other topology optimisation methods, expanding their applicability to other structural design problems. Secondly, extending the existing strategies to consider design objectives other than compliance minimisation may be useful for specific applications; the overall stiffness may be less important, as the designers could be more concerned about the local performance. Thirdly, incorporating geometric constraints into the existing strategies may lead to more useful solutions that can simultaneously satisfy diverse design requirements, such as fabrication limitations and aesthetic requirements. Lastly, it is highly desirable to extend existing strategies to 3D structural design problems for more realistic applications. However, the 3D extension faces challenges related to visualisation, interaction and structural performance loss, highlighting the need for further research. Undoubtedly, there is significant potential for further development of topology optimisation

techniques considering subjective preferences that can be applied in real-world scenarios to create innovative, efficient and satisfactory structural designs.

Abstract

The overhang problem remains a critical issue that prevents components with complex geometry from being fabricated by additive manufacture (AM) without support structures. To address this problem, previous studies have extensively investigated the design of support-free structures by including overhang constraints in topology optimisation approaches. However, the previous research mainly focused on AM machines with 3-axis (i.e., movable printing nozzle in x, y, and z directions), and the recently developed multi-axis machines (i.e., with rotatable base platform) were not considered. In addition, it was reported that the performance sacrifice brought by the overhang constraints for 3-axis AM could be high in structures with low volume fractions (i.e., the ratio between structure and domain volume). Therefore, to reduce the performance sacrifice, this paper proposes an optimisation approach that considers the overhang constraints for multi-axis AM. This approach starts with an optimised structure obtained by using the free-form topology optimisation approach. Firstly, the design domain is divided into several zones. Then a novel linear optimisation problem is solved to determine the local build directions for each zone, aiming to maximise the optimised structure's printable proportion. Several examples are presented to demonstrate the effectiveness of the proposed approach. It is found that the previous significant performance sacrifice brought by the 3-axis approach can be reduced to a negligible level with the novel approach based on multi-axis AM.

Keywords: topology optimisation, multi-axis additive manufacture, overhang constraint, Hangai Prize applicant

1. Introduction

Topology optimisation aims to identify structures with optimised performance while satisfying specified conditions and constraints [1-3], and it has been applied to many different fields [4-5]. However, although topology optimisation can be used to create ultra-high-performance structures, the optimised free-form shapes are often difficult to fabricate with traditional manufacturing technique. To address the problem, additive manufacture (AM) have been frequently employed [6].

Although AM can be used to print complex geometries, current technologies do not guarantee that structures with arbitrary geometries are printable. One foremost reason is the overhang effect [7-9]. As illustrated in Figure 1, if the overhang angle ϕ_{ov} of the component exceeds the maximum threshold angle ϕ_{max}, the deposited part cannot consolidate due to gravity [10]. To address this problem, temporary support structures can be used [11]. However, support structures consume additional materials and are difficult to remove in certain cases (e.g., metal AM).

Figure 1. The overhang effect: (a) structure failing to consolidate when the overhang angle ϕ_{ov} is larger than the threshold ϕ_{max}; (b) structure successfully consolidating when the overhang angle ϕ_{ov} is smaller than ϕ_{max}.

In order to avoid the overhang effect while not using support structures, some studies have modified the geometrical shape of the components to be printable. In this thread, Leary et al. and Li et al. used a post-processing approach to design efficient support-free structures for optimised solutions [12-13]. However, since the resulting structures required additional materials, the volume fraction constraint of the optimisation formulation was violated. Therefore, other studies added the overhang constraints into the topology optimisation formulation. This concept has been extensively studied via filtering out the elements violating overhang constraints or adding explicit overhang constraints to the optimisation formulation. For example, Gaynor et al. considered overhang constraints through projection methods [14]. Zhang et al. applied the overhang constraints by restricting the orientation of elemental density gradients [15]. Garaigordobil et al. used a SUSAN algorithm to extract the structural boundaries and then controlled the structural boundary to avoid the overhang effect [16]. Although these studies can eliminate the overhang parts, the overhang constraints considered are all based on 3-axis AM. Consequently, the performance sacrifice caused by overhang constraints was usually high, especially in problems with low volume-fraction values.

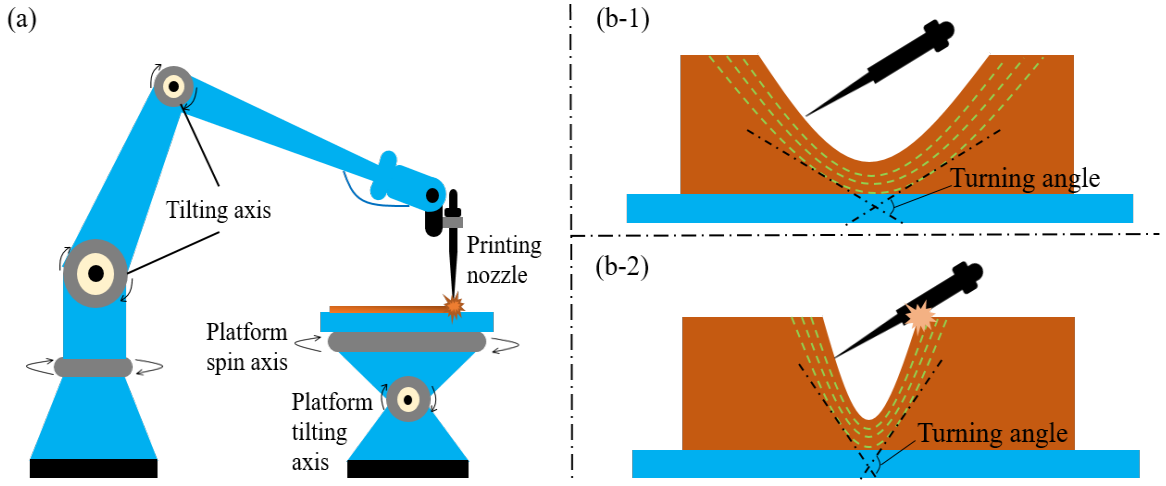

Figure 2. Multi-axis AM: (a) Multi-axis AM machine; (b) potential collision problem of concave printing surfaces: (1) less likely with small turning angle; (2) more likely with increased turning angle.

Besides the aforementioned optimisation-related studies, other research focused on addressing the overhang problem by improving the machine flexibility; hence AM machines with multi-axis configuration were developed in recent years [17-18]. Multi-axis machines differ from 3-axis machines by having rotatable platforms that allow for continuous build direction adjustments, thus enabling the printing of curved surfaces [19]. Compared with 3-axis printing, multi-axis printing can reduce the component's overhang angle and improve the quality of fabrication [10]. Therefore, some studies have focused on reducing the overhang effect by decomposing the structure into several parts and applying different build directions for each part [20-22]. Further studies customised the curved printing surfaces

to reduce the overhang effect [23]. However, in multi-axis AM, concave printing surfaces can lead to potential collisions between the printing nozzle and the printed component when the turning angle of the printing surface is large (Figure 2 (b-2)). These studies related to multi-axis AM can significantly reduce the support materials.

Whilst multi-axis AM can effectively reduce the overhang effect, most studies in the topology optimisation area considered the overhang constraints for 3-axis AM. Therefore, to achieve support-free designs that have higher performance, this study proposes an optimisation approach that considers the overhang constraints for multi-axis AM. This approach starts with an optimised design obtained through the traditional topology optimisation, then a novel approach is developed to identify the curved printing surfaces that can make the optimised structure printable as much as possible. With the proposed workflow, the optimised structures and their associated curved printing surfaces can both be identified.

The following parts of the paper are organised as follows: in Section 2, the previous topology optimisation approach is reviewed; in Section 3, the new approach for multi-axis AM is introduced; two examples are given to demonstrate the effectiveness of the proposed approach in Section 4 and conclusions are drawn in Section 5.

2. Review of topology optimisation and 3-axis overhang constraints

2.1. Review of free-form topology optimisation

The approach proposed in this paper is based on SIMP (Solid Isotropic Material with Penalty), which is briefly reviewed in this section. SIMP uses the finite element discretisation approach to divide the domain into many elements, with the existence of each element is determined by its density ρ_i, which is 0 for void and 1 for solid. The traditional topology optimisation formulation is:

$$\text{find: } \boldsymbol{\rho} = (\rho_1, \rho_2, ..., \rho_{n_{ele}}) \tag{1.a}$$

$$\text{min: } C = \boldsymbol{F}^T \boldsymbol{U} \tag{1.b}$$

$$\text{s.t.: } \boldsymbol{K}(\rho)\boldsymbol{U} = \boldsymbol{F} \tag{1.c}$$

$$\frac{\sum_{i=1}^{n_{\text{ele}}} \rho_i v_i}{\sum_{i=1}^{n_{\text{ele}}} v_i} \le f \tag{1.d}$$

$$0 \le \rho_i \le 1,\ i=1,2,\ldots,n_{\text{ele}} \tag{1.e}$$

where n_{ele} is the number of elements, v_i is each element's volume; f is the allowable volume fraction; $\boldsymbol{K}(\rho)$, $\boldsymbol{U}$ and $\boldsymbol{F}$ are the structural stiffness matrix, displacement and load vector, respectively.

Young's modulus E_i of element i can be obtained by Eqn. (2) [24]:

$$E_i = E_{\min} + \rho_i^p (E_0 - E_{\min}) \tag{2}$$

where p is the penalisation factor (typically p=3); E_0 is the material's Young's modulus; $E_{\min}$ is a near 0 parameter used to avoid numerical singularity problems.

In addition, element filters are frequently employed to overcome the check-board problem, and Heaviside projection can be used to guarantee a black-and-white solution. More details of these approaches can be found in [25] and [26].

2.2. Review of 3-axis overhang constraint

For the concerned element i, with its neighbour element densities equal to ρ_1^i to ρ_9^i as shown in Figure 3, its density gradient direction $\nabla\rho_i = (a_i, b_i)$ is:

$$a_i = -\frac{1}{6}\rho_1^i + \frac{1}{6}\rho_3^i - \frac{1}{6}\rho_4^i + \frac{1}{6}\rho_6^i - \frac{1}{6}\rho_7^i + \frac{1}{6}\rho_9^i \tag{3.a}$$

$$b_i = \frac{1}{6}\rho_1^i + \frac{1}{6}\rho_2^i + \frac{1}{6}\rho_3^i - \frac{1}{6}\rho_7^i - \frac{1}{6}\rho_8^i - \frac{1}{6}\rho_9^i \tag{3.b}$$

With the density gradient obtained, a boundary element is self-supportable when its boundary orientation λ_i (i.e., perpendicular to the density gradient direction) lies within the allowable range associated with the build direction (Figure 3), that is [15]:

$$\tau_i = \nabla\rho_i \cdot \gamma - \sin(\phi_{\max}) < r_{i1} \tag{4}$$

where τ_i is the overhang value, γ is the build direction and r_{i1} is a near 0 parameter used to avoid numerical problems.

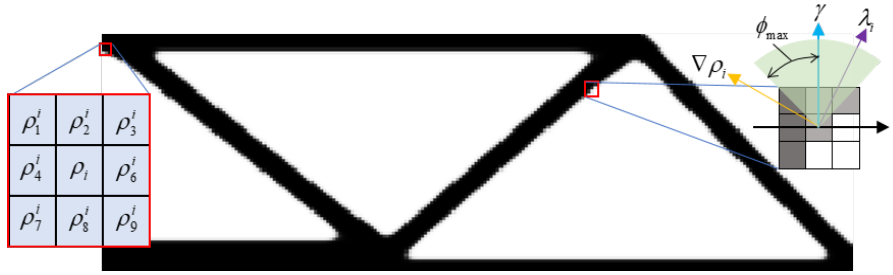

Figure 3. A boundary element *i* considered as self-supported since its boundary orientation λ_i lies within the allowable overhang range (i.e. green region).

3. Printing plan optimisation for multi-axis AM

3.1. Domain subdivision

To reach a favourable zone arrangement, we first identify structural corner positions (Figure 4 (a)). Subsequently, the structure is subdivided at the structural corner position; with this approach, members with different orientations are separated into different zones. Nevertheless, it is found that the zone arrangement that can lead to a (near) 100% printable proportion is not unique, and the effect of different zone arrangements is discussed in detail later in Section 4.2.

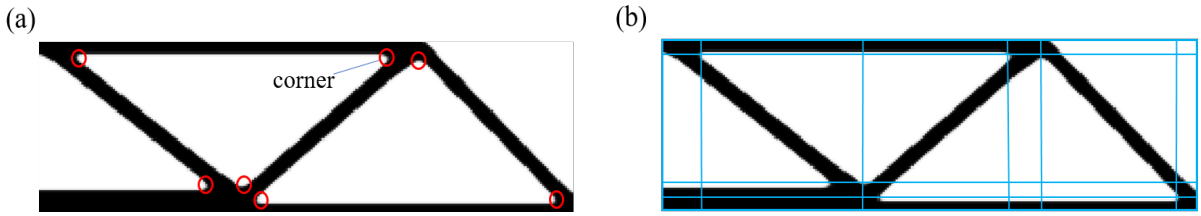

Figure 4. Construct zones based on structural corner locations; (a) structural corners; (b) zone boundaries on the structural corner positions.

3.2. Determination of build direction in each zone

Similar to the approach in the 3-axis AM, we consider the structure fully printable when all the boundary elements are support-free. If a boundary element *i* whose incline angle is $\phi_{i,g}$ in zone *j* whose build direction is ϕ_j satisfy:

$$\left|\phi_j - \phi_{i,g} - \phi_{\max}\right| + \left|\phi_j - \phi_{i,g} + \phi_{\max}\right| = 2\phi_{\max} \tag{5}$$

element i is determined to be support-free. Note that if a boundary element is not support-free, the left side of Eqn. (5) becomes greater than $2\phi_{\max}$, causing an overhang violation. Therefore, to maximise the printable proportion of the structure, the following optimisation problem can be formulated:

$$\text{find: } \boldsymbol{\phi} = (\phi_1, \phi_2, ..., \phi_{n_z})^T \tag{6.a}$$

$$\min: \boldsymbol{\eta} \cdot \tilde{\boldsymbol{\rho}} \tag{6.b}$$

$$\text{s.t.: } \boldsymbol{\eta} \geq \left| \boldsymbol{M}\boldsymbol{\phi} - \boldsymbol{\phi}_g - \phi_{\max} \right| + \left| \boldsymbol{M}\boldsymbol{\phi} - \boldsymbol{\phi}_g + \phi_{\max} \right| \tag{6.c}$$

where $\boldsymbol{\phi} = (\phi_1, \phi_2, ..., \phi_{n_z})^T$ is the local build direction vector with n_z denotes the number of zones; $\boldsymbol{\eta} = (\eta_1, \eta_2, ..., \eta_{n_{ele}})^T$ is the vector of elements' overhang violation; $\tilde{\boldsymbol{\rho}} = (\tilde{\rho}_1, \tilde{\rho}_2, ..., \tilde{\rho}_{n_{ele}})^T$ with $\tilde{\rho}_i \in \{0,1\}$ and $\tilde{\rho}_i = 1$ for boundary elements and $\tilde{\rho}_i = 0$ for others; $\boldsymbol{M}$ is a 0-1 mapping matrix used to link the corresponding zone to each element; $\boldsymbol{\phi}_g = (\phi_{1,g}, \phi_{2,g}, ..., \phi_{n_{ele},g})$ is the elemental incline angle vector. If the proportion of unprintable elements r_{un} is less than a threshold r_s, the structure can be considered as fully printable.

3.3. Collision between the printing nozzle and the structure

In multi-axis AM, the printing nozzle and the already printed component may collide if the printing surfaces are concave and have a large turning angle, as shown in Figure 2 (b-2). To avoid this problem, the turning angle of the printing surfaces are required to be restricted:

$$\phi_{\text{next}} - \phi_{\text{first}} < \phi_{\text{t,max}} \tag{7}$$

where ϕ_{next} and ϕ_{first} is defined as the build direction of two adjacent zones (see Figure 5), $\phi_{\text{t,max}}$ is the allowable turning angle.

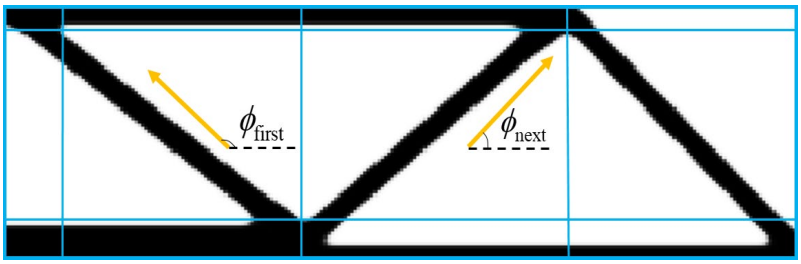

Figure 5. The local build direction ϕ_{first} and ϕ_{next} of two adjacent zones.

3.4. Consideration of always printable elements

If Problem (6) is directly solved to determine the local build directions, two types of "always-printable" elements will affect the quality of the optimised result, leading to solutions with lower printable proportions. The first type of the "always-printable" elements is illustrated in Figure 6. The highlighted elements are always printable by using a vertical build direction since they are directly attached to the base platform. To identify this type of element, a scanning process is conducted, as illustrated in Figure 6, where a vertical build direction $\boldsymbol{\gamma}_v$ is used to evaluate the printability of each element using Eqn. (4).

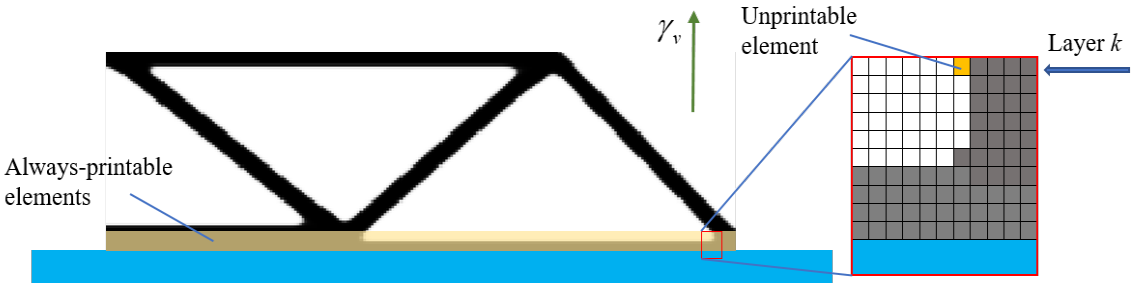

Figure 6. Elements attached to the base platform considered as "always-printable" elements.

The scan process starts from the elements on the first layer that are directly attached to the base platform and ends when an unprintable element appears in the kth layer. Then all the elements under the kth layer are considered "always-printable" elements and excluded from Problem (6).

The second type of "always-printable" elements are illustrated in Figure 7, whose density gradient are always within the printable range if the platform's allowable rotatable angle is ϕ_{allow}.

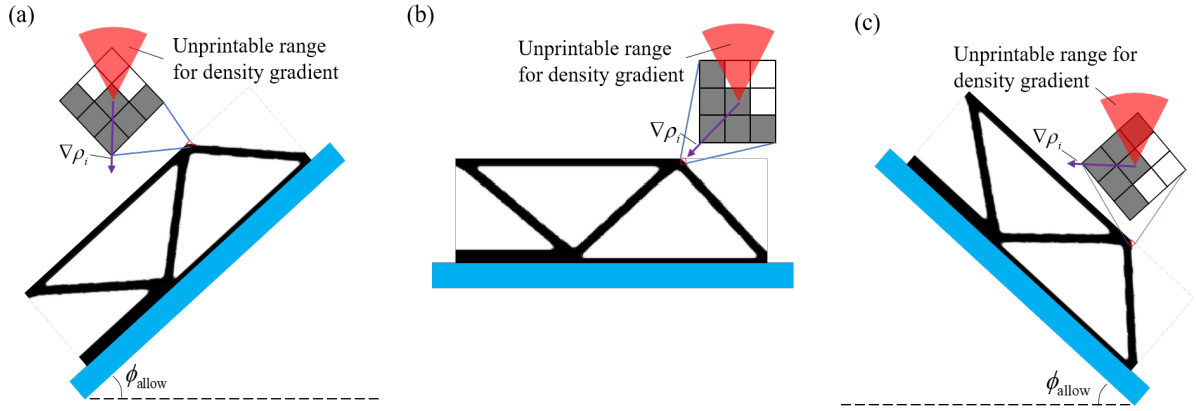

Figure 7. "Always-printable" elements for all base platform orientations within [- ϕ_{allow} , ϕ_{allow}].

3.5. Optimization of local printing directions

By combing (6) and (7), the following optimisation problem can be used to obtain the build directions of all the printing zones:

$$\text{find: } \boldsymbol{\phi} = (\phi_1, \phi_2, ..., \phi_{n_z})^T \tag{8.a}$$

$$\text{min: } \boldsymbol{\eta} \cdot \tilde{\boldsymbol{\rho}} \tag{8.b}$$

$$\text{s.t.: } \boldsymbol{\eta} \geq \left| \boldsymbol{M}\boldsymbol{\phi} - \boldsymbol{\phi}_g - \phi_{\max} \right| + \left| \boldsymbol{M}\boldsymbol{\phi} - \boldsymbol{\phi}_g + \phi_{\max} \right| \tag{8.c}$$

$$\boldsymbol{\phi}_{\text{next}} - \boldsymbol{\phi}_{\text{first}} < \phi_{\text{t,max}} \tag{8.d}$$

where $\tilde{\boldsymbol{\rho}} = (\tilde{\rho}_1, \tilde{\rho}_2, ..., \tilde{\rho}_{n_{\text{ele}}})^T$ with $\tilde{\rho}_i \in \{0,1\}$ and $\tilde{\rho}_i = 1$ for non-always-printable boundary elements and $\tilde{\rho}_i = 0$ for others. Since Problem (8) is a linear programming problem. Modern interior point solvers such as *MOSEK* can be used to solve this problem efficiently. In addition, the optimized solutions are guaranteed to be the global optimum.

4. Numerical examples

In this section, two numerical examples are presented to demonstrate the effectiveness of the proposed approach. Young's modulus E_0 and the Poisson's radio v are assumed to be 1.0 and 0.3, respectively; the minimum Young's modulus $E_{\min}$ is 1×10^{-9}; the parameter p is 3. All design domains are meshed by quadrilateral elements. The allowable rotatable angle for the platform ϕ_{allow} is taken as 90°. The maximum turning angle $\phi_{\text{t,max}}$ is 90° and the unprintable threshold r_s is taken as 1.5% by default.

4.1. Influence of the maximum overhang angle

To investigate the influence of $\phi_{\max}$ on results, the half MBB (Messerschmitt-Bölkow-Blohm) beam is studied. The case description is shown in Figure 8 (a). The size of the design domain are 180×60, the maximum volume fraction is 0.2, and the magnitude of F is taken as 1. In the printing plan optimisation, the zone arrangement is shown in Figure 8 (b), and $\phi_{\max}$ = 60°,45° and 30° are considered.

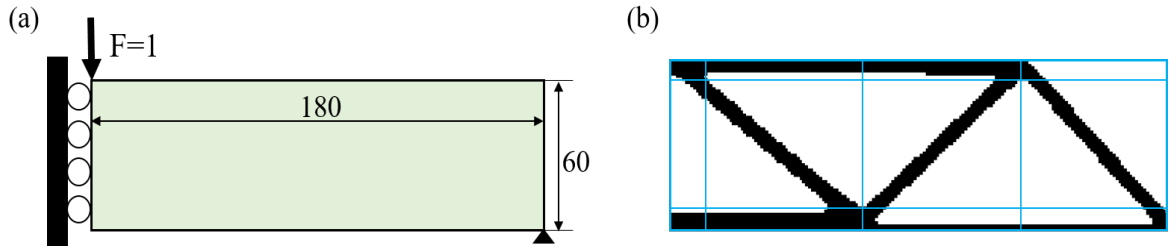

Figure 8. MBB beam example: (a) design domain, load and boundary conditions; (b) solution of traditional topology optimisation (Compliance C=86.18) and the zone arrangements in multi-axis AM optimisation.

The optimised results are shown in Figure 9 (a-c), and the corresponding r_{un} are 0.55%, 0.74%, 0.92%. r_{un} increases as $\phi_{\max}$ decreases, which suggests that the structures are more challenging to be printed in situations with low $\phi_{\max}$. In addition, the optimisation difficulty brought by low $\phi_{\max}$ is also reflected in the reduction of always-printable elements, as shown in Figure 9 (a). It is worth noting that the unprintable elements are mainly distributed near the corners of the structure. As expected, by excluding the second type of always-printable elements, the proportion of the unprintable elements at these corner positions is reduced to a negligible level.

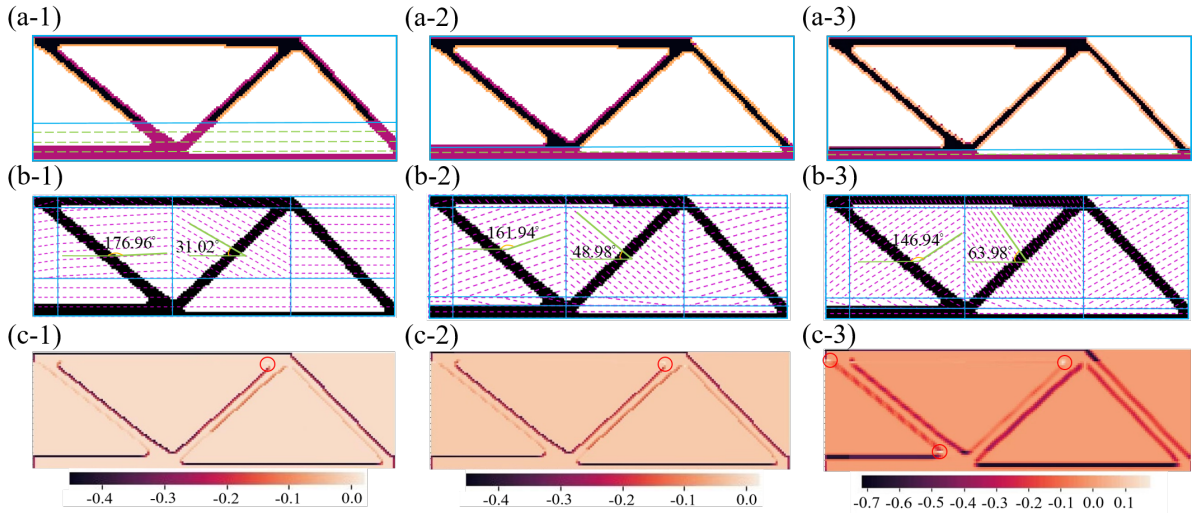

Figure 9. Optimised results of the MBB example: (a) The always-printable elements (i.e., coloured in purple) and non-always-printable boundary elements (i.e., coloured in orange); (b) optimised solutions for multi-axis

printing; (c) value τ_i for the structure, where few unprintable elements are marked within the red circles, when the maximum overhang angle ϕ_{max} is (1) 60°; (2) 45°; (3) 30°; purple lines represent printing surfaces.

A similar MBB example with $\phi_{max} = 45^{\circ}$ has been investigated by Gaynor using the approach for 3-axis in [14]. The sacrifices of structural performance are 10.43% and 20.64% when volume fraction is 0.4 and 0.25, respectively, which is far greater than the sacrifices using the approach proposed in this paper.

4.2. Influence of different zone arrangements

Since it is mentioned in Section 3.1 that different zone arrangements may be used on the same structure, their influences are investigated in this section with the cantilever example. The case description is shown in Figure 10 (a). The length L=160 and the height H=80, the load F=1.0, and the allowable volume fraction f is 0.2. The optimised solution from the traditional SIMP method is shown in Figure 10 (b).

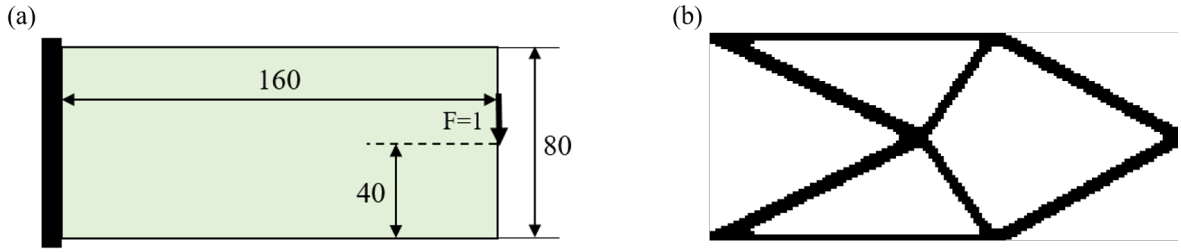

Figure 10. Cantilever example: (a) design domain, load and boundary conditions; (b) solution obtained with the traditional topology optimisation (structural compliance C=145.25).

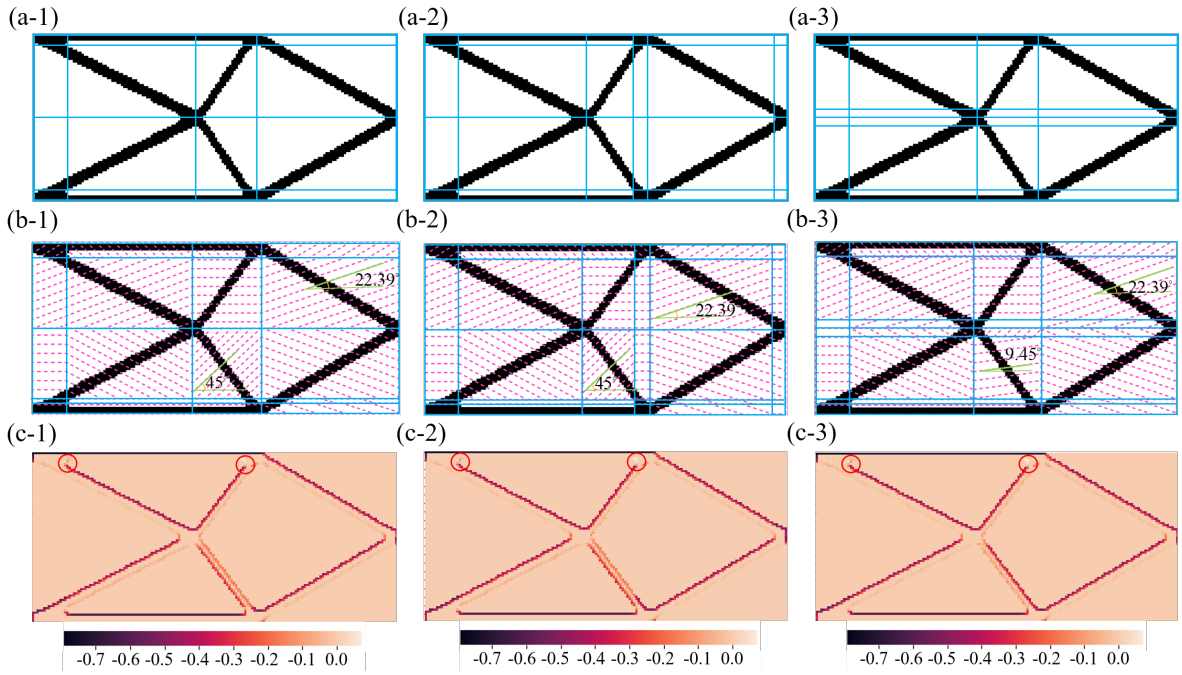

Figure 11. Optimised results of the cantilever example: (a) three different zone arrangements; (b) optimised printing surfaces with different zone arrangements; (c) value τ_i for the structure, where few unprintable elements are marked within the red circles.

In the printing plan optimisation step, ϕ_{max} = 45° is considered, and we study three different zone arrangements, as shown in Figure 11 (a). The associated unprintable ratios r_{un} are 0.69%, 0.69% and 0.49%, which are all far less than the threshold 1.5%. The achieved r_{un} values for Figure 11 are

remarkably close, which is as expected since members with different orientations are all arranged into different zones in the three zone arrangements.

5. Conclusion

This paper proposes a novel optimisation approach to consider the overhang constraints for multi-axis AM (i.e., machines with rotatable base platforms). Different from the previous studies for 3-axis printing, the design domain is subdivided into a number of zones and each zone is assumed to correspond to one build direction. Two numerical examples have been presented to demonstrate the effectiveness of the proposed approach, and the following conclusions can be drawn:

1) Compared to the 3-axis-based approaches, the proposed multi-axis-based approach can significantly reduce the structural compliance increase caused by overhang constraints.
2) Since each zone corresponds to one build direction, the proportion of printable elements will be low if two structural members with vastly different orientations are allocated in the same zone. Therefore, we propose to subdivide the domain at the structural corner positions. The results show by following the proposed corner subdivision approach, the zone arrangement that can lead to a satisfactory proportion of printable elements is not unique.
3) Unlike the 3-axis AM, collisions can happen in multi-axis AM when a concave printing surface is used. To reduce the possibility of potential collisions, an angle constraint is used to restrict the maximum turning angle $\phi_{\mathrm{t,max}}$ of the optimised printing surface.

The approach proposed in this paper has the potential to be extended to three-dimension cases and can be applied to the design of complex metal structures (e.g. steel nodes, aeronautical structures and medical titanium alloy bones) and their multi-axis printing plans. With this design approach, structural performance and fabrication quality can both be effectively improved, and it can promote the application of 3D printing in the fabrication of structures with high performance.

However, due to the possible impact of potential collisions, it is hard to ensure that the structure is support-free in certain cases. A possible solution to overcome the collision problem is to suppress the unprintable elements based on the identified optimal printing plan, that is, the local build directions obtained from solving Eq. (8) are used, and the structure is adjusted accordingly to avoid the overhang effect. Further research is required in the future.

Abstract

The constrained damping laminate structure is used as an optimization object in this paper, the optimization of the optimal layout of the constrained damping in the substrate is taken as the research problem, a finite element model of a 7-degree of freedom constrained damping laminate structure is established, on this basis, the dynamic load acting on the structure is transformed into a static load in multiple analysis steps by using the basic principle of equivalent static load, so this dynamical problem is transformed into a static problem. The BESO optimization method is combined with the finite element analysis model to analyse the optimal topological configuration of the constrained damping on the substrate structure with the optimization objective of maximizing the dynamic stiffness, and a MATLAB program is written for the topological optimization algorithm of the dynamic stiffness response based on the equivalent static load method. The optimal layout of the restrained damping on the substrate under different iterative processes is obtained.

Keywords: topology optimization, BESO, multi-objective, power flow, stiffeners, constraint damping

1. Introduction

The constrained damping structure is formed by laying a viscoelastic layer on top of the plate and shell structure and then laying a constrained layer on top of the viscoelastic layer. The structure corresponding to the constrained damping plate is the free damping structure, and Kerwin [1] verified the difference in action between the free damping structure and the constrained damping structure by means of an experiment. DiTaranto [2] established a multi-order partial differential equation for the mathematical modeling of constrained damped beams as the object of study. On the basis of DiTaranto's study Mead [3] et al. further derived the sixth-order partial differential equations and derived the corresponding transverse displacements at different boundaries. Rao [4] derived the dynamic equations and boundary condition equations for constrained damped structures and proposed design algorithms with practical implications through the process of solving them by numerical methods. Zhang and Sainsbury [5] et al. analytically studied the vibration characteristics of sandwich plates when subjected to loads by combining the traditional finite element model and the basic principle of Gerlerkin's orthogonal function. The reinforced laminate shell structure can improve the overall stiffness and other mechanical properties of the structure, while the constrained damped laminate shell structure can suppress the overall vibration response amplitude of the structure [6]. In this paper, a finite element model of a 7-degree-of-freedom constrained damped laminate structure is established to optimize the optimal layout of the substrate for the constrained damped laminate structure [7]. The BESO optimization method is combined with the finite element analysis model to analyze the optimal topological configuration of the constrained damping on the substrate structure with the optimization objective of maximizing the dynamic stiffness.

2. Finite element modeling and verification of constrained damped laminate

In the process of structural topology optimization, it is necessary to establish the overall stiffness matrix and mass matrix of the constrained damped structure, which are the basis for solving the structural dynamics and static response. Finally, a finite element model with 7 degrees of freedom of constrained damped finite units is developed.

2.1. Structural description and assumptions of the constrained damped laminate

The overall schematic diagram of the constrained damped composite structure is shown in Figure 1 below, which consists of three superimposed layers, namely the substrate structure layer, the intermediate damping layer, and the constrained layer structure. The subscript c represents the constraint layer, the subscript v represents the damping layer, and the subscript p represents the substrate layer. As shown in the figure below h indicates the thickness of each layer and the other dimensions are shown in the figure.

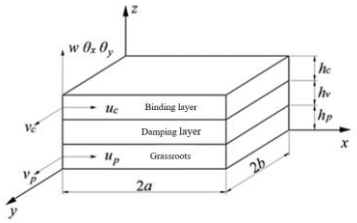

Figure 1. Schematic diagram of the structural model of the constrained damped laminate

In order to establish the finite element model of the constrained damped laminate simply and easily and to facilitate the calculation, the following assumptions are made in this paper.

(1) It is assumed that the overall restrained damping plate in this study is a thin plate structure, and the deformation is small after the force is applied.

(2) It is assumed that the base and restrained plates conform to the Kichhoff assumption and the damping layer conforms to the Mindlin assumption.

(3) Neglecting the relative movement between the layers of the restrained damping plate structure;

(4) Assume equal lateral displacements of the layers at the same location;

(5) It is assumed that the rotational inertia of each layer of material is neglected.

In order to facilitate the study of the geometric displacement relationships within the constrained damping plate structure, Figure 2 is used as an example to illustrate the geometric displacement relationships between the different material layers during deformation. Where u_c, u_v, and u_p represent the displacement in the x-direction of the neutral plane of each layer respectively, and similarly represents the displacement in the y-direction of each layer.

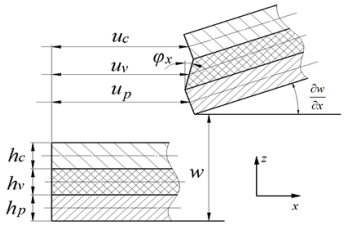

Figure 2. Geometric deformation relationship of the constrained damping plate model

The in-plane displacement of the constrained damped laminate in the direction of x can be obtained from the first-order shear deformation theory u as

$$u = u_0 + s\frac{\partial w}{\partial x}(-\frac{h}{2} \le s \le \frac{h}{2}) \tag{1}$$

In the above equation u is the displacement of the restrained damping laminate in an arbitrary plane and s is the distance between that arbitrary plane and the neutral plane.

The in-plane displacements u_1, u_2 of the upper and lower ends of the intermediate damping layer in the direction of x can be obtained from equation (1) as

$$u_1 = u_c - \frac{h_c}{2}\frac{\partial w}{\partial x} \tag{2}$$

$$u_2 = u_p - \frac{h_p}{2}\frac{\partial w}{\partial x} \tag{3}$$

From the deformation relationship, it is obtained that the rotation angle of the intermediate damping layer around the y-axis direction φ_x is

$$\varphi_x = \frac{u_1 - u_2}{h_v} \tag{4}$$

The angle of shear deformation generated by the intermediate damping layer around the y-axis can be expressed as in equation (5):

$$\beta_x = \frac{\partial w}{\partial x} + \varphi_x \tag{5}$$

Bringing (1), (2), (3), and (4) into (5) yields the following transformation equation:

$$\beta_x = \frac{u_c - u_p}{h_v} + (\frac{h_c + h_p}{2h_v} + 1)\frac{\partial w}{\partial x} \tag{6}$$

From the geometric relationship in Figure 2, the plane displacement in the direction of the damping layer a x xis can be obtained u_v and by bringing equation (2) into (5) we can obtain equation (7):

$$u_v = \frac{1}{2}\left[(u_c + u_p) + \frac{h_c - h_p}{2}\frac{\partial w}{\partial x}\right] \tag{7}$$

β_y The shear deformation of the middle damping layer of the constrained damping laminate around the x axis can be obtained from the above reasoning process in the same way as equation (8):

$$\beta_y = \frac{u_c - u_p}{h_v} + (\frac{h_c + h_p}{2h_v} + 1)\frac{\partial w}{\partial y} \tag{8}$$

Similarly the plane displacement in the direction of the intermediate damping layer y is

$$-\frac{d}{dx}\frac{\partial F}{\partial y'} + \frac{d^2}{dx^2}\frac{\partial F}{\partial y''} = 0 \tag{9}$$

2.2. Displacement patterns and their shape functions

In the process of finite element analysis of the constrained damping laminate structure, the unit division is consistent with the conventional unit division, and the division rule in this paper adopts the general principle of plate unit division, each unit includes four physical nodes, and each node includes seven degrees of freedom, including the displacement of the base plate and the constrained plate in the neutral

plane in the direction of x axis and y axis, which can be expressed as u_p, v_p, u_c, v_c; the transverse displacement of the overall unit of the constrained damping laminate w; and The angle of rotation of the constrained damped laminate unit around the x, y axis θ_x, θ_y, the above seven degrees of freedom are used as all the degrees of freedom in the finite element analysis to describe the displacements of each unit, and their displacement interpolation functions are Eqs. (10):

$$\begin{aligned}
u_c &= a_1 + a_2 x + a_3 y + a_4 xy \\
v_c &= a_5 + a_6 x + a_7 y + a_8 xy \\
u_p &= a_9 + a_{10} x + a_{11} y + a_{12} xy \\
v_p &= a_{13} + a_{14} x + a_{15} y + a_{16} xy \\
w &= a_{17} + a_{18} x + a_{19} y + a_{20}\,\mathrm{x}^2 + a_{21} xy + \\
&\quad a_{22} y^2 + a_{23} x^3 + a_{24} x^2 y + a_{25} xy^2 + \\
&\quad a_{26}\,\mathrm{y}^3 + a_{27}\,\mathrm{x}^3\,\mathrm{y} + a_{28}\,\mathrm{xy}^3 \\
\theta_x &= \frac{\partial w}{\partial \mathrm{y}} \qquad \theta_y = \frac{\partial w}{\partial \mathrm{x}}
\end{aligned} \tag{20}$$

where the displacement vector of each cell can be approximated by the four nodal displacements in the following equation (11):

$$u = \left[\mathrm{u}_1 \;\; \mathrm{u}_2 \;\; \mathrm{u}_3 \;\; \mathrm{u}_4\right]^{\mathrm{T}} \tag{31}$$

In the above equation u_i represents the displacement vector of each cell node, where $i = 1,2,3,4$ is the sequential number of the node.

$$u_{\mathrm{i}} = \left[\mathrm{u}_{\mathrm{ci}}\ \mathrm{v}_{\mathrm{ci}}\ \mathrm{u}_{\mathrm{pi}}\ \mathrm{v}_{\mathrm{pi}}\ \mathrm{w}_{\mathrm{i}}\ \theta_{\mathrm{xi}}\ \theta_{\mathrm{yi}}\right] \tag{42}$$

Therefore, in order to obtain all the displacements within a cell can be achieved by interpolating the displacements of the four nodes to satisfy the displacement solution at any position within the cell with the interpolation function shown in (10) below, which can be obtained by the association of (10), (11) (12):

$$\left[\mathrm{u}_{\mathrm{c}}\ \mathrm{v}_{\mathrm{c}}\ \mathrm{u}_{\mathrm{p}}\ \mathrm{v}_{\mathrm{p}}\ \mathrm{w}_{\mathrm{i}}\ \theta_{\mathrm{xi}}\ \theta_{\mathrm{yi}}\right]^{\mathrm{T}} = Nu \tag{53}$$

In the above equation (4-13) N is the matrix of form functions, where the form function N contains seven column vectors from N_1 to N_7.

The above displacement expressions and the corresponding components of the form functions are brought into Eqs. (7) and (9) to obtain the form functions N_8 and N_9 for the two directions of displacement on the neutral surface of the middle damping layer . x, y

$$N_8 = \frac{1}{2}\left[\left(N_1 + N_3\right) - \left(\frac{\mathrm{h}_c - \mathrm{h}_p}{2}\right)N_7\right] \tag{64}$$

$$N_9 = \frac{1}{2}\left[\left(N_2 + N_4\right) - \left(\frac{\mathrm{h}_c - \mathrm{h}_p}{2}\right)N_6\right] \tag{75}$$

Similarly, the shape functions of the intermediate damping layer around the x axis and the shear strain β_x, β_y around the y axis can be obtained at N_{10}, N_{11}.

$$N_{10} = \frac{1}{\mathrm{h_v}}\left[\left(N_1 - N_3 \right) - \left(\frac{\mathrm{h}_c - \mathrm{h}_p}{2} + \mathrm{h_v} \right) N_7 \right] \tag{86}$$

$$N_{11} = \frac{1}{\mathrm{h_v}}\left[\left(N_2 - N_4 \right) - \left(\frac{\mathrm{h}_c - \mathrm{h}_p}{2} + \mathrm{h_v} \right) N_6 \right] \tag{97}$$

Use right tabs at the right margin to justify equation numbers to that edge, and the equation numbers shall be sequential and in parentheses. Simple equations and assignments, like $v = 0$, may appear within the text. The equation editor shall be used to produce equations.

2.3. Structural principal structure relationship

From equation (1), the positive strain in the direction of x, y for each ply in the constrained damped laminate can be obtained by taking the partial derivative of x, y for that ply respectively, so the positive strain in the direction of x and y at any point in the base ply can be expressed by the following equations (18) and (19): The

$$\varepsilon_{px} = \frac{\partial u}{\partial x} = \frac{\partial u_p}{\partial x} + s\frac{\partial^2 w}{\partial x^2} \tag{108}$$

$$\varepsilon_{py} = \frac{\partial u}{\partial y} = \frac{\partial u_p}{\partial y} + s\frac{\partial^2 w}{\partial y^2} \tag{119}$$

The shear strain is expressed as equation (20):

$$\gamma_{pxy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} = \frac{\partial u_p}{\partial y} + \frac{\partial v_p}{\partial x} + 2s\frac{\partial^2 w}{\partial x \partial y} \tag{20}$$

Relying on the basic assumptions, Hooke's law is used to express the stress-strain relationship at any point within the base plate in the constrained damping plate, so the positive stress at any point within the base plate is

$$\sigma_{px} = \frac{E_p}{1-\nu_p^2}\left(\varepsilon_{px} + \nu_p \varepsilon_{py}\right) \tag{212}$$

$$\sigma_{py} = \frac{E_p}{1-\upsilon_p^2}\left(\varepsilon_{py} + \upsilon_p \varepsilon_{px}\right) \tag{22}$$

The shear stress can be expressed as follows: equation (23)

$$\tau_{pxy} = G_p \gamma_{pxy} = \frac{E_p}{\left(1-\upsilon_p\right)}\gamma_{pxy} \tag{23}$$

As above, the positive and shear strains at any point within the constraint level can be obtained as in Eqs. (24), (25):

$$\varepsilon_{cx} = \frac{\partial u}{\partial x} = \frac{\partial u_c}{\partial x} + z\frac{\partial^2 w}{\partial x^2} \tag{24}$$

$$\varepsilon_{cy} = \frac{\partial u}{\partial y} = \frac{\partial v_c}{\partial y} + z\frac{\partial^2 w}{\partial y^2} \tag{25}$$

$$\gamma_{cxy}=\frac{\partial u}{\partial y}+\frac{\partial u}{\partial x}=\frac{\partial u_c}{\partial y}+\frac{\partial v_c}{\partial x}+2z\frac{\partial^2 w}{\partial x\partial y} \tag{26}$$

The positive stress-strain relationship in the direction of the confining layer x, y can be found by Hooke's law as follows:

$$\sigma_{cx}=\frac{E_c}{1-\upsilon_c^2}\left(\varepsilon_{cx}+\upsilon_c\varepsilon_{cy}\right) \tag{27}$$

$$\sigma_{cy}=\frac{E_p}{1-\upsilon_c^2}\left(\varepsilon_{cy}+\upsilon_c\varepsilon_{cx}\right) \tag{28}$$

$$\tau_{cxy}=G_c\gamma_{cxy}=\frac{E_c}{\left(1-\upsilon_c\right)}\gamma_{cxy} \tag{29}$$

Similarly the positive and shear strains at any point within the intermediate damping level can be expressed as Eqs. (30), (31), (32):

$$\varepsilon_{vx}=\frac{\partial u}{\partial x}=\frac{\partial u_v}{\partial x}+z\frac{\partial^2 w}{\partial x^2} \tag{30}$$

$$\varepsilon_{vy}=\frac{\partial u}{\partial y}=\frac{\partial v_v}{\partial y}+z\frac{\partial^2 w}{\partial y^2} \tag{313}$$

$$\gamma_{vxy}=\frac{\partial u}{\partial y}+\frac{\partial u}{\partial x}=\frac{\partial u_v}{\partial y}+\frac{\partial v_v}{\partial x}+2z\frac{\partial^2 w}{\partial x\partial y} \tag{32}$$

From the two-bit Hooke's law, the positive stress in the intermediate damping layer in the direction of x, y and the shear stress are obtained as shown in the following equations (33), (34), and (35):

$$\sigma_{vx}=\frac{E_v}{1-\upsilon_v^2}\left(\varepsilon_{vx}+\upsilon_v\varepsilon_{vy}\right) \tag{33}$$

$$\sigma_{vy}=\frac{E_v}{1-\upsilon_v^2}\left(\varepsilon_{vy}+\upsilon_v\varepsilon_{vx}\right) \tag{34}$$

$$\tau_{vxy}=G_v\gamma_{vxy}=\frac{E_v}{\left(1-\upsilon_v\right)}\gamma_{vxy} \tag{35}$$

The symbol E represents the modulus of elasticity of each layer and G represents the shear modulus of each material.

2.4. Kinetic equations

Based on the theoretical knowledge of elastic mechanics, the kinetic and potential energy of the bound damping plate unit in each layer of the laminate is solved using the principle of energy method, and the kinetic and potential energy principles are used to represent the dynamic equations of the bound damping plate structure. The expressions for the kinetic and potential energy of each laminate unit are derived specifically below, where the kinetic energy of the substrate layer unit is:

$$\mathrm{T}_{\mathrm{p}}^{\mathrm{e}}=\frac{1}{2}\rho_{\mathrm{p}}\iiint_{\mathrm{V}}\left[\left(\frac{\partial u_{\mathrm{p}}}{\partial \mathrm{t}}\right)^2+\left(\frac{\partial v_{\mathrm{p}}}{\partial \mathrm{t}}\right)^2+\left(\frac{\partial w}{\partial \mathrm{t}}\right)^2\right]\mathrm{d}\,\mathrm{V} \tag{36}$$

In the grassroots level, u_p , v_p , w are used to represent the internal displacement of the cell, and the shape functions corresponding to the above three displacement components are substituted into the above equation (36) to obtain the following expression (37).

$$\begin{aligned} \mathrm{T}_{\mathrm{p}}^{\mathrm{e}} &= \frac{1}{2}\left\{\dot{u}^{\mathrm{e}}\right\}^{\mathrm{T}} \rho_p \, \mathrm{h}_{\mathrm{p}} \int_{-\mathrm{a}}^{\mathrm{a}} \int_{-\mathrm{b}}^{\mathrm{b}} \left(N_3^{\mathrm{T}} N_3 + N_4^{\mathrm{T}} N_4 + N_5^{\mathrm{T}} N_5\right) \mathrm{d}\,\mathrm{x}\,\mathrm{d}\,\mathrm{y} \left\{\dot{u}^{\mathrm{e}}\right\} \\ &= \frac{1}{2}\left\{\dot{u}^{\mathrm{e}}\right\}^{\mathrm{T}} m_{\mathrm{p}} \left\{\dot{u}^{\mathrm{e}}\right\} \end{aligned} \tag{37}$$

The mass matrix of the substrate layer cell in the above equation is $\boldsymbol{m}_{\boldsymbol{p}}$, and

$$m_{\mathrm{p}} = \rho_{\mathrm{p}} \, \mathrm{h}_{\mathrm{p}} \int_{-\mathrm{a}}^{\mathrm{a}} \int_{-\mathrm{b}}^{\mathrm{b}} \left(N_3^{\mathrm{T}} N_3 + N_4^{\mathrm{T}} N_4 + N_5^{\mathrm{T}} N_5\right) \mathrm{d}\,\mathrm{x}\,\mathrm{d}\,\mathrm{y} \tag{38}$$

From the theory of elasticity, the strain potential energy of the base plate is given by equation (39)

$$\begin{aligned} \mathrm{E}_{\mathrm{p}}^{\mathrm{e}} &= \frac{1}{2} \iiint_V \varepsilon_{\mathrm{p}} \sigma_{\mathrm{p}} \mathrm{d}\,\mathrm{V} \\ &= \frac{1}{2} \iiint_V \left(\varepsilon_{\mathrm{px}} \sigma_{\mathrm{px}} + \varepsilon_{\mathrm{py}} \sigma_{\mathrm{py}} + \tau_{\mathrm{pxy}} \gamma_{\mathrm{pxy}}\right) \mathrm{d}\,\mathrm{V} \left\{\dot{u}^{e}\right\}^{\mathrm{T}} k_p \left\{\dot{u}^{e}\right\} \end{aligned} \tag{39}$$

Bringing the equations (18)-(20) into the above equation (39) and bringing the shape functions corresponding to the three displacement components of the base plate into the above equation yields

$$\begin{aligned} \mathrm{E}_{\mathrm{p}}^{\mathrm{e}} &= \frac{1}{2}\left\{\dot{u}^{e}\right\}^{\mathrm{T}} \left(\mathrm{h}_p \int_{-a}^{a} \int_{-b}^{b} B_{\mathrm{p}}^{\mathrm{T}} D_{\mathrm{p}} B_{\mathrm{p}} \mathrm{d}\,\mathrm{x}\,\mathrm{d}\,\mathrm{y} + \frac{\mathrm{h}_{\mathrm{p}}^3}{12} \int_{-a}^{a} \int_{-b}^{b} B^{\mathrm{T}} D_{\mathrm{p}} B \mathrm{d}\,\mathrm{x}\,\mathrm{d}\,\mathrm{y} \right) \left\{\dot{u}^{e}\right\} \\ &= \frac{1}{2}\left\{\dot{u}^{e}\right\}^{\mathrm{T}} k_p \left\{\dot{u}^{e}\right\} \end{aligned} \tag{40}$$

Therefore, the stiffness matrix of the base plate is

$$k_{\mathrm{p}} = h_{\mathrm{p}} \int_{-\mathrm{a}}^{\mathrm{a}} \int_{-\mathrm{b}}^{\mathrm{b}} B_{\mathrm{p}}^{\mathrm{T}} D_{\mathrm{p}} B_{\mathrm{p}} \mathbf{d}\,\mathrm{y}\,\mathbf{d}\,\mathrm{x} + \frac{h_{\mathrm{p}}^3}{12} \int_{-\mathrm{a}}^{\mathrm{a}} \int_{-\mathrm{b}}^{\mathrm{b}} B^{\mathrm{T}} D_{\mathrm{p}} B \mathbf{d}\,\mathrm{y}\,\mathbf{d}\,\mathrm{x} \tag{41}$$

According to the above reasoning process of mass matrix and stiffness matrix, the damping layer mass matrix and stiffness matrix can be obtained.

$$m_{\mathrm{v}} = \rho_{\mathrm{v}} \, \mathrm{h}_{\mathrm{v}} \int_{-\mathrm{a}}^{\mathrm{a}} \int_{-\mathrm{b}}^{\mathrm{b}} \left(N_8^{\mathrm{T}} N_8 + N_9^{\mathrm{T}} N_9 + N_5^{\mathrm{T}} N_5\right) \mathrm{d}\,\mathrm{x}\,\mathrm{d}\,\mathrm{y} \tag{42}$$

$$k_{\mathrm{v}} = h_{\mathrm{v}} \int_{-\mathrm{a}}^{\mathrm{a}} \int_{-\mathrm{b}}^{\mathrm{b}} B_{\mathrm{v}}^{\mathrm{T}} D_{\mathrm{v}} B_{\mathrm{v}} \mathbf{d}\,\mathrm{y}\,\mathbf{d}\,\mathrm{x} + \frac{h_{\mathrm{v}}^3}{12} \int_{-\mathrm{a}}^{\mathrm{a}} \int_{-\mathrm{b}}^{\mathrm{b}} B^{\mathrm{T}} D_{\mathrm{v}} B \mathbf{d}\,\mathrm{y}\,\mathbf{d}\,\mathrm{x} \tag{43}$$

Similarly, the stiffness matrix and mass matrix of the constrained layer cells are shown below

$$m_{\mathrm{c}} = \rho_{\mathrm{c}} \, \mathrm{h}_{\mathrm{c}} \int_{-\mathrm{a}}^{\mathrm{a}} \int_{-\mathrm{b}}^{\mathrm{b}} \left(N_1^{\mathrm{T}} N_1 + N_2^{\mathrm{T}} N_2 + N_5^{\mathrm{T}} N_5\right) \mathrm{d}\,\mathrm{x}\,\mathrm{d}\,\mathrm{y} \tag{44}$$

$$k_{\mathrm{c}} = h_{\mathrm{c}} \int_{-\mathrm{a}}^{\mathrm{a}} \int_{-\mathrm{b}}^{\mathrm{b}} B_{\mathrm{c}}^{\mathrm{T}} D_{\mathrm{c}} B_{\mathrm{c}} \mathbf{d}\,\mathrm{y}\,\mathbf{d}\,\mathrm{x} + \frac{h_{\mathrm{c}}^3}{12} \int_{-\mathrm{a}}^{\mathrm{a}} \int_{-\mathrm{b}}^{\mathrm{b}} B^{\mathrm{T}} D_{\mathrm{c}} B \mathbf{d}\,\mathrm{y}\,\mathbf{d}\,\mathrm{x} \tag{45}$$

where the elasticity matrix of the constrained damping plate structure can be expressed as equation (46)

$$D = \frac{\mathrm{E}}{1-\mu^2}\begin{bmatrix} 1 & \mu & 0 \\ \mu & 1 & 0 \\ 0 & 0 & \dfrac{1-\mu}{2} \end{bmatrix} \tag{46}$$

The strain conversion matrix for each layer of the constrained damped laminate is

$$B_{\mathrm{p}} = \begin{bmatrix} \dfrac{\mathrm{d}\,\mathrm{N}_3}{\mathrm{d}\,\mathrm{x}} & \dfrac{\mathrm{d}\,\mathrm{N}_4}{\mathrm{d}\,\mathrm{y}} & \dfrac{\mathbf{d}\,\mathrm{N}_3}{\mathbf{d}\,\mathrm{y}} + \dfrac{\mathbf{d}\,\mathrm{N}_4}{\mathbf{d}\,\mathrm{x}} \end{bmatrix}^{\mathrm{T}} \tag{47}$$

$$B_{\mathrm{c}} = \begin{bmatrix} \dfrac{\mathrm{d}\,\mathrm{N}_1}{\mathrm{d}\,\mathrm{x}} & \dfrac{\mathrm{d}\,\mathrm{N}_2}{\mathrm{d}\,\mathrm{y}} & \dfrac{\mathbf{d}\,\mathrm{N}_1}{\mathbf{d}\,\mathrm{y}} + \dfrac{\mathbf{d}\,\mathrm{N}_2}{\mathbf{d}\,\mathrm{x}} \end{bmatrix}^{\mathrm{T}} \tag{48}$$

$$B_{\mathrm{v}} = \begin{bmatrix} \dfrac{\mathrm{d}\,\mathrm{N}_8}{\mathrm{d}\,\mathrm{x}} & \dfrac{\mathrm{d}\,\mathrm{N}_9}{\mathrm{d}\,\mathrm{y}} & \dfrac{\mathbf{d}\,\mathrm{N}_8}{\mathbf{d}\,\mathrm{y}} + \dfrac{\mathbf{d}\,\mathrm{N}_9}{\mathbf{d}\,\mathrm{x}} \end{bmatrix}^{\mathrm{T}} \tag{49}$$

$$B = \begin{bmatrix} \dfrac{\mathrm{d}^2\,\mathrm{N}_5}{\mathrm{d}\,\mathrm{x}^2} & \dfrac{\mathrm{d}^2\,\mathrm{N}_5}{\mathrm{d}\,\mathrm{y}^2} & \dfrac{2\mathbf{d}^2\,\mathrm{N}_5}{\mathbf{d}\,\mathrm{y}^2} \end{bmatrix}^{\mathrm{T}} \tag{50}$$

Since the middle damping plate of the constrained damping laminate structure will not only generate positive strain, but also shear deformation will occur in the transverse direction while deforming, the potential energy of shear deformation can be determined according to the assumptions started in the text as

$$\mathrm{E}_{\mathrm{p}}^{\mathrm{e}} = \frac{1}{2}\iiint_{V}\left(\mathrm{G}_{v}\,\beta_{v}^{2} + \mathrm{G}_{v}\,\beta_{y}^{2}\right)\mathrm{d}\,\mathrm{V} \tag{51}$$

Bringing the form function corresponding to β_v, β_y in the above equation yields the following relation:

$$\mathrm{E}_{\beta}^{\mathrm{e}} = \frac{1}{2}\left\{\dot{u}^{e}\right\}^{\mathrm{T}}\left(\mathrm{G}_{\mathrm{v}}\mathrm{h}_{\mathrm{v}}\int_{-a}^{a}\int_{-b}^{b} N_{10}^{\mathrm{T}}N_{10} + N_{11}^{\mathrm{T}}N_{11}\,\mathrm{d}\,\mathrm{x}\,\mathrm{d}\,\mathrm{y}\right)\left\{\dot{u}^{e}\right\} = \frac{1}{2}\left\{\dot{u}^{e}\right\}^{\mathrm{T}} k_{\mathrm{v}\beta}\left\{\dot{u}^{e}\right\} \tag{52}$$

The shear stiffness of the constrained damping plate structure can be obtained from the above equation as

$$k_{\mathrm{v}\beta} = \frac{1}{2}\mathrm{G}_{\mathrm{v}}\mathrm{h}_{\mathrm{v}}\int_{-a}^{a}\int_{-b}^{b}\left(N_{10}^{\mathrm{T}}N_{10} + N_{11}^{\mathrm{T}}N_{11}\right)\mathrm{d}\,\mathrm{x}\,\mathrm{d}\,\mathrm{y} \tag{53}$$

The kinetic energy, potential energy and shear energy of the three-layer laminate structure of the constrained damped laminate structure are brought in according to the variational equation of Hamilton's principle, and the kinetic equation of the laminate unit can be obtained;

$$m\left\{\ddot{u}^{\mathrm{e}}\right\} + k\left\{u^{\mathrm{e}}\right\} = \left\{F\right\} \tag{54}$$

In the above equation, $\boldsymbol{m}$ is the mass matrix, $\boldsymbol{k}$ is the stiffness matrix, and F is the external excitation force. Where the stiffness matrix and mass matrix of each cell are integrated in the form of a total assembly into the overall mass matrix and stiffness matrix.

$$M = \sum_{\mathrm{i}=1}^{\mathrm{N}}\left(m_{\mathrm{p}}^{\mathrm{i}} + m_{\mathrm{c}}^{\mathrm{i}} + m_{\mathrm{v}}^{\mathrm{i}}\right) \tag{55}$$

$$K=\sum_{\mathrm{i}=1}^{\mathrm{N}}\left(k_{\mathrm{p}}^{\mathrm{i}}+k_{\mathrm{c}}^{\mathrm{i}}+k_{\mathrm{v}}^{\mathrm{i}}+k_{\mathrm{vb}}^{\mathrm{i}}\right) \tag{56}$$

From the above series of equations the kinetic equations of the bound damping plate as a whole can be determined:

$$M\{\ddot{u}\}+K\{u\}=\{F\} \tag{57}$$

3.Equivalent static load fundamentals

Equivalent static load is a method of solving the dynamic response of a structure under dynamic load, which works by converting the dynamic problem into a static problem through multiple analysis steps, so that the displacement response generated in the same time and the displacement generated by the dynamic load is the same, so that the dynamic response problem is converted into a multi-case static problem by multiple analysis steps to solve [11]. The specific equivalent process can be represented by Figure 3, and the equivalent process of vibration control equation 58 is shown below:

$$\mathbf{M}\ddot{\mathbf{d}}+\mathbf{K}\mathbf{d}=\mathbf{f}=\{0 \quad \ldots \quad f_i \ldots f_{i+l-1} 0 \ldots 0\} \tag{58}$$

In the above equation, M represents the overall mass matrix of the structure, K represents the overall stiffness matrix of the structure, d is the displacement response under load, $\ddot{d}$ is the corresponding acceleration response, f is the applied load on the structure, where l is the number of equivalent static loads.

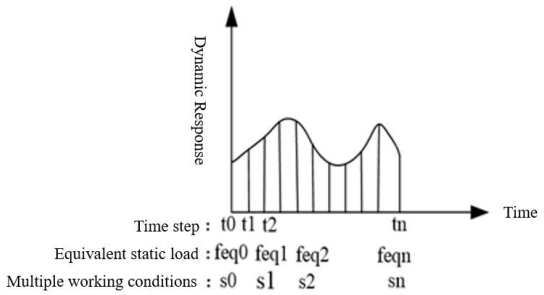

Figure 3. Schematic diagram of the equivalent process

4. Optimization Example and Analysis

4.1 Mathematical modeling of the optimization problem

In this section, with maximization of stiffness as the optimization objective, dynamic loads are applied to the structure with volume as the constraint objective, and the equivalent static load method approach is used to solve for the structural dynamic response, with the following mathematical model:

$$\begin{cases} \text{Minimize} & C=\sum_{u=1}^{l} w_u\left(\frac{1}{2} f_{tu}^{T} z_{\mathrm{ou}}\right); & u=1,\ldots,l \\ \text{Subject to} & V^{*}-\sum_{i=1}^{N} V_i x_i=0 & \\ & \mathbf{K}(\mathbf{x})\mathbf{z}(s)-\mathbf{f}_{eq}(s)=0; \quad s=1,\ldots,l & \\ & x_i \in \{x_{\min},1\} & \end{cases} \tag{59}$$

In the above equation, l is the total time step, w_u is the time step weight factor, which is 1 if the time analysis steps have the same time. $1/2*(f^T z_{tu})$ is the stiffness value of the structure during the time step, V^* is the volume constraint, x_i is the relative cell density, z_{tu} is the displacement at the u time step, and f_{tu} is the dynamic load.

4.2 Unit sensitivity and optimization process analysis

4.2.1. Unit sensitivity calculation

The sensitivity of the cell under equivalent static load is calculated by the following equation:

$$\begin{cases} dc_{ij} = \dfrac{1}{2} p x_{ij}^{p-1} \mathbf{u}_{ij}^T \mathbf{K}_i \mathbf{u}_{ij} \\ dc_i = \dfrac{1}{2} \displaystyle\sum_{j=1}^{l} p x_{ij}^{p-1} \mathbf{u}_{ij}^T \mathbf{K}_i \mathbf{u}_{ij} \end{cases} \tag{60}$$

In the above equation, dc_{ij} is the sensitivity of the i cell at the j step, dc_i indicates the cell sensitivity, p is the total time step of the penalty factor expressed by l , and x_{ij} indicates the relative density of the i cell at the j time step.

4.2.2 Optimization process analysis

a) first need to assign values to the initial variables of the structure as well as to the initial optimization parameters;

b) Calculation of the dynamic response at each analysis step time under dynamic load using the Newmark method of analysis;

c) Solving the load values for each analysis step time using the equivalent static load method;

d) Establish the mathematical model of the objective function in the optimization model:

$$\begin{cases} \text{Minimize} & C = \displaystyle\sum_{u=1}^{l} w_u \left(\frac{1}{2} f_{tu}^T z_{tu} \right); \quad u = 1, \ldots, l \\ \text{Subject to} & V^* - \displaystyle\sum_{i=1}^{N} V_i x_i = 0 \\ & \mathbf{K}(\mathbf{x})\mathbf{z}(s) - f_{eq}(s) = 0; \quad s = 1, \ldots, l \\ & x_i \in \{x_{\min}, 1\} \end{cases} \tag{61}$$

e) Combined with the BESO method to add and delete structural units, the cycle ends when the convergence conditions are met; the criteria for determining convergence are as follows:

$$\left(\left| x_i^{k+1} - x_i^k \right| \geq \varepsilon_1 \right) \leq n \times \varepsilon_2; \quad i = 1, \ldots, n \tag{62}$$

In the above equation ε_1 , the ε_2 is the defined minimal value.

4.3 Analysis of dynamic stiffness optimization algorithm based on equivalent static load method

In this section, the dynamic response of the structure under dynamic load is solved by using the equivalent static load method to construct the optimal topology of constrained damping with dynamic stiffness as the optimization objective. $f(t)$ Based on the theory of equivalent static load and the theoretical knowledge of the finite element model of the restrained damped laminate, Matlab is used to

write the above analysis and calculation process. The specific parameters are as follows: plate length is 0.3480m, plate width is 0.3048m, volume constraint is 0.3, cell division is 40×40 , three-layer material parameters are shown in Table 2.1, set the total time step is 20, material penalty factor is 3, in order to avoid the singular matrix to take the virtual cell $x_{\min}$ value is 0.0001

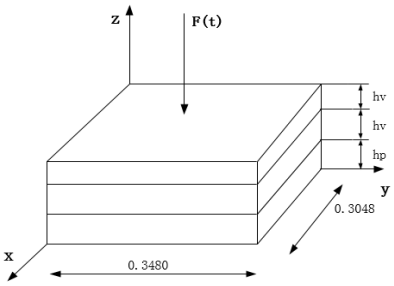

Figure 4. Laminate under equivalent static load

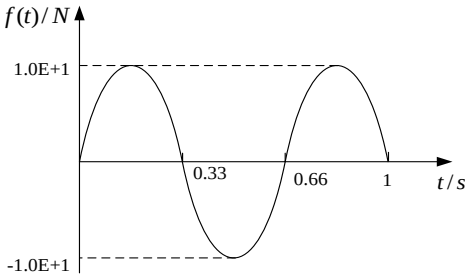

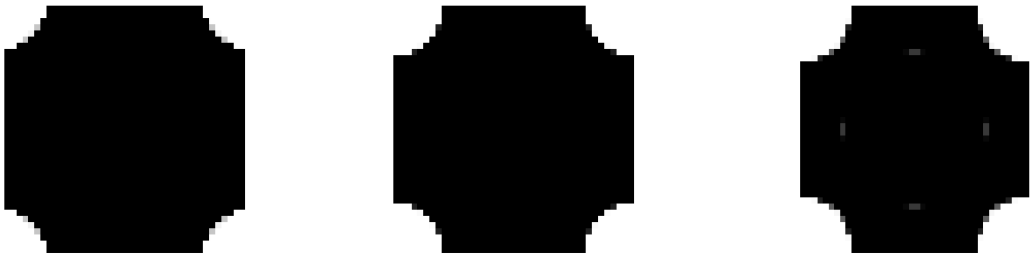

Figure 5. Simple harmonic excitation load diagram

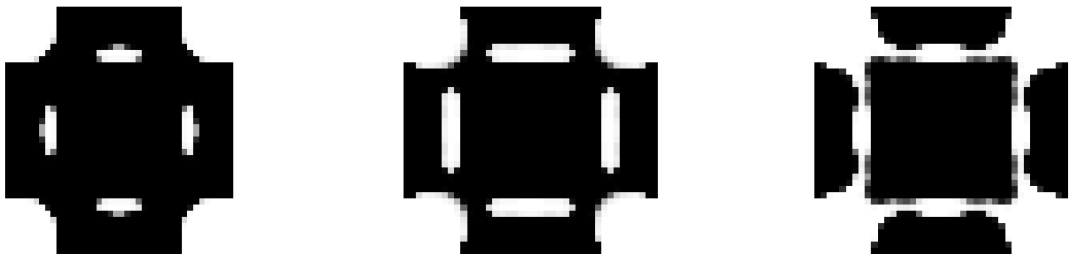

By writing the BESO optimization algorithm program, a topology optimization program with the minimum flexibility as the optimization objective is established, and the constrained damping volume ratio is used as the constraint, and the topology diagram of each stage iteration and the final constrained damping optimal topology configuration are obtained through multiple iterations, and the topology diagram of the whole iteration process is shown in Figure 6 below.

(a) Iterative optimization of the 10th constrained damping layout configuration

(b) Iterative optimization of the 15th constrained damping layout configuration

(c) Iterative optimization of the 20th constrained damping layout configuration

(d) Iterative optimization of the 30th constrained damping layout configuration

(e) Iterative optimization of the 50th constrained damping layout configuration

(f) Final constrained damping layout configuration

Figure 6. Topology optimization process of four-sided solid support constrained damped laminate layout

In the above figures 6 represent the constrained damping topology after optimization of the four-sided fixed-supported constrained damping laminate, where the dynamic load is loaded in the middle of the

constrained damping laminate, and the dynamic stiffness is maximized under the action of the dynamic load as the optimization objective. The restrained damping material is uniformly distributed in the four sides and the middle of the plate. The above distribution of the restrained damping reflects the transmission path of the center load plate under the restrained condition of four-sided solid support.

5. Conclusion

In this paper, the topological optimization method of BESO optimization is used to optimize the constrained damping laminate structure, and the dynamic stiffness is used as the optimal design objective to distribute the constrained damping material in the best position. In order to obtain the stiffness matrix and mass matrix of the restrained damping structure as a whole, a finite element analysis model of the restrained damping laminate is developed and verified. In order to convert the problem of dynamics analysis into a static problem for calculation, the equivalent static load method combined with BESO topology optimization is applied to solve this problem. In order to obtain the final topological distribution of the constrained damping during the optimization iterations, a MATLAB program based on the topological optimization algorithm of the dynamic stiffness response of the equivalent static load method is written, and finally the optimal layout of the constrained damping on the substrate under different iterations is obtained.

Abstract

In order to solve the problems of low efficiency and inaccurate identification of member stability in structural topology optimization model with section area as design variable considering member stability, a linear allowable stress iteration method considering member stability limit is proposed. In this paper, the nonlinear structural optimization problem considering member buckling is transformed into a linear optimization problem, and an optimization model and program for spatial grid structures are established. Finally, the effectiveness of the algorithm in spatial grid structures is explored through numerical examples. The results show that topology of the structure can be changed by using the iterative allowable stress method to meet the requirements of the stable buckling of members. In addition, the linear allowable stress iteration method considering the stability limit of members not only can optimize the topology of spatial grid structures based on Euler buckling, but also through the buckling of Chinese codes, making the practical engineering application of topology optimization of spatial grid structures possible.

Keywords: spatial grid structure, topology optimization, member stability, linear allowable stress iteration

1. Introduction

Topology optimization is one of the most important and challenging areas in structural optimization, as it allows for the optimization of both the topology structure and geometric shape of trusses, providing an effective method for generating optimized truss designs. The ground structure method is a commonly used method in topology optimization. Based on the ground structure method, many truss optimization methods are achieved by reducing or increasing the number of truss members while keeping the node positions unchanged.

However, in topology optimization using the ground structure method, two existing challenges are the low computational efficiency and inaccurate stability criteria for the design variable of cross-sectional area of the bar and the consideration of bar stability constraints [1,2]. Firstly, due to the nonlinear function of bar stability constraints as optimization variables, the optimal solution may be located in the degenerate domain of the feasible domain, making the solution efficiency of optimization problems considering bar stability very low [3,4]. Secondly, because the Euler buckling criterion is relatively simple compared to the more complex requirements of structural design standards, previous studies mainly relied on the Euler buckling criterion rather than actual structural design standards to determine whether bars buckle.

However, many studies have shown that the critical buckling force of bars calculated using the Euler buckling criterion algorithm may be overestimated, which could lead to unsafe optimized structures [5]. Most national and regional structural design standards not only consider the length and cross-sectional shape of bars, but also initial defects when determining whether bars buckle. For example, the British

steel design standard BS5950 [6] and the European steel design standard Eurocode 3 [7] require consideration of the influence of the slenderness ratio when determining bar stability.

Due to the high number of bars in spatial grid structures, optimization algorithms are required to have high computational efficiency. A feasible approach is to set the allowable compressive stress of the material to a relatively small value, which transforms the nonlinear optimization problem of considering bar stability into a linear optimization problem that only considers stress constraints [8]. However, determining the appropriate value for the allowable compressive stress remains a challenge [9]. If the allowable compressive stress is set too high, it may result in instability of the optimized structure, while setting it too low may cause material waste and affect optimization performance [10, 11].

Building upon the aforementioned modifications to the allowable stress method, this study proposes a linear iterative method for allowable stress. This method iteratively modifies the material allowable stress for each rod, transforming the non-linear rod stability constraints into linear constraints, thereby improving computational efficiency. Additionally, this method can use either the Euler buckling criterion or the "Code for Design of Steel Structures" (GB 50017) as the criterion for rod buckling.

2. Theoretical methods

2.1. Structural optimization formula considering the stability of members

Although the Euler buckling criterion and the "Code for Design of Steel Structures" (GB 50017) have different formulas for calculating the critical buckling force of a member, both require the axial force of the member to be greater than the negative value of its corresponding critical buckling force in the structural optimization model, i.e., satisfying Equation (1). We define the cross-sectional area of the member in the buckling state as the critical buckling cross-sectional area. Therefore, the critical buckling cross-sectional areas calculated by the Euler buckling criterion and the "Code for Design of Steel Structures" (GB 50017) are:

$$a_i^{Euler} = 2l_i\sqrt{\frac{S_i^{Euler}}{\pi E}} \tag{1}$$

$$a_i^{code} = \frac{S_i^{code}}{\varphi\sigma_f} \tag{2}$$

In the above equations, a_i^{Euler} and a_i^{code} represent the Euler critical section area and the specification critical section area, respectively. Therefore, during the optimization process, as long as the cross-sectional area of the member is not less than the critical section area, it can be considered that the member satisfies the local buckling constraint, that is: $a_i \geq a_i^{cr}$.

Based on the above discussions, the optimization formula for three-dimensional space grid structures, with the minimum structural weight as the optimization objective and stress, static equilibrium, and member stability as the constraint conditions, can be expressed as:

Objective function: $\min\limits_{\mathbf{A,q}} M = \rho \mathbf{A}^{\mathrm{T}}\mathbf{L}$

constraint condition: $\mathbf{BS}^k = \mathbf{f}^k$

$$-\sigma^{-}\mathbf{A} \leq \mathbf{S}^{\alpha} \leq \sigma^{+}\mathbf{A} \qquad \alpha = 1, 2, \ldots, k+6$$

$$\mathbf{BS}^{k+1}=\mathbf{f}_x \qquad \mathbf{BS}^{k+2}=-\mathbf{f}_x \qquad \mathbf{BS}^{k+3}=\mathbf{f}_y$$

$$\mathbf{BS}^{k+4}=-\mathbf{f}_y \qquad \mathbf{BS}^{k+5}=\mathbf{f}_z \qquad \mathbf{BS}^{k+6}=-\mathbf{f}_z$$

$$\mathbf{f}_x \geq \frac{1}{2} r \mathbf{T}_x \mathbf{S}^k \qquad \mathbf{f}_y \geq \frac{1}{2} r \mathbf{T}_y \mathbf{S}^k \qquad \mathbf{f}_z \geq \frac{1}{2} r \mathbf{T}_z \mathbf{S}^k$$

$$a_i \geq a_i^{cr} \qquad \mathbf{A} \geq 0$$

In the formula, ρ represents material density, **A**, **L**, and **S** represent the cross-section, length, and axial force vector of the member, respectively. **B** is the static moment matrix of the structure, $\mathbf{f}^k$ is the external load matrix, and k represents the number of external load cases. $\mathbf{S}^{\alpha}$ represents the member axial force under k external load cases and 6 nominal disturbance force cases. $\mathbf{f}_x$, $\mathbf{f}_y$, and $\mathbf{f}_z$ represent the nominal disturbance force vectors along the positive x, y, and z directions, respectively, while $-\mathbf{f}_x$, $-\mathbf{f}_y$, and $-\mathbf{f}_z$ represent the nominal disturbance force vectors along the negative x, y, and z directions, respectively. Here, "$\geq$" indicates that the nominal disturbance force should satisfy k external load cases. $\mathbf{T}_x$, $\mathbf{T}_y$, and $\mathbf{T}_z$ represent the conversion matrices that convert the member axial force to the x, y, and z directions, respectively. r is the disturbance force coefficient, and in this study, r is set to 0.02. $\mathbf{M}_{com}$ represents the set of compression members.

2.2. Linear allowable stress iteration method

In this section, we propose a linear permissible stress iteration method for linearizing the stability constraints of beam elements in structural optimization problems. The feasible domain of such problems is nonlinear and difficult to solve. The proposed method is illustrated in Figure 1.

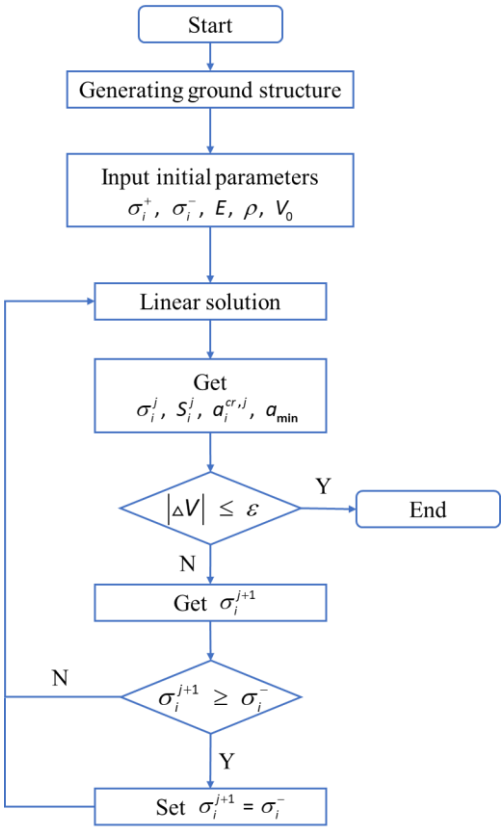

Figure 1. Linear Allowable Stress Iteration Process.

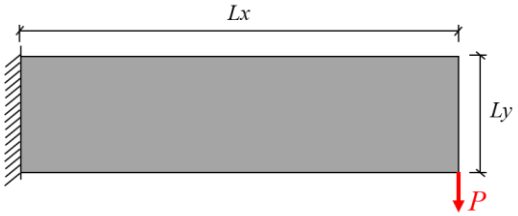
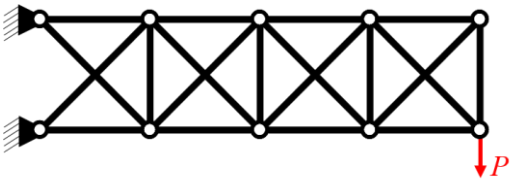


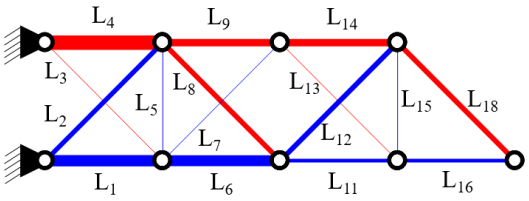
3. Numerical examples

In this section, numerical examples are presented to demonstrate the effectiveness of the linear allowable stress iteration method proposed in this study. The material used in the numerical examples is Q 345 steel with allowable compressive and tensile stress values of $\sigma^+ = \sigma^- = 305$ MPa, yield strength $\sigma_y = 345$ MPa, density $\rho = 7.85$ g/cm3, and elastic modulus E = 206 GPa. As short bars are commonly encountered in practical engineering, a first-order connectivity is adopted in the construction of the base structure, where only adjacent nodes are connected to form bar elements. Consequently, overlapping bar elements do not exist in the base structure. Unless specified otherwise, the solid circular bar section is selected. The minimum section is chosen to be 10% of the average effective section in the previous iteration. Moreover, to address the issue of unstable nodes, the nominal perturbation method proposed in Chapter 5 of this study is employed, with a perturbation force coefficient of r = 0.02. In the optimized structure, the blue, red, and green bars represent bars subjected to compression, tension, and support, respectively. A support bar is a bar with zero axial force under the main external loading condition, which serves to maintain node stability.



3.1. Two-dimensional cantilever beam

As shown in Figure 2 (a), this study optimizes the design domain of a classical cantilever beam subjected to concentrated loads at its ends. The size of the cantilever beam design domain is $L_x \times L_y$ = 2000 mm × 500 mm。 The left end of the design domain is hinged to limit the horizontal and vertical movement of the structure, and the lower part of the right end bears a vertical concentrated load P = 8 kN. Uniformly arrange node elements within the design domain, with a distance of 500 mm between any two adjacent node elements. Connecting two adjacent node elements to form a member element, together forming a base structure containing 10 node elements and 20 member elements, as shown in Figure 2 (b). In order to better reflect the difference between the optimization results obtained based on the Euler buckling algorithm and the algorithm based on the Design Standard for Steel Structures (GB 50017) (hereinafter referred to as the code), the minimum section and minimum allowable stress are not set in this calculation example.



The optimization result without considering the stability of the member is shown in Figure 2 (c), with a structural mass of 2.491 kg and a calculation time of 2.1 *s*. The optimized structure considering the stability of the member according to the Euler buckling criterion is shown in Figure 2 (d). The structural mass is 5.356 kg, with a total of 23 iterations and a calculation time of 10.5 seconds. Finally, the optimized structural mass obtained by the algorithm for judging the buckling of the rod according to the regulations is 5.898 kg, the program has been iterated 12 times, and the running time is 6.8 seconds. In the three cases, the axial force, cross-sectional area, and buckling critical force of the effective member of the optimized structure are shown in Table 1.

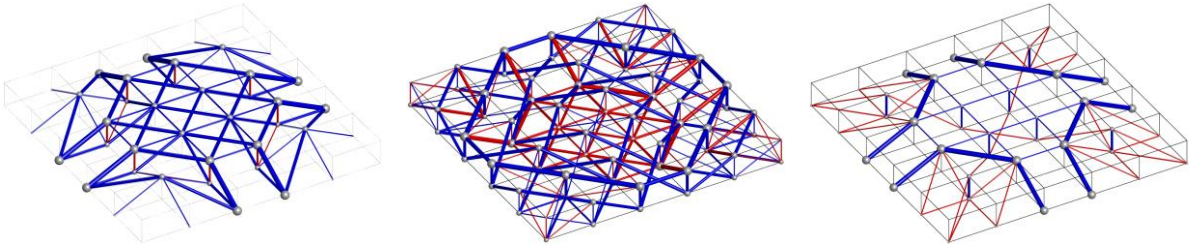
3.2. Grid structure



This study optimizes the design domain of the bottom chord supported grid structure shown in Figure 3 (a). The design domain size is $L_x \times L_y \times L_z = 10\ m \times 10\ m \times 1\ m$, the upper surface bears a vertically downward uniform surface load of 1.5 kN/m^2. Uniformly arrange nodes within the design area, with a horizontal spacing of 2 m and a vertical spacing of 1 m. In the study, the uniformly distributed surface load was converted into a concentrated load acting on the upper surface node, with a load value of 6 kN. Due to the fact that node loads around the upper surface can be directly transferred to the support through the maintenance structure, which has a small impact on the overall topology of the structure, in order to simplify the calculation, no concentrated loads are applied to the surrounding nodes. Set the member connection level to Lvl=1, that is, connect only adjacent nodes in the base grid, and the resulting base structure is shown in Figure 3(b). The base structure contains 476 rod elements and 72 node elements. The nominal perturbation method is used to consider the impact of node stability, and the nominal perturbation coefficient is set to r=0.02.

(a) Design area (b) Ground Structure

Figure 3. Design area of bottom chord braced grid structure

Without considering the stability of the rod, the optimized structure is shown in Figure 4(a), with a structural mass of 33.59 kg. At this point, most of the members in the structure are under pressure. Figure 5 shows the comparison of the actual axial force value, Euler buckling critical force, and gauge buckling critical force of the compression rod in Figure 4 (a). As can be seen from Figure 5, none of these compression rods can meet the requirements for rod buckling. Therefore, it is necessary to consider member buckling in structural topology optimization.

(a) Structure before iteration (b) Structure after iteration 1 (c) Structure after iteration 36

Figure 4 Optimization results of grid structures based on Euler buckling

When using the Euler buckling criterion to assess the local buckling of the truss members, the resulting topology of the optimized structure at different iterations is shown in Figure 4, while the corresponding structural quality changes after each iteration are demonstrated by the black line in Figure 6. Figure 4 indicates that the topology of the structure changes significantly in the early stages of the iterations. As the number of iterations increases, the topology of the structure tends to be stable, which explains the significant changes in the structural quality in the early iterations. The optimized structure with a mass of Me = 374.502 kg is obtained as shown in Figure 4 (c) at the end of the process. In addition, there are relatively few truss members (shown by green lines) used solely for supporting unstable nodes in the

final optimized structure, indicating that the structure gradually converges towards a topology with high material efficiency.

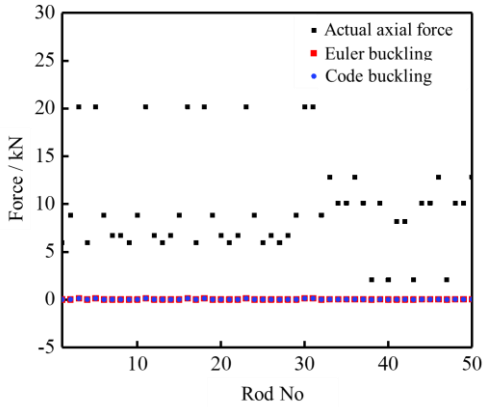


Figure 5. members without rod buckling

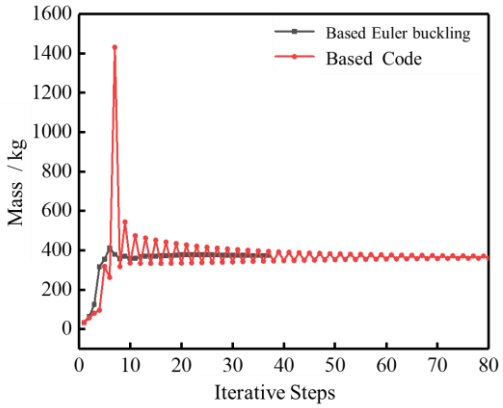

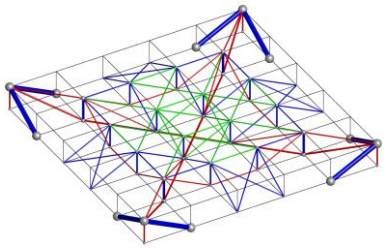

Figure 6. Structural mass of each iteration step

When using the code buckling method to determine the local buckling of a member, the structural topology corresponding to different iteration steps is shown in Figure 7, it is similar to the optimization process considering the Euler buckling criterion, the topology of the structure changes greatly in the early stages of the iteration process. With the increase of the number of iterations, the topology of the structure tends to stabilize, and the optimized structure mass is Mc=360.447 kg. In addition, the optimized structure obtained using the gauge buckling method is lighter than the structure obtained using the Euler criterion method.

(a) Structure after iteration 79

Figure 7. Optimization results of grid structures based on code buckling

The compression bar in the topological optimization structure obtained by using the Euler buckling method cannot meet the requirements of structural specifications for the buckling of the bar. However, the compression bar in the topology optimized structure obtained by using the standard buckling method can not only meet the structural code requirements for member buckling, but also meet the requirements of the Euler buckling criterion. Comparing the optimized structures generated by the two optimization types, it can be seen that the topological forms of the optimized structures obtained by the two methods considering the buckling of the members differ greatly. This indicates that using the iterative allowable stress method can meet the buckling requirements of members by changing the topology of the structure. This also shows that the iterative allowable stress method has the ability to globally search for the optimal solution.

5. Conclusion

This paper proposes a linear permissible stress iterative method for considering the stability constraints of truss members in spatial grid structure optimization, and establishes a structural optimization model. The linear permissible stress iterative method uses an iterative approach to convert the nonlinear stability

constraints of truss members into linear constraints, making it possible to solve topology optimization problems of spatial grid structures containing a large number of members. The main conclusions are as follows:

(1) Compared to the traditional structural optimization models that rely solely on the Euler buckling criterion to assess the stability of members, the linear permissible stress iteration method proposed in this study can evaluate the stability of members based on both the Euler buckling criterion and the design code. This versatility makes the proposed method applicable to practical engineering design.

(2) Through the comparison of optimization results, it can be seen that the optimized topology of the structure based on the Euler buckling criterion and the one based on actual design standards may differ in the optimization model. Additionally, the optimized structure obtained through the Euler buckling-based optimization algorithm may not meet the requirements of the actual structural design standards for rod stability. Therefore, it is recommended to directly use a rod stability judgment algorithm based on structural design standards in structural optimization calculations.

(3) The quality of the optimized structure using the actual design specifications may be lower compared to the one optimized using the Euler buckling-based method. This indicates that the linear iterative allowable stress method proposed in this study has the ability to perform global optimization search.

Abstract

In this study, the nominal perturbing force (NPF) method and the allowable stress iteration (ASI) method are proposed to address nodal instability and local buckling instability problems in truss topology optimization, respectively. In the NPF approach, an infinite number of disturbing forces that a node may suffer are considered by a finite number of nominal perturbation force conditions whose magnitude and direction are analyzed to capture the worst-case perturbation. In the ASI method, the allowable compressive stresses in the members are recalculated according to Euler buckling criterion in each iteration to make the buckling constraint active. Finally, a truss topology optimization formulation incorporating the NPF and ASI methods is proposed and demonstrated through two numerical examples.

Keywords: conceptual design, topology optimization, truss, local buckling, nodal stability

1. Introduction

A typical truss topology optimization problem might comprise a design domain containing an array of fixed nodal points connected by potential members, called the ground structure. Typically, the truss topology optimization based on the ground structure method is mainly divided into four steps. Firstly, as shown in Figure 1a, the design domain with appropriate supports and loads is determined. Secondly, as shown in Figure 1b, the nodes are arranged, usually evenly, to discrete the design domain. Thirdly, as shown in Figure 1c, these nodes are connected with potential members to generate the ground structure. Finally, as shown in Figure 1d, some optimization algorithms are used to remove the redundant members to generate the optimal structure. However, the optimized structure obtained by using the ground structure method always contains unstable nodes within successive parallel compression members, such as node N_5 in Figure 1d, which may lead to structural instability.

In previous studies, lots of attempts had been made to solve the nodal instability problem. An intuitive approach is to eliminate unstable nodes and merge these consecutive members into a single long member. However, the inclusion of local buckling in an optimization formulation means that any method which involves this approach is highly unlikely to obtain an optimal design. Another approach is to add constraints on the minimum number of active members connected to the active nodes in the truss topology optimization problem. The original intention of this approach is to add enough bracings to the unstable nodes to limit the node motion. However, in this approach, it may be neither guaranteed that all directions of freedom of the nodes are constrained nor that the bracings can provide sufficient support forces. The inclusion of a global elastic stability criterion in the optimization algorithm can also, to some extent, solve the nodal stability problem in truss topology optimization, since the global stability of the structure requires nodal stability by default. However, due to the low computational efficiency of solving the semidefinite programming, only ground structures containing a relatively small number of members can be solved in this way. Therefore, the nodal stability problem in truss optimization still needs to be addressed.

In addition to nodal stability, local buckling of members should be considered in the optimization of truss structures. The first observation on Euler buckling constraints is that they exhibit similar behavior as stress constraints that are known for making the feasible set non-convex and for inducing degenerated regions, where the optimal point may lie. These regions can be treated in the solution process by the so-called ε-relaxed approach [1], a technique adapted from a similar idea for stress constraints. However, even though the disjointness and degeneracy of the feasible set can be solved, one still has to face the numerical difficulties related to non-convexity and choosing the parameter ε. Furthermore, it has been shown that this method may not yield reasonable optimization results for pressure constraints. Therefore, in many studies of truss structure optimization, the local buckling problem of the members is neglected. In order to use the optimized structure in the practical structural design, an intuitive approach is to increase the cross-sectional area of the buckling member after optimization. However, since this approach cannot take the local buckling stability into account in the optimization process, it does not lead to better optimization results. A rudimentary approach for taking member local buckling stability into account is to set the allowable stress in compression to be some specified constant fraction of the tensile stress. This reduces the problem to one with unequal permissible stresses in tension and in compression, and no further modifications are needed for member local stability. However, in general, it is very difficult to choose a correct constant lower stress constraint for members with different lengths or axial forces. Therefore, this method does not provide a practical means for taking member local buckling stability into account in truss optimization. In summary, the local buckling of members still needs to be addressed in the optimization of truss structures.

This study mainly addresses the nodal instability and the local buckling of member problems in topology optimization of truss structures, which is organized as follows. In section 2, the framework for truss topology optimization with constraints on member stress is present. Then, in section 3, the nominal perturbing force method and the allowable stress iteration method are introduced, respectively. In Section 4, the effectiveness of the proposed methods is demonstrated on numerical examples. Finally, the paper is summarized in Section 5.

2. Truss topology optimization

For convenience, the structures studied in this section are plane trusses defined by N_n nodal points and N_b members. For spatial trusses, there is a similar derivation. The number of supports is denoted N_s and the number of degrees of freedom of the nodes is $N_{dof} = d \times N_n - N_s$, where $d = 2$ for plane truss. The sectional area of the member i is given as a_i collected in $\mathbf{a} \in \mathrm{R}^{N_b \times 1}$. Similarly, the lengths of members are collected in $\mathbf{l} \in \mathbf{R}^{N_b \times 1}$. The plastic formulation for the minimized truss volume with member stress constraint subjected to M external load conditions can be formulated as,

$$\begin{aligned} &\min_{\mathbf{a},\mathbf{q}} \; V = \mathbf{a}^{\mathrm{T}}\mathbf{l} && \\ \text{s.t.} \quad &\mathbf{B}\mathbf{q}^{t} = \mathbf{f}^{t} && t = 1, 2, ..., M \\ &-\sigma^{-} a_i \le q_i^{t} \le \sigma^{+} a_i && \\ &a_i \ge 0 && i = 1, 2, ..., N_b \end{aligned} \tag{1}$$

where $\mathbf{B} \in \mathrm{R}^{N_{dof} \times N_b}$ is the equilibrium matrix, built from the directional cosines of the members, $\mathbf{q}^{t} \in \mathrm{R}^{N_b \times M}$ is a matrix containing the axial force for all members under M external load conditions, and $\mathbf{f}^{\mathbf{t}} \in \mathrm{R}^{N_{dof} \times M}$ is a matrix containing the external loads, $\sigma^{+} > 0$ and $\sigma^{-} > 0$ are limiting tensile and compressive yield stresses respectively, q_i^{t} is the axial force of the member i under loading case f^{t}. The optimization variables are the cross-sectional areas in **a** and the internal force in **q**. It can be observed that the element in matrix **B** is determined by the positions and connectivity of the nodes in the ground structure. Therefore, the optimization formulation is a linear programming problem, which can be solved very efficiently by a state-of-the-art solver.

2.2 Nominal perturbing force method

In order to address the nodal instability problem in the optimized structure, the Nominal perturbing force (NPF) approach is proposed in this study. In the NPF approach, an infinite number of disturbing forces at nodes in the ground structure are incorporated into the truss topology optimization problem in the form of nominal perturbing force conditions, whose magnitude and direction will be determined in the following section.

2.2.1 Magnitude of the nominal perturbing force

Considering a single primary external load case, each of these axes is considered in turn with the sum of all the components of axil forces pushing onto the node normal to this axis being determined, and a nominal force taken as some specified proportion of this sum.

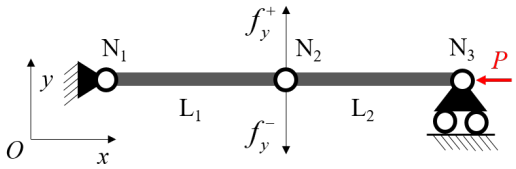

Figure 2. Two-member structure parallel to the coordinate axis

Using the two-member structure shown in Figure 2 as an example, the nominal perturbing forces can be calculated from the following equation,

$$f_y^{+} = f_y^{-} = \frac{1}{2} r \sum_{i=1}^{m_j} q_i d_i^{x} \tag{2}$$

where f_y^{+} and f_y^{-} are two nominal perturbing force conditions at node N_2 in the same and opposite directions to the y-axis, respectively, m_j is the number of members connected to node j, d_i^{x} is the direction cosine of the member i relative to the x-axis, r is the nominal perturbing force coefficient, which reflects the ratio of the magnitude of the bracing force to the axial force of the braced members. In this paper, the nominal perturbing force calculated by using formula (2) is called calculated nominal force. The magnitude of the perturbing force required to stabilize the internal nodes within compressive members can be reflected in the requirements of the practical design code that stipulates the strength

standards of bracings. For example, both BS5950[2] and EC3 code[3] require that, the bracing force should be not less than 1% of the compression force that is being resisted. Therefore, the magnitude of the nominal perturbing force perpendicular to the braced members is taken as 1% of the magnitude of the compression force of the braced members.

2.2.2 Direction of the nominal perturbing force

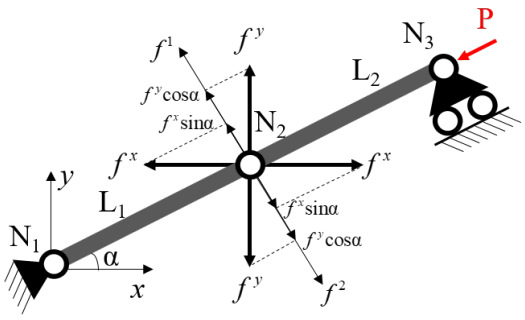

Figure 3. Two-member structure not parallel to the coordinate axis [4]

When the orientation of the members does not necessarily coincide with the Cartesian axis, one of the main concerns is how to evaluate the direction and magnitude of the nominal perturbing forces. In the following, we discuss this issue using the two-member structure shown in Figure 3. Four perturbing force conditions are applied to node N_2, which are load conditions f^x and $-f^x$ along with the positive and negative directions of the *x*-axis, and f^y and $-f^y$ along with the positive and negative directions of the *y*-axis, respectively. According to formula (2), the perturbing forces can be stated as,

$$f^x = rP\sin\alpha \qquad \alpha \in [0,\ \pi/2] \tag{3}$$

$$f^y = rP\cos\alpha \qquad \alpha \in [0,\ \pi/2] \tag{4}$$

where P is the axial force of the compression member, α is the angle between the member and the *x*-axis. Then, the maximum component forces of the nominal perturbing force perpendicular to the members L_1 and L_2 can be given as

$$f^1 = f^2 = \max\left\{rf^x\sin\alpha, rf^y\cos\alpha\right\} \qquad \alpha \in [0,\ \pi/2] \tag{5}$$

Adding equations (3) and (4) to equation (5), the nominal perturbing force perpendicular to the braced members can be stated as

$$f^1 = f^2 = \max\left\{rP\sin^2\alpha, rP\cos^2\alpha\right\} \qquad \alpha \in [0,\ \pi/2] \tag{6}$$

Therefore, as the angle between the member and the Cartesian coordinate axis varies from 0 to $\pi/2$, the perturbing force perpendicular to the braced members can be stated as

$$\frac{1}{2}rP \le f^1 = f^2 \le rP \tag{7}$$

This shows that when the member dose not coincide with any Cartesian coordinate axis, the effective component of nominal force in the direction perpendicular to the member axis is 0.5 to 1 time the calculated nominal force. According to equation (6), when the angle α is $\pi/4$, the nominal force perpendicular to the direction of the member obtains the minimum value, which is 0.5 times the calculated nominal force.

In this study, as an approximation, four nominal perturbing forces cases projected in either direction to the two Cartesian axes in plane truss are adopted. To ensure the axial force that can be provided by the bracing is at least 0.01 times the axial force of the braced member, the nominal perturbing force coefficient r is taken as 0.02.

2.3 Local buckling of member constraint

By introducing the critical Euler buckling load for a simply supported member, the local buckling constraint for the member i can be given as

$$-q_i \le P_i^{cr} = \frac{\pi^2 E I_i}{l_i^2} \tag{8}$$

where P_i^{cr} and I_i are the critical buckling load and the second moment of the sectional area of the member i, respectively, E is Young's modulus. For the tension member, formulation (8) is automatically satisfied since the axial force $q_i \ge 0$. Therefore, inequality (8) is only active for the compression members. For a member with a solid circular section, the second moment of sectional area can be expressed as,

$$I_i = \frac{a_i^2}{4\pi} \tag{9}$$

Adding the second moment of sectional area (9) into the local buckling constraint, the critical buckling area can be expressed as,

$$a_i^{cr} = \sqrt{\frac{4P_i^{cr} l_i^2}{\pi E}} \tag{10}$$

Obviously, the critical buckling load is a concave function on the cross-sectional area, which is difficult to obtain the optimal solution. Therefore, in this study, a novel iteration approach is used to make the local buckling problem into a linear expression on the cross-sectional area, as shown in Figure 3.

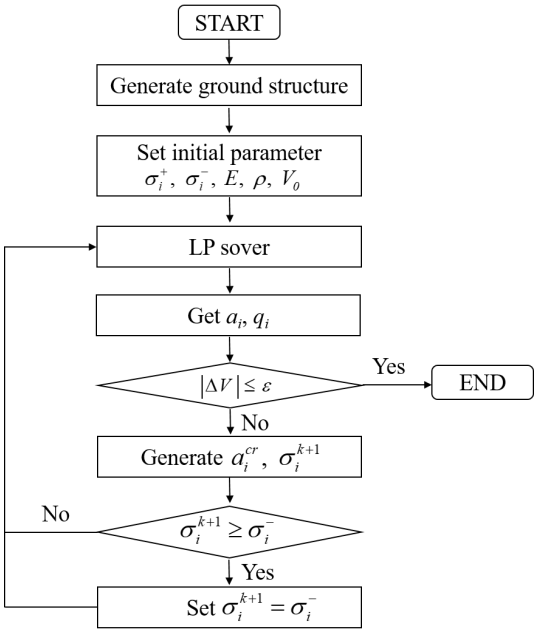

Figure 4. Flowchart of ASI method

where $|\Delta V|$ is the change in structural volume between four consecutive iteration steps, which can be expressed as

$$\left|\Delta V\right| = \left|\left(V^k + V^{k-1}\right) - \left(V^{k-2} + V^{k-3}\right)\right| \tag{11}$$

where V^k , V^{k-1} , V^{k-2} , V^{k-3} ($k \geq 4$) are the volume of structure at iteration *k, k*-1*, k*-2 and *k*-3, respectively. In addition, ε is taken as 0.001 in this study. If the convergence criteria are not met, for each member that is active in the solution, the limiting compressive yield stress for the next iteration *k* + 1 can be obtained by

$$\sigma_i^{k+1} = \sigma_i^k \frac{a_i}{a_i^{cr}} \tag{12}$$

where σ_i^k is the compressive stress in the member *i* at iteration *k*, a_i^{cr} is the critical buckling area of the member *i*, which can be stated as

$$a_i^{cr} = \sqrt{\frac{4\left|q_i^k\right| l_i^2}{\pi E}} \tag{13}$$

where q_i^k is the axial force of the member *i* at iteration *k*, $\left|\ \right|$ indicates the absolute value. However, direct use of σ_i^{k+1} obtained by (12) in the iterations is likely to cause cycling to occur. Therefore, a relaxation term η, the value of which is to be taken within zero to one, is introduced in the calculation, then the limiting compressive stress can be expressed as

$$\sigma_i^{k+1} = \eta\sigma_i^k \frac{a_i}{a_i^{cr}} + \left(1-\eta\right)\sigma_i^k \tag{14}$$

For members with other sectional areas, it is sufficient to modify the second moment formula (9).

It should be noted that the cross-sectional area of the bracing is generally small, and the minimum cross-sectional area of the member is limited in the structure design according to practical codes. Therefore, in this study, the local buckling of the bracing member is not considered.

3. Numerical applications

3.1 2D column

In this section, a two-dimensional column subjected to a vertical concentrated load are studied in order to verify the validity of the nominal perturbing force method. The bottom boundary of the design domain is hingedly constrained, where the horizontal and vertical displacements of the nodes are constrained. The middle of the top boundary of the column design domain is subjected to a vertical downward load $P = 1$. The design domain, boundary conditions and load are shown in Figure 5(a), where $H = 5$, $W = 1.6$. In addition, the height of the mesh grid is 1 and the width is 0.4. As shown in Figure 5(b), the ground structure contains 89 bars and 30 nodes.

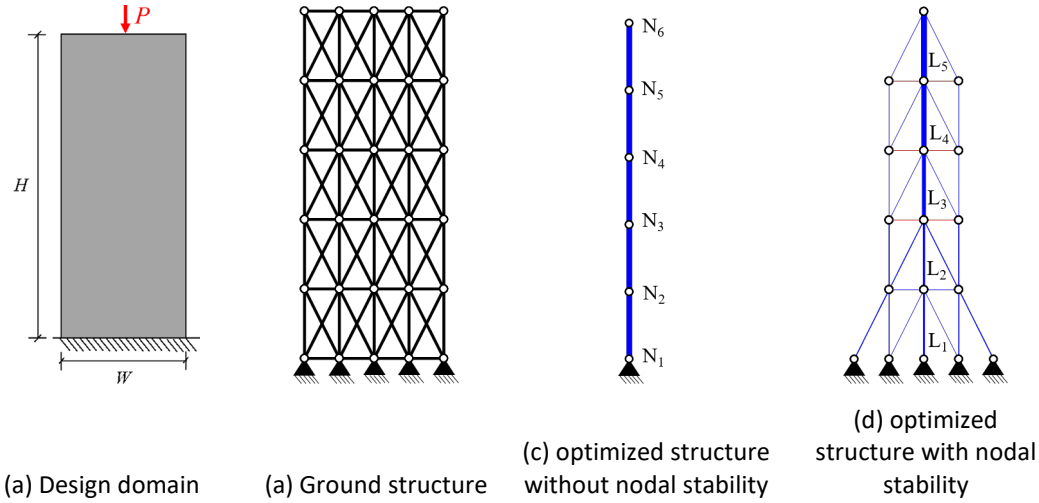

Figure 5. Topology optimization of 2D column design domain

Without considering the node stability, the optimized structure is shown in Figure 5(c), and the volume of the structure is $V_0 = 4$. Obviously, nodes $N_2 \sim N_5$ are all unstable nodes due to lake of lateral supports. When the nominal perturbing forces are applied to the ground structure, the optimized structure is obtained as shown in Figure 5(d). The volume of the structure is $V_1 = 4.286$, which is only $(V_1 - V_0)/V_0 = 7.15\%$ more than the volume of the structure shown in Figure 5(c).

As can be seen in Figure 5 (d), the cross-sectional area of the vertical bars of the structure gradually increases from bar L_1 to the upper L_5. This is because the lateral support bars provide not only lateral support but also vertical support for the unstable nodes. Obviously, the topology of the optimal structure considering node stability is completely different from that of the optimal structure without considering node stability. This shows that the use of the nominal perturbing forces method can ensure node stability by adjusting the topological form of the structure during the optimization process. It also shows that the optimization algorithm has the ability to globally search for optimal solutions.

3.2 Crane domain

As shown in Figure 4a, a crane design domain example is studied in this section, where L is 0.2 m. As shown in Figure 4 a, in the design domain, pinned supports are present on the bottom face and four-point loads P = 20 kN is applied downwards at the tip of the upper beam. Limiting tensile and compressive stresses are taken as 355 MPa. The design domain is discretized using 38 neighboring nodes (Figure 4b) connected by 173 potential members to generate an adjacent connectivity ground structure (Figure 4c).

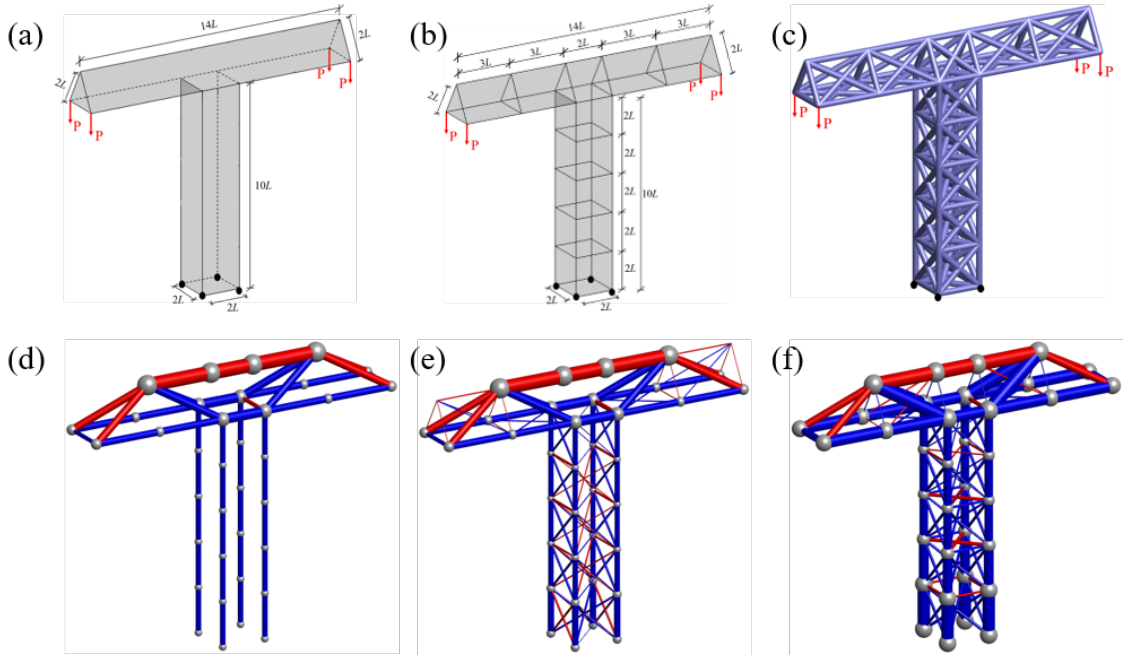

Figure 6. Optimization of crane [5]. (a) Design domain, (b) Mesh grid, (c) Ground structure, (d) optimized structure without stability, (e) optimized structure with nodal stability, (f) optimized structure with nodal stability and local buckling stability

The optimized structure with a volume of $V_{OSW} = 2.428 \times 10^6$ mm^3 is shown in Figure 4d when neither the nodal stability nor local buckling stability is considered in the optimization. However, almost all the nodes within compressive members are unstable, which cannot be used in practical applications, obviously. As shown in Figure 4e, when only the nodal local buckling stability is considered in the optimization, an optimized structure with a volume of $V_{OSN} = 2.635 \times 10^6$ mm^3 is obtained, where $\left(V_{OSN} - V_{OSW}\right)/V_{OSW} \times 100\% = 8.526\%$ more material is used to make the nodes stable. As shown in Figure 4f, an optimized structure with volume $V_{OSNL} = 5.607 \times 10^6$ mm^3 is obtained with both nodal and local buckling stability, where $\left(V_{OSNB} - V_{OSW}\right)/V_{OSW} \times 100\% = 130.931\%$ more material is used to make the nodes and local buckling stable.

Figure 6 shows two comparisons of the axial and critical buckling forces of the optimized structures. As shown in Figure 6a, when local buckling stability is not considered, the magnitudes of the axial forces of many members in the optimized structure exceed their critical buckling forces. When local buckling is considered in the optimization using the ASI method, the axial force and critical local buckling force of all compression members in the optimized structure are shown in Figure 6b. It can be seen from Figure 6b that the magnitudes of the axial forces of all the compression members do not exceed their critical buckling forces, which demonstrates the effectiveness of the ASI method proposed in this study.

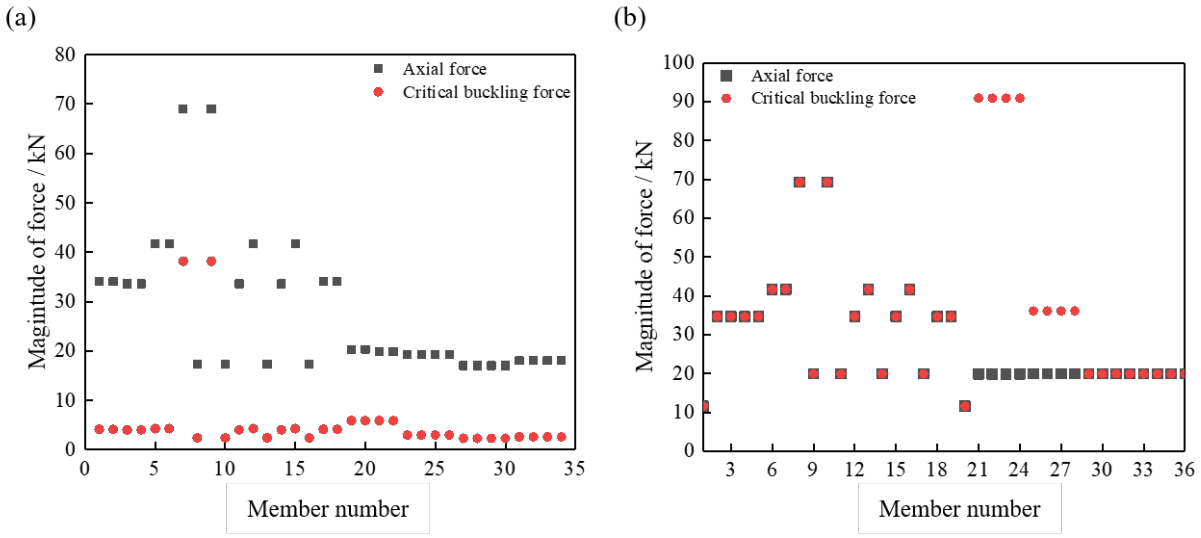

Figure 7. Comparison of axial force and critical buckling force of the crane. (a) optimized structure with nodal stability, (b) optimized structure with nodal stability and local buckling of members.

4. Conclusions

The nominal perturbing force (NPF) approach has been proposed to address the nodal instability in the truss topology optimization problem. In the NPF approach, nominal perturbing forces consistent with the directions of the Cartesian axes are used to model the possible perturbations of the unstable nodes. Compared with the conventional nominal lateral force (NLF) approach, (a) the NPF approach has higher computational efficiency because it contains fewer optimization variables; (b) the effect of tension members connected to the nodes is considered in determining the unstable nodes, which can lead to a better optimization result. In addition, the nominal allowable stress iteration (ASI) approach is proposed to address the local buckling instability in the truss topology optimization problem. In this way, the concave local buckling instability problem is linearized in each iteration and can be solved efficiently by a linear programming solver. Numerical examples have shown the practical applicability of the proposed method for the preliminary design of truss structures.

Abstract

Trusses are efficient structures that have been widely employed for stadiums, large-span bridges, and roofs among other numerous structural applications. In addition to being reasonably simple to build and maintain, trusses can also be aesthetically beautiful. Discrete topology optimisation focuses on finding the optimal truss configuration and cross-sectional dimension for the truss members within a particular domain, for given boundary and loading conditions. In most cases, the optimal structures (e.g. Michell trusses) may not be easily constructible or conceptually feasible. In actual practice, other design constraints and restrictions that are specified by regulatory (structural design and construction) standards also come into play. In this study, the discrete topology optimization is applied on different types of truss structures using a heuristic optimiser. Structural and architectural constraints are formulated based on structural design codes and constructability considerations for each structure type. A parametric study is then conducted to understand and compare the effects and importance of different constraints on the final optimal solutions, with respect to their feasibility and constructability.

Keywords: discrete topology optimisation, ground structure, buildability, design standards, optimization for design and fabrication, layout optimization

1. Introduction

The known history of structural optimization can be traced back to Galileo, who in 1638 determined the optimal parabolic shape of a cantilever beam with a point load at its free end [1]. Structural optimization of truss like structures began with the pioneering work by Michell [2]. Different structural optimisation problems have been solved including both continuous and discrete approaches. Discrete topology optimization problems are mostly used for topology optimization of frame like structures such as trusses. Frame like structures (including trusses) achieve the most optimal or economic design when every member in the structure is completely utilised with respect to its available strength. Truss optimisation methods can be categorised into size, shape and topology methods. The most common approach for topology optimization is to use a domain discretization such as the ground structure method which employs removal of elements from the ground structure [3]. Alternatives approaches include adaptive member adding methods [4] and growth methods [5].

The topology optimization problems are generally non-convex where gradient evaluations are impractical to solve by traditional optimization methods. In the last few decades many non-gradient optimization methods have been developed. Heuristic optimization methods are class of non-gradient

methods in which only function evaluations are employed. They are often inspired from natural phenomenon or behaviour of animals, birds or insects. Some of the popular heuristic methods are particle swarm optimization (PSO), genetic algorithm (GA), simulated annealing (SA), differential evolution (DE). The grey wolf optimiser (GWO) has been shown to be relatively performant and more robust with respect to the other heuristics [6]. The advantage of these methods is that the gradient of the objective function and constraints need not be found, while also ensuring a global solution. More insight about the heuristic methods can be found from the review article [7].

Most of the topology optimisation methods, however, focus heavily on minimising the total weight or the compliance of the system. Displacement, stress and buckling constraints are usually included as constraints [7], but the constraint limits are usually constant and simplified. However, most code limits are highly nonlinear. Structural design standard checks also include other factors such as member imperfection, slenderness, etc. Directly minimising the weight or maximising the stiffness may also lead to optimal solutions that are impractical or difficult to construct. There can be interest regions which are may be taken as infeasible or regions of interest. There are a few limited studies focusing on the constructability aspect of a topology optimisation process [8].

In this study, the ground-structure optimisation process is used for the discrete topology optimisation problem. The study also includes more realistic constraints based on the Indian standard on structural steel buildings (IS 800:2007) [9] for steel structures. The Grey Wolf (GWO) optimiser is employed to solve the minimal weight problem with the nonlinear code constraints and discrete cross-section variables. GWO has been shown to be relatively performant with respect to other common heuristic solvers [6]. A new constraint is proposed to include the regions of interest where structural members are required to present. This allows for the inclusion of constructability constraints that may be an important criterion by the designer. An optimisation formulation for topology optimisation is developed based on the proposed constraints.

The paper is organised as follows. Sec. 2 gives the formulation of the topology optimisation used in this study. The Grey Wolf optimiser is detailed in Sec. 3. This is followed by a numerical case study in Sec. 4. In Sec. 5, the final and concluding remarks are presented.

2. Topology optimisation

2.1. Standard constrained formulation

The most common objective function in truss optimization is the total cost of the structure. This may be expressed as the total weight or volume of members as scaling of the objective does not affect the optimizer. The standard constrained formulation can be formulated as [7]

$$\begin{aligned} &\text{Minimise: } W(\mathbf{A}) = \sum_{i=1}^{m} \rho A_i l_i \\ &\text{subject to: } -\min(\sigma_i^{cr}, \sigma_y) \le \sigma_i \le \sigma_y \\ &\qquad\qquad d_{\max} \le d_{\text{limit}} \end{aligned} \tag{1}$$

where the member cross-sectional areas comprises the design variable $\mathbf{A}=[A_1, A_2, \ldots, A_m]$ and bounded as $\epsilon \le A_i \le A_{\max}$, ρ is the density of steel, σ_i is the member stress for the i^{th} element, $d_{\max}$ is the maximum absolute nodal displacement due to the external loading, the strength in compression is the minimum of the Euler buckling stress (σ_i^{cr}) and yield strength (σ_y). The buckling stress for the i^{th} element is found using the known equation $\sigma_i^{cr} = \frac{\pi^e E I_i}{A_i l_i^2}$. Furthermore, the tensile strenght is taken as the yield strength σ_y with the displacement limit denoted by d_{limit}. The value of ϵ is taken to be a very small number so as to ensure the stiffness matrix is non-singular.

2.2. Implemented constraints

In this study, the optimization problem aims to minimize the total weight by selecting optimal discrete design variables from a database subset of cross-sections provided in IS 1161:1998 [10]. Apart from the constraints corresponds to strength and serviceability limit states of IS 800:2007, constraints based on regions of interest are also defined.

2.2.1 Design standard constraints

The IS 800:2007 is used to derive the design strengths used for the strength limits. The design tensile strength is similar to the constraint given in Equation (1) with the only difference being a reduction in the yield strength due to a partial safety factor. The tensile strength σ_t of a member is given as

$$\sigma_t = \frac{\sigma_y}{\gamma_{m0}} \tag{2}$$

where γ_{m0} is the material partial factor and is given as 1.1.

In the calculation of the compressive strength, the design strength formulation is more complex with the inclusion of the geometric imperfection parameter and the yield strength in the slenderness parameter. The design compressive strength σ^i_c of an i^{th} member is given as

$$\sigma_c = \min\left(\frac{\sigma_y / \gamma_{m0}}{\phi + [\phi^2 - \lambda^2]^{0.5}}, \sigma_y / \gamma_{m0} \right) \tag{3}$$

$$\phi = 0.5[1 + \alpha(\lambda - 0.2) + \lambda^2]; \qquad \lambda = \sqrt{\sigma_y / \sigma_i^{cr}} \tag{4}$$

where α is the imperfection factor dependent on the cross-sectional type and manufacturing process.

The displacement constraint is taken as the serviceability constraint given as

$$d_s = \frac{L}{100} \tag{5}$$

where L is the total span.

2.2.1 Interest regions

In most ground structure implementations, cross section area of all the members in the ground structure are taken as design variables for minimising the objective function. However, there can be constructability considerations such as infeasible regions where structural members are refrained to be present or regions of interest where non-loading building components such as service ducts in roof trusses may require members for connection or support. A simplified region can be defined by a rectangular region given as $I = [x_1, x_2] \times [y_1, y_2]$, where certain members in the ground-structure pass through. In the case the region represents an infeasible region, the ground structure can be generated so that no structural members are present within I [4].

This study introduces a new concept of including a region of interest in the domain. This constraint penalises the solution when there are no or very few members that cross a region of interest. This can ensure that the optimal solution may come out to a local solution, which may be of interest to the designer. The steps for enforcing the interest region are

Step 1. Find ground structure members within the region I denoted as $\mathbf{A}_I$

Step 2. Find number of members (c) in $\mathbf{A}_I$ with the tolerance minimal area given as

$$c = |\{A \in \mathbf{A}_I : A \leq \upsilon\}| \tag{6}$$

where $|\ .\ |$ denotes the number of elements or cardinality of the set and υ is the minimal tolerance cross-section value.

Step 3. The constraint is given such that

$$c < c_N \tag{7}$$

where c_N is a parametric value that limits the number of elements that should not have an area less than the tolerance area υ within the region of interest I. c_N can be regarded as the number of elements that can vanish from the ground structure in the region I.

2.3. Proposed optimisation formulation

The formulated topology optimisation formulation in this study is therefore given as

$$\begin{aligned} &\text{Minimise: } W(\mathbf{A}) = \sum_{i=1}^{m} \rho A_i l_i \\ &\text{subject to: } -\sigma^i{}_c \leq \sigma_i \leq \sigma^i{}_t \\ &d_{\max} \leq d_s \\ &c < c_N \end{aligned} \tag{8}$$

where $\mathbf{A}$ is the set of available cross sections that can be used in the truss structure.

3. The Grey Wolf Optimiser (GWO)

The Grey Wolf Optimiser (GWO) is a type of swarm-based optimisation algorithm inspired by the hunting behaviour of grey wolves [6]. The algorithm consists of a population or pack of grey wolves, where each grey wolf represents a candidate solution. The heuristic models the social behaviour and leadership hierarchy of the pack where an alpha wolf leads the pack. The update process of the

population is dependent on a searching step, circling prey step, attacking prey step and updating the alpha wolf position step. The population of the optimisation algorithm is given as

$$\mathbf{P} = [\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n] \tag{9}$$

where $\mathbf{P}$ is the population is categorised into α, β, δ and ω individuals, $\mathbf{X}_i$ is the i^{th} wolf candidate solution with fitness W_i. The individual positions of these enlist wolfs is given as $\mathbf{X}_\alpha^t$, $\mathbf{X}_\beta^t$ and $\mathbf{X}_\delta^t$ respectively. The α wolf is having the best fitness, followed by β and δ wolfs. The rest of wolfs are identified as ω which follows their superior wolfs while hunting. The pseudo-code for GWO is shown in Algorithm 1 with the detailed implementation given in [6]. An objective function $W(\mathbf{X})$ with a constraint $g_i \leq 0$ is formulated using a penalty approach where any violation in the constraint leads to the objective function being penalised as

$$W(\mathbf{X}) + W_{penalty} \tag{10}$$

$$W_{penalty} = W \sum k \max(g_i, 0)$$

where k is a constant.

4. Numerical study

In this section, the topology optimisation problem defined in Equation (8) is demonstrated using two truss problems. The initial ground structure considered and final optimal solutions is shown. In all the case studies, the values of $\sigma_y = 250\,\text{MPa}$, $E = 200000\,\text{MPa}$ and $\rho = 7750\,\text{kg/m}^3$ corresponds to E250 grade steel. GWO (Sec. 3) is used to minimise the penalized weight of the ground structure. The

constraints are added to the total weight using a penalty approach as shown in Equation (10). The number of search agents is taken as 30 and 6000 iterations have carried out for each run. A series of 20 runs is preformed, with the best solution from the above runs shown in the results. The problems are implemented in *MATLAB* in a Linux system having 8GB RAM. The set for available cross sections, $\mathbf{A}$ is taken from a subset of discrete tubular sections listed in IS 1161:1998.

4.1. Example 1

The first truss problem consists of a 5486.4 mm wide domain having a height of 2743.2 mm. Two loads of 445 kN are applied at the two points as shown in Figure (1a). The used ground structure is shown in Figure (1a). The diagonal members in the ground structure cross each other without a node, where physically the members may cross besides each other but not connected at that point. The optimal solution by solving the standard problem in Equation (1) is shown in Figure (1b). The formulated optimisation problem in Equation (8) results in the optimal solution shown in Figure (1c). In this problem, the region of interest constraint is not considered. The total weight for the two structures is 555.11 kg and 614.50 kg for the first and second case respectively. It can be seen that the weight of the standard solution is lesser than the constructable solution using the IS code constraint. The solution in Figure (1c) has thicker section, specifically along the diagonal as the constraint due to the design compressive strength is more conservative. The more conservative and lesser design strength with respect to global buckling causes the section to be thicker than the simplified Euler bucking constraint. Using the formulation based on a constant constraint limit can be therefore problematic especially in the case of structures that are optimally designed.

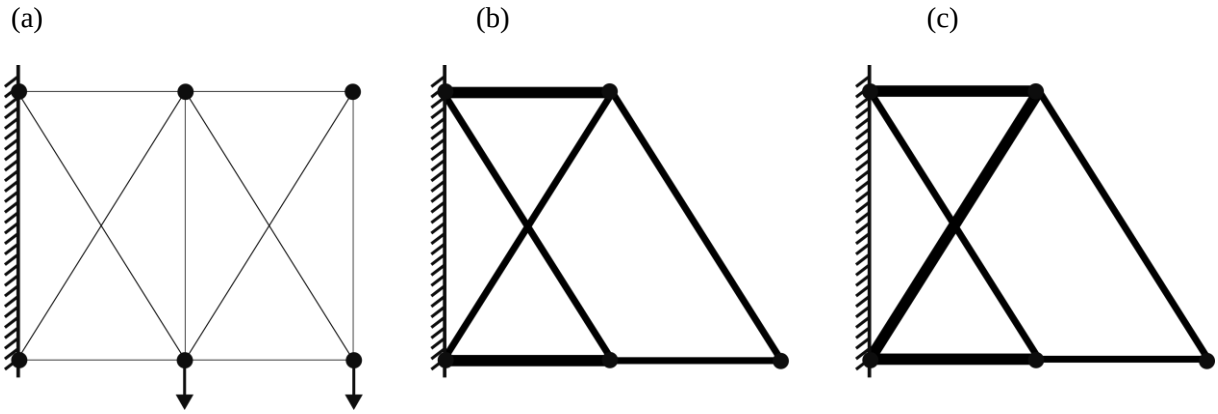

Figure 1. (a) Initial ground-structure with loading; (b) Optimal solution with standard constraints; (c) Optimal solution with codal constraints

4.2. Example 2

The second case study consists of 18.288 m $\times$ 18.288 m. A ground structure with a higher connectivity topology is taken as shown in Figure (2b). A single load of 445 kN is applied at the mid-point of right edge of the domain. The region of interest I is shown in Figure (2b) by the shaded region. The region of interest is constructed on the basis that some service lines pass through that region which needs to be supported by the members. The minimal area is taken as υ. Therefore, the constraint imposes that there should be at-least $c_N = 4$ members in the region I. The optimal solution while solving Equation (1) without the interest region constraint is shown in Figure (2c). The optimal solution for the constrained solution ($c \leq c_N$) is shown in Figure (2d). It should be noted that both cases consider the code design constraints. The total weight in the first case is 1855.7 kg and in the second case is 2051.3 kg. It is

observed that the truss in the second case has members present in the grey interest region. The weight of the structure is also not significantly different from the unconstrained case. Therefore, the proposed approach can help in finding local solutions that satisfy the defined constructability constraints.

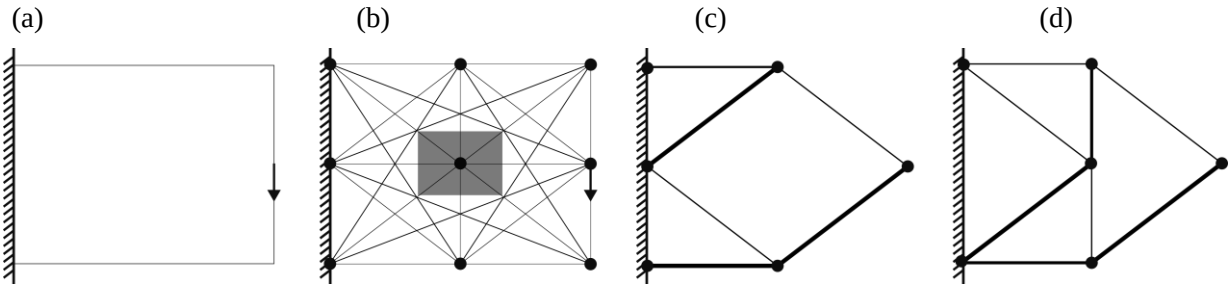

Figure 2. (a) Initial domain; (b) Ground-structure with region of interest I (shaded area); (c) Optimal solution without interest region constraint; (d) Optimal solution with interest region constraint

5. Conclusion

Topology optimization can be an elegant tool in finding the most optimal form of structures particularly for discrete truss systems. This study introduces a topology optimisation formulation based on Indian standard design limits and additional constructability constraints. The concept of interest regions is introduced to shift the optimal solution to slightly local solutions having members located at the specified regions of interest. This is advantageous as different local solutions can be attained by the designer on the basis of construction and service requirements. The optimal solution is found using a GWO heuristic solver which is overall found to be relatively robust. Overall, the proposed study is shown to highlight the importance of using actual design constraints. The use of the interest regions is also shown to be helpful in providing an alternative constraint defined by the designer in the topology solution.

Abstract

We propose a new strategy for generating staggered patterns for standard, rectangular tiles on free-form surface. The given input surface is firstly tessellated into near-square quadrilateral faces using a re-meshing algorithm. Afterwards, we run a matching algorithm that assigns each tile to two adjacent faces. We use binary integer programming to find a tessellation on the surface that minimises the number of unique tiles and tiles that are not staggered. Lastly, we generate the tiles and post-process the tessellation result.

Keywords: tile vaulting, tile pattern, free-form surface, quadrangulation, binary integer programming

1. Introduction

Shells and vaults are efficient structures whose form follows the flow of forces. They emerge again in contemporary architecture because of the emergence of computational form-finding techniques to design them as well as for their sustainability. Specifically, for longer spans, shell structures require less material quantities and for funicular vaults lower-strength materials, which typically have reduced embodied carbon coefficients [1–3].

Among the methods of constructing shells and vaults, thin-tile vaulting is a 600-year-old Mediterranean technique that requires minimum formwork during its construction and relies on traditional manufacturing of the tiles. The flexibility offered by non-uniformly spacing of the tiles, by using small offset deviations in the mortar joints, a wide range of shell geometries can be achieved with standard tile shapes. However, tile vaulting dropped in popularity due to (among many factors) the high cost of skilled labour, emerging competitive materials, namely steel and concrete, modern building codes and the onset of modernism that favoured straight lines [4–6] . The construction of tile vaults involves skilled masons adjusting the direction of the tile, handling the mortar thickness, and cutting the tiles on site dextrously to follow the curvature and gradually fill the surface. This process can become especially challenging when the surface is geometrically intricate [7], [8].

Recent research suggests that this complexity can be partially overcome with the help of robotic fabrication and augmented reality, as the tiles can be precisely registered in 3D. The craft-specific tasks can be executed in a fully automated manner or by collaboration between humans and machines [9–11]. However, the main challenge remains in the generation of tiling patterns, i.e., where, and how to place the single-sized tiles on a free-form surface.

This paper focuses on how to compute a tiling pattern on a free-form surface and tries to find a global solution to the tiling pattern that can achieve both aesthetic requirements and reduce fabrication complexity, which means a minimal amount of customised cutting on-site. Specifically, this paper focuses on the shells and vaults with small to medium span and surface curvature large compared with the tile size.

2.1. Surface geometry and tile pattern

The process of traditional tile laying involves a series of technical decisions that impact various aspects of a structure, such as its strength, stability, aesthetics, constructability, and cost-effectiveness [1], [6], [8]. This section will discuss two examples of tile-laying patterns, examining the challenges and opportunities they present in terms of research and construction.

Guastavino vaulting is not only structural but also decorative [6]. The sophisticated decorative tile patterns exposed in their buildings (Figure 1. left) are accomplished by highly skilled masons by applying a final decorative layer from below. This step allowed the creation of more complex tile patterns without consideration of the construction sequence. However, in some cases, it's simply impossible to use a single pattern to fill a surface, for example, using a herringbone pattern to construct a dome without compensating for the smoothness and customised cutting (Figure 1. middle). In such situations, Guastavino uses multiple pattern patches instead of using a single pattern, which not only makes the vault decorative but also resolves the tiling problem for the three-dimensional forms.

The method of separating the shell in a full or partial manner also exists in other designs, to accommodate the surface aesthetics and tessellation pattern. For example, the glass vault is a doubly-curved barrel vault built by two robotic arms without a centring [10]. It adopts a herringbone pattern to interlock the bricks and defines a clear construction sequence for the robots to build alongside the first arch, and from bottom to top. To accommodate the amplified gap sizes due to curvature changes at the scale of the final structure, the tessellation pattern is shifted by half a brick along the reset lines (Figure 1. right), along which the herringbone pattern stops. Moreover, the vault uses irregular tiles at the boundary to ensure compete pattern on the shell surface.

Figure 1. left: some examples of Guastavino tiling patterns[6]; middle: the dome at the Chapel of Our Lady (photo credits: Michael Freeman); right: tiling pattern and reset lines of the glass vault [10].

2.2. Computational tile and brick laying

A few researchers have tackled the problem of tile laying to find a suitable mediation between aesthetics and structural behaviour. Shaghayegh [12] developed a design tool that can semi-automatically tessellate bricks on a curved surface by sequentially projecting the tiles. The workflow requires the designer to first choose a pattern in 2D and the start point of the first tile. Afterwards, the algorithm can compute the location of the adjacent tile by referring to the previous ones. However, the transformation and projection of the next tile is based on the local positions of the previous tiles, and thus globally, cutting the tiles is inevitable.

Adiels et al. [13] compute the geodesic distance on the curved surface to guide their tessellation process. This approach yields several benefits, such as effectively aligning patterns with boundaries and enabling the creation of running bond designs. However, this method faces challenges to accommodate other tiling patterns and singularities, where tiles need to be arranged circularly.

Unlike these methods based on geometry, Panozzo et al. [14] formulate the patterning as a 2-colouring graph problem on a quad mesh, i.e. the staggered pattern is created by removing every second edge of a regular grid. Although this research does not focus on tessellation with rectangular tiles, the approach of combining geometric and topological methods serves as an inspiration for our research.

2.3. Surface paneling and rationalisation

Surface panelling, a related topic to tile laying, involves filling a curved surface with geometric or manufacturing constraints. The problem is typically tackled through a two-step process: first, segmenting the shape into smaller pieces, and then, approximating each segment with a panel within a given tolerance [15], [16].

According to Pottmann et al. [17], good segmentation is crucial to achieving an accurate approximation. This can be accomplished through techniques such as polygonal mesh layout, re-meshing, and patch decomposition. Though segmentation is usually a decision driven by the designers, a good segmentation can lead to a good approximation.

One typical approximation task is driven by the need to fabricate the panels with a limited number of moulds to reduce the overall cost. Eigensatz et al. [16] assign the panel type, such as planar, cylindrical or custom, to each segment and interleave discrete and continuous optimisation steps to improve the quality of the panelling and to reduce the number of moulds while still keeping the kink angles and gaps within tolerance.

Approximation can also be driven by a desired panel shape. Shape-up [18] is an optimisation framework for geometry processing that enforces shape constraints in a local-global iterative algorithm. In the local step, the distance between each vertex in the mesh and its projections under multiple constraints is encoded. The global step then minimally relocates the vertices on the mesh to match the projected fragments and solves a single energy function to minimise deviation from the local shape approximation, input surface, and surface smoothness.

3. Proposed approach

In this paper, we propose a three-step method to generate tile-laying patterns on a free-form surface, as shown in Figure 2. This method finds a global solution to tessellate the surface and while keeping the need for unique cutting small.

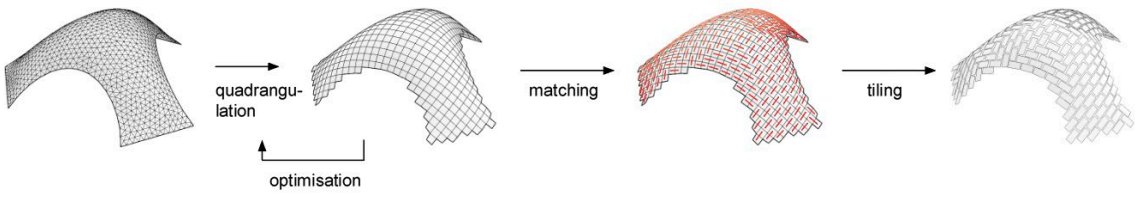

Figure 2. The proposed three-step tile patterning workflow.

The three steps are:

1. quadrangulation: generating a global quad mesh from the input surface;
2. matching: finding a (mostly) surface-covering combination of pairs of two neighbouring quadrilateral faces; and,

3. tiling: generating tile geometries.

3.1. Quadrangulation

We first convert the input surface into a quad mesh. Quadrangulation is an important topic in computer graphics and architectural geometry [19]. Similar to the panelling task described in Section 2.3, a good initial quadrangulation can reduce the efforts of post-processing and further optimising the mesh surfaces. We aim to partition our reference surface into a semi-regular quad mesh, whose quadrilateral faces are close to squares of equal size and where the number of singularities remains small.

We have considered two approaches. The first one is based on parametrisation, which means mapping the surface embedded in 3D to a domain in 2D and tessellating the 2D domain by regular grids. However, to reduce distortion, we need to find a correct set of seams either to cut the geometry and restitch it or the correct placement of singularities, which is challenging to compute and easily leads to areas with locally high distortion. These situations are not ideal for our tile arrangement in the next steps.

Thus, we instead adopt a field-guided approach, which uses an orientation field and prioritises higher distortion reduction. This approach is typically composed of three steps:

1. Generate an orientation field. This orientation field is driven by principal curvature and defined continuously over the surface. If the field is locally not smoothly aligned in a region, a singularity can occur, resulting in an irregular vertex in the quad mesh, which in our case, means an irregular tile.
2. Compute a position field, determining where the vertices are placed. Since square faces are preferred, the sizing function should be isotropic.
3. Synthesise the quad mesh.

We use the QuadriFlow algorithm without boundary constraints for this re-meshing step [20]. It allows for the efficient production of scalable quad meshes with minimal distortion while maintaining a low number of singularities. We use the tile dimension to estimate the target mesh edge length. In general, the algorithm provides a reasonable approximation of the half-tile locations; however, some level of distortion is inevitable. Here we present two quadrangulation outcomes for a surface (as illustrated in Figure 3, left and middle), and evaluate their area and angle distortion with respect to the squares. For this surface, the presence of the singularity can cause the faces near it to become smaller and more distorted, resulting in overlapping tiles. If the singularity is removed, bigger gaps will appear in the middle of the shell. If neither of the two solutions is satisfactory, we can further enhance the mesh quality by imposing square shape constraints. For the latter, we use the shapeup optimisation solver implemented in libigl [21], and the outcome is displayed in Figure 3, right. It is important to note though that due to the shapeup optimisation the shape of the mesh deviates from the original input shape.

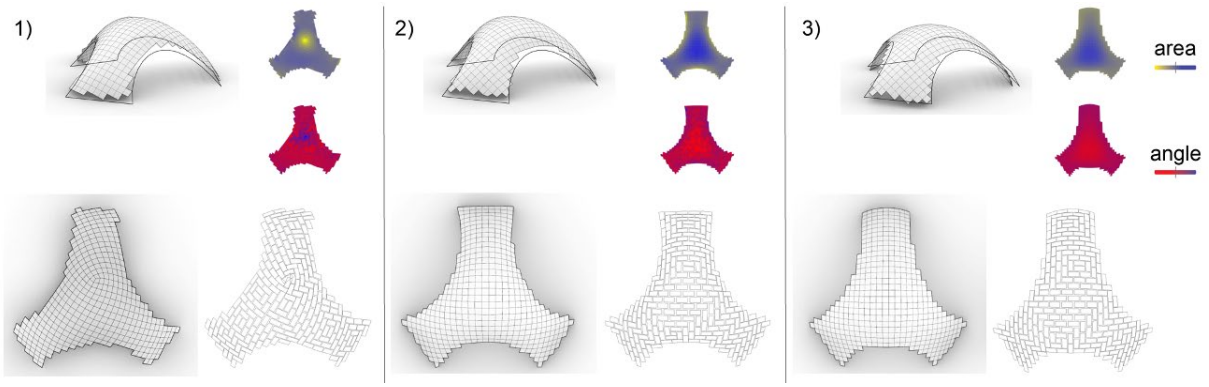

Figure 3. Left and middle: quadrangulation result with singularities without singularities; right: quadrangulation result after shapeup optimisation.

3.2. Maximal matching

Section 3.1 has discussed how to generate a high-quality quadrilateral mesh with faces close to squares of equal size. Based on this mesh, an arrangement of rectangles can be generated by connecting pairs of adjacent faces. One face can only be connected either 1 time or 0 times. If it is not connected, the face represents a half-tile, which needs additional cutting. Thus, maximising the pair of adjacent faces to generate as many tiles as possible can be formulated as a graph-matching problem.

Given the set of faces F and the possible edges E that connect adjacent faces, the goal is to find the maximal number of matched edges E', where E' is a subset of E, such that no two edges in E' share an adjacent face.

This problem can be formulated as a binary integer program:

Let edge connectivity $\mathrm{x_e} \in \{0,1\}$, $x_e = 1$ if $e \in E'$, else $x_e = 0$. For one face, let $E(f)$ denote all edges that connect a face f. Taking Figure 4. left as an example. For face f_4, the edges that connect to it are listed in $E(f_4) = \{e_{14}, e_{34}, e_{45}, e_{47}\}$. One face can be at most connected to one adjacent face. If f_4 and f_7 are connected, for example, $x_{47} = 1$ and $\mathrm{x_{14}} = \mathrm{x_{34}} = \mathrm{x_{45}} = 0$.

Our problem can be written as follows:

$$\begin{aligned} &\max \sum_{e \in \mathrm{E}} x_e \\ &s.t. \sum_{e \in \mathrm{E(f)}} x_e \leq 1, \forall f \in \mathrm{F} \end{aligned} \tag{1}$$

We use the Gurobi Optimizer [17] to solve the binary integer program (1). Figures. 3-2, middle and right, show the matching result for a 10x10 grid and an 11x11 grid. The total number of faces for an 11x11 grid is odd, resulting in one unmatched face. Note that many edges are parallel, which can cause continuous mortar joints in real tile-laying. We address this problem in the next section.

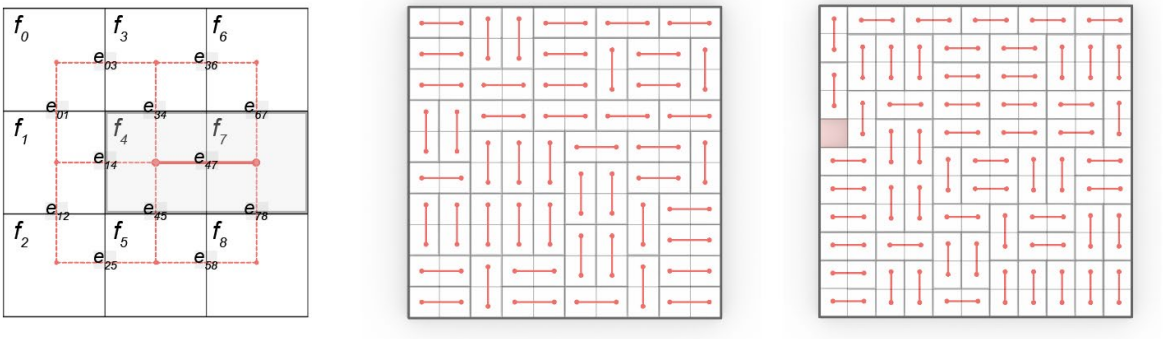

Figure 4. left: A mesh composed of nine faces and the connectivity between them. f_4 and f_7 are a connected face pair; middle and right: the matching result for a 10x10 grid and an 11x11 grid using binary integer program (1).

3.3. Staggered pattern

In tile vaulting, the tiles are often staggered to avoid continuous mortar. To avoid parallel edges, as is the case in Section 3.2, we can formulate them as penalties in the objective function.

We introduce a new set of variables $\mathrm{y_{e1,e2}}$ to describe neighbouring parallel edges. Let $\mathrm{y_{e1,e2}} \in \{0,1\}$, $\mathrm{y_{e1,e2}} = 1$ if and only if both $e_1, e_2 \in E'$, else $\mathrm{y_{e1,e2}} = 0$. Taking the example in Figure 4. left, edge e_{47} has only two neighbouring parallel edges e_{36}, and e_{58}. We know that f_4 and f_7 are connected, so

$x_{47} = 1$. Assume f_3 and f_6 are connected, $x_{36} = 1$. Now, we have a pair of parallel neighbouring edges, so $y_{e47,e36} = 1$. In our objective, we can penalise this situation.

The optimisation problem with penalties can be written as follows:

$$\begin{aligned} &\max \sum_{e\in E} x_e - w * \sum y_{e1,e2} \\ &s.t. \sum_{e\in E(f)} x_e \leq 1, \forall f \in F, \\ &x_{e1} + x_{e2} - y_{e1,e2} \leq 1, \forall y_{e1,e2} \end{aligned} \tag{2}$$

The weight w for the penalty term can be chosen to tell the optimiser how it should balance between avoiding unmatched faces and parallel edges if no solution is possible that avoids both.

The solutions found by Gurobi for the 10x10 and 11x11 grids are shown in Figure 5. The results show high similarities to state-of-the-art patterns observed in tile vaults built by expert masons. Our algorithm can also generate a staggered pattern for mesh with singularities (Figure.5 right).

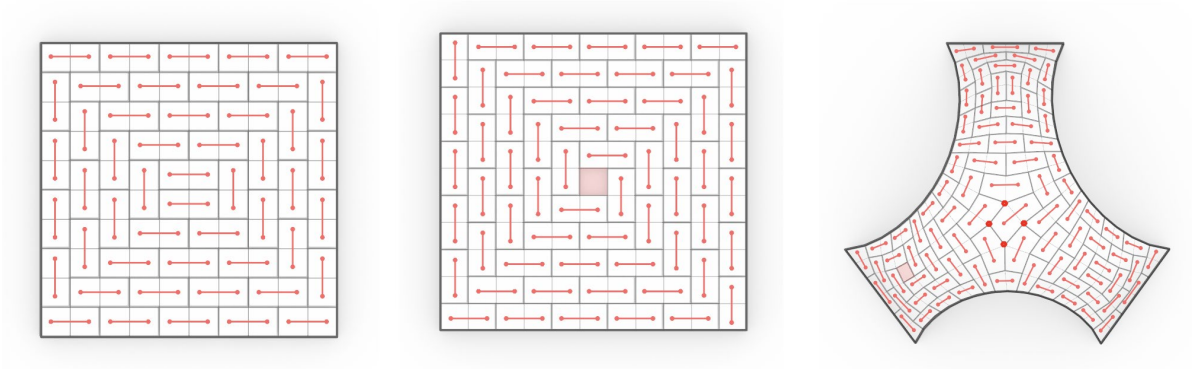

Figure 5. left and middle: staggered pattern for a 10x10 grid and an 11x11 grid, respectively; and right: staggered pattern for mesh with singularities, which are shown as red dots.

3.4. Other patterns

Other tile patterns, e.g., a running-bond or herringbone pattern, can be targeted by replacing the penalty term for parallel edges described in Section 3.3 with a different term that penalises or rewards certain combinations of edges.

For example, we can optimise for a running-bond pattern by using a term that rewards pairs of parallelly shifted edges, as shown in Figure 6. left (i.e. the edges are in neighbouring columns or rows of the grid but "shifted" by one row/column). This can be done by introducing a new set of binary variables $z_{e1,e2} \in \{0, 1\}$, which exists for every neighbouring shifted pair $e_1, e_2 \in E$. Again, as in Section 3.3, we add a set of constraints that enforces $z_{e1,e2} = 1$ if and only if both $e_1, e_2 \in E'$. These constraints look different because the $z_{e1,e2}$ contributes positively to the objective function while the $y_{e1,e2}$ in Section 3.2 contribute negatively. Our problem is written as follows:

$$\begin{aligned} &\max \sum_{e\in E} x_e + w_R * \sum z_{e1,e2} \\ &s.t. \sum_{e\in E(f)} x_e \leq 1, \forall f \in F, \\ &z_{e1,e2} \leq x_{e1}, z_{e1,e2} \leq x_{e2}, \forall z_{e1,e2} \end{aligned} \tag{3}$$

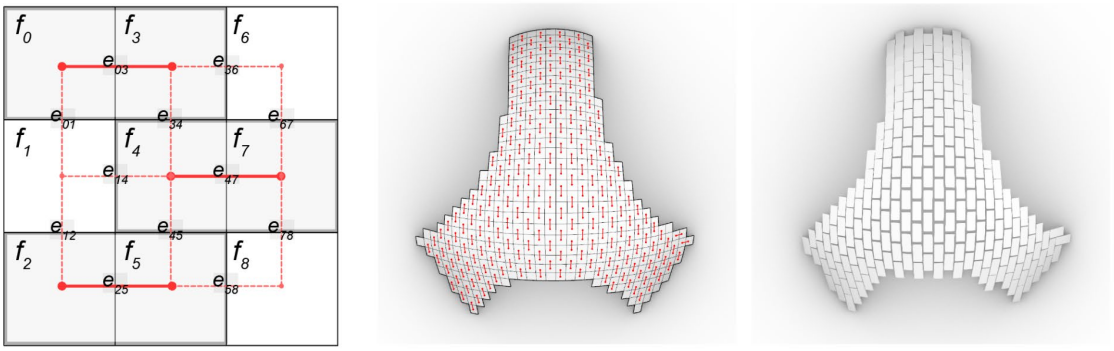

Figure 6. Running bond pattern and the connected face pairs; middle and right: running bond pattern outcome using quad mesh from Figure 3. right.

3.5. Generate tiles

After the matching process, the tile geometries can be generated using the facial information of the matched faces. We establish the origin of the tile by determining the midpoint of the line that connects the two centroid points of the face, and consider the direction of the line as the tile's length direction. Next, we compute the best-fit plane of all the vertices on the two faces, with the plane's normal being used as the thickness direction of the tile. By calculating the cross product of these two directions, we obtain the height direction, allowing us to construct the tile using these three directions. We implemented this step in Rhino 7 using the COMPAS framework [22]. The results are displayed in Figure 3. and Figure 6., right.

4. Results and discussion

4.1. Results

We apply the tile laying method explained in section 3 to the doubly curved free-form shells shown below. Our method produces satisfactory results for the shallow shell with small curvature (as depicted in Figure 7.), accurately computing the quadrilateral mesh and staggered pattern without any noticeable gaps or overlaps. However, for the shell shown in Figure 8., taking the geometry of [8], we observe larger gaps in regions with higher curvature, as explained in Section 3.1.

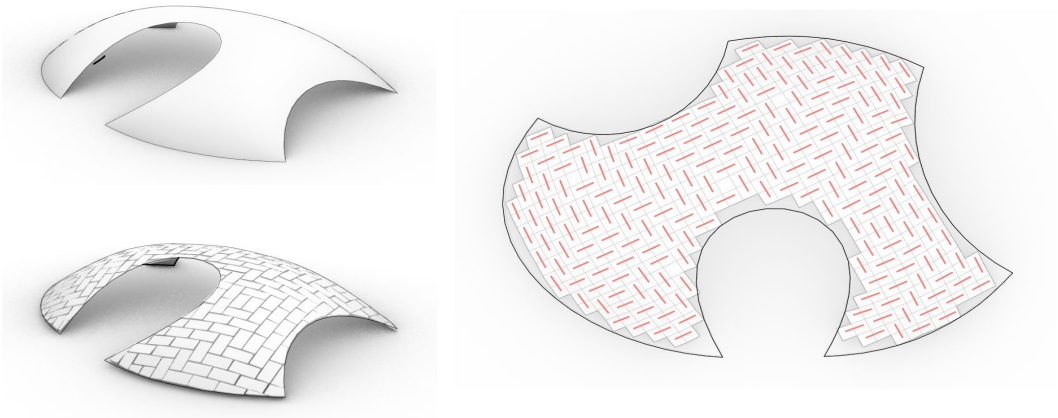

Figure 7. input mesh, tiled surface with irregular tiles at the boundary, and quadrangulation and matching outcome of a shallow shell.

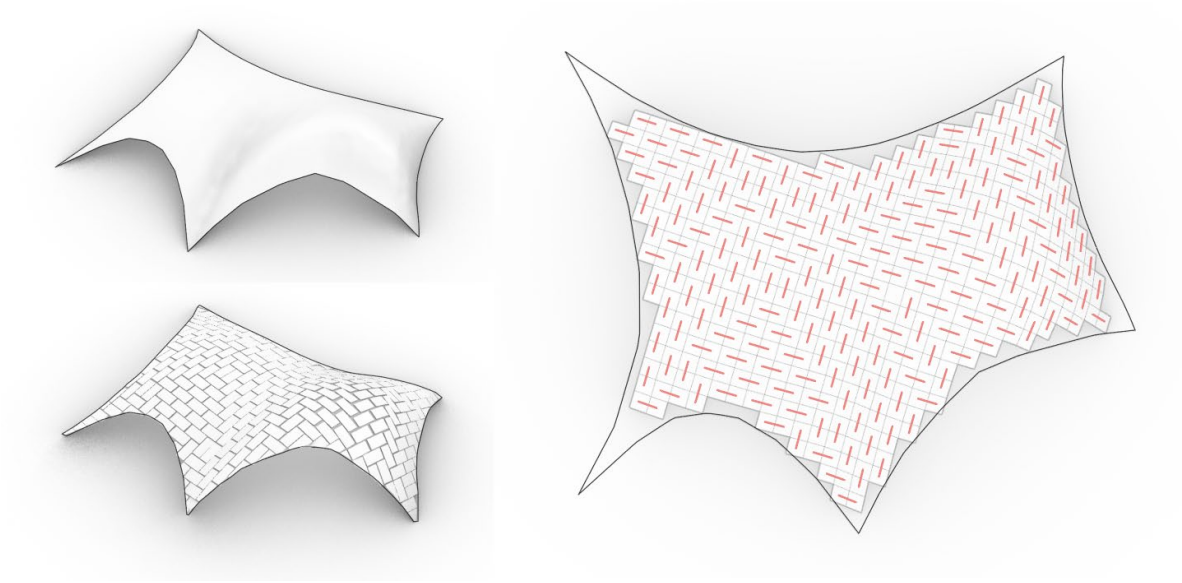

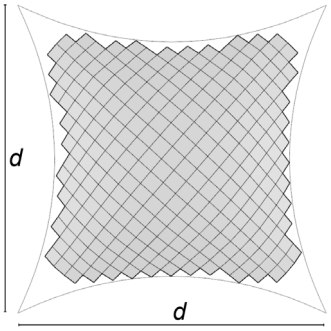

Figure 8. input mesh, tiled surface with irregular tiles at the boundary, and quadrangulation and matching outcome of a shell with higher curvature.

4.2. Performance

To evaluate the performance of our method in section 3, we conduct tile patterning on a shell with dimensions (d) as shown in Figure 9. left. The shell is supported at its four corners and tessellated with tiles measuring 280 × 140 × 15 mm. We ensure that all the quadrilateral faces have edge lengths greater than 140 mm. The dimension of the shell and the number of the faces are shown in Figure 9. right. The experiments are performed on a MacBook Pro (2020) with macOS 13.2.1, Apple M1 CPU and 8 physical cores. The computing time for section 3.1 is less than 1 second, and the computing time for section 3.2 using Gurobi Optimiser v10.0.0rc2 is listed in Figure 9. right. The time is the total (real) time reported by the time command. Our results indicate that the computing time grows exponentially with the input size. For a shell covering an area of approximately 50 m^2, the computing time is about 3 minutes.

Shell dimension	Number of faces	Time (section 3.2)
1.5 m	89	0.01 sec
2.5 m	185	0.20 sec
3.0 m	270	1.29 sec
4.5 m	531	8.85 sec
5.8 m	1192	30.58 sec
7.2 m	1679	183.19 sec

Figure 9. left: The input shell geometry; right: comparison of different shell dimensions, number of faces derived from section 3.1, and the corresponding computing time for section 3.2.

4.3. Contribution

Our approach tackles tile laying as a three-step global problem instead of a sequence of local problems. The presented approach allows us to adapt to different laying patterns by modifying the objective function in the matching step (as described in Section 3.4). Compared to other state-of-the-art methods, our approach can significantly reduce the need for customised cutting in the tiling pattern, particularly for smaller shell surfaces where the curvature is high in comparison to the tile dimension. For nearly developable surfaces, our approach can almost automate the tile-laying process, with little decision-making from the designers. For other free-form surfaces, our approach requires the designer to run an optimisation step after the variable quadrangulation to find a tileable mesh or separate the input surface into more developable patches.

4.4. Discussion

Our method relies purely on geometry and topology. We can compute different design solutions by changing the direction of the orientation field, such as changing it by 45 degrees or modifying the objective function in our matching step. However, our method cannot avoid distortion at the singularities, and in most cases, the resulting quadrangulation cannot align with the input surface boundary. The responsibility of balancing constructability and aesthetics still lies with the designer.

Additionally, solving the matching problem using a binary integer program solver can be prohibitively expensive for larger inputs (as discussed in Section 4.2). To deal with larger input sizes, one can split the input into smaller parts and solve the problem one part at a time.

Finally, our method does not consider structural behaviour. If we extend this method for tessellation patterns in masonry structures, there is potential for improvements by aligning the orientation field with the direction of force flow within the structure.

Acknowledgement

This research is supported by the A/T doctoral fellowship at ITA, ETH Zurich. Thanks to Ziqi Wang for the discussions and the suggestion for using Shape-Up for the shape optimisation step. Thanks to Stephan A. Kollmann for the discussion about the binary integer program, and correcting the notations in Section 3.

Abstract

The manufacturing industry is undergoing rapid changes, requiring flexible and adaptable production environments. Mobile transformable structures, based on rigid folding origami, offer a solution for creating self-supporting rigid enclosures that can be easily transported and opened. Longitudinal folding systems allow for compactness by reducing the thickness of the axes, and origami-based patterns can be modified to adapt enclosures made of lightweight composite materials. Spherical scissor systems offer constant trajectories for actuating the transformable system. This study presents the design and implementation of a hybrid folding and scissors system enclosure for manufacturing tasks. The enclosure can be manually opened and closed and compacts to less than one-third of its original size. The lightweight and rigid folding shield is composed of composite panels with elastic hinges. A scaled prototype was developed and tested, demonstrating the potential of the system for use in manufacturing tasks. This study highlights the potential of the system for providing protection in manufacturing environments and suggests that it could be further optimized for a range of applications.

Keywords: deployable structures, folded plate structures, origami, scissor systems

1. Introduction

Mobile transformable structures can adapt to different environments, allowing easy transport or opening. With rigid folding origami, these structures generate self-supporting rigid enclosures [1] suitable for dividing spaces or as movable walls or roofs. Longitudinal folding systems tolerate great compactness due to the ability to slide hinges and reduce the thickness of the axes [2]. These origami-based patterns are modified to adapt enclosures that may be composed of lightweight composite materials [3]. A study of the movement of its deployment allows us to design specific trajectories for actuating the transformable system. Spherical scissor systems can adapt to constant trajectories with spherical mechanisms [4]. Implementing several transformable hybrid systems enables its deployment and limits the number of degrees of freedom.

1.1. Protection enclosures

Integrating digital manufacturing techniques in construction has revolutionized the creation of personalized designs that cater to specific procedures, such as cutting, milling, assembling, and welding. These procedures are often carried out by industrial robots, which exhibit exceptional scalability and versatility but require specific installation specifications. However, the current approach to creating manufacturing spaces typically involves static elements like sturdy walls or enclosures that are challenging to modify to meet new requirements, especially when frequent assembly and disassembly are necessary. With the rapid development of the manufacturing industry, there is a growing demand for flexible production environments.

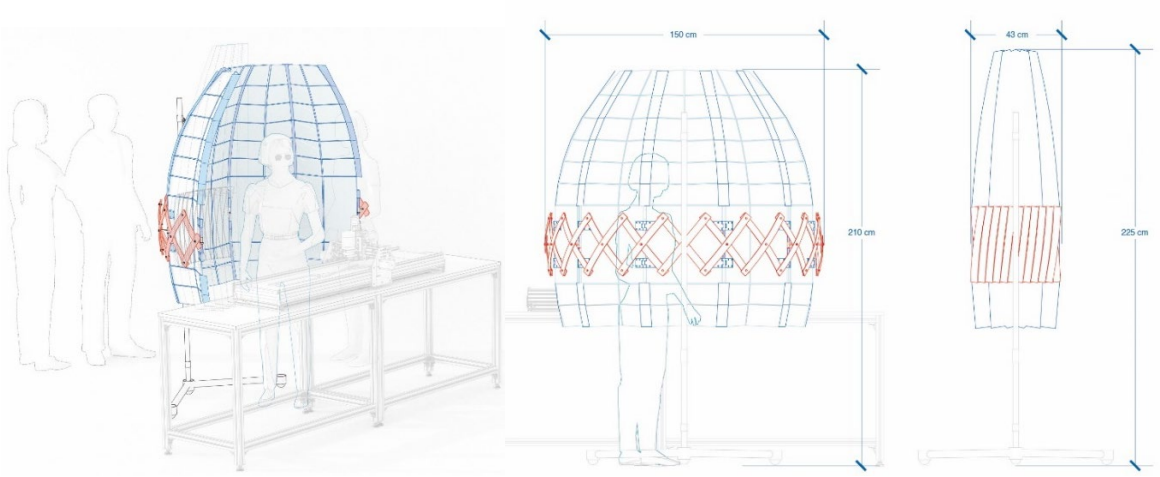

Figure 1. Concept of a foldable spherical shield for manufacturing.

To meet the demands of the industry, protection elements such as transportable shields are necessary to provide a safe working environment, either for machines or workers during manual labour. The shields aim to contribute for a safe environment protecting from hazards that may arise during manufacturing: flying sawdust chips, grinding sparks, intense welding lights or others.

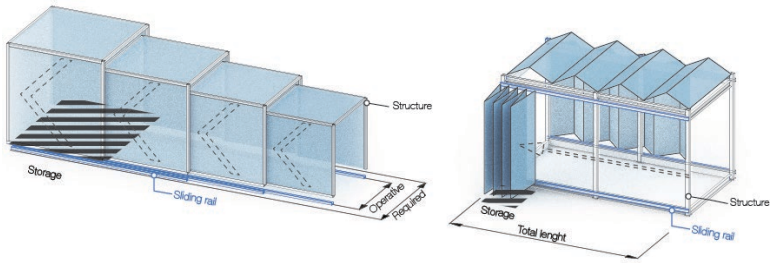

Figure 2. Standard sliding and folding transformable enclosures in manufacturing and industrial production cells.

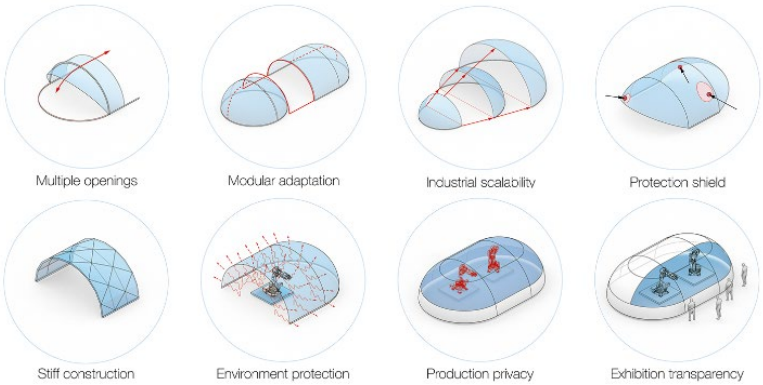

Figure 3. Characteristics of deployable enclosures and protective shields for manufacturing environments

To keep pace with the evolving manufacturing industry, the design of mobile enclosures and protection shields has become increasingly critical (Figure 2). The flexibility of production processes requires the use of highly adaptable and transportable elements. These enclosures allow manufacturing processes to be carried out in different locations, reducing the need for extensive capital investments in permanent

facilities. Mobile and deployable enclosures and shields can be easily reconfigured to suit different production needs and are ideal for responding quickly to changing market demands.

1.2. Technical origami and folded plate structures

The combination of origami patterns and quasi-rigid plates with finite thickness can be called technical origami or technical folding [5]. The efficient load transfer of such structures is known to this effect. If a locking of defined states is ensured for convertible folding structures, the load-bearing behavior is identical to rigid folding structures. For locking, frames and/or guides are necessary which also have to fulfill complex movement tasks due to the connection with the folding surfaces. In the case of non-parallel folding lines, the folding mechanisms for finite-thickness panels must be assigned to spherical or even spatial gears.

The folding mechanisms can be designed in such a way that they can be easily assembled and disassembled. Due to these properties, there is a high potential for their use in the manufacturing industry.

Example [6], [7] shows how the presented process can be applied in production environments. By incorporating a spherical geometry, a folding pattern can be brought closer to the workspace in question (Figure 2). Folding units with convertible frames offer advantages over conventional motion devices with rigid frames. However, the complex kinematic and dynamic dependencies involved complicate the design and planning process. Motion task-oriented design processes [8] incorporate the kinematic and kinetostatic metrics. The integration of a folding mechanism toolbox for multibody simulations ensures that the folding mechanism is designed to effectively perform the necessary motion tasks.

2. Deployable foldable design

In the following, the design and its geometrical optimization of a spherical folding unit including the frame for a protective shield that can be used flexibly in production is explained.

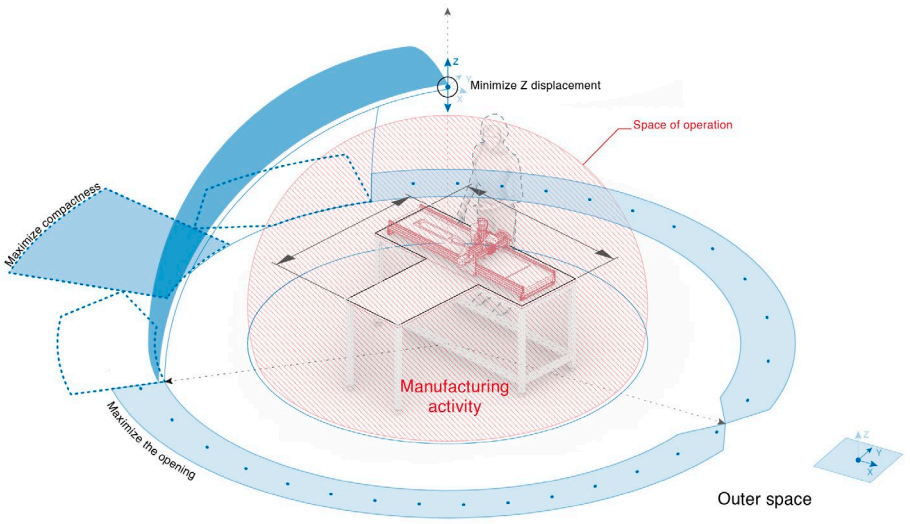

Figure 4. Design constraints: definition of the space for manufacturing tasks (red), the definition of the opening ways on the floor (blue), the definition of the storage area to maximize the compactness (left).

2.1. Geometry definition

The geometry design starts by defining design constraints (see Figure 4). In this phase, we define which zones must be protected in order to design the shield. The spherical shield is the closest to all trajectories of harmful substances, such as flying chips or sparks, emitted from one or more specific zones.

The folding is defined through the given surface. This surface is discretized, and different origami patterns were applied (see Figure 5). The procedure is as follows.

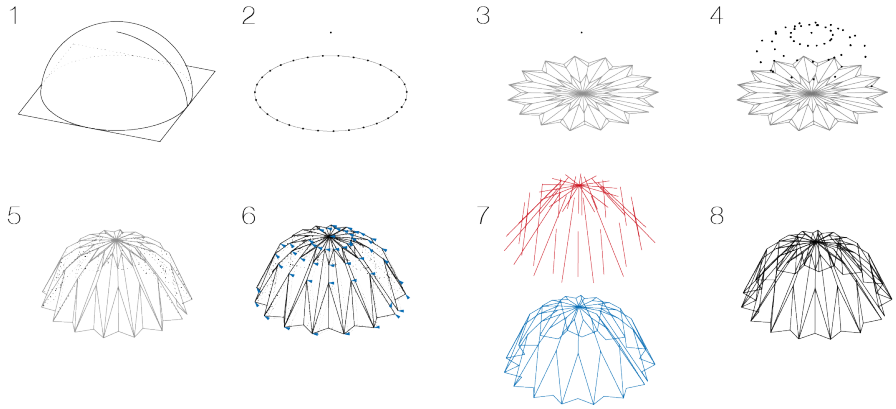

Figure 5. Folding pattern definition for a given surface.

First, the spherical base surface (1) is generated, then the folding path is subdivided in the XY plane (2), pattern definition (3), projection on the base surface (4), folding definition (5), geometry relaxation (6), the definition of the folding lines (7) and simulation of the folding (8). The development of the design was carried out using Rhinoceros ® [9], with the support of relaxation and planarization optimizations with Kangaroo [10] and constraints and rigidity definitions using Crane [11]. FE Analysis was carried out with Ansys [12]. After the automation and generation of the final model, a kinematic check using the MATLAB suite [13] was performed to validate the motion of the model.

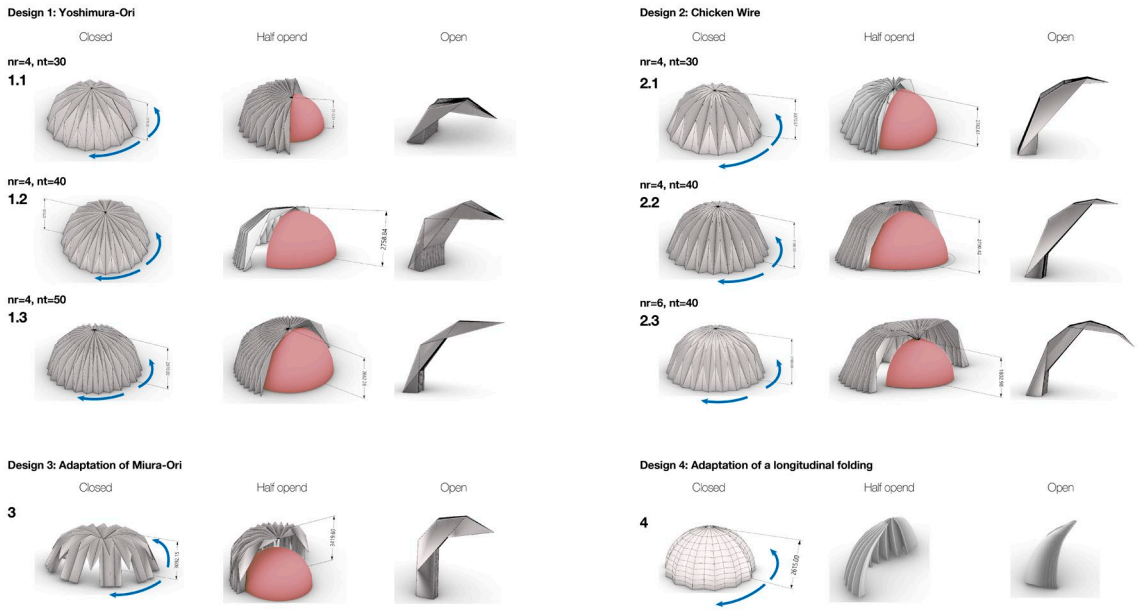

Figure 6. Geometry generation: 3 iterations of Design 1 and 2, and 1 iteration of Design 3 and 4 were generated.

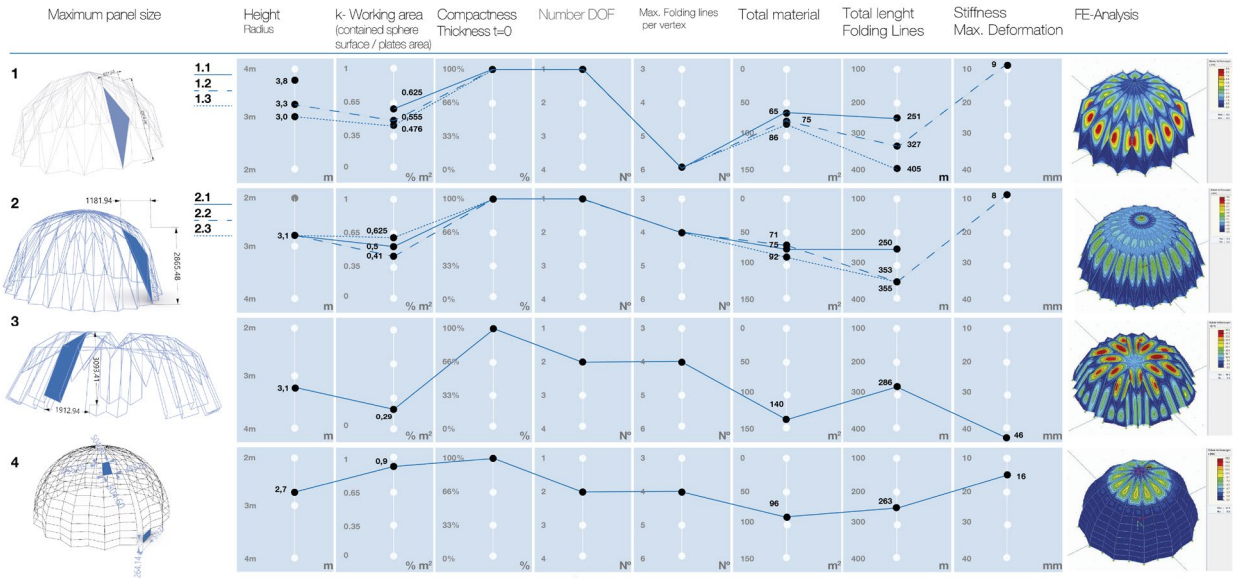

In this project, four types of origami patterns that can be adapted into a spherical geometry were studied: Yoshimura-Ori (Design 1), Chicken Wire (Design 2), and two from the literature: an adaptation of Miura-Ori [14] (Design 3), and an adaptation of a longitudinal folding [3] (Design 4). Here we study different factors that may lead to selecting one pattern or another, such as the displacement of the apex or center point, which is influenced by the subdivision of panels (see Figure 6, Design 1 and 2). Design

4, however, does not interrupt or collide with the workspace since that pattern only moves its center point upwards. In contrast to the previous ones, Design 3 does not move its center point.

2.2. Pattern design analysis

Table 1 shows the manly geometrical characteristics that were investigated: the dimensions of the largest panels, the maximum height of the structure, the working-area coefficient (obtained by dividing the surface of the contained sphere and the area of the total panels), the compactness (for a panel thickness of 0), the degrees of freedom, the maximum number of folding lines per vertex, the total area of the panels, and the length of all folding lines. Finally, the maximum deformation and support forces (self-weight and impact) were determined by FE analysis.

Table 1. Comparison of folding patterns.

It can be observed that designs 1, 2, and 3 are the ones that require larger panels. In contrast, Design 4 has smaller panels and, therefore with, a higher k- coefficient since it is closer to the working space. Further on, it can be seen how design 3 is the one that requires the most material, needing up to 140 m^2, the other designs remaining in a range from 65 to 96m^2. It can be seen that Design 1 and 2 are the stiffest, followed by Design 4, and Design 3 is the one with the most significant deformation, due to the geometric configuration, largest panels and cantilever.

In addition, other issues based on Figure 6 were observed: In Design 1 and 2, the central point moves downward when opening; circular trajectory only with mountain or valley folds possible circular trajectory approximately maintained; low degree of difficulty. In Design 3 it is observed that the circular trajectory not possible with rigid surfaces, the lower end open and therefore special solution for open areas in the base is necessary; construction is only stable to semi-open; and medium degree of difficulty.

Finally, it is observed that Design 4, the pattern does not correspond to the principles of folding (mountain-valley ratio is not equal to 3 to 1). It is a necessarily well-faceted geometry not to be full longitudinal folding. It is only possible with very flexible material. The circular trajectory is maintained and has a high degree of difficulty due to the number of joints.

For these reasons, it was concluded that the most suitable designs for a realization would be 1 and 2. Later it was supposed that the Chicken-Wire pattern would be the most suitable because it has less folding lines in the same vertex (4 in contrast to 6 of the Yoshimura-Ori). The realization and development of this design is described in [7].

On the other hand, in this project we wanted to explore design 4, since it does not comply with the folding conditions. Therefore, a construction concept was developed with flexible hinges and a semi-opening of the panels to allow folding. This would allow us to explore a more spherical design, with a more optimal k- ratio (see Table 1), and a smaller overall panel size.

3. Hybrid concept integrating scissor systems

In order to design actuation and supports of deployable structures, the motion trajectories of individual surfaces and points must be determined on a coordinate basis. This can be done e.g. with the Folding Mechanisms Library for Simulink [15]. Scissor systems with telescopic motors as in [16] can reduce the degrees of freedom of entire structures and simplify actuation. In contrast to the trivial geometry of the scissor system for parallel folding lines, the design of actuation systems for spherical or spatial gears is much more complex.

3.1. Movement trajectory analysis

The examples analyzed (see part 2), which were optimized with the [9] [10] tools, differ from the initial circular trajectory required. We can visualize the trajectory in the image, where we can see how the trajectory of the pattern lower points (on the floor) tends to be linear until we exceed 30º of folding. This non-linear area is then not considered, since the thickness of the panels would not allow that folded position.

This trajectory, with rigid panels, varies in the radius of the circle at 2.8 cm at its outer points and 12.9 cm at its inner points, with a z-displacement of 7.5 cm of the outer points. According to this analysis, it is observed that, by placing actuation at the outer points, the deviation of 2.8 cm can be absorbed with the flexibility of the panels (see construction in part 4). The inner points are suitable for support in z-direction. This consideration can be applied to the different patterns analyzed in Table 1.

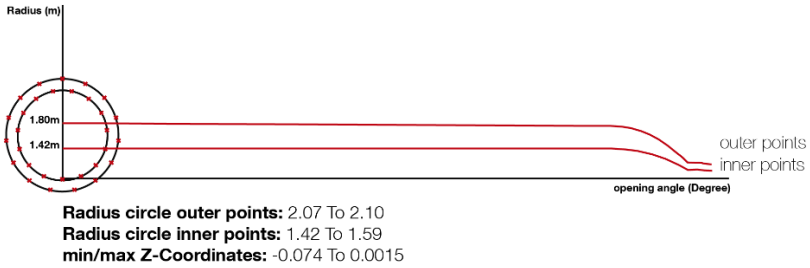

Figure 7. Trajectory analysis of the lower points.

3.1.1. Flat scissors

Simple symmetrical flat scissors, consisting of only two elements, can be inscribed in circles, which, however, vary in radius during their deployment. For this reason, a simple circular motion cannot be executed with this mechanism. Alternatively, independent scissors can be generated which, when actuated simultaneously with a linear actuator, can accomplish this operation. Design 2 (Figure 5) is executed with this consideration in the project [6].

3.1.2. Spherical scissors development

Scissors based on spherical geometries [4] are a variation of the geometry of a flat scissors. These scissors are projected onto the target sphere with a result of curved elements [17].

The center of the spherical scissors is identical to the center of the same sphere that generates the folding, with a larger radius, accommodating the external anchor points (see Figure 8). The connection of the scissor construction to the folding construction must allow rotations in all three directions.

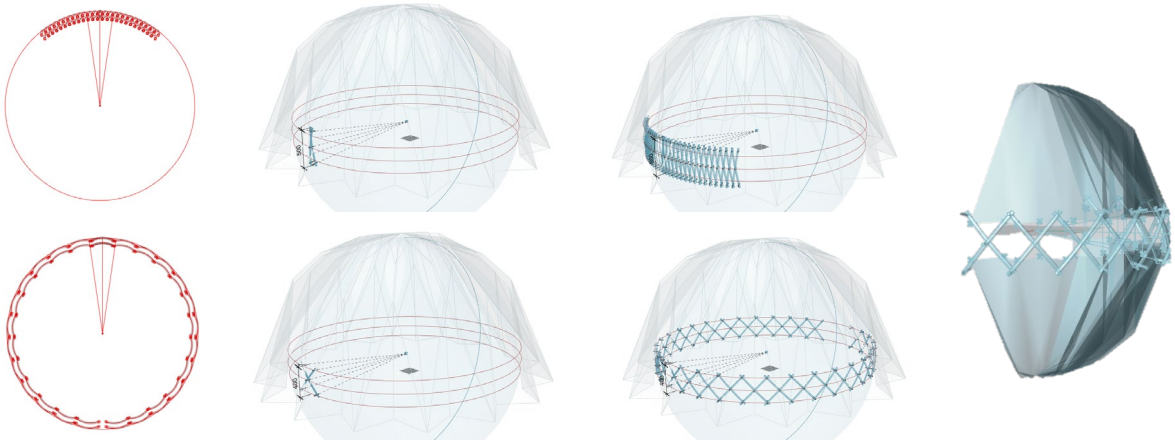

Figure 8. Development of spherical scissors. (Left to right): Top view of the scissor folded and unfolded. View of the scissor in combination with the folding. Positioning of the scissor according the outer points.

4. Construction development

The construction concept is divided into two main elements: folding and scissors. For the folding, following the methodology in [6], the material used was the composite material "Thermhex-Organosandwich" (6THPP120-CP820) (3-), composed of two 0.5 mm fiberglass face sheets and a honeycomb polypropylene core, was used for the 6mm thick rigid panels. Its stiffness satisfies static and dynamic calculations without compromising the overall structure's compatibility, and its low weight of 2.4 kg/m² limits stress on joints, frames, and drives. To avoid compatibility restrictions, low thickness continuous joints were developed using "Hylite" (4- and 5-), a 2 mm thick material with 0.2 mm aluminum cover layers and a 1.6 mm polypropylene core. A two-sided milling process with a width of 5 mm and a depth of 0.6 mm was used to give the material its joint properties, with an additional engraving milling of 0.6 mm and 0.2 mm widths on all valley folds for improved joint activation. CNC-drilled screw and rivet connections were used for surface connection to ensure spatial precision. The detachable connections of surfaces and joints allow for easy replacement of individual elements and material separation for complete disassembly e.g. for transportation or reusability of single parts or elements. Discontinuous 5- hinges were included to facilitate the deployment of this particular geometry.

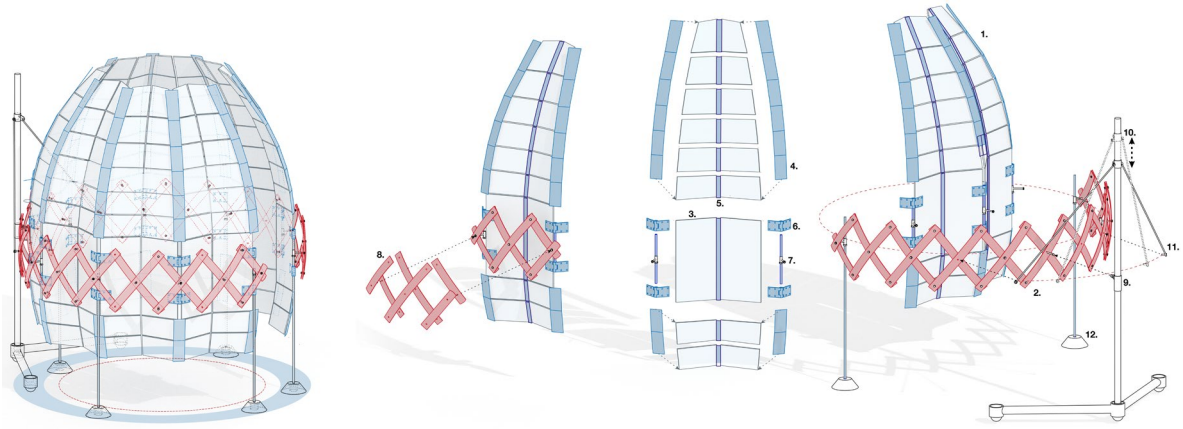

Figure 9. Construction concept and assembly: 1- Folding elements, 2- Spherical scissor, 3- Composite panels, 4- Continuous composite hinges, 5- Discontinuous composite hinges, 6. Aluminium hinge, 7-Vertical rod and scissor connector, 8-Scissors elements (internal and external). 9- Horizontal connector, 10- Vertical connector, 11- Diagonal rods and spherical joint connector, 12-Additional supports with spherical wheels.

The scissor system (8-) is composed of 4mm "Alucobond" (ALUCOBOND® PLUS) aluminum composite elements, which were precisely bent using a metal bending machine. The assembly is done with bearings and screws. Its assembly with the folding is carried out with through rods that are anchored to integrated vertical rods (7-).

The tripod that supports the structure integrates a horizontal connector (9-), which is anchored to the scissors, as well as a vertical connector (10-) which is mobile. The vertical connector (10-), by means of a vertical slide, activates the opening and closing movement of the scissors.

4.1. Construction demonstration and set-up

The construction of the prototype was carried out on a 1:1 scale (Figure 9), and was tested as a shield for grinding operations (Figure 10).

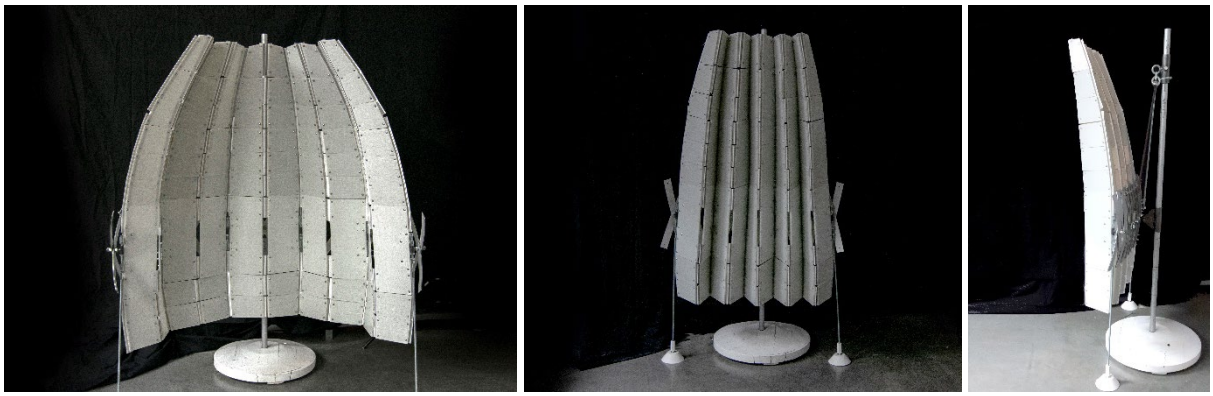

Figure 11. Proof of concept (left to right): Deployed shield, folded shield, lateral view of the folded shield.

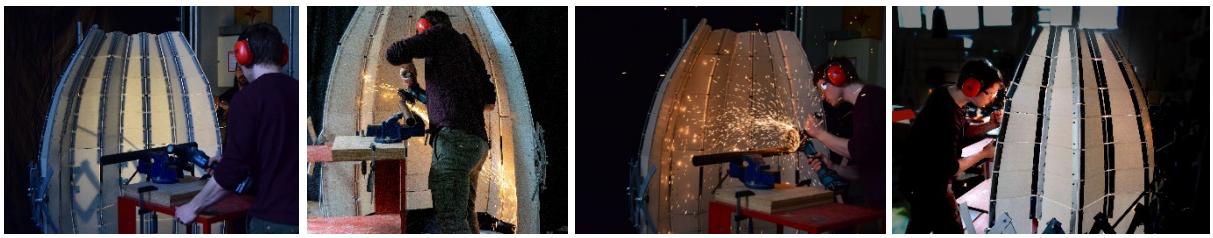

Figure 12. Proof of concept (left to right): grinding preparation, protection from downward sparks protection, upward sparks protection, rear view of the action.

5. Conclusions

This paper shows the design and implementation of a novel enclosure as a protective shield for manufacturing tasks, where a working environment in a workshop must be protected. The structure comprises a hybrid folding and scissors system, which opens and closes manually and compacts itself

in less than one-third of the surface. The lightweight and rigid folding shield consist of composite panels with elastic hinges. The spherical scissor system follows a pattern of parallel axis bent in aluminium on a specific radius to deploy the circular trajectory. The two systems demonstrate the ability to collaborate to generate a self-supporting system with one degree of freedom, which simplifies the use of multiple motors to drive the mechanism. The project presented here has been executed with a scaled prototype that can be integrated into workshops environments.

Acknowledgements

This project was carried out complementary to the E^2F project, which was funded by the Deutsche Forschungsgemeinschaft (DFG) Project: 289387994, aimed at designing and developing transformable folding structures, conducted during the period of 2020-2021[6]. This project realization also involved the collaboration of student research assistants Sheldon Stephens, Clemens Braumann, Viktor Wages and Tobias Grüters, as well as students who contributed to its assembly during the elective course Transformable Structures held in the summer semester 2022 at the Faculty of Architecture of the RWTH-Aachen University.

Snap-through buckling detection and analysis method for multi-stable structures

Ruta STANKEVICIUTE[a,*], Jun SATO[a]

Abstract

Buckling is usually observed in structural engineering as a failure of the structure. However, using snap-through buckling, a multi-stability can be achieved in animated structures. While there is numerous research on analysing structural behaviour when snapping-through occurs, there is little study on detecting snap-through buckling occurrence, which is essential to multi-stable structures. In this paper, we propose a computational method for detecting snap-through buckling events, which analyses the critical load estimated through eigenvalue buckling analysis. The workflow was developed by first simulating the multi-stable structure using the dynamic relaxation method and capturing the structure's behaviour while transforming from one state to another by recording iterations of the animation. Since simulation produced a high number of geometric models, we used a linear buckling analysis, which proved to be faster than a non-linear analysis. By observing results throughout the animation, we detected a drastic fluctuation in eigenvalue, which correlated with geometry changes from the simulation and physical experiment. A sudden drop in eigenvalue corresponded with large deformation of the structure, indicating snap-through occurrence. The results suggest that our proposed analysis method can be a fast way to detect the occurrence of snap-through buckling in multi-stable structures.

Keywords: snap-through buckling, buckling analysis, eigenvalue, multi-stability

1. Introduction

Thin structures tend to bend rather than stretch; therefore, this tendency often results in elastic instability. Designing thin and lightweight structures using high-strength materials is inherently prone to instability due to this behaviour [1]. Once an unwanted phenomenon in structural engineering, elastic instability is now employed in making structures multi-stable. With the need for deployable compact, lightweight structures growing, architects and engineers draw inspiration from nature, designing structures ranging from metamaterials [2] and micro-robotics [3] to meter-scale structures like emergency shelters [4]. The field of multi-stable structures has never been as influential and growing as now.

Although there has been extensive research on employing snap-through buckling to create multi-stable structures, a limited amount of study focuses on detecting such a phenomenon. There are ways to detect snap-through occurrence physically, by measuring the strain distribution along the structure with a fibreglass sensor [5] or by measuring the voltage of the energy produced during the snap-through event [6]. In addition, the snap-through signature can be observed digitally by measuring the change in the tilting angles of the members in buckled regions [7].

However, the research on the effect of snap-through buckling and post-event focuses on one stage of the structure, usually the final deployed shape, rather than analysis throughout the deployment. It is possible to acquire pre-snap-through and post-snap-through states, as well as the iterations in between, by using the incremental displacement numerical method [8]. Even so, there are no tools for detecting

Copyright © 2023 by Ruta STANKEVICIUTE and Jun SATO. Published in the Proceedings of the IASS Annual Symposium 2023 with permission.

snap-through occurrences during deployment animation, which is essential to multi-stable structures since snap-through can occur anytime throughout the deployments and change the structural integrity and behaviour of the structure.

Although structural analysis tools can animate incremental displacement or even visualise snap-through phenomena, they cannot simulate deployment animation. The most common approach towards analysing animated structures is developing a simulation and analysis using two different software, which often results in the incompatibility of models and interruption of the workflow [9]. While geometry animation and buckling analysis have been seen as separate methods, we bridge the gap by proposing a computational method for multi-stable structures, which simulates the deployment and analyses the structure in parallel. Using linear eigenvalue buckling analysis, we enable quick computation and unburdened workflow to detect snap-through buckling occurrence throughout the animation process.

2. Method basis

The fundamental mathematical difference between a bifurcation and a snap-through phenomenon lies in how the structure responds to instability: bifurcation entails a shift to a new equilibrium path, while snap-through involves a sudden jump to a new point on the same equilibrium path [1]. Bifurcation is characterized as a gradual deformation, while snap-through buckling results in a rapid, discontinuous deformation that involves an instability phase [6]. Additionally, the critical load threshold for bifurcation refers to the point where the structural stability transitions from its current stable state to a new equilibrium, which could be either stable or unstable, emanating from the original equilibrium state [10] [11]. Concurrently, the critical points for snap-through buckling signify the instance when the structure transitions abruptly to a new point of stability whilst maintaining stable equilibrium. [12]. This transition drastically changes the structure's integrity, resulting in collapse or, in the case of multi-stable structures, a new stable state. Therefore, observations of any sudden change in the stability of the structure during deployment could identify a snap-through event.

Multi-stable structures require a critical load to snap through between deployed states [13]. In the case of snap-through buckling, structural stability changes drastically, sometimes leading to significant stress reversals [14] [15]. Therefore, the critical load changes significantly at the snap-through buckling occurrence, which would reflect in the eigenvalue that identifies the stability of the structure through buckling analysis [16] [17] [18]. Based on our study, the rapid, significant displacement and drastic change in stability reflected in eigenvalue are proposed to be used as a signature for detecting snap-through events.

Since snap-through buckling is a complex non-linear problem, it is commonly solved using non-linear analysis methods, such as the arc-length method [7] or the Newton-Raphson method [19]. However, fundamental linearised buckling analysis is sufficient for predicting the collapse load. Specifically, the linear eigenvalue approximation is just as precise as both the analytical and rigorous non-linear pre-buckling analysis [20]. Moreover, even though eigenvalue buckling analysis may over-predict the critical buckling strength, it needs less computational effort compared with a non-linear buckling analysis [21]. Therefore, our hypothesis is focused on using linear eigenvalue analysis for quick detection of possible snap-through occurrence by reading eigenvalue fluctuations throughout the deployment of a multi-stable structure.

3. Deployment simulation

Our study uses an inflatable origami structure as a deployable multi-stable structure. The origami geometry is composed of sharp and soft folds. Sharp folds are curve-creased folds, which are folded

along a curve instead of a straight line and can store elastic strain energy [22]. Using curved-creased folds enables us to control snapping [23] by increasing the crease curvature raising the critical force needed for snap-through instability [24]. Soft folds are folded along an edge using a radius. Thus, their behaviour is more similar to the surface than the crease.

3.1 Physical set-up

A physical experiment was conducted to validate the proposed computational method for simulating and detecting snap-through sequences. The origami structure is built using a 0.3mm aluminium sheet. Inflated, it spans 2m in length and 1m in width and rises to 0.5m (see Figure 1(a)). The freestanding structure was inflated via a tube attached at the top of the model. The primary folds, sharp edges of the geometry, are created by cutting the sheets of aluminium and joining the creases using hinges, which gives the fold almost no resistance when folding. Secondary folds, soft edge folds, are created by bending the sheet without making a cut or joining with hinges. Therefore, they have bending stiffness inherited from the material. The behaviour of the structure observed during the deployment of the physical experiment was used to tune up the deployment simulation.

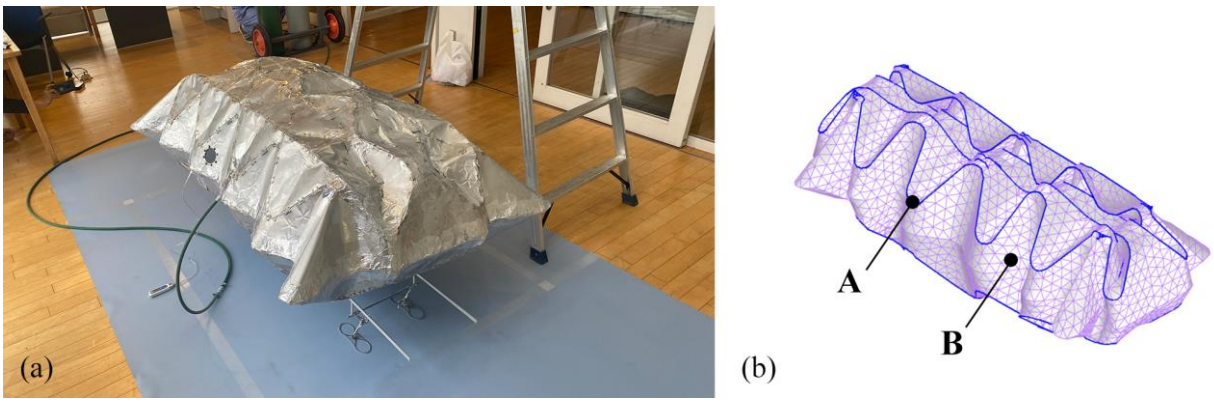

Figure 1. Inflatable multi-stable origami structure: (a) physical set-up, (b) simulation set-up, indicating: A – primary, sharp folds, B – secondary, soft folds.

3.2 Simulation set-up

It is essential to analyse the structure throughout the deployment process. Therefore, a simulation was used to produce the geometry at multiple stages of the animation. The method was built using Rhinoceros software, commonly used by architects and engineers. It houses various plug-ins that can be used together within one environment called Grasshopper. This makes workflow between different software uninterrupted.

Deployment of the origami structure was simulated using Kangaroo physics plug-in – an interactive physics engine that reaches set goals using a form of dynamic relaxation. A technique that, through an iterative solving process, combines all the acting forces and transforms geometry accordingly until the equilibrium of forces can be reached [25]. The Kangaroo physics components are used to set up goals for the simulation while Kangaroo solvers run the simulation and provide the result.

A ‘Plastic Hinge’ component was used for sharp folds, which acts as an angular spring [26] and allows deformation of the crease once the plastic angle is exceeded. However, for the soft folds, – the ‘Hinge’ component was more suitable because, although similar to Plastic Hinge, it has no deformation angle constraint, allowing the fold to recover to its original state. The length component is used to transform

the origami structure into a network of springs, representing rigid beams. The 'NoFoldThrough' component ensures that no faces can pass through each other during animation.

All goal components used in setting up the geometry of the origami structure can be assigned a strength parameter corresponding to axial stiffness. Value can be calculated based on the structure's material using the formula: EA/L, where E is the elastic modulus, A is the cross-sectional area, and L is the length of the element [24].

In the simulation set-up, the strength parameter of the Hinge and Plastic Hinge components was tuned to match the behaviour observed during the physical experiment.

The origami structure is deployed by inflation. For that purpose, air pressure was represented using a Pressure component. However, the pressure is assumed to be constant throughout the simulation, and animation using a Kangaroo solver component or step solver component only represents the iteration solutions or deformation until a final solution is achieved. Thus, it is impossible to know how pressure changes throughout the deployment.

Seeing that it is essential to the study to know the exact pressure at a given point throughout the deployment of the structure, it was crucial to set up a recursive flow that allows an incremental increase in pressure during simulation. Therefore, a loop was created using an Anemone plug-in, which enabled the incrementation of the pressure. Each loop runs one simulation using the Zombie solver at a given pressure, which is increased in each loop until recursion is broken once the model is fully deployed.

4. Buckling analysis

The key point of the multi-stable structure is the ability to lock in place after deployment; thus, it is essential to transition from one stable state to another using snap-through buckling and not folding. It is hard to detect which buckling mode the crease underwent simply by observing the deformation scale; therefore, it is necessary to conduct a buckling analysis.

4.1 Analysis set-up

For buckling analysis, an in-house software Hogan was chosen. Hogan solves the generalised eigenvalue problem using the bisection method. It is a fast linear buckling analysis solver capable of detecting the smallest eigenvalue and corresponding mode.

Hogan can be linked directly within the Grasshopper environment via a plug-in called GHogan. Therefore, buckling analysis can be set up inside the Anemone loop and run simultaneously with the Kangaroo simulation. First, GHogan components are used to construct a file Hogan uses for buckling analysis. Afterwards, an output file can be read in the Grasshopper environment to observe the eigenvalue result.

Assuming that the model is symmetrical on the x and y-axis, only one-quarter of the geometry was used for structural analysis to make the calculations faster (see Figure 2(a)). As a result, points on the xz plane were locked on the y-axis, while points on the yz plane were locked on the x-axis, respectively (see Figure 2(b)).

Inner pressure applied during inflations is used as a load for the buckling analysis. First, it is calculated using plankton mesh, which uses a half-edge data structure to create polygon mesh. Afterwards, vertices and vortex normal are used to define the vector for the nodal load (see Figure 2(c)).

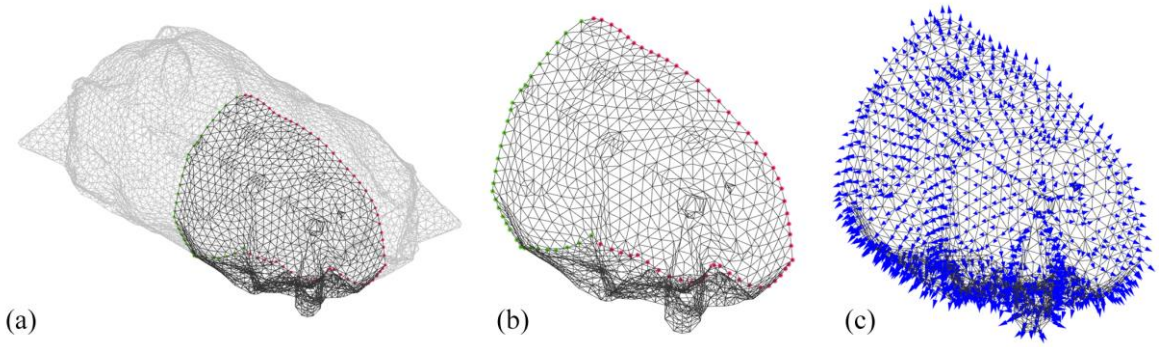

Figure 2. Buckling analysis set-up: (a) quarter model, (b) red - points fixed on the xz plane, green – points fixed on the yz plane, (c) blue – nodal load vectors representing internal pressure.

5. Results

5.1 Snap-through detection and sequence observing deformation throughout the physical experiment

During the physical deployment test, Snap-through occurrence was confirmed. 12 snaps were detected (see Figure 3), and three different snap-through sequences were recorded (see Figure 4(a)). Due to imperfections of the prototype model, deployment was asymmetrical. Therefore, it is hard to determine the correct sequence.

Furthermore, air leakage occurred during inflation, which might have affected the deployment and the sequence of snapping. After pressure was removed, some snaped areas reversed to the original state, indicating that snap-through might not have occurred or the critical load for deformation was too low to sustain the shape. However, most of the model stayed deployed, validating the multi-stability of the structure.

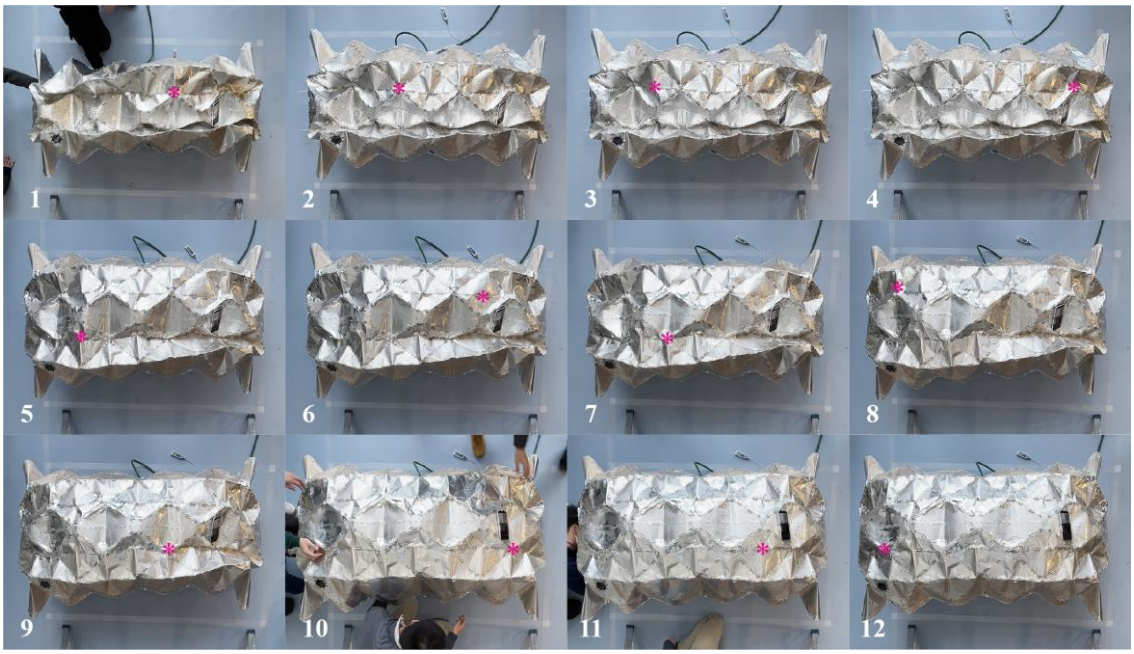

Figure 3. Physical experiment result: 12 snap-through events recorded in sequence.

5.2 Snap-through detection and sequence observing large deformation throughout the simulation

The snap-through-like motion could be detected by measuring the deformation vector between iterations. Tracking how points moved after pressure was increased indicated possible snap-through occurrence. Since vector length changed drastically between iterations, it is more likely reflected as a snap-through deformation rather than folding. However, after decreasing pressure incrementation to make the deployment simulation more accurate, detecting snap-through-like events became harder because deformation became more subtle. Compared to the physical experiment, the geometry could be deployed symmetrically. Only one snap-through sequence was recorded, which correlated to one of the sequences observed during the physical experiment (see Figure 4(b)).

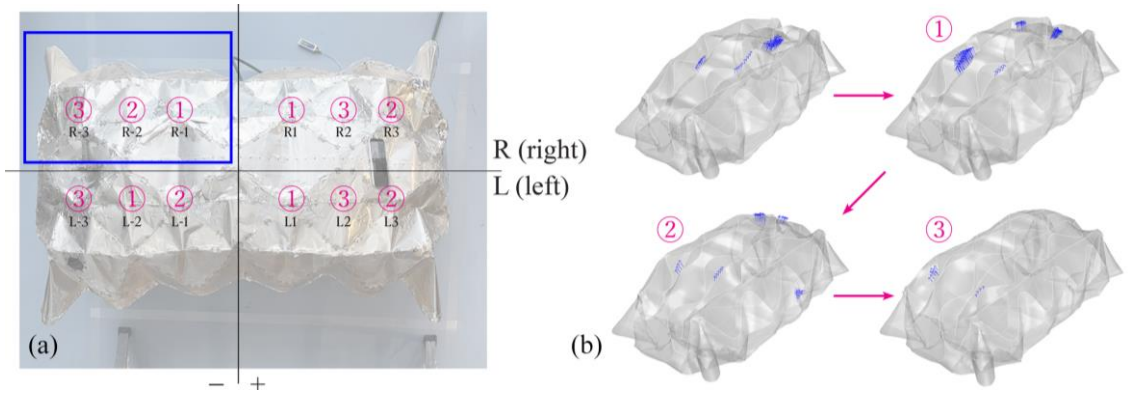

Figure 4. Comparison between physical experiment result and simulation result: (a) 3 different snap-through sequences occurred during physical model deployment, (b) only one snap-through sequence was recorded during the deployment simulation.

5.3 Snap-through detection using eigenvalue buckling analysis

The first simulation and analysis were conducted in 0.1atm (10.1325kPa) pressure increments. A drastic fluctuation in eigenvalue was detected by observing buckling analysis results throughout the animation (see Figure 5(a)), which correlated with geometry changes from the simulation. A sudden drop in eigenvalue corresponded with large deformation of the structure, previously indicated as a snap-through event.

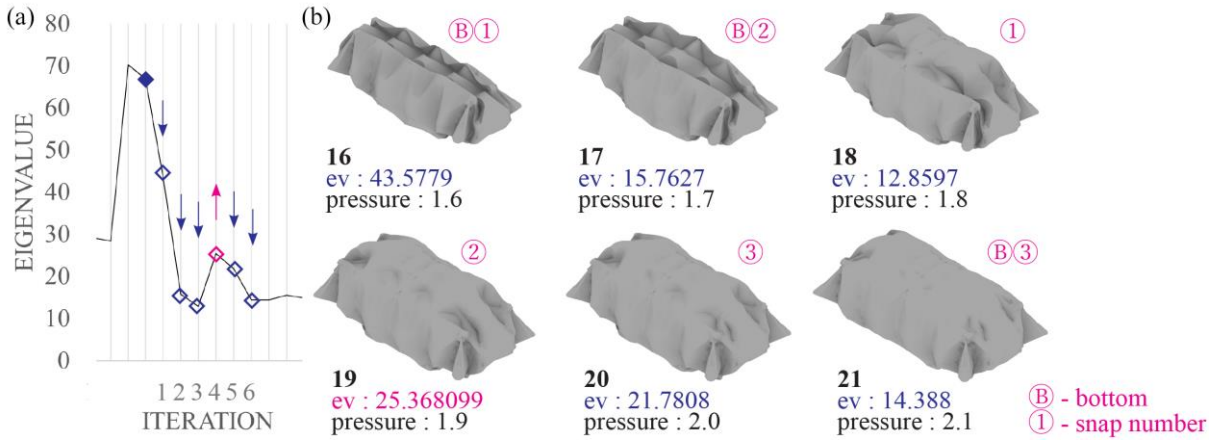

Figure 5. 0.1 incremental pressure simulation eigenvalue buckling analysis result: (a) eigenvalue fluctuation indicating 6 snap-through events, (b) snap-through sequence.

A sequence of 6 snaps was recorded (see Figure 5(b)). The first two snaps indicated rapid deployment and snap-through-like behaviour at the bottom of the shape. Afterwards, 3 snaps occurred on the top of the structure. The final snap appeared on the bottom. Each snap was followed by a drastic change in eigenvalue.

While 5 out of 6 snaps were indicated by the drop in eigenvalue, an increase was detected around the 4th snap occurrence, which did not follow the proposed hypothesis. For in-depth research, a more precise analysis was conducted.

The second simulation and analysis were conducted in more precise 0.02 atm (2.0265kPa) pressure increments. Compared with the first simulation and analysis, more fluctuations in eigenvalue could be recorded, providing more data regarding the deployment sequence (see Figure 6(a)). Eight eigenvalue spikes were recorded. Six spikes indicated a rise of eigenvalue and then afterwards a sudden drop, which suggests snap-through-like behaviour. After observing the 3D model, we could confirm that the eigenvalue spikes matched the snaping seen during the deployment animation.

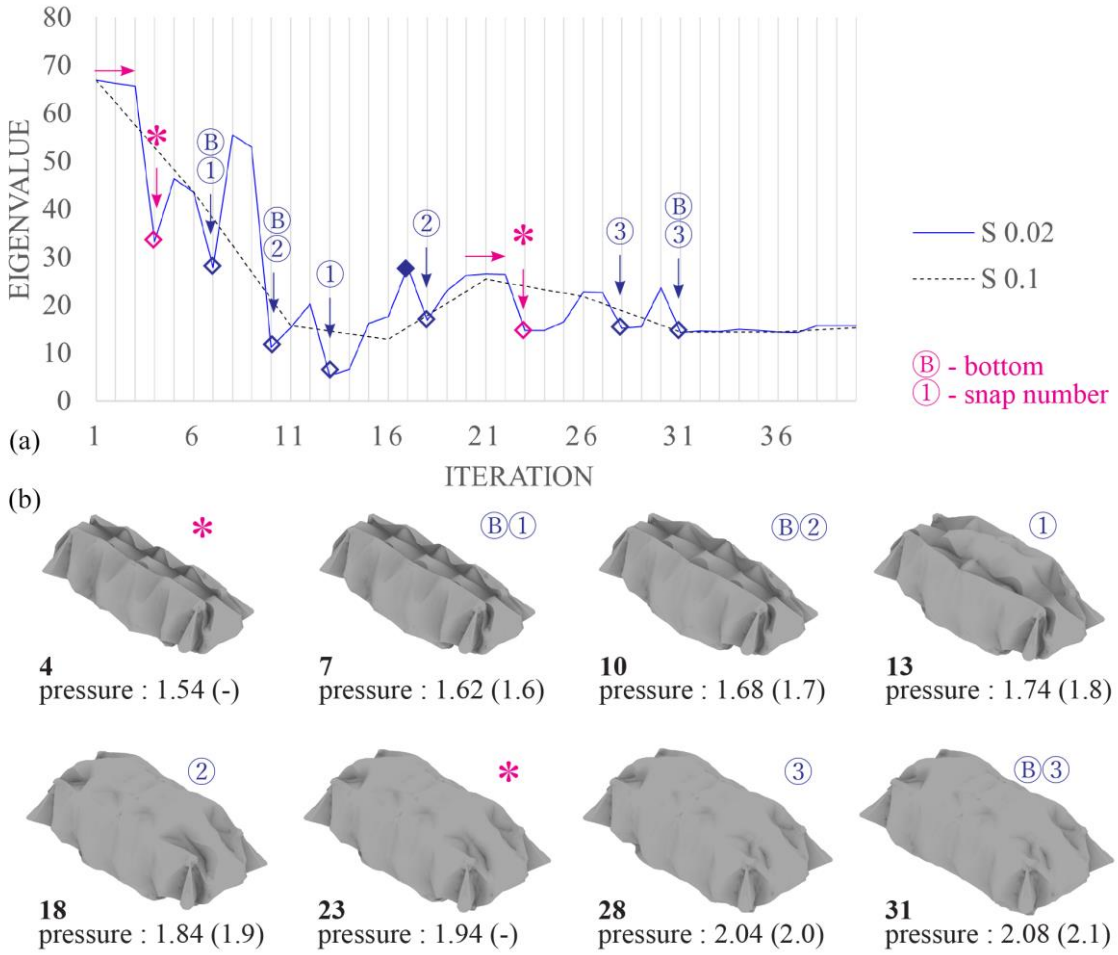

Figure 6. 0.02 incremental pressure simulation eigenvalue buckling analysis result: (a) eigenvalue fluctuation indicating 6 snap-through events and 2 unidentified events, (b) snap-through sequence.

However, around iterations no. 4 and no. 23, no snap-through could be identified from simulation images, while the eigenvalue from buckling analysis spiked (see Figure 6(b)). The rise of eigenvalue was smoother than the spikes associated with snap-through events. However, the value dropped just as rapidly. By observing the eigenvalue analysis result, a large deformation was visible at the front of the model (see Figure 7). Two more snaps happened afterwards in the area indicated by the analysis, which suggests that folding motion or a different type of buckling might have occurred during the unidentified eigenvalue spike.

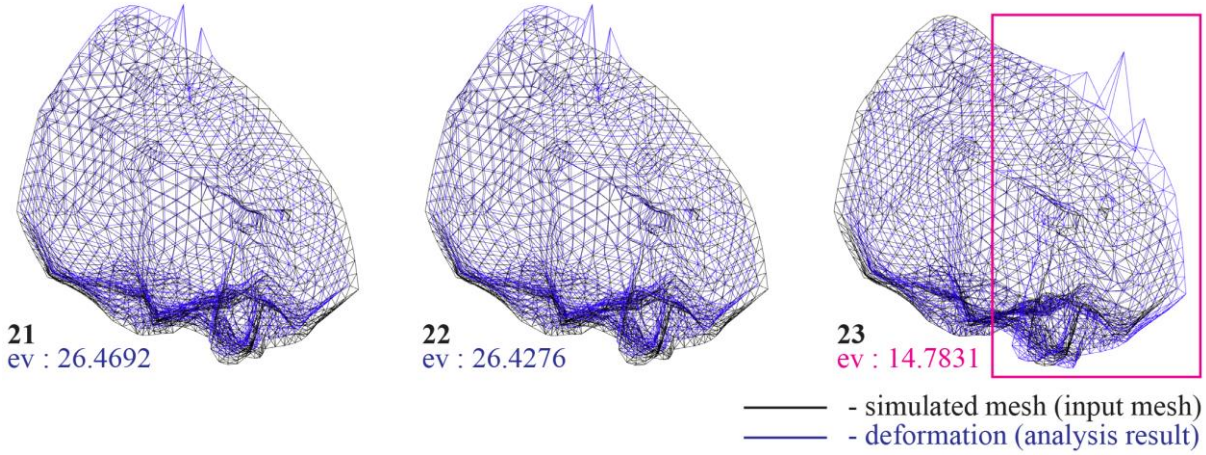

Figure 7. Iteration no. 23 eigenvalue buckling analysis result indicating large deformation.

Using smaller increments, more precise snap-through detection could be achieved using our developed method. Furthermore, the pressure required for each snap-through to occur could be specified. Finally, the results showed that rapid, significant displacement and change in eigenvalue are strong indicators of snap-through buckling occurrence.

6. Conclusion

This paper presents a computational method for simulating and analysing the deployable structure using linear eigenvalue buckling analysis for snap-through buckling detection. It is based on the fact that eigenvalue drastically increases just before the snap-through buckling occurs; therefore, it can be used as a signature detecting snap-through phenomenon. We achieved a realistic simulation correlating with the behaviour of the structure observed during the physical experiment. Furthermore, this study is the first to demonstrate an animated linear eigenvalue buckling analysis for deployable multi-stable structures with snap-through detection. However, there is much scope for improvement of our proposed method. While we could identify most of the eigenvalue spikes as snap-through buckling by observing the physical experiment as well as data from the simulation, there were unknown fluctuations that need more thorough study in the future. Additionally, the deformation result from the analysis could be used to identify the location of the snap-through occurrence.

Being able to work with geometry and quickly detect snap-through sequences in parallel allows us to use the method with geometry optimisation, presenting an opportunity for innovative ways to work with multi-stable structures.
